Notwithstanding the bad success of those who have attempted to repeat M. Loriot's experiments, however, Dr Black informs us, that a cement of this kind is certainly practicable. It is done, he says, by powdering the lime while hot from the kiln, and throwing it into a thin paste of sand and water; which, not slacking immediately, absorbs the water from the mortar by degrees, and forms a very hard mass. "It is plain, he adds, that the strength of this mortar depends on using the lime hot or fresh from the kiln."

By mixing together gypsum and quicklime, and then adding water, we may form a cement of tolerable hardness, and which apparently might be used to advantage in making troughs for holding water, or lining small canals for it to run in. Mr Wiegley says, that a good mortar or cement, which will not crack, may be obtained, by mixing three parts of a thin magma of slacked lime with one of powdered gypsum; but adds, that it is used only in a dry situation. A mixture of tarras with slacking lime acquires in time a stony hardness, and may be used for preventing water from entering. See MORTAR and STUCCO.

CEMENT, among engravers, jewellers, &c. is the same with the hot cement used in building*; and is used for keeping the metals to be engraven firm to the block, and also for filling up what is to be chisseled.

* See the foregoing article.

CEMENT, in *Chemistry*, is used to signify all those powders

powders and pastes with which any body is surrounded in pots or crucibles, and which are capable by the help of fire of producing changes upon that body. They are made of various materials; and are used for different purposes, as for parting gold from silver, converting iron into steel, copper into brass; and by cementation more considerable changes can be effected upon bodies, than by applying to them liquids of any kind; because the active matters are then in a state of vapour, and assisted by a very considerable degree of heat.

Cement which quickly hardens in water. This is described in the posthumous works of Mr Hooke, and is recommended for gilding live craw fish, carps, &c. without injuring the fish. The cement for this purpose is prepared, by putting some Burgundy pitch into a new earthen pot, and warming the vessel till it receives so much of the pitch as will stick round it, then strewing some finely-powdered amber over the pitch when growing cold, adding a mixture of three pounds of linseed oil, and one of the oil of turpentine, covering the vessel and boiling them for an hour over a gentle fire, and grinding the mixture as it is wanted with as much pumice-stone in fine powder as will reduce it to the consistence of paint. The fish being wiped dry, the mixture is spread upon it; and the gold leaf being then laid on, the fish may be immediately put into water again, without any danger of the gold coming off, for the matter quickly grows hard in the water.

Cement Pots, are those earthen pots used in the cementation of metals.

CEMENTATION, the act of corroding or otherwise changing a metal by means of a Cement.

CEMETERY (Κοιμητηριον, from Κοιμαω, to "*sleep*"); a place set apart or consecrated for the burial of the dead.

Anciently none were buried in churches or churchyards; it was even unlawful to inter in cities, and the cemeteries were without the walls. Among the primitive Christians these were held in great veneration. It even appears from Eusebius and Tertullian, that, in the early ages, they assembled for divine worship in the cemeteries. Valerian seems to have confiscated the cemeteries and other places of divine worship, but they were restored again by Gallienus. As the martyrs were buried in these places, the Christians chose them for building churches on, when Constantine established their religion; and hence some derive the rule which still obtains in the church of Rome, never to consecrate an altar without putting under it the relicks of some saint. The practice of consecrating cemeteries is of some antiquity. The bishop walked round it in procession, with the crosier or pastoral staff in his hand, the holy water pot being carried before, out of which the aspersions were made.

CENCHRUS. See Botany *Index*.

CENEGILL, in the Saxon antiquities, an expiatory mulct, paid by one who had killed a man to the kindred of the deceased. The word is compounded of the Saxon *cinne*, i. e. *cognatio*, "relation," and *gild*, *solutio*, "payment."

CENOBITE. See Coenobite.

CENOTAPH, in antiquity, an empty tomb, erected by way of honour to the deceased. It is distinguished from a sepulchre, in which a coffin was deposited. Of these there were two sorts; one for those who had, and another for those who had not, been honoured with funeral rites in another place.

The sign whereby honorary sepulchres were distinguished from others, was commonly the wreck of a ship, to denote the decease of the person in some foreign country.

CENSER, in antiquity, a vase containing incense to be used in sacrifices. Censer is chiefly used in speaking of the Jewish worship. Among the Greeks and Romans it is more frequently called *thuribulum*, λιβανωτις, and *acerra*.

The Jewish censer was a small sort of chafing dish, covered with a dome, and suspended by a chain. Josephus tells us, that Solomon made 20,000 gold censers for the temple of Jerusalem, to offer perfumes in, and 50,000 others to carry fire in.

CENSIO, in antiquity, the act or office of the censor. See Census.

Censio included both the rating or valuing a man's estate, and the imposing mulcts and penalties.

Censio hastaria, a punishment inflicted on a Roman soldier for some offence, as laziness or luxury, whereby his *hasta* or spear was taken from him, and consequently his wages and hopes of preferment stopped.

CENSITUS, a person censed, or entered in the censual tables. See Census.

In an ancient monument found at Ancyra, containing the actions of the emperor Octavius, we read,

Quo lustro civium Romanorum
Censita sunt capita quadragies
Centum millia et sexaginta tria.

Censitus is also used in the civil law for a servile sort of tenant, who pays capitation to his lord for the lands he holds of him, and is entered as such in the lord's rent roll. In which sense, the word amounts to the same with *capite census*, or *capite censitus*. See *Capite Censi*.

CENSOR, (from *censere* to "think" or "judge"), one of the prime magistrates in ancient Rome.—Their business was to register the effects of the Roman citizens, to impose taxes in proportion to what each man possessed, and to take cognizance or inspection of the manners of the citizens. In consequence of this last part of their office, they had a power to censure vice or immorality, by inflicting some public mark of ignominy on the offender. They had even a power to create the *princeps senatus*, and to expel from the senate such as they deemed unworthy of that office. This power they sometimes exercised without sufficient grounds; and therefore a law was at length passed, that no senator should be degraded or disgraced in any manner until he had been formally accused and found guilty by both the censors. It was also a part of the censorian jurisdiction, to fill up the vacancies in the senate, upon any remarkable deficiency in their number; to let out to farm all the lands, revenues, and customs, of the republic; and to contract with artificers for the charge of building and repairing all the public works and edifices both in Rome and the colonies of Italy. In all parts of their office, however, they

they were subject to the jurisdiction of the people; and an appeal always lay from the sentence of the censors to that of an assembly of the people.

The first two censors were created in the year of Rome 311, upon the senate's observing that the consuls were so much taken up with war as not to have time to look into other matters. The office continued to the time of the emperors, who assumed the censorial power, calling themselves *morum præfecti*; though Vespasian and his son took the title of censors. Decius attempted to restore the dignity to a particular magistrate. After this we hear no more of it, till Constantine's time, who made his brother censor, and he seems to have been the last that enjoyed the office.

The office of censor was so considerable, that for a long time none aspired to it till they had passed all the rest; so that it was thought aspiring that Crassus should be admitted censor, without having been either consul or prætor. At first the censors enjoyed their dignity for five years, but in 420 the dictator Mamercus made a law restraining it to a year and a half, which was afterwards observed very strictly. At first one of the censors was elected out of a patrician, and the other out of a plebeian family; and upon the death of either, the other was discharged from his office, and two new ones elected, but not till the next lustrum. In the year of Rome 622, both censors were chosen from among the plebeians; and after that time the office was shared between the senate and people. After their election in the Comitia Centuriata, the censors proceeded to the capitol, where they took an oath not to manage either by favour or disaffection, but to act equitably and impartially throughout the whole course of their administration.

The republic of Venice still has a censor of the manners of their people, whose office lasts six months.

Censors of Books, are a body of doctors or others established in divers countries to examine all books before they go to the press, and to see they contain nothing contrary to faith and good manners.

At Paris, before the late revolution, the faculty of theology claimed this privilege as granted to them by the pope; but, in 1624, new commissions of four doctors were created, by letters patent, the sole censors of all books, and answerable for every thing contained therein.

In England, we had formerly an officer of this kind, under the title of licenser of the press: but, since the Revolution, our press has been laid under no such restraint.

CENSORINUS, a celebrated writer in the third century, well known by his treatise *De die Natali*. This treatise, which was written about the year 238, Gerard Vossius calls a little book of gold; and declares it to be a most learned work of the highest use and importance to chronologers, since it connects and determines, with great exactness, some of the principal eras in pagan history. It was printed at Cambridge, with the notes of Lindenbrokius, in 1695.

CENSURE, a judgment which condemns some book, person, or action, or more particularly, a reprimand from a superior. Ecclesiastical censures are penalties, by which, for some remarkable misbehaviour, Christians are deprived of the communion of the church, or prohibited to exercise the sacerdotal office.

CENSUS, in Roman antiquity, an authentic declaration made before the censors, by the several subjects of the empire, of their respective names and places of abode. This declaration was registered by the censors; and contained an enumeration, in writing, of all the estates, lands, and inheritances they possessed; their quantity, quality, place, wives, children, domestics, tenants, slaves. In the provinces the census served not only to discover the substance of each person, but where, and in what manner and proportion, taxes might be best imposed. The census at Rome is commonly thought to have been held every five years; but Dr Middleton hath shown, that both census and lustrum were held irregularly and uncertainly at various intervals. The census was an excellent expedient for discovering the strength of the state; for by it they discovered the number of the citizens, how many were fit for war, and how many for offices of other kinds; how much each was able to pay of taxes, &c. It went through all ranks of people, though under different names: that of the common people was called *census*; that of the knights, *census, recensio, recognitio*; that of the senators, *lectio, relectio*.—Hence also *census* came to signify a person who had made such a declaration; in which sense it was opposed to *incensus*, a person who had not given in his estate or name to be registered.

The census, according to Salmasius, was peculiar to the city of Rome. That in the provinces was properly called *professio* and απογραφη. But this distinction is not everywhere observed by the ancients themselves.

CENSUS was also found for the book or register wherein the professions of the people were entered: In which sense, the census was frequently cited and appealed to as evidence in the courts of justice.

CENSUS is also used to denote a man's whole substance or estate.

Census Senatorius, the patrimony of a senator, which was limited to a certain value; being at first rated at 800,000 sesterces, but afterwards, under Augustus, enlarged to 1,200,000.

Census Equester, the estate or patrimony of a knight, rated at 400,000 sesterces, which was required to qualify a person for that order, and without which no virtue or merit was available.

CENSUS was also used for a person worth 100,000 sesterces, or who was entered as such in the censual tables, on his own declaration. In which sense, census amounts to the same with *classicus*, or a man of the first class; though Gellius limits the estate of those of this class to 125,000 asses. By the Voconian law, no census was allowed to give by his will above a fourth part of what he was worth to a woman.

CENSUS was also used to denote a tax or tribute imposed on persons, and called also capitation. See *Capite Censi*.

Census Dominicatus, in writers of the lower age, denotes a rent due to the lord.

Census Duplicatus, a double rent or tax, paid by vassals to their lord on extraordinary or urgent occasions; as expeditions to the Holy Land, &c.

Census Ecclesiæ Romanæ, was an annual contribution voluntarily paid to the see of Rome by the several princes of Europe.

CENT signifies properly a hundred, being an abridgement of the word *centum;* but is often used in commerce to express the profit or loss arising from the sale of any commodity: so that when they say there is 10 per cent. profit, or 10 per cent. loss, upon any merchandise that has been sold, it is to be understood that the seller has either gained or lost 10l. on every 100l. of the price at which he bought that merchandise; which is $\frac{1}{10}$ of profit, or $\frac{1}{10}$ of loss, upon the total of the sale.

CENTAUR, in *Astronomy*, a part or moiety of a southern constellation, in form half man half horse; usually joined with the wolf. The word comes from κενταυρος, formed of κεντεω, *pungo;* and ταυρος, *bull;* q. d. *bull-pricker*. The stars of this constellation, in Ptolemy's Catalogue, are 36; in Tycho's 4; and in the Britannic Catalogue, with Sharp's Appendix, 35.

CENTAURS, in *Mythology*, a kind of fabulous monsters, half men and half horses.—The poets pretended that the Centaurs were the sons of Ixion and a cloud; the reason of which fancy is, that they retired to a castle called νεφελη, which signifies "a cloud."—This fable is differently interpreted: some will have the Centaurs to have been a body of shepherds and herdsmen, rich in cattle, who inhabited the mountains of Arcadia, and to whom is attributed the invention of bucolic poetry. Palæphætus, in his book of incredibles, relates, that under the reign of Ixion, king of Thessaly, a herd of bulls on Mount Thessaly run mad, and ravaged the whole country, rendering the mountains inaccessible; that some young men who had found the art of taming and mounting horses, undertook to clear the mountains of these animals, which they pursued on horseback, and thence obtained the appellation of *Centaurs*. This success rendering them insolent, they insulted the Lapithæ, a people of Thessaly: and because when attacked they fled with great rapidity, it was supposed they were half horses and half men.—The Centaurs in reality were a tribe of Lapithæ, who inhabited the city Pelethronium, adjoining to Mount Pelion, and first invented the art of breaking horses, as is intimated by Virgil.

CENTAUREA, GREATER CENTAURY. See BOTANY *Index*. There are 61 species belonging to this genus. The root of one of them, called *glastifolia*, is an article in the materia medica. It has a rough, somewhat acrid taste, and abounds with a red viscid juice. Its rough taste has gained it some esteem as an astringent, its acrimony as an aperient, and its glutinous quality as a vulnerary; but the present practice takes very little notice of it in any intention. Another of the species is the cyanus or blue bottle, which grows commonly among corn. The expressed juice of this flower stains linen of a beautiful blue colour, but is not permanent. Mr Boyle says, that the juice of the inner petals, with a little alum, makes a beautiful permanent colour, equal to ultramarine.

Lesser CENTAURY. See GENTIANA, BOTANY *Index*.

CENTELLA. See BOTANY *Index*.

CENTENARIUS, or CENTENARIO, in the middle age, an officer who had the government or command, with the administration of justice, in a village. The centenarii as well as vicarii were under the jurisdiction and command of the court. We find them among the Franks, Germans, Lombards, Goths, &c.

CENTENARIUS was also used for an officer who had the command of 100 men, most frequently called a CENTURION.

CENTENARIUS, in monasteries, was an officer who had the command of 100 monks.

CENTENINUM OVUM, among naturalists, denotes a sort of hen's egg much smaller than ordinary, vulgarly called a *cock's egg;* from which it has been fabulously held that the cockatrice or basilisk is produced. The name is taken from an opinion, that these are the last eggs which hens lay, having laid 100 before; whence *centeninum*, q. d. the hundredth egg.—These eggs have no yolks, but in other respects differ not from common ones, having the albumen, chalazes, membranes, &c. in common with others. In the place of the yolk is found a little body like a serpent coiled up, which doubtless gave rise to the fable of the basilisk's origin from thence. Their origin is with probability ascribed by Harvey to this, that the yolks in the vitellary of the hen are exhausted before the albumina.

CENTER, or CENTRE, in a general sense, signifies a point equally distant from the extremities of a line, figure, or body. The word is formed from the Greek κεντρον, a *point*.

CENTER of an Arch. Under the article BRIDGE, the different forms of arches have been particularly considered.

Under this article, it comes very properly to be ascertained in what manner the arch-stones are supported till the arch is completed, and the most commodious and least expensive manner in which this can be accomplished. When the span is small, and upon a limited scale, as cellars, and vaults below ground, the foundation of the side walls is dug out, the earth rounded off betwixt, the arch thrown over upon it, and the earth is afterwards dug out and carried away. This must have been done on any account. By this method the wood and workmanship are saved; but it is only in particular instances that this can be done. When the arch to be cast is on land, and at no great height above the surface of the earth, a frame for supporting the arch-stones can be raised from the earth, and bound together, frequently, with a great profusion of wood, which on account of the smallness of the arch is not taken into account; but, when the span is great, or at a great height above the surface of the earth, the expence of a frame formed in the same manner would be enormous, and in many cases impracticable; but whether the arch be great or small, high or low, a proper economy ought to be observed; and the less the expence in wood and workmanship incurred, so much the more advantage to those concerned, and the purpose being obtained, so much more credit is due to the engineer.

It is again to be considered, on the other hand, that in order to save some expence, either in wood or workmanship, the frame or center, as we shall call it, is made too slight, and so unconnected in its parts, that the pressure of the arch-stones is greater than it can support. The whole work is brought down, and the saving on the one part produces a more serious loss on the other; so that both the workmen and proprietors agree, that it is better that the center be too strong than too weak; better have too much wood in it than too

too little. To assist the mechanic in this important affair, is the design of treating this article with particular attention; for which purpose we shall be at pains to acquire every assistance that can be collected, from the most experienced engineers, and from the researches and experiments of the most distinguished philosophers who have treated of such arts as may enable us to elucidate the subject, and make it worth the attention of engineers and mechanics who may have occasion to exert their genius in that line.

In the first place, it will be necessary to consider the weight to be supported: 2dly, The quantity of the materials to be used, that shall be of strength sufficient to support such a weight: 3dly, The most effective method to apply these materials, as supported by the most approved authorities, or practised by the ablest engineers. The weight to be supported is the arch-stones. Suppose an arch 20 feet span, (see figures for the arches, a new figure being unnecessary). It has been shown under the article Bridge, that the arch can be raised to 30 degrees and upwards, without the support of the center; after which it begins to rest upon the frame of which the center is composed, if the arch is a semicircle, or semiellipse; if a segment of a circle, it will press sooner upon the center, and the more so the flatter the arch is. 1st, Suppose a semicircle; then there is 120 degrees of the arch to be supported by the center, the diameter supposed is 20 feet. One hundred and twenty degrees will measure 20.94393 feet; but as it is advisable to give the advantage to the center, we call it 21 feet in an arch of 20 feet span. If the stone is of a durable and hard quality, perhaps an arch-stone of 12 or 14 inches might be of sufficient strength; yet it is not probable that any one would think of less than 18 inches for the thickness of the arch; for it will not have too heavy an appearance if it should be two feet thick. We shall calculate the weight at 18 inches square; the thickness of the stone is not here to be considered, as the weight of the whole is to be supported till the key-stone is driven: the specific gravity of good free stone is 2.532, the solid feet in an arch of 120 degrees; the span 20 feet is 21 feet, nearly as above. The stone 18 inches square by 21 feet gives 47.25 solid feet; the weight by the above specific gravity is 7477.3076 lb. avoirdupoise, about 66.753 cwt. being the weight that one rib of the center frame must sustain, without warping, or by the pressure on its haunches make it rise in the crown; neither must it sink under the pressure: in either case the consequences would be fatal, either in causing the arch to give way, upon striking out the center, or in weakening it in such a manner as to shorten its durability; being twisted in its shape, the equilibrium would be destroyed, and the consequence would be either to spring the key-stone, or, if that was prevented by the weight above it, the same weight would cause it to yield at about, or a little above, 30 degrees from the spring of the arch. From all which the necessity of the strength and firmness of the center frame is evident.

If the arch exceeds 20 feet, suppose 50, the weight will evidently become greater, and an additional strength necessary on that account; and likewise on account of its greater extent, the frame that would be sufficiently firm at 20 feet would be supple at 50. To prevent any error on this account, another calculation for 50 feet will become necessary. In the span of 50 the arch of 120 degrees measures 52.36 feet; suppose the arch-stone, $2\frac{1}{2}$ feet deep by 2, is five superficial feet, multiplied by 52.36 is 261.8 solid feet, and at the above specific gravity gives 41429.7154748 lb. avoirdupoise, equal to 369.908 cwt. Here the weight is increased upon the center frame, in the proportion of 66.5 to 369.9, that is, more than five times, besides what allowance it will be necessary to make for the difference of the stiffness of the center frame; both which will be considered in their proper places.

Let us now consider what will be the increase of weight, upon a span of 100 feet. The rise of the arch, before it presses on the center frame in a semicircle, being in the same proportion, the arch of 120 degrees in 100 feet span measures 104.719 feet; the arch-stone may be supposed abundantly strong of 4 feet length, for the depth of the arch, and 3 feet broad, which makes a superficies of 12 feet, and multiplied by 104.719 gives 1256.628 solid feet, the specific gravity, that is, the stone is supposed of the same durability gives 198.861.381 lb. avoirdupois, equal to 1775.548 cwt. about five times more weight than upon the arch of 50 feet span. If the arch is 130 feet span, 120 degrees measures 136.13556 feet. Suppose the arch-stone 5 feet, as in the arch-stones of the bridge over the Dee at Aberdeen, at least they are between $4\frac{1}{2}$ and 5 feet. The Aberdeen granite is a very hard stone, and perhaps exceeds the specific gravity above. The arch-stone is here supposed to be 5 feet by 3, equal to 15 square feet, multiplied by 136.13556, gives 2042.0334 solid feet. According to the above specific gravity, the weight to be supported till the key-stone is drove, is 2885.2838 cwt. The weight of the key-stone in the whole of the above may be deducted.

As center-frames must likewise be used for iron bridges, we shall consider them, and take the span 236 feet, still supporting a semicircle.

It may be proper to take the weight that it would be if the arch were the segment of a circle, the span of the arch 236, the height above the spring of the arch or the versed sine of the arch, 34 feet, in which case the diameter of the circle would be 444 feet nearly; the arch-stones in this segment would press upon the center-frame, at about 18 feet from the spring of the arch. Suppose the arch-stone 5 feet by 4, equal to 20 superficial feet, the whole measure of the arch is 444.154 lineal feet, the solid content is 4131.84 feet, and weight 318.689 tons; but the weight of the iron was only 260 tons. It may not be improper here to observe, that in a stone bridge of that span, 5 feet of arch-stone would be too small to sustain the arch. It may perhaps be admitted, that it would be sufficient to support its own weight; and if so, the arch being smoothed above, a second arch of a five feet stone may be thrown over above it. These two together may form a stronger arch than a stone of ten feet depth would do. And thus a stone arch may be extended to any span, and made of abundant strength; and experience has shown its durability to withstand the weather. Thus the old London bridge has performed its faithful ssrvices to the public for 600 years: that it was an incumbrance in passing up and down the

Center

the river, and clumsy in its construction, were owing to the taste of the times. Perhaps few will be found that would be willing to insure an iron bridge against the ruin occasioned by the weather for the same time, or perhaps much above one-half that time. But this is not a fit place to enter into the full discussion of this subject. To return to the weight pressing upon a center-frame. Having now taken a view of the weight to be supported, it comes next to be considered what strength of wood is necessary to resist this force, and the most proper and commodious manner of combining the parts. To determine this, we must have recourse to such experiments as have been made for trying the strength of different species of stone and wood.

Experiments have been made to ascertain the strength of timber, and many of them appear to have been conducted with great care and attention. Some of these the reader will find collected and detailed under the article *Strength of Materials.* We shall here state the result of some of the curious experiments which were instituted by the Count de Buffon to ascertain this point. According to these experiments, the batten of five inches square, whose length was 14 feet, and which supported a weight of 5300, which may be called its breaking force, should have double the strength of a batten of 28 feet long. But it has a great deal more. The latter by the experiment is equal to 1775 only; whereas the half of 5300 is 2650. But it is to be considered, that the power of the lever is in proportion to its distance from the fulcrum; this power arising from the weight of the log, is the weight of one foot of wood acting as a weight at a distance from the fulcrum. The log increases in its power to break by its length; 12 inches of this log, five inches square, weighs about 10.4 lb. somewhat more or less; and 10.4 lb. at 13 feet distance, acts with a force of 135.2 lb.: this we consider the last term; and 0, the point of fracture, is the first term; the first and last term, multiplied by half the number of terms, are equal to the sum of all the terms; that is, $135.2 \times 6\frac{1}{2}$, amount 878.8 lb. added to 1775, equal 2653.8; so near to the half, that the difference may easily be accounted for, from the real weight of the wood on which the experiment was made; and our taking the weight from tables of specific gravity, of the supposed 60 lb. To take another example, a batten of nine feet is double the strength of one of the same size of 18 feet long. The weight that breaks a batten of nine feet, five inches square, is 8308 lb.; the half is 4154; but by the experiment, 3700 lb. break the batten at 18 feet. N. B. The weight being laid upon the middle, $9\frac{1}{2}$ is the number of terms, one-half is 4.625. Seventeen feet one-half is $8\frac{1}{2}$; 10.4 lb. multiplied by $8\frac{1}{2}$, is 102×4.625, half the number of terms, is $471.25 + 3700$, is 4171.25, somewhat greater, but which is so near, that the smallest accident for failure, not discernible in the wood, will occasion the difference. Now, to reduce the experiment of this given size to any other of greater dimensions; suppose one foot; similar solids of the same altitude are to one another as their bases; that is, 25, the base of the five inch square, is to 144, the base of the 12 inch square, as the weight that would break the batten of nine feet, to the weight that will break another of the same nine feet length, and of one-foot square (5. 6. El. 12.), that is, as the base 25 is to the weight 8308, so is 144 to 47854 lb.: equal 213.8125 ton, and the proportion as above, for greater or less length of logs or spars. As we have no experiments made of logs of 12 inches square, unless there is something in the texture of the fibres, in pieces of different diameters, we have every reason to conclude, the above proportion will give the proper strength of the material used. It must, however, not be forgot, that the pieces upon which the experiments were made, were nicely chosen for the purpose. It will scarcely be practicable to find a piece of 12 inches square, and even of nine feet length, equally well adapted to bear a proportionable strain; and much more difficult to find a piece of still greater length. These experiments and proportions afford a safe criterion for proper limits to be attended to in practice. In this, we do not mean to apply such a load upon the beam as will break it; we intend the beam to support the load, without giving way or yielding to it.

In the same experiments, we are told by the author, that two-thirds of the weight broke the beam in the space of two months; that one-half the weight gave a set or bend which it did not recover, but shewed no farther tendency to break; that one-third of the weight, after long continuance, did not give it a set; but the weight being removed, the beam returned to the same position as before it was loaded. Betwixt one-third and the half of load or weight that would break the beam, is the strength we allot to it for permanent use. Before we proceed to put the above observations into full practice, let us examine whether the log is necessary to be square to give it the greatest strength; practice, in a great measure, determines that it is not. It is, however, necessary to inquire what breadth to a given depth is sufficient as a *maximum* that we ought not to exceed; or what is the *minimum* that we may use, so as not to lose the principal intended effect. Belidor has made a series of experiments on the transverse strength of bodies, which are detailed in his *Science des Ingenieurs*, but the spars are only of one inch, not exceeding two inches in breadth or thickness. Among these, we select one spar two inches breadth, one inch depth, and 18 inches length; which at the *medium* of three trials was broken, lying loose at both ends, by 805 lb. Another one inch board, two inches deep, and 18 inches long, broke with the force of 1580 lb.; nearly in the proportion of the square of the depth, being only a diminution of 20 lb. weight. In the present case, the quantity of matter is the same in both.

It may therefore be concluded from this experiment, that a batten of any depth, and one-half breadth, is equally strong in that position as if it had been square timber; and that the strength is according to the depth, if the breadth is only such as that it does not yield in that direction. And hence the advantage in point of economy; for if the piece is set upon its edge, suppose nine inches deep and one broad, provided that by straining the piece in depth, it shall not yield in the lateral direction, it will bear as much strain as if nine inches square. The experiment may be performed upon a small scale. Suppose five inches, and one inch broad, the thin section may be inclosed at different distances with pieces five inches square. Suppose at the distances of 1, 2, 3, &c. fig. 1. Plate CXXXVIII. and the weight applied that broke the five inch square of the length of 14 feet, viz. 5300 lb. All

All the experiments which have been alluded to above were made upon scantling of sound oak. But it has already been observed, that in practice, such pieces cannot always, if at all, be selected. But the practical mechanic, confining himself to between one-third and one-half of the absolute strength, according as his judgment directs him, respecting the soundness of the piece he uses; there can be no doubt, that, upon occasions, he will be convinced, that he cannot, with safety, allow even one-third of the absolute strength, but must take it considerably below that proportion.

As to other species of wood, trials have also been made; and the result from different experiments has occasioned some deviation. We are told that Buffon makes fir about $\frac{6}{10}$ths of the strength of oak, Parent $\frac{10}{12}$ths, and Emerson $\frac{2}{3}$ds; all of them different. The difference between Buffon and Parent is $\frac{1}{10}$; between Parent and Emerson is $\frac{1}{6}$th; and between Buffon and Emerson is $\frac{1}{7}$th. It is easy to conceive that the different states of the wood, and different circumstances in the same species of fir and oak, will make a considerable difference; although the same persons were employed on the same materials, the experiments would probably vary; much more, may it be allowed that at different times different states of the wood must make the results different.

The experiments made by different persons vary in their amount. Belidor's experiments agree one part with another, and so do Buffon's, but differ in their results from Belidor's. Belidor's slips of oak are only of one inch square, and Buffon's are from four to eight inches square, and from 7 to 28 feet in length. When the one is reduced to the standard of the other, they do not agree: the difference may arise from various causes. We know that there is a difference in the strength of oak of different growths, and from different soils, as well as in other species of wood; there is likewise a difference in the degree of seasoning of the wood. Buffon gives the weight of his wood, Belidor does not. If Buffon's log or batten, four inches square, weighs about 60 lb. that is, about 77 lb. the solid foot; whereas a solid foot of dry oak will not weigh above 60 lb.; but Buffon acknowledges that his wood was in the sap, as vapours issued at both ends in the bending. These differences may make all the odds in the breaking, unless the proportion was established to be, as the squares of the diameter of the battens; but this is not the case, for in Buffon's experiments, the square of four, to the square of five of the seven feet batten, the breaking force is 8300lb.; but the experiment gives it 11525; that of six inches square 16 : 36 :: 5312.11952; exp. 18950. In the seven inch square 16 : 49.5312.16268; exp. 32200. In the eighth inch square 16.64.5312 : 21248; exp. 4709, the difference between the four and five inch square is one-third part of the experiment weight; the difference between the four and six is somewhat more than one-third the experiment weight; and in the seventh, the difference is a little less than half the experiment weight; between the seventh and the eighth the difference is greater than half the experiment weight.

There is likewise a difference at the different lengths; for it does not appear that the different lengths bear a proportion to their parts; a batten of four inches square of seven feet length, is expected to be double the strength of one of the same dimensions of 14 feet length; that is, the one of 14 feet length is expected to break with one half of the weight that breaks the seven feet batten; but we find it much less; but when it is considered that the weight of the materials acting at a greater distance from the center of motion, this must be taken into the account, and added to the weight of the breaking force. For example, the batten of five inches square and 12 inches length, weighs 13.368lb. at the rate of 77lb. per solid foot. This weight, acting upon the batten of 14 feet, taking the amount of the whole in an arithmetical ratio, is $13.368 \times 52\frac{1}{2} = 701.5$lb. acting upon the whole, added to 5300, the breaking force 6001. The breaking force, at seven feet, is 11525; one half is 5762.2.5, one twenty-fourth part greater than the half. The batten of six inches square, the breaking force at 14 feet is 7475, the weight of 12 inches of this batten is 19.25lb. at 77lb. per solid foot; the acting force of this weight at 14 feet length is $19.25 \times 52\frac{1}{2}$, is 1010.625, added to 7475, equal to 8485625. Now the breaking force of seven feet length is 18950; one half is 9475, difference is 989, that is, nine and a half times less than the half. In the seven inch batten of seven feet length, the breaking force is 32,200lb. and of 14 feet length, the breaking force is 13.225. The weight of 12 inches of the seven inch square is 2602lb. acting upon the 14 feet length, is $1370.5 + 1322.5 =$ 14600lb. which is one-ninth less than the half. Again, 12 inches of the eight inch batten weighs 34.2lb. at 77lb. per solid foot, acting upon the 14 feet length, is 1796lb. added to 19775, the force that broke it at 14 feet length is 21575lb. about one-tenth part less than the half of 47,649lb. which broke it at seven feet length. From the above comparison, it may be allowed, that the difference of the force that broke the spar at seven feet, and that which broke it at 14, so far as it differs from the half, is accounted for upon philosophical principles; and when we consider that the spars or battens cannot be supposed to be mathematically exact in their measure, and that a difference in point of breaking, may be accounted for from that cause; but further, it may be observed that the weight of the materials is not equal in the solid foot. For example, the spar four inches square, and several feet in length, weighs 60lb.; that is, at the rate of 77.14lb. per solid or cubic foot, the eight feet spar at the rate of 76.5lb. do.; the nine feet spar at the rate of 77 feet; the 10 feet spar at the rate of 75.6; the 12 feet spar at the rate of 75lb. per cubic foot; which difference of weight, with the difference of exact mathematical measure, may fully account for all the difference that takes place in the manner of accounting for the above-mentioned difference of the weight of breaking at 7 and 14 feet; as also the difference that takes place between 8 and 16; 9 and 18, &c. The experiments being made upon green wood, cannot be approved of; they ought to have been made of such seasoned wood as is fitted for mechanical purposes, of which none of this kind can be used; or if experiments are made with unseasoned wood, as being of the greatest strength, they ought likewise to have been made with dry wood seasoned for use. A cubic foot of dry oak

Center.

oak will not weigh much above 60lb. Those spars upon which the experiments were made, must have been very green, and very unfit for mechanical purposes, which gives an unfair account of the strength, when in a proper state for use. But experiments were made with wood of different weights, which may be supposed better seasoned. For example, the seven feet spar that weighs 56lb. that is, 72lb. per cubic foot; the nine feet spar is at 71lb. per solid foot, and the 10 feet spar at 73.8lb. per solid foot, none of which are seasoned wood. And yet it is not mentioned which of these were used. This may be adduced as a very good reason why the variations were so great.

We shall now consider the force in bruising materials, according as we may be directed by experiments made in this way. And, 1st, upon that of stone, which will in some measure lead to the pressure in the same direction upon other materials.

The experiments selected from M. Gauthey, engineer, in erecting the bridge of Chalons sur Saone (tom. iv. *Rozier Journal de Physique*, November 1774), are now to be considered.

Experiments Selected.

	Length of the Stone.	Breadth.	Superficies.	Force.	Upon each square line.	Proportion.	Difference.
		Lines.		lb.			
Hard Stone	8	8	$64\frac{4}{9}$	46	$10\frac{2}{3}$	12	$\frac{2}{15}$
	8	12	$96\frac{2}{3}$	164	27	24	$\frac{1}{8}$
	8	16	$128\frac{7}{8}$	281	$35\frac{1}{3}$	36	$\frac{1}{34}$
Soft Stone	9	16	144.1	35	$3\frac{2}{3}$	4	$\frac{1?}{32}$
	9	18	$162.1\frac{1}{8}$	53	5	$4\frac{1}{2}$	$\frac{1}{9}$
	18	18	$324.2\frac{1}{4}$	183	$8\frac{1}{2}$	9	$\frac{15}{18}$
	18	24	432.3	131	$12\frac{2}{3}$	12	$\frac{11}{28}$

In general, the force is greater as the surfaces increase, but a regular proportion to fix upon a theory is not found; but the last line in the table, the weight that crushes the 432.3 surface must be greater than 131, the stone being of the same quality; if in the proportion of $8\frac{1}{2}$ to $12\frac{2}{3}$, the crushing weight will be 272.7 instead of 131.

The measures here taken are cubic, and the pressing force is upon cubic lines, the thickness one line; where the pressure is upon a square foot, it is likewise to be understood one foot deep, or upon a cubic foot; the stone used, he terms *Givry stone*, of which he gives its absolute force to be 870911, that it will bear 663552lb. In the cubic foot of soft stone the strength is 248832lb. The proportional force of the hard and soft is $2\frac{1}{4}$ to 1.

A cubic foot of a stone fixed in a wall, and projecting one foot, was broken by a force of 55728lb. And a cubic foot of soft, by 10080lb. the proportion $5\frac{1}{2}$ to 1.

A cubic foot of hard stone, supported upon two fulcrums at 1 foot distance, was broken by 205632lb. suspended from its middle; and the soft by 38592, the proportion about $5\frac{1}{4}$ to 1.

In fine, a cubic foot of the hard stone was torn asunder by 45,500lb.; and the soft by 15,850lb. the proportion $2\frac{1}{4}$ to 1. Thus far Gauthey's account.

It is to be observed, that the above table does not strictly correspond with itself; for the proportion upon the square line, or $\frac{1}{12}$ of an inch, in place of $10\frac{2}{3}$ is upwards of 11. Now, the increase of force which crushes 96 square lines, and 128 one line thick, is 7.8 oz. nearly upon the square line, that is a little more than $\frac{1}{5}$ of 35 oz. upon the square line; then, as 128 square lines is to 4496oz. so is 144 square lines to 5058, to which add one-fifth, viz. $1011\frac{1}{4}$, this makes $6069\frac{1}{4}$ upon the square inch, and this multiplied by 144, the square inches in a foot, is 874,022.4oz. but Mr Gauthey says, that the square foot of surface of one foot deep, is of the strength of 870,911lb.

Again there are 20,736 square lines in a square inch, the force upon a surface of 64 square inches being about 11.5 upon each square line, is 238,464 oz. upon the square foot. Upon the surface of 96 lines, 27oz. to the square line, gives 559,872 to the square foot. Upon the surface of 128 lines, $35\frac{1}{3}$ to the square line, is 878,806 to the square foot, the proportion of 238464oz. to 870,911 is about $53\frac{1}{4}$ nearly, and of 559,872 to 870,911 is $\frac{2}{3}$ nearly; but by the experiment the number 870,911 is lbs. upon the square foot; the other numbers are only ozs. The variation between the first difference and between the pressing force of $6069\frac{1}{4}$oz. upon the square inch, makes in that proportion 874,022oz. The increase of force from one square inch to one square foot, must be $\frac{1}{16}$ part of what the above experiment upon the square foot produces. Further experiments upon this therefore become necessary. In the mean time, we have no reason to doubt the experiment upon the square foot, or upon the smaller parts; intermediate experiments only can make them accord. One example adduced is of consequence. A pillar in the church of All Saints, in Angers, of 24 feet height, and 11 inches square, supports a weight of 60,000lb. that is $\frac{1}{5}$ being added 85685.9 upon the square foot, which is said not to be $\frac{1}{7}$ part of the load that would crush it. From this it is evident, that the load it supports exceeds the weight of an arch of 50 feet span, of a semicircular form; the arch-stones being $2\frac{1}{2}$ feet long, or depth of the arch, and 2 feet in breadth. It is asserted under the article BRIDGE, that instead of an arch $\frac{1}{5}$ of the opening or 10 feet thick, that a pier of 2 feet thick would be sufficient, but that it is given twice the length of the arch-stone, that is 5 feet thick in place of of 10; but from this example, it is five times thicker than necessary, and has therefore superabundant strength, allowing even for the force of a current. How superfluous then will these clumsy piers be reckoned, whose sole effect is a useless obstruction to the water! But as our principal design at present is upon the strength of wood, in prosecution of this inquiry, we have paid particular attention to the strength of this material, in the transverse direction, in so far as it can be supported by experiment. Before we proceed to make particular application to its use, it will be necessary to consider its strength or power of resistance in its breadth and thickness. In this it may be with safety averred that such force as will bruise or crush its fibres, although only of $\frac{1}{10}$ or $\frac{1}{11}$ of an inch; the same weight continued will produce the same effect upon the next stratum, till the whole piece is bruised, and its cohesive power overcome. This is supported by the experiments of celebrated mechanicians, as those of Buffon, Muschenbroek, Bouguer. Muschenbroek, in his *Essai de Physique*, says, that a piece of sound oak $\frac{27}{100}$ of an inch is torn asunder by 1150lb.; and that a plank 12 inches broad, and 1 thick, will just bear 189,168lbs. These give for the cohesion of an inch 15,755, and 15,763 lbs. Bouguer in his *Traité de Navire* says, that it is very well known that a rod of sound oak, of $\frac{1}{4}$ inch square can be torn asunder by 1000 lb.; this gives 16,000 for the square inch. Bouguer speaks with certainty, that $\frac{1}{4}$ inch square of sound oak can be torn asunder by 1000 lb. If we reduce the above proportion of the experiment, it will appear, that the force will be much greater than 16,000, to tear asunder a piece of sound oak of one inch square. It must in the mean time be allowed, that Buffon's experiments being upon a larger scale, can be followed with more security than those upon a smaller scale.

But, after all, we have not yet got sufficient data to form a criterion for an arch; nor can this be expected till we have more precisely ascertained the strength of an arch above a right line, parallel to the horizon.

In the first place, as an arch is in form, one part of it towards the perpendicular, and the other towards a horizontal line; the force that it will sustain, is between that force that a body will carry in the perpendicular, and that which produces a fracture upon any material in the horizontal direction. If the perpendicular is greater than the horizontal line, it will have more of the strength of the bruising force, than of the transverse fracture; and the force may be expressed by the ratio compounded of the bruising or crushing force, and that of the transverse fracture; or not improperly expressed, as it has been denominated by others, the absolute and relative force.

Unfortunately we have not yet a sufficient variety of experiments to ascertain the absolute force, as those made are only upon a small scale; and the number is not adequate to form a proportion of the increase for the force that will crush a piece of wood of $\frac{1}{10}$, or, as the French philosophers have done most this way, we take their measure $\frac{1}{11}$ of an inch, or one line, and from that to an inch; but the force required is found to be greater than that of the square of the diameter, as also the force to produce a transverse fracture, or to give the relative strength. This increases in a greater *ratio* than that of the square of the diameters; for in the above experiments, the weight that broke a batten 4 inches square, was to that weight which broke an 8-inch square batten, each of the length of 7 feet, more than double of the square of 4 to the square of 8 as above; we are, therefore, much limited as to an exact procedure.

At the same time, by keeping the experiments in view, and the observations made upon them, we shall be able to give such a *ratio*, as to the necessary strength, and will furnish the ingenious artist with a pretty sure principle to act upon, and prevent his using superfluous materials, either in their application to horizontal right lines, or inclined in the right-lined direction, or in curves.

If we attend to the weight that crushes one inch of sound oak, by Muschenbroek's experiments, we find that it is 17,300 lb. but, if computed from the increase, being as the squares of the diameters, it is only 16,000 lb. but it has been found as above, that the power to break, or make a transverse fracture in the same wood, of the same length, of different diameters, if a considerable difference in diameters is taken, the difference of weight is twice that produced by the square of the diameter. This comparison makes the proportion between the strength of stone, and that of wood, to be as 17,300 is to 6048, or 1 to $2\frac{1}{4}$ nearly. Thus we may with a sufficient degree of accuracy substitute the one for the other in point of strength, and form a proportion between the arch and the strength of a horizontal line. As several experimentalists agree, that a square inch of wood can be crushed or pulled asunder with a weight of between 16,000 and 17,300lb. and that a piece of wood one inch square, 18 inches in length, can be broken by 406 lb. or at 12 inches by 609, or at 6 inches by 1218; attending to the addition as mentioned above, which has been proved by comparison of experiments, to be upon the principle of the lever. If, then, the geometrical mean is taken between the elevation of the arch, as pressure or absolute strength, and the length of the horizontal line, this mean will be the strength of the arch above the horizontal line; for it is evident, that so much as the piece of wood is elevated towards the perpendicular, so much the nearer it approaches to its absolute strength, and by so much as the arch is flatter or the piece of wood less inclined, the nearer it is to a straight line, and so much the more reduced to its relative strength; the position of the arch, therefore, must be in the ratio compounded of these two.

Having now established the principles, let us endeavour to apply them to practice, in forming a center or supporting an arch, to produce the intended curvature or mould for an arch of any intended span, and at the same time have strength to support the same. Several ingenious artists have not only formed, but have written and laid down principles for forming these moulds, both with regard to strength and economy; at the same time we have not found any that have treated the subject upon principles that are fully established. We have, therefore, been the more particular, according to the principles laid down. 1st, We have assigned the weight to be supported, as established by uncontroverted principles: And, 2dly, established the strength of

Center.

of wood as to its thickness or diameter, that is sufficient to sustain such weight; which we have supported by the most approved experiments, comparing one with the other; and in the third place, we have considered the effects when the materials are applied in the horizontal direction, or elevated in any degree toward the perpendicular.

In a work of this kind, it is not only necessary to lay before our readers well grounded principles, and a well supported theory, but along with these, the different opinions, and various modes used by the most distinguished artists, who have exhibited their plans to the public, together with the principles on which they were founded, and the success they have met with, in answering the purposes proposed.

Among the most distinguished who have treated this subject, we may consider Pitot, a member of the Academy of Sciences, who wrote about the beginning of the last century. His method undoubtedly shows considerable ingenuity; but, at the same time, we must observe that he has been rather too profuse in the quantity of materials which he has employed.

To lay his plan of operation before our readers, we shall give a figure showing the constructions. The arch of the circle or ellipse being formed; as little or no weight lies upon the center, till between 30 and 35 degrees of the arch, a stretcher is extended at this height, to the same height on the opposite side; two struts support this stretcher from the spring of the arch; upon the upper part of the stretcher, immediately above, or a little within the upper end of the truss on each side, two spars joining upon the king-post, spring from about the middle of the arch, the stretcher being divided into four parts. Another strut springs from the rise of the arch, meeting the stretcher at this fourth part, from each side of the arch; these last struts are joined by a tie-beam, which gives additional strength to the first stretcher; upon these, on the upper side of the stretcher, two spars join the king-post, a little below the other; these spars are joined by bridles or cross spars, from the circular arch, to the lower strut; ribs of the same formation being placed at proper distances, according to the width of the bridge, and joined by bridging joints, which may be of greater or lesser strength, according to the span of the arch, and of consequence the weight it has to support. Pitot is the first writer who has given us any account of the method of forming frames, according to the above general description. If no rests are left at the spring of the arch, as a base for the center to rest upon; let AB, fig. 1. Plate CXXXVIII. be the ends of two planks raised from the foundation, upon which the center may rest; let CD be the stretcher, extended about 35 or 40 degrees from the spring of the arch; or, as little weight rests upon the center till that height, the stretcher may be as high as 45 degrees; let AE, AG, BD, BG be the two struts on each side; from each extremity of the center, let BE, AE, be fixed to the stretcher near C and D, and AG, BG, at $\frac{1}{4}$ of CD; their stretcher or tie-beam GG, equal to one-half of CD, the bridles, 1, 2, 3, &c. from A to C, and from B to D, are intended to prevent the arch from yielding from A to C, and from B to D. The struts EF, EF, meeting the king-post K in F, and the interior struts GH, GH, meeting the king-post in H, support the bridles 4, 5, 6, on each side of the king-post; their use is to stiffen the frame of the center, which supports the upper and more weighty part of the arch.

The arch for which Pitot allots this center, is of 60 feet span; and the arch stones seven feet in length, the weight of a solid cubic foot he makes 160 lb. The Portland stone is admitted to weigh 160 lb.; but we do not find any other freestone of such weight. It is however to be considered, that the Paris foot is 12.788 of our inches; that is, a little more than $12\frac{3}{4}$ths of our measure, which will make a difference of the weight upon the foot; as also their lb. is lighter than ours about 1.2 oz. by which the stone here mentioned is not better than ours. In a matter of this kind, such exactness is not necessary. As was proposed, we first consider the weight to be supported by the frame; and here it is evident from the figure that no strain lies upon the frame below C; the arch is raised, or can be raised to this height, before the frame is set; therefore the perpendicular C *c* determines the limits of the absolute pressure upon the frame. The triangle C *e c* presses on the frame, and the triangle C *fg* adds to the lateral pressure; the weight of the arch, that actually presses upon the frame, is contained between the perpendicular lines C *c*, D *d*; no more can press upon the center frame. The part of the arch below C will rest upon the abutment raised upon the pier; but if it is insisted that there is a pressure upon the lower part of the center frame, what can only possibly rest, or press upon it, must be contained between the parallels C *c* and *fg*: although it will be admitted, that the arch can be raised to the height C, without the center frame; but to indulge such as say it is not advisable to do it, we will admit what lies between these parallels to press upon the frame. Now to determine the weight of these parts of the arch, the distance between the perpendiculars C *c*, D *d* is 53 feet; the arch-stone is 7 feet, and admit it to be three feet broad, $53 \times 7 \times 3 \times 160\text{ lb.} = 178{,}080\text{ lb.}$

To determine the area between the two parallels C *c*, *f g*, the line *f g* perpendicular to the diameter AB, is $13\frac{1}{2}$, the base is $9\frac{1}{2}$, and C *f* perpendicular to it is 7 feet, the area is $33\frac{1}{4}$ feet; C *c* the base of the triangle C *f c* is 7.2, and *f c* is 7; the area is 25, the difference is $8\frac{1}{4}$. If this difference had been the excess of the triangle C *f c* above the triangle C *f g*, it would have been a pressure upon the frame; but as it is the reverse, the pressure is upon the abutment. This distinction is requisite to be taken notice of, that an unnecessary expence of wood and workmanship be not expended where it is unnecessary; as well as its being unworkman-like, or having an appearance of ignorance in the engineer.

Let us now inquire, what strength of materials is sufficient to support this weight. It has been laid down as a principle, that the parts of wood in an arch act upon one another by their absolute strength; but are liable to the transverse fracture; in proportion to the length of the piece, in a span of 60 feet, the length of the piece may be 7 feet without sensibly impairing its strength, in reducing it to the round; and experiment gives the relative strength of 7 feet to be 47649 lb. by 8 inches square. It has been formerly illustrated from

from experiments, that the strength is according to the depth, with this precaution, that the breadth or thickness be such, that it is prevented from warping, the absolute strength being nearly, by last experiment mentioned, as the squares of the depth. The absolute strength to the relative force has been found nearly 60 to 1, although by some it is said to be only 42 to 1; the absolute strength of the plank 12 inches broad by one thick, is 189163lb.; if two inches, it would be no more than 189163lb. If it had been 8 inches square, then every 7 feet of the arch might be broken with the weight 189163 lb.; but the whole weight of the arch is only 178080lb. that is, 11080 less weight than what that part of the frame would bear; but 7 feet is only about one-seventh part of 53; the frame is therefore of sufficient strength to support the whole weight of the arch when equally divided along its whole length. This is not the case with the center frame of an arch, as it is loaded at one place, and not at another; it is therefore apt to yield between the parts where the load is laid; that is, it may rise in the middle, and thus change the form of the arch; for the center frame is not only intended to support the arch, but likewise to preserve its true form; for this cause some struts may be necessary to prevent its putting the arch out of shape. To remedy this, where the arch begins to press upon the frame at C, draw the chord line C *c*, fig. 2. which acts as a tie-beam to the arch, from C at 35 degrees to *c* at 51 degrees, as, beyond this, if the arch frame had been permitted to alter its shape, it would begin to be restored to it, at least the force would tend that way. At that part of the arch, where its weight begins to flatten the frame, as at 2, draw the stretcher 2, 2, which likewise acts as a tie-beam, and gives support to the bridle 1, on one side, and to 3 the bridle upon the other side, from D *d*; and thus the arch *c d* is prevented from sinking by the tie-beams *e d*. This will effectually prevent any warping or yielding of the frame, notwithstanding the enormous load from the size of the arch-stones.

But it is necessary to attend to the relative strength of different kinds of timber of which frames may be constructed. The relative proportion of the strength of oak and fir has been ascertained by different experiments; and although the results do not exactly agree, yet the mean or least proportion may be taken. Let us take $\frac{6}{10}$, that of Buffon. Now to reduce a frame of oak to one of fir of equal strength, divide 8 inches, the diameter of the oak, by $\frac{6}{10}$, the relative strength of fir; this gives $1\frac{1}{3}$ inches. Allow $1\frac{1}{2}$ inches. The depth of the frame will then be $9\frac{1}{2}$ inches by $\frac{1}{3}$ or $\frac{1}{2}$ inches in breadth; that is, $9\frac{1}{2}$ by $2\frac{1}{2}$ inches. In this way the strength of the fir arch is rendered equal, and by the additional allowance superior to the oak in strength, and of less expence in wood and workmanship.

We have here taken the most simple method of investigation and computation, that every mechanic, whether scientific or not, can easily follow it in every step, and judge of the propriety or impropriety of what is advanced.

It will now be necessary to follow Mr Pitot in estimating the quantity of materials which he allows. The ring of his arches consists of pieces of oak 12 inches broad and six thick. The stretcher CD is 12 inches square, the straining piece GG is likewise 12 inches square, the lower struts 10 inches by 8; the king-post 12 inches square, the upper struts 10 by 6, the ridges 20 by 8, French measure. Pitot allows the square inch to carry 8650lb. that is, one half of the absolute strength, which is ascertained by experiment to be 17300lb. nearly, and not by the square of the diameter, which would be only 16000lb. But on account of knots he reduces it to 7200lb. per inch. He then computes the whole load upon the frame to be 707520lb. which is the weight of the whole arch-stones, supposing each to be three feet broad, and the whole to press upon the frame. This comes so very near, that it would be needless to dispute about the difference. We have shown that no more than 178080lb. presses upon the frame; but we are not so fully satisfied as to the weight that rests upon the center. Pitot supposes it to be $\frac{11}{14}$ths of the whole weight; but he has assigned no reason for this conjecture. Mr Couplet assumes that it presses by $\frac{4}{9}$ths. Another writer, who makes some comment upon the whole, says that $\frac{11}{14}$ths is nearer the truth than $\frac{4}{9}$ths, but gives no reason for his opinion, which seems to be equally vague as the other. The pressure here allowed, and the reason of assigning such a pressure, have been already explained. Our readers, therefore have it in their power to examine the principles, and decide for themselves.

It has been asserted by some, that the arch does not press upon the center frame below C. At the same time, were we inclined to dispute this opinion, we might state our objection in the following manner: Suppose the area of the triangle C *c f* was equal to the area of the triangle C *f g*, so that the friction above would make the triangle C *c f* rest upon the side *c f*; and as the triangle C *f g* is greater than C *c f* in the proportion of $33\frac{3}{4}$ths to $25\frac{1}{3}$d, the cohesion of the parts will determine the intermediate space between C *c* and *g f*, to rest upon the abutment as has been said, and not on the perpendicular, unless a scissure is made in the direction *g f*, in which case it would be detached from the lateral pressure, and so rest upon the center. As this is not the case, any plea for a pressure below C is entirely removed; and a method to determine with precision the actual pressure upon the center frame is shewn. If the arch is the center of a circle or an ellipse, a frame so much stronger is necessary, as more of the arch presses upon the frame; but the method of determining the strength is the same as here laid down. A second figure of the ellipse and another calculation are required. It is here to be understood, that the frame calculated for is only one rib; and the weight it supports is that of the arch-stones, between the parallels C *c*, D *d*, to three feet in breadth. If, therefore, the bridge is 42 feet broad, it requires 14 ribs of the above strength. These are joisted over with planks, suppose of two inches thick, and upon these the arch-stones are laid, equally carried on from C and D, and rising equally on each side, till the key-stone is set, in which state they remain, till the engineer judges it proper to slacken the frame, by striking out the wedges at the rests, A and B (or, as the French use logs between the frame and arch), so far as to allow the arch-stones to press upon one another, by the equilibrated curvature

Center. curvature of the arch; after which, it being found, that the arch is perfectly just and secure, the frame is entirely removed. In the frame, fig. 2. the tie-beams are not taken into the account for strength, the arch being abundantly strong without them. Their use is merely to stiffen the frame, on account of the manner in which the weight is laid on. In an elliptic arch, it has been mentioned that it is somewhat different, requiring more strength and the binding likewise different. In what are termed elliptical arches, few or none are strictly so, the true elliptic curve being difficult to form on so large a scale. It may therefore be acceptable to our readers, and also to the ingenious mechanic, if we give the form of an ellipse that will answer nearly to the elliptic equation, and upon an universal plan, easy of construction. The greater and lesser axes of the ellipse being given, divide the excess of the greater axis above the lesser into three equal parts; set off two of these from the center of the greater axis each way; upon this distance describe an equilateral triangle on each side of the greater axis, and produce the sides of the triangle both ways from the vertex of these triangles, to the extremity of the lesser axis; describe two arches till terminated by the sides of the triangle produced gives the flat part of the ellipse. At the intersection of the produced sides of the triangle as a center, with the distance of the extremity of the greater axis, describe an arch which will meet the other arch, and complete the ellipse. Let AB, fig. 3. be the greater axis 60, and DE the lesser axis 40, be drawn at right angles, bisecting one another in C. Set off AF 40, upon AB, then the excess FB is 20, which divide into three parts; set off two of these from C to G and H; upon GH describe the equilateral triangles GHK, GHL; produce KG, KH, to any indefinite length; which may be cut by the arch drawn through D and E; from the centers KL at the intersections GH, and distance AB, let the other part of the ellipse be described; thus an universal method of describing a beautiful ellipse, and so just that it answers the elliptic equation exceedingly near, at least till it becomes very flat.

A second form of a center frame described by Pitot, is adapted to an elliptical arch. The construction differs nothing from the former, only the two upper struts are parallel; the strength as in the former is superabundant, which is easily accounted for, from not knowing the real weight that lies upon the frame, or by considering the whole weight of the arch to rest upon the frame. Both this and the former Pitot has considered as divisible into three pieces, which renders it more manageable in erecting, particularly in large spans. See fig. 4.

Fontana has given a description of a very neat frame consisting of two pieces, the upper and the lower. The struts 1 2, 1 2 taken from fig. 4. leave a representation of Fontana's frame. Different constructions being laid before our readers, the ingenious artist may improve the hints that have been thrown out; and thus form a more simple or better construction.

We shall now select draughts of the most approved center frames that we are able to collect; and make such remarks upon them as may occur. Fig. 5. exhibits a form, which the experienced engineer will readily allow to be neat and ingenious; but there is much more wood and work expended than is necessary. It is divided into two parts, the base or stretcher LL, of the upper part, resting upon the lower part of the frame, the greatest part of which at least must appear quite superfluous. The lower rests, EF, appear only necessary to prevent the stretcher LL from yielding, and thereby allowing the arch to lose its true curvature.

The general maxim of construction adopted by Perronet, a celebrated French architect, is to make the truss consist of several courses of separate trusses, independent, as he supposes, of each other, and thus to employ the united support of them all. Each truss spans over the whole distance of the piers. It consists of a number of struts, set end to end, so as to form a polygon. By this construction, the angles of the ultimate truss lie in lines pointing towards the centre of the curve. It is the invention of Perrault, a physician and architect, and was practised by Mandsard de Sagonnc at the great bridge of Moulins.

In the centering of the bridge of Cravant, fig. 6. the arches are elliptic. The longer axis or span is 60 feet, the semi-transverse axis or rise 20 feet. The arch-stones weigh 176 lb. per foot, and are four feet in length, which is the thickness of the arch. The truss beams were from 15 to 18 feet long, and 9 inches deep by 8 broad. The whole frame was constructed of oak. The distance between the trusses, which were five in number, $5\frac{1}{2}$ feet. The whole weight of the arch amounted to 1,350,000lb. which is nearly equal to 600 tons, making 112 tons for the weight on each truss. Ninety tons of this must be allowed really to press the truss; but a great part of the pressure is sustained by the four beams which make the feet of the truss, joined in pairs on each side. The diagonal of the parallelogram of forces drawn for these beams is to one of the sides as 360 to 285. Then $360:285::90:17\frac{1}{3}$ tons the weight on each foot. The section of each is 144 inches. Three tons may be laid with perfect safety on every inch; and the amount of this is 432 tons, which is six times more than the real pressure on the foot-beams in their longitudinal direction. The absolute strength of each foot-beam is equal to 216 tons. But being more advantageously placed, the diagonal of the parallelogram of forces which corresponds to its position is to the side as 438 to 285. This is equal to $58\frac{1}{16}$ tons for the strain on each foot; which is not much above one-fourth of the pressure it is able to bear. This kind of centering, therefore, undoubtedly possesses the advantage of superabundant strength. The upper row of struts is quite sufficient; nothing is wanted but to procure stiffness for it.

In his executing the bridge at Neuilly, fig. 7. of 120 feet span, and only 30 feet rise; the arch 5 feet thick; his strut-beams are 17 by 14 inches of size, and king-post 15 by nine, the strut-beams placed in three parallel polygons, each abutting upon the king-post, he uses the binders or bridges of 9 inches square. This arch is remarkable for its flatness. The account Perronet gives of his success with this frame, and the effects it produced in his work, are as follows. Notwithstanding the different improvements he had made upon his center frame, he here found that it sunk 13 inches, before the

the key-stones were set, and that the crown rose and sunk as the different courses were laid. At 20 courses on each side, with a load of 16 tons upon the crown, it sunk an inch; when 20 more courses were laid, it sunk half an inch more, and continued sinking as the work advanced. When the key-stone was set, it had sunk 13 inches; and, as it sunk at the crown, and in the advance, to the crown, it rose at the haunches, so as to open the upper parts of the joints almost an inch; which gradually lessened towards the crown, and of consequence the joints in the lower part opened as the upper part was compressed. This no doubt showed a suppleness in the frame, and at the same time inattention in the architect, to load the crown, when he perceived it sinking with having already too much weight upon it. If he had observed the crown to rise, it would then have been proper to give it additional weight.

Let us now attend to the description of the centre frame of the bridge of Orleans, fig. 8. The architect to this bridge was Hupeau; and it is universally allowed to be an elegant structure. The arch stones are six feet in length, the form is elliptical, the span 100 feet, and rise 30. Hupeau died before any of the arches were complete. The center-frame had been placed, and some rows of the arch laid. Upon his demise, Perronet succeeded as architect, and finished the bridge. As the work advanced, he found that the crown of the center rose; he then found it sink as remarkably, which showed that there was some defect; he inserted the long beam AB, on each side; he then found the frame sufficiently stiff; for this made a change in the nature of the strut.

Having taken a view of the practice of the French architects, as to their form and effects, let us direct our attention to those of our own country, which are well worthy of notice. We shall only name some that have used trussings, and among these we find the center-frame of Blackfriars bridge, fig. 9. The span here is 100 feet; the form is elliptical, the arch-stones from the haunches seven feet, near the key-stone not quite so much, as they decrease in length from the haunch to the key-stone.

A particular description of this arch is not necessary: a view of the figure will show the use of the different parts; it may be sufficient to observe, that when the arch stone was placed, it had changed its shape only one inch, and when the frame was taken out, the arch remained firm without any sinking of consequence. The great arch did not sink above one inch, and none of them above an inch and a half; whereas those already mentioned sunk by the suppleness of the frame 13 inches, and some of them 9 inches more when the frame was removed.

Different methods are employed for easing the frame or disengaging it from its weight. We shall give a short description of Mr Mylne's method of placing and disengaging his center-frame from the mason-work. Each end of the truss was mortised into a plank of oak cut in the lower part as in the figure; a similar piece of oak was placed to receive the upper part of the posts. The blocks rested upon these posts, but were not mortised into them, pieces of wood being interposed. The upper part of this block was cut similar to the lower part of the other; the wedge E, being intended to be driven betwixt them, was notched as in the figure, and filled up with small pieces of wood, to prevent the wedge from sliding back by the weight of the arch; which, it will appear from the figure, would have been the case: the event proved the fact. When the centre was to be struck, the inserted pieces of wood were taken out, and the wedge, which was prepared for driving back by being girt with a ferule round the top, was removed by a piece of iron driven in with the head so broad as to cover the whole of the wood. A plank of wood was prepared armed with iron in the same manner at the one end, and suspended so that it could freely act in driving back the wedge to any distance, however small, with certainty. Thus, by an equal gradation, the centre was eased from the arch, which appeared to have been so equally supported throughout the whole of the operation, and the arch-stones so properly laid, that it did not sink above one inch; and thus it was evident that the centre might be entirely removed, having completely answered the purpose.

The above examples may be considered as sufficient to show the effects of the trussed arches, which have been employed by the French architects. We shall now take the liberty of suggesting some hints which may tend to improve the construction, and remedy the faults and failures that have occurred in practice.

Trussed arches for center frames being found expedient in navigable rivers, and almost in every river which is apt to be raised by rains, or other rise in the river, the frame is apt to be endangered or carried off, to the great risk of bringing down the arch, and ruining the work before it is finished. In arches were there is no such danger, the frame may be properly secured by posts from below, which are made to abut upon these parts of the arch where the greatest strain must fall.

In the centre used by Pitot we have only to complain of an unnecessary expenditure of wood and workmanship. We have already shown what strength of oak is necessary, and have reduced the strength of oak to an equal strength of fir-wood for the ring of his frame, which alone ought to have the strength required to be fully adequate to the load; but as this weight must be gradually applied, the frame must likewise have such a degree of firmness as to form the exact mould of the arch that is intended. And, for this purpose, it must be prevented from yielding in any part of its arch. Now, as it has been made to appear, that the frame supports no part of the arch till it rise from the spring to about 35 degrees, if a semicircle, and so in proportion for a segment of a circle; in an ellipse, to a part similar according to the nature of that curve; the supporting struts and ties can be more particularly directed to support that part of the arch which produces the greater strain upon the centre. In fig. 2. where the necessary strength for Pitot's arch is pointed out, the frame of fir requisite to stiffen the frame is $9\frac{1}{2}$ by $2\frac{1}{2}$. The tie-beam C *c* is joined to those parts of the arch where the strain being greatest, would tend most to raise it in the crown. The strength of this tie-beam being $9\frac{1}{2}$ by $2\frac{1}{2}$ and its length 25 feet, would require a weight of 30495 lb. to make the transverse

Centre.

verse fractnre; one-third of this at the bridle 1, 3, is sufficient to resist the strain at the part of the arch; and the abutment, being according to the principles laid down under the article BRIDGE, prevents the possibility of its rising at the haunches; but if not formed according to these principles, the two tie-beams *C c D d* are joined by a third tie-beam 2, 2 with its bridle 3, 4. Fig. 4. is Pitot's centering for his elliptic arch: the strength of fig. 2. may suffice to this by giving the ring and tie-beams $\frac{1}{2}$ an inch more depth.

Fig. 6. represents two centerings used by Perronet; A is that used by him in erecting the bridge at Nogent, and B that at Maxence; they differ little from one another. That at Nogent is 90 feet by 28 of height. The span of the latter being greater, we shall here consider the weight to be supported. This is the arch from A to C, which is an arch of 47° 45′. The measurement is 42 feet; the arch stones $4\frac{1}{2}$, and supposing them 3 feet broad, they would amount to 567.9 solid feet, which at 160 lb. per foot, is equal to 90866.88 lb. This is little more than one-half of the semicircular arch: and although it is flatter, the weight is so much less, that no additional strength is necessary to be given to the frame, fig. 2. for the 60 feet span. There is likewise abundance of strength of materials for the 90 feet arch; but on the greater extent, that it may be rendered more stiff, a tie-beam 1, 4, 3, 4 may be added on each side of the arch, as represented by the dotted line.

It is scarcely necessary to make any farther calculations on the centering used by Perronet. It appears, that notwithstanding the superabundance of wood employed, they were so supple as when used upon an extended arch, they rose and sunk so much, that the arch was changed from its intended form by a radius of several feet. These changes took place in erecting the bridges at Nogent and Maxence, which are represented in fig. 6. Perronet, it would appear, was not satisfied with these; and, convinced of their insufficiency, changed the form of the frame of the bridge at Neuilly. But this form is far from answering the purpose; for, when the arch-stones began to press upon the centering, it yielded to the weight. He then loaded the crown to prevent its rising there, but it still sunk; he added more weight to the crown, it continued sinking as the work advanced. When the key-stone was set, it had sunk more than 13 inches, and it was found to have raised the haunches; for when the centering was slackened, the arch still sunk for about 9 inches more. The arch-stones being raised at the haunches, the joints were of necessity opened; for the pressure from the crown, when the centering was removed, forced them again into contact, by which the arch flattened to such a degree, that from an arch intended to have a radius of 150 feet, it flattened till part of it was as if formed from a radius of 244 feet. It here appeared to be settled, from which a considerable deformity must appear in the structure; which deformity took its rise from two evident causes; the want of firmness in the centering, and the bridge not properly loaded at the haunches. It is evident, that if the load at the haunches is only equal to the weight of the arch-stones from the place where they begin to rest on the centering to the crown of the arch, the pressure of the arch could never overcome itself or its equal weight upon the haunches; much more, if the weight upon the haunches, before it comes to press upon the centering, was made to exceed that part of the arch that did press upon it, the load upon the crown of the arch would have restored the figure of the centering. It seems to be a strange oversight, that Perronet, when he saw that his centering was rising at the haunches, did not apply his loading to this part of the arch, by which he might have restored it to its equilibrium before his centre was struck, and before his lime had lost the band; if this is once done, it is allowed that it does not again recover it.

From the whole of this it appears evident, that filling up the haunches to a proper height, so as to make a firm abutment to the pressing part of the arch, serves two good purposes. It acts as an abutment to the centre frame, in preventing its sinking by the load as the work advances; and likewise prevents the arch-stones at the haunches being raised from their beds; for it is only acted upon by a force considerably less than what they have a power to resist. Having now seen the defects of this centering, and animadverted on the manner of executing the work, let us now examine the weight of this arch, and what resistance would have prevented its change in shape, and preserved its intended form.

The part of the arch that presses upon the center, is from C to C, fig. 10. an arch of 36 degrees, and measures $94\frac{1}{4}$ feet nearly; the stones 5 feet in length, and breadth 3, make 1979.035 solid feet, × 160 lb. the weight of a solid foot, make the whole weight 216645.88 lb. Allow each beam of the truss to be 7 feet, and its absolute strength, to tear it at 12 inches deep, by one inch thick, 189163; the absolute power of transverse fracture, 95416 lb. The strength of the arch is the mean of these, or ratio compounded; taking one-third of each, the geometrical mean is 44285 lb. that each 7 feet can sustain when formed into an arch; there are 13 times 7 in 94 feet, equal to a power of 582764, to sustain the weight of 316645.68 if equally distributed. But this not being the case, a tie-beam of about 30 feet marked *c c*, *d d*, will prevent the arch yielding to the pressure. It is supported at *e* by the struts *E e*, *h h*; and these by the joint support of *e f*, *h f* tied at *k*. The whole centre frame is supported by the upright posts CC, DD. Two wedges A and B are placed across between two blocks which are fitted for a rest to the frame. When it is required to be slackened, and the frame withdrawn from the arch, they allow it to rest by its own pressure. This, it must appear obvious, ought to be done when the key-stone is set before the lime has begun to be dry and solid.

The centre frame of the bridge of Orleans is represented fig. 8. It has been already noticed in this undertaking, that Perronet succeeded Hupeau. As the work advanced, he found the arch and frame to sink, and trying his ordinary mode of loading the crown of the arch, he was now taught by experience to strengthen his centre frame, and happily succeeded by continuing his strut. By forming the base of the triangle 1, 2, 3, on each side, his frame was rendered sufficiently stiff, and the inner part below AB, AB became superfluous. The weight that presses upon this frame is great both on on account of the flatness of the arch, and the length of the arch-stone. The pressing arch is an arch of 57 degrees; it measures 88.87 feet, ×6 the length of the arch-stone, and by 3 in width, makes 1599.66 solid feet × 160lb. the weight of a solid foot, gives 255945.6lb. The length of each plank of the truss being 7 feet, depth 12 inches by 2 inches thick, the strength is 189163 lb. The weight for every 7 feet in length of the arch, one third of this 63054⅓lb. in 88 feet, there is 12 times 7, that is 63054.3+12=756,652lb. to support 255945.6lb. more than 3 times stronger, without taking into account the strength of the arch, being the mean of the splitting force and transverse section: the tie-beams, as in fig. 7. will be of abundant strength to stiffen the frame.

The next we take notice of is, the truss-frame, fig. 9. used by Mr Mylne, at Blackfriars bridge, London. This is supported by ties and struts in such a manner, that no sinking took place during the mason work going on, although the arch-stones at the haunches were 7 feet, gradually lessening to the crown of the arch; and, when the frame was struck, which was done by a very ingenious method, by the wedges of the constructions as in the figure, in place of sinking 9 inches, it did not sink above 1, which may well be accounted for by the compression of the mortar; whether a smaller quantity of materials might not have answered the same purpose, such as fig. 7. we shall refer to the judicious reader, or to the ingenious artist who may have occasion to depend upon such frames for support of this work, or a tie-beam between 1 and 3 on each side, represented by the dotted line. As there is a strain upon the frame at *s*, *s*, let these tie-beams be supported by the struts *a* 3, *b* 3 on each side, and tied at 4, 4 as represented by the dotted line 4, 4. It does not appear that what lies between the dotted line *a* 4, 4 *b* bears any part in the support or stiffness of the frame, and therefore becomes unnecessary; nor does it appear, that the different beams used as king-posts are of so much advantage for strengthening the frame, as tie-beams would be. At the same time, those used by Mr Mylne are employed with so much judgment, that none of their effects are misapplied. This cannot be said of any of the frames used by the French architects, even of that used at the bridge of Orleans. They are not often employed by the British architects; they rather prefer a tie-beam at the spring of the arch from one side to the other. This, however, might be as judiciously applied at the height where the arch begins to rest upon the frame, especially if the shoulders are properly loaded or filled up, so as to be a counterpoise to the arch-stones, that rest upon the frame. In this case they effectually prevent the necessity of a tie-beam, as a diameter at the spring of the arch; and from the spring proper supports may be given at the upper tie-beam, and from it to any part of the arch, where the greatest strain lies.

Having, from the examples adduced, and the observations made upon them, found center-frames of sufficient strength to support arches of very extensive spans, and even greater extent than they have yet been applied; it may be said, why not continue these frames for the bridge, without the very great additional expence of throwing a stone arch over them? The mason would answer, that the stone was more durable, and had other advantages, particularly as to neatness, when once thrown, and freed from the uncouth trusses and tie-beams necessary in the wooden frame. The carpenter would reply, that if wood was not so durable as stone, it could be raised at much less expence; and, when it failed in any part, it could be replaced at a small expence, and made to last longer than a stone arch; which latter, when it fails, requires as much expence as at first, and even more, in clearing off the rubbish of its decayed and now useless materials. As to neatness, the frame of wood vies with the arch of stone in elegance, and is erected at half the expence, and even less. But now since iron materials are introduced in place of stone, there is room for experiments with regard to neatness and extent of span.

We shall here suppose the carpenter exhibits this plan. Let AB be a span of 60 feet, (fig. 11.) the arch a semicircle, the absolute strength of oak a plank 12 inches by one is 189163 lb. Let the arch be composed of pieces 5 feet long, 12 inches deep, and 2 inches broad; a second arch joining to this, of the same depth and breadth in close contact, but the joints of the one to the middle of the other, like brick-building, or as the carpenters express it breaking-joint. The absolute strength of this arch is, before the two trusses are joined, more than 84 ton, as may be collected from the calculations above, which is more than 3 times what can ever come upon it. The beauty of this arch would be hurt by placing struts below to stiffen it, for which there is not the smallest occasion: for it can be stiffened to better advantage above the arch. But this is not practicable in center-frames. Let the road-way be CDEF, resting upon the perpendicular support 1, 2, 3, &c. As the carriage acts upon these in the oblique direction, transepts from the arch in a radial direction, give them the advantage of equal pressure upon the arch. Each of these perpendiculars is mortised into short pieces, that will form into an arch, the pieces all abutting one upon another, and forming a fillet over the arch, and projecting so far, that the faces of an architrave of any order may be formed along the face of the arch, which adds both to its strength and beauty. Thus there is formed a rib, 12 inches deep and 4 thick, with its fillet over it 4 inches deep and 6 inches broad, to cover the faces of the architrave. Suppose the arch 44 feet wide, 7 of these ribs may give a strength not inferior to the strength of stone or any metal; but it will be said, it will not be so durable. It is well known how long wood lasts in the roofs, and joists of flooring, and even when it forms a part of the wall of a house built of brick. The interstices between these perpendicular bearings of the wood may be built up with brick; even brick on edge, or brick thick will render its preservation equal to what it is in a house, and will preserve it from the bad effects of wet and dry; and the lower part of the ribs covered with a thin lining. A door being left in the side to observe at different times any failure in the wood, it may be repaired without interrupting the passage by the bridge. It ought to be so covered above, that water may be prevented from going through to the injury of the bridge. It has been formerly mentioned, in speaking

ing of the proportional strength of oak and fir, and by the calculation it appeared, that fir plank $13\frac{1}{2}$ inches is equal in strength to oak of 12 inches. And thus a framing of wood does not much exceed the expence of centering either a stone or iron bridge; and is not inferior even in elegance.

The span here proposed is only 60 feet. But an arch of 600 feet may be required, which must have a centering to support the weight and preserve the figure; the size of that center frame can be made of strength equal, and even to exceed the weight it has to support. It can be rendered stiff by the method proposed for the 60 feet arch. This, therefore, will be a bridge that will support any weight that can be laid upon it, and may be of any figure, elliptical, or at the pleasure of the architect, any other curve which may be required. It may be framed in a similar manner to those formed of iron, but it is natural to suppose that one arch over the other will be equally strong and more easily preserved from the weather, constructed in the way described above.

In the simple wooden bridges not curved, it is only necessary to refer to fig. 7. where the struts E *c*, *f*, *h g*, will be a support for planks, that will form a straight bridge, joining so many ribs as are necessary for the bridge according to its breadth.

The joints may be secured from opening by dovetailed pieces being inserted across the joints on the inside of the rib; the abutments prevent the ends of the arch from flying out. The pressure above coming upon it obliquely, may be said to tend to make it rise at the crown, especially when of a great span. In the center-frame, the only manner of preventing this is by struts and tie-beams judiciously applied. Here the rise may be prevented more effectually without hurting the ornamental part of the arch. In the abutment, which must be of mason-work, let a beam be built into the wall, the ends at G and K projecting 1 foot, corresponding to each rib, the road-way formed by the beam DE: let a tie-beam GD, KE, join these in the manner the carpenter knows to be the most secure: from this tie-beam, let the radial struts be mortised into the fillets at G, K, formerly described, instead of the perpendiculars there named, and perpendiculars joining the road-way CPEF, and resting on the tie-beam GD, KE, supported by the radial struts 4, 5, 6, as in the figure. Thus the crown of the arch cannot rise without lifting up the whole body of the abutment at each end, and it cannot sink till the weight laid upon it is sufficient to crush the materials of which the arch is composed. In this manner a neat and elegant arch is procured, that may at a small comparative expence be kept up for centuries. Here is then a choice of three species of arches, that may vie with each other in point of strength. With the last none may compare in point of elegance, and in duration perhaps not inferior to the iron bridge.

Center *of Gravity*, in *Mechanics*, that point about which all the parts of a body do in any situation exactly balance each other.

Center *of Motion*, that point which remains at rest, while all the other parts of a body move about it.

Center *of a Sphere*, a point in the middle, from which all lines drawn to the surface are equal.

Hermes Trismegistus defines God an intellectual sphere, whose center is everywhere, and circumference nowhere.

CENTESIMA usura, that wherein the interest in a hundred months became equal to the principal, *i. e.* where the money is laid out at one per cent. per month; answering to what in our style would be called 12 per cent., for the Romans reckoned their interest not by the year, but by the month.

CENTESIMATION, a milder kind of military punishment in cases of desertion, mutiny, and the like, when only every hundredth man is executed.

CENTILOQUIUM, denotes a collection of 100 sentences, opinions, or sayings.

The centiloquium of Hermes contains 100 aphorisms, or astrological sentences, supposed to have been written by some Arab, falsely fathered on Hermes Trismegistus. It is only extant in Latin, in which it has several times been printed.—The centiloquium of Ptolemy is a famous astrological piece, frequently confounded with the former, consisting likewise of 100 sentences or doctrines, divided into short aphorisms, entitled also in Greek καρπος, as being the fruit or result of the former writings of that celebrated astronomer, viz. his *quadripartitum* and *almagestum*; or rather, by reason that herein is shown the use of astrological calculations.

CENTIPES, in *Zoology*. See Scolopendra.

CENTIPED worm, a term used for such worms as have a great many feet, though the number does not amount to 100, as the term seems to import.—M. Malouet relates the history of a man, who, for three years, had a violent pain in the lower part of the forehead near the root of the nose; at length he felt an itching, and afterwards something moving within his nostril, which he brought away with his finger; it was a worm of the centiped kind, an inch and a half long, which run swiftly. It lived five or six days among tobacco. The patient was free of his pain ever after. Mr Littre mentioned a like case in 1708, of a larger centiped voided at the nose, after it had thrown the woman, in whose frontal sinus it was, into convulsions, and had almost deprived her of her reason.

CENTLIVRE, Susanna, a celebrated comic writer, was the daughter of Mr Freeman of Holbeach, in Lincolnshire; and had such an early turn for poetry, that it is said she wrote a song before she was seven years old. Before she was twelve years of age, she could not only read Moliere in French, but enter into the spirit of all the characters. Her father dying, left her to the care of a step-mother, whose treatment not being agreeable to her, she determined, though almost destitute of money and every other necessary, to go up to London to seek a better fortune than what she had hitherto experienced. As she was proceeding on her journey on foot, she was met by a young gentleman from the university of Cambridge, the afterwards well known Anthony Hammond, Esq. who was so extremely struck with her youth and beauty, that he fell instantly in love with her; and inquiring into the particulars of her story, soon prevailed upon her unexperienced innocence to seize on the protection he offered her, and go with him to Cambridge. After

some months cohabitation, he persuaded her to come to London, where, in a short time, she was married to a nephew of Sir Stephen Fox. But that gentleman not living with her above a twelvemonth, her wit and beauty soon procured her a second husband, whose name was Carrol, and who was an officer in the army; but he having the misfortune to be killed in a duel about a year and a half after their marriage, she became a second time a widow. For the sake of support she now applied to her pen, and became a votary of the muses: and it is under this name of Carrol that some of her earlier pieces were published. Her first attempt was in tragedy, in a play called the *Perjured Husband;* yet natural vivacity leading her afterwards to comedy, we find but one more attempt in the buskin, among 18 dramatic pieces which she afterwards wrote.

In 1706, she wounded the heart of one Mr Joseph Centlivre, yeoman of the mouth, or, in other words, principal cook to her majesty, who married her; and, after passing several years happily together, she died at his house in Spring Garden, Charing-cross, in December 1723.

This lady for many years enjoyed the intimacy and esteem of the most eminent wits of the time, viz. Sir Richard Steele, Mr Rowe, Budgell, Farquhar, Dr Sewell, &c.; and very few authors received more tokens of esteem and patronage from the great. With regard to her merit as a writer, it must be allowed that her plays do not abound with wit, and that the language of them is sometimes even poor, enervate, incorrect, puerile; but then her plots are busy and well conducted, and her characters in general natural and well marked.

CENTNER, or Docimastic Hundred, in *Metallurgy* and *Assaying*, is a weight divisible, first into a hundred, and thence into a greater number of other smaller parts; but though the word is the same both with the assayers and metallurgists, yet it is to be understood as expressing a very different quantity in their different acceptation of it. The weights of the metallurgists are easily understood, as being of the common proportion; but those of the assayers are a thousand times smaller than these, as the portions of metals or ores examined by the assayers are usually very small.

The metallurgists, who extract metals out of their ores, use a weight divided into a hundred equal parts, each part a pound; the whole they call a *centner* or *hundred weight;* the pound is divided into thirty-two parts, or half ounces; and the half ounce into two quarters of ounces, and these each into two drachms.

These divisions and denominations of the metallurgists are easilly understood; but the same words, though they are equally used by assayers, with them express very different quantities; for as the centner of the metallurgists contains a hundred pounds, the centner of the assayers is really no more than one dram, to which the other parts are proportioned.

As the assayers weights are divided into such an extreme degree of minuteness, and are so very different from all the common weights, the assayers usually make them themselves in the following manner, out of small silver, or fine solder plates, of such a size, that the mark of their weight, according to the division of the dram, which is the *docimastic* or essaying *centner*, may be put upon them. They first take for a basis one weight, being about two-thirds of a common dram: this they mark (64 lb.) Then having at hand some granulated lead, washed clean, well dried, and sifted very fine, they put as much of it into one of the small dishes of a fine balance as will equipoise the (64 lb.) as it is called, just mentioned: then dividing the granulated lead into very nice halves, in the two scales, after taking out the first silver weight, they obtain a perfect equilibrium between the two scales; they then pour the granulated lead out of one dish of the scales, and instead of it put in another silver weight, which they make exactly equiponderant with the lead in the other scale, and mark it (32 lb.). If this second weight, when first put into the scale, exceed by much the weight of the lead, they take a little from it by a very fine file; but when it comes very near, they use only a whetstone to wear off an extremely small portion at a time. When it is brought to be perfectly even and equal to the lead, they change the scales to see that no error has been committed, and then go on in the same manner till they have made all the divisions, and all the small weights. Then to have an entire centner or hundred weight, they add to the (64 lb.) as they call it, a 32 lb. and a 4 lb. and weighing against them one small weight, they make it equal to them, and mark it (100.) This is the docimastical or essaying centner, and is really one dram.

CENTO, in poetry, a work wholly composed of verses or passages promiscuously taken from other authors, only disposed in a new form and order.—Proba Falconia has written the life of Jesus Christ in centos taken from Virgil. Alexander Ross has done the like in his Christiados, and Stephen de Pleure the same.

CENTONARII, in antiquity, certain of the Roman army, who provided different sorts of stuff called *centones*, made use of to quench the fire which the enemy's engines threw into the camp.

These centonarii kept with the carpenters and other officers of artillery.

CENTRAL forces, the powers which cause a moving body to tend towards, or recede from, the centre of motion. See Mechanics.

Central Rule, a rule discovered by Mr Thomas Baker, whereby to find the centre of a circle designed to cut the parabola in as many points as an equation to be constructed hath real roots. Its principal use is in the construction of equations, and he hath applied it with good success as far as biquadratics.

The central rule is chiefly founded on this property of the parabola, that, if a line be inscribed in that curve perpendicular to any diameter, a rectangle formed of the segments of the inscript is equal to the rectangle of the intercepted diameter and parameter of the axis.

The central rule has the advantage over Carter and De Latere's methods of constructing equations, in that both these are subject to the trouble of preparing the equation by taking away the second term.

CENTRIFUGAL force, that force by which all bodies that move round any other body in a curve endeavour to fly off from the axis of their motion in a tangent

Centrifugal Force, Centrifugal Machine.

tangent to the periphery of the curve, and that in every part of it. See MECHANICS.

CENTRIFUGAL Machine, a very curious machine, invented by Mr Erskine, for raising water by means of a centrifugal force combined with the pressure of the atmosphere.

It consists of a large tube of copper, &c. in the form of a cross, which is placed perpendicular in the water, and rests at the bottom on a pivot. At the upper part of the tube is a horizontal cog-wheel, which touches the cogs of another in a vertical position; so that by the help of a double winch, the whole machine is moved round with very great velocity.

Near the bottom of the perpendicular part of the tube is a valve opening upwards; and near the two extremities, but on the contrary sides of the arms, or cross part of the tube, are two other valves opening outwards. These two valves are, by the assistance of springs, kept shut till the machine is put in motion, when the centrifugal velocity of the water forces them open, and discharges itself into a cistern or reservoir placed there for that purpose.

On the upper part of the arms are two holes, which are closed by pieces screwed into the metal of the tube. Before the machine can work, these holes must be opened, and water poured in through them, till the whole tube be full: by this means all the air will be forced out of the machine, and the water supported in the tube by means of the valve at the bottom.

The tube being thus filled with water, and the holes closed by the screw caps, it is turned round by means of the winch, when the water in the arms of the tube acquires a centrifugal force, opens the valves near the extremities of the arms, and flies out with a velocity nearly equal to that of the extremities of the said arms.

The above description will be very easily understood by the figure we have added on Plate CXXXVII. which is a perspective view of the centrifugal machine, erected on board of a ship. ABC is the copper tube. D, a horizontal cog-wheel, furnished with twelve cogs. E, a vertical cog-wheel, furnished with thirty-six cogs. F, F, the double winch. *a*, the valve near the bottom of the tube. *b*, *b*, the two pivots on which the machine turns. *c*, one of the valves in the cross piece; the other at *d*, cannot be seen in this figure, being on the other side of the tube. *e*, *e*, the two holes through which the water is poured into the machine. GH, the cistern or reservoir. I, I, part of the ship's deck. The distance between the two valves *c*, *d*, is six feet. The diameter of these valves is about three inches: and that of the perpendicular tube about seven inches.

If we suppose the men who work the machine can turn the winch round in three seconds, the machine will move round its axis in one second; and consequently each extremity of the arms will move with a velocity of 18.8 feet in a second. Therefore a column of water of three inches diameter will issue through each of the valves with a velocity of 18.8 feet in a second: but the area of the aperture of each of the valves is 7.14 inches; which being multiplied by the velocity in inches = 225.6, gives 1610.784 cubic inches, the quantity of water discharged through one of the apertures in one second; so that the whole quantity discharged in that space of time through both the apertures is =3221.568 inches; or 193294.08 cubic inches in one minute. But 60812 cubic inches make a tun beer-measure; consequently, if we suppose the centrifugal machine revolves round its axis in one second, it will raise nearly 3 tuns 44 gallons in one minute: but this velocity is certainly too great, at least to be held for any considerable time; so that, when this and other deficiencies in the machine are allowed for, two tuns is nearly the quantity that can be raised by it in one minute.

Centrifugal Machine || Centurion.

It will perhaps be unnecessary to observe, that as the water is forced up the perpendicular tube by the pressure of the atmosphere, this machine cannot raise water above 32 feet high.

An attempt was made to substitute this machine in place of the pumps commonly used on shipboard; but the labour of working was found to be so great as to render the machine inferior to the chain-pump. A considerable improvement, we apprehend, would be, to load with a weight of lead the ends of the tubes through which the water issues, which would make the machine turn with a great deal more ease, as the centrifugal force of the lead would in some measure act the part of a fly.

CENTRIPETAL FORCE, that force by which a body is everywhere impelled, or any how tends, towards some point as a centre. See MECHANICS.

CENTRISCUS, in *Ichthyology*, a genus of fishes belonging to the order of amphibia nantes. See ICHTHYOLOGY *Index*.

CENTRONIA, in *Natural History*, a name by which the echini marini have been distinguished. Dr Hill makes them a distinct class of animals, living under the defence of shelly coverings formed of one piece, and furnished with a vast number of spines moveable at the creature's pleasure.

CENTUMCELLÆ, in *Ancient Geography*, Trajan's villa in Tuscany, on the coast, three miles from Algæ; with an excellent port, called *Trajanus Portus*, (Ptolemy); and a factitious island at the mouth of the port, made with a huge block of stone, on which two turrets rose, with two entrances into the bason or harbour, (Rutilius). Now *Civita Vecchia*. E. Long. 12. 30. N. Lat. 42°.

CENTUMVIRI, in Roman antiquity, judges appointed to decide common causes among the people: They were chosen three out of each tribe; and though five more than a hundred, were nevertheless called *centumviri*, from the round number *centum* a hundred.

CENTUNCULUS. See BOTANY *Index*.

CENTURION, among the Romans, an officer in the infantry, who commanded a century, or a hundred men.

In order to have a proper notion of the centurions, it must be remembered, that every one of the thirty manipuli* in a legion was divided into two *ordines*, or ranks; and consequently the three bodies of the hastati, principes, and triarii, into 20 orders a piece, as into 10 manipuli. Now, every manipulus was allowed two centurions, or captains, one to each order or century: and, to determine the point of priority between them, they were created at two different elections. The 30 who were made first always took the precedency of their fellows; and therefore commanded the right-hand orders, as the others did the left. The triarii, or

* See Manipulus.

or *pilani*, so called from their weapon the *pilum*, being esteemed the most honourable, had their centurions elected first, next to them the principes, and afterwards the hastati; whence they were called *primus et secundus pilus, primus et secundus princeps, primus et secundus hastatus;* and so on. Here it may be observed, that *primi ordines* is sometimes used in historians for the centurions of these orders; and the centurions are sometimes styled *principes ordinum*, and *principes centurionum*. We may take notice too what a large field there lay for promotion: first through all the orders of the hastati; then quite through the principes; and afterwards from the last order of the triarii to the primipilus, the most honourable of the centurions, and who deserves to be particularly described. This officer, besides his title of primipilus, went under the several titles of *dux legionis, præfectus legionis, primus centurionum*, and *primus centurio:* and was the first centurion of the triarii in every legion. He presided over all the other centurions, and generally gave the word of command by order of the tribunes. Besides this, he had the care of the eagle or chief standard of the legion: hence, *aquilæ præesse* is to bear the dignity of primipilus; and hence *aquila* is taken by Pliny for the said office. Nor was this station only honourable, but very profitable too: for he had a special stipend allowed him, probably as much as a knight's estate; and, when he left that charge, was reputed equal to the members of the equestrian order, bearing the title of *primipilarius*, in the same manner as those who had discharged the greatest civil offices were styled ever after, *consulares, censorii, &c.*

CENTURIPÆ, Centoripa, or Centuripe, in *Ancient Geography*, a town in the south-west of the territory of Etna, on the river Cyamasorus: Now *Centorbi* or *Centurippi*. It was a democratical city, which, like Syracuse, received its liberty from Timoleon. Its inhabitants cultivated the fine arts, particularly sculpture and engraving. In digging for the remains of antiquities, cameos are nowhere found in such abundance as at Centurippi and its environs. The situation of the place is romantic: it is built on the summit of a vast group of rocks, which was probably chosen as the most difficult of access, and consequently the properest in times of civil commotion. The remains still existing of its ancient bridges are a proof of its having been a considerable city. Cicero speaks of it as such. It was taken by the Romans, plundered and oppressed by Verres, destroyed by Pompey, and restored by Octavius, who made it the residence of a Roman colony.

CENTURY, in a general sense, any thing divided into, or consisting of, a hundred parts.

The marquis of Worcester published a *Century* of inventions, (for a specimen of which, see Acoustics,) and Dr Hooke has given a *decimate* of inventions, as part of a *Century*, of which he affirmed himself master. It is remarkable, that both in the century of the former, and the decimate of the latter, we find the principle on which Savary's fire or steam engine is founded. See *Steam-Engine*.

Century, in antiquity. The Roman people, when they were assembled for the electing of magistrates, enacting of laws, or deliberating upon any public affair, were always divided into centuries, and voted by centuries, in order that their votes might be the more easily collected, whence these assemblies were called *comitia centuriata*. The Roman cohorts were also divided into centuries. See Centurion and Cohort.

Century, in *Chronology*, the space of 100 years. This method of computing by centuries is generally observed in church history, commencing from the time of our Saviour's incarnation: in which sense we say the first century, the second century, &c.

Centuries of Magdeburg, a famous ecclesiastical history, ranged into 13 centuries, carried down to the year 1298, compiled by several hundred Protestants of Magdeburg, the chief of whom was Flavius Illyricus.

CENTUSSIS, in Roman antiquity, a coin containing 100 asses.

CENTZONTLI, in *Ornithology*, the Mexican name of the *Turdus polyglottus*. See Turdus, Ornithology *Index*.

CEODES, in *Botany*, a genus of the diœcia order, belonging to the polygamia class of plants. There is no calyx; the corolla is monopetalous, with a short turbinated tube; the stamina are ten subulated filaments; the antheræ roundish.

CEORLES, the name of one of the classes or orders into which the people were distinguished among the Anglo-Saxons. The ceorles, who were persons completely free, and descended from a long race of freemen, constituted a middle class between the labourers and mechanics (who were generally slaves, or descended from slaves), on the one hand, and the nobility on the other. They might go where they pleased, and pursue any way of life that was most agreeable to their humour: but so many of them applied to agriculture, and farming the lands of the nobility, that a ceorl was the most common name for a husbandman or farmer in the Anglo-Saxon times. These ceorls, however, seem in general to have been a kind of gentlemen farmers; and if any one of them prospered so well as to acquire the property of five hydes of land, upon which he had a church, a kitchen, a bell-house, and great gate, and obtained a seat and office in the king's court, he was esteemed a nobleman or thane. If a ceorl applied to learning, and attained to priest's orders, he was also considered as a thane; his weregild, or price of his life, was the same, and his testimony had the same weight in a court of justice. When he applied to trade, and made three voyages beyond sea, in a ship of his own, and with a cargo belonging to himself, he was also advanced to the dignity of a thane. But if a ceorl had a greater propensity to arms than to learning, trade, or agriculture, he then became the fithcunman, or military retainer, to some potent and warlike earl, and was called the *huscarle* of such an earl. If one of these huscarles acquitted himself so well as to obtain from his patron either five hydes of land, or a gilt sword, helmet, and breastplate, as a reward of his valour, he was likewise considered as a thane. Thus the temple of honour stood open to these ceorls, whether they applied themselves to agriculture, commerce, letters, or arms, which were then the only professions esteemed worthy of a freeman.

CEOS, Cea, Cia, or Cos, in *Ancient Geography*, one of the Cyclades, lies opposite to the promontory of Achaia called *Sunium*, and is 50 miles in compass. This island is commended by the ancients for its fertility and the richness of its pastures. The first silk stuffs, if

Pliny and Solinus are to be credited, were wrought here. Ceos was particularly famous for the excellent figs it produced. It was first peopled by Aristæus, the son of Apollo and Cyrene, who being grieved for the death of his son Actæon, retired from Thebes, at the persuasion of his mother, and went over with some Thebans to Ceos, at that time uninhabited. Diodorus Siculus tells us, that he retired to the island of Cos; but the ancients, as Servius observes, called both these islands by the name of Cos. Be that as it will, the island of Ceos became so populous, that a law prevailed there, commanding all persons upwards of sixty to be poisoned, that others might be able to subsist; so that none above sixty were to be seen in the island, being obliged, after they arrived at that age, either to submit to the law, or abandon the country, together with their effects. Ceos had, in former times, four famous cities, viz. Julis, Carthæa, Coressus, and Præessa. The two latter were, according to Pliny, swallowed up by an earthquake. The other two flourished in Strabo's time. Carthæa stood on a rising ground at the end of a valley, about three miles from the sea. The situation of it agrees with that of the present town of Zea, which gives name to the whole island. The ruins both of Carthæa and Julis are still remaining; those of the latter take up the whole mountain, and are called by the modern inhabitants Polis, that is, *the city*. Near this place are the ruins of a stately temple, with many pieces of broken pillars, and statues of most exquisite workmanship. The walls of the city were of marble, and some pieces are still remaining above 12 feet in length. Julis was, according to Strabo, the birthplace of Simonides, Bacchylides, Erasistratus, and Aristo. The Oxford marbles tell us that Simonides the son of Leoprepis invented a sort of artificial memory, the principles of which he explained at Athens; and add, that he was descended of another Simonides, who was a poet no less renowned than himself. One of these two poets invented those melancholy verses which were sung at funerals, and are called by the Latins *næniæ*. Strabo says, that the Athenians, having besieged the city of Julis, raised the siege, upon advice that the inhabitants had resolved to murder all the children under a certain age, that useful persons might not be employed in looking after them. Ceos was, with the other Greek islands, subdued by the Romans, and bestowed upon the Athenians by Mark Antony the triumvir, together with Ægina, Tinos, and some other adjoining islands, which were all reduced to one Roman province by Vespasian. The island is now called *Zea*.

CEPA, the ONION. See ALLIUM, BOTANY *Index*.

CEPHALANTHUS, BUTTON-WOOD. See BOTANY *Index*.

CEPHALIC, in a general meaning, signifies any thing belonging to the head.

CEPHALIC Medicines, are remedies for disorders of the head. Cordials are comprehended herein, as are also whatever promotes a free circulation of the blood through the brain.

Except when the disorder arises from excess of heat, or an inflammatory disposition in the head, moist topicals should never be used, but always dry ones.

To rub the head after it is shaved proves an instantaneous cure for a cephalalgia, a stuffing of the head, and weakness of the eyes, arising from a weak and relaxed state of the fibres. And as by every fresh evacuation of the humours their quantity is not only lessened, but also their recrementitious parts derived thither, the more frequently the head is shaved, the larger quantity of humour is discharged; so that the frequent shaving of the head and beard is likewise a perpetual blister; and in as much as it is useful, it is a cephalic.

CEPHALIC Vein, in *Anatomy*, creeps along the arm between the skin and the muscles, and divides it into two branches; the external goes down to the wrist, where it joins the basilica, and turns up to the back of the hand; the internal branch, together with a small one of the basilica, makes the mediana.

The ancients used to open this vein for disorders of the head, for which reason it bears this name; but a better acquaintance with the circulation of the blood informs us that there is no foundation for such a notion.

CEPHALENIA, or CEPHALLENIA, the largest of the islands constituting the Ionian republic. It was known in Homer's time by the names of Samos and Epirus Melæna, is about forty miles in length, twenty in breadth, and a hundred and thirty in compass. It had anciently four cities, one of which bore the name of the island. Strabo tells us, that in his time there were only two cities remaining; but Pliny speaks of three; adding, that the ruins of Same, which had been destroyed by the Romans, were still in being. Same was the metropolis of the island, and is supposed to have stood in the place which the Italians call Porto Guiscardo. It contains now three small towns, 130 villages, and 60,000 inhabitants. This island was subdued by the Thebans, under the conduct of Amphitryo, who is said to have killed Pterelas, who then reigned here. After it had been long in subjection to the Thebans, it fell under the power of the Macedonians, and was taken from them by the Ætolians, who held it till it was reduced by M. Fulvius Nobilior, who having gained the metropolis after a four months siege, sold all the citizens for slaves, adding the whole island to the dominions of the republic. It was subject to the Venetians from the year 1449 till the peace of Campo Formio in 1797. It was taken from the French in 1799, and formed into an independent commonwealth. It was again brought under the dominion of the French in 1807, but was taken by the British in 1809, and continues under their protection. See IONIAN ISLES, SUPPLEMENT.

CEPHALONIA, the capital of the island of the same name, situated in the Mediterranean, near the coast of Epirus, and subject to the Venetians. E. Long. 21. N. Lat. 38. 30.

CEPHEUS, in fabulous history, a king of Arcadia, on whose head Minerva fastening one of Medusa's hairs, he was rendered invincible.

CEPHEUS, in *Astronomy*, a constellation of the northern hemisphere. See ASTRONOMY *Index*.

CERAM, an island in the Indian ocean, between the Molucca islands on the north, and those of Amboyna and Banda on the south, lying between E. Long. 126. and 129. in S. Lat. 3. It is about 150 miles long, and 60 broad; and here the Dutch have

have a fortress, which keeps the natives in subjection.

CERAMBYX, in *Zoology*, a genus of insects, of the beetle kind, belonging to the order of insecta coleoptera. See ENTOMOLOGY *Index*.

CERASTES, in *Zoology*, the trivial name of a species of ANGUIS and COLUBER. See OPHIOLOGY *Index*.

CERASTIUM, MOUSE-EAR. See BOTANY *Index*.

CERASUS. See PRUNUS, BOTANY *Index*.

CERATE, in *Pharmacy*, a thickish kind of ointment applied to ulcerations, excoriations, &c. See PHARMACY *Index*.

CERATION, the name given by the ancients to the small seeds of ceratonia, used by the Arabian physicians as a weight to adjust the doses of medicines; as the grain weight with us took its rise from a grain of barley.

CERATION, or *Ceratium*, was also a silver coin, equal to one-third of an obolus.

CERATOCARPUS. See BOTANY *Index*.

CERATONIA, the CAROB TREE, or *St John's bread*. See BOTANY *Index*. The pods of this plant are called *St John's bread*, from an ill-founded assertion of some writers on Scripture, that these were the locusts which St John ate with his honey in the wilderness.

CERATOPHYLLUM. See BOTANY *Index*.

CERAUNIA, CERAUNIAS, or CERAUNIUS *Lapis*, in *Natural History*, a sort of flinty stone, of no certain colour, but of a pyramidical or wedge-like figure: popularly supposed to fall from the clouds in the time of thunder-storms, and to be possessed of divers notable virtues, as promoting sleep, preserving from lightning, &c. The word is from the Greek κεραυνος, *thunderbolt*. The ceraunia is the same with what is otherwise called the thunder-stone, or thunder-bolt; and also sometimes *sagitta* or arrow's head, on account of its shape. The cerauniæ are frequently confounded with the ombriæ and brontiæ, as being all supposed to have the same origin. The generality of naturalists take the ceraunia for a native stone, formed among the pyrites, of a saline, concrete, mineral juice. Mercatus and Dr Woodward assert it to be artificial, and to have been fashioned thus by tools. The ceraunia, according to these authors, are the heads of the ancient weapons of war, in use before the invention of iron; which, upon the introduction of that metal, growing into disuse, were dispersed in the fields through this and the neighbouring country. Some of them had possibly served in the early ages for axes, others for wedges, others for chissels; but the greater part for arrow-heads, darts, and lances. The ceraunia is also held by Pliny for a white or crystal-coloured gem, that attracted lightning in itself. What this was, is hard to say. Prudentius also speaks of a yellow ceraunia; by which he is supposed to mean the carbuncle or pyropus.

CERBERA. See BOTANY *Index*.

CERBERUS, in fabulous history, a dreadful three-headed mastiff, born of Typhon and Echidna, and placed to guard the gates of hell. He fawned upon those who entered, but devoured all who attempted to get back. He was, however, mastered by Hercules, who dragged him up to the earth, when, in struggling, a foam dropped from his mouth, which produced the poisonous herb called *aconite* or *wolf's bane*.

Some have supposed that Cerberus is the symbol of the earth, or of all-devouring time; and that its three mouths represent the present, past, and future. The victory obtained by Hercules over this monster denotes the conquest which this hero acquired over his passions. Dr Bryant supposes that Cerberus was the name of a place, and that it signified the temple of the Sun; deriving it from *Kir Abor*, *the place of light*. This temple was called also *Tor-Caph-El*, which was changed to τρικηφαλος; and hence Cerberus was supposed to have had three heads. It was likewise called *Tor-Keren*, *Turris Regia*; whence τρι καρηνος, from τρεις, *three*, and καρηνον, *head*.

CERCELE, in *Heraldry*. A cross cercele is a cross which, opening at the ends, turns round both ways like a ram's horn. See CROSS.

CERCIS, the JUDAS TREE. See BOTANY *Index*.

CERCOPITHECI, in *Natural History*, the name given by Mr Ray to monkeys, or the class of apes with long tails. See SIMIA, MAMMALIA *Index*.

CERDA, JOHN LEWIS DE LA, a learned Jesuit of Toledo, wrote large commentaries on Virgil, which have been much esteemed; also several other works. He died in 1643, aged 80.

CERDONIANS, ancient heretics who maintained most of the errors of Simon Magus, Saturninus, and the Manichees. They took their name from their leader *Cerdon*, a Syrian, who came to Rome in the time of Pope Hyginus, and there abjured his errors; but in appearance only; for he was afterwards convicted of persisting in them, and accordingly cast out of the church again. Cerdon asserted two principles, the one good and the other evil; this last, according to him, was the creator of the world, and the god that appeared under the old law. The first, whom he called *unknown*, was the father of Jesus Christ; who, he taught, was incarnate only in appearance, and was not born of a virgin; nor did he suffer death but in appearance. He denied the resurrection, and rejected all the books of the Old Testament, as coming from an evil principle. Marcion, his disciple, succeeded him in his errors.

CEREALIA, in antiquity, feasts of Ceres, instituted by Triptolemus, son of Celsus king of Eleusine in Attica, in gratitude for his having been instructed by Ceres, who was supposed to have been his nurse, in the art of cultivating corn and making bread.

There were two feasts of this kind at Athens; the one called *Eleusinia*, the other, *Thesmophoria*. See the article ELEUSINIA. What both agreed in, and was common to all the *cerealia*, was, that they were celebrated with a world of religion and purity; so that it was esteemed a great pollution to meddle, on those days, in conjugal matters. It was not Ceres alone that was honoured here, but also Bacchus. The victims offered were hogs, by reason of the waste they make in the products of the earth; whether there was any wine offered or not, is matter of much debate among the critics. Plautus and Macrobius seem to countenance the negative side; Cato and Virgil the positive. Macrobius says, indeed, they did not offer wine to Ceres, but *mulsum*, which was a composition of wine and honey boiled up together; that the sacrifice

crifice made on the 21st December to that goddess and Hercules, was a pregnant sow, together with cakes and mulsum; and that this is what Virgil means by *Mili Baccho*. The *cerealia* passed from the Greeks to the Romans, who held them for eight days successively; commencing, as generally held, on the fifth of the ides of April. It was the women alone who were concerned in the celebration, all dressed in white: the men, likewise in white, were only spectators. They ate nothing till after sunset; in memory of Ceres, who in her search after her daughter took no repast but in the evening.

After the battle of Cannæ, the desolation was so great at Rome, that there were no women to celebrate the feast, by reason they were all in mourning; so that it was omitted that year.

CEREALIA, in *Botany*, from *Ceres*, the goddess of corn; Linnæus's name for the larger esculent seeds of the grasses: these are rice, wheat, rye, barley, oats, millet, panic grass, Indian millet, holcus, zizania, and maize. To this head may be likewise referred darnel *(lolium)*; which, by preparation, is rendered esculent.

CEREBELLUM, the hinder part of the head. See ANATOMY *Index*.

CEREBRUM, the BRAIN. Its structure and use are not so fully known as some other parts of the body; and different authors consider it in various manners. However, according to the observations of those most famed for their accuracy and dexterity in anatomical inquiries, its general structure is as given in ANATOMY. See *Index*.

Dr Hunter observes, that the principal parts of the medullary substance of the brain in idiots and madmen, such as the *thalami nervorum opticorum*, and *medulla oblongata*, are found entirely changed from a medullary to a hard, tough, dark-coloured substance, sometimes resembling white leather.

CEREMONIAL *(ceremoniale)* a book in which is prescribed the order of the ceremonies to be observed in certain actions and occasions of solemnity and pomp. The ceremonial of the Roman church is called *ordo Romanus*. It was published in 1516 by the bishop of Corcyra; at which the college of cardinals were so scandalized, that some of them voted to have the author as well as book burnt, for his temerity in exposing the sacred ceremonies to the eyes of profane people.

CEREMONIAL is also used for the set or system of rules and ceremonies which custom has introduced for regulating our behaviour, and which persons practise towards each other, either out of duty, decency, or civility.

CEREMONIAL, in a more particular sense, denotes the manner in which princes and ambassadors used to receive and to treat one another. There are endless disputes among sovereigns about the *ceremonial:* some endeavouring to be on a level, and others to be superior; insomuch that numerous schemes have been proposed for settling them. The chief are, 1. To accommodate the difference by compromise or alteration; so that one shall precede now, the other the next time; or one in one place, and the other in another: 2. By seniority; so that an elder prince in years shall precede a younger, without any other distinction. These expedients, however, have not yet been accepted by any, except some *alternate princes*, as they are called, in Germany.

CEREMONIAL is more particularly used in speaking of the laws and regulations given by Moses relating to the worship of God among the ancient Jews. In this sense it amounts to much the same with what is called the *Levitical law*, and stands contradistinguished from the moral as well as judicial law.

CEREMONY, an assemblage of several actions, forms, and circumstances, serving to render a thing more magnificent and solemn.

In 1646, M. Ponce published a history of ancient ceremonies, tracing the rise, growth, and introduction of each rite into the church, and its gradual advancement to superstition therein. Many of them were borrowed from Judaism; but more seemingly from Paganism. Dr Middleton has given a fine discourse on the conformity between the Pagan and Popish ceremonies, which he exemplifies in the use of incense, holy water, lamps, and candles, before the shrines of saints, votive gifts or offerings round the shrines of the deceased, &c. In effect, the altars, images, crosses, processions, miracles, and legends; nay, even the very hierarchy, pontificate, religious orders, &c. of the present Romans, he shows, are all copied from their heathen ancestors.—We have an ample and magnificent account of the religious ceremonies and customs of all nations in the world, represented in figures designed by Picart, with historical explanations, and many curious dissertations.

Master of the CEREMONIES, an officer instituted by King James I. for the more honourable reception of ambassadors and strangers of quality. He wears about his neck a chain of gold, with a medal under the crown of Great Britain, having on one side an emblem of peace, with this motto, *Beati pacifici;* and on the other, an emblem of war, with *Dieu et mon droit:* his salary is 300l. per annum.

Assistant Master of the CEREMONIES, is to execute the employment in all points, whensoever the master of the ceremonies is absent. His salary is 141l. 13s. 4d. per annum.

Marshal of the CEREMONIES, is their officer, being subordinate to them both. His salary is 100l. per annum.

CERENZA, a town of Italy, in the kingdom of Naples, and in the Hither Calabria, with a bishop's see. It is seated on a rock, in E. Long. 17. 5. N. Lat. 39. 23.

CERES, a pagan deity, the inventor or goddess of corn; in like manner as Bacchus was of wine.

According to the poets, she was the daughter of Saturn and Ops, and the mother of Proserpine, whom she had by Jupiter. Pluto having stolen away Proserpine, Ceres travelled all over the world in quest of her daughter, by the help of a torch, which she had lighted in Mount Ætna.

As Ceres was thus travelling in search of her daughter, she came to Celeus king of Eleusis, and undertook to bring up his infant son Triptolemus. Being desirous to render her charge immortal, she fed him in the day time with divine milk, and in the night covered him with fire. Celeus observing an unusual improvement in his son, resolved to watch his nurse;

to which end he hid himself in that part of the house where she used to cover the child with fire: but when he saw her put the infant under the embers, he cried out and discovered himself. Ceres punished the curiosity and indiscretion of the father with death. Afterwards she taught the youth the art of sowing corn and other fruits, and mounted him in a chariot drawn by winged dragons, that he might traverse the world, and teach mankind the use of corn and fruits. After this, having discovered, by means of the nymph Arethusa, that Proserpine was in the infernal regions, she applied to Jupiter, and obtained of him that Proserpine should be restored, on condition that she had tasted nothing during her stay in that place: but it being discovered, by the information of Ascalaphus, that, as she was walking in Pluto's orchard, she had gathered an apple, and had tasted of some of the seeds, she was for ever forbidden to return. Ceres, out of revenge, turned Ascalaphus into an owl. At length, Jupiter, to mitigate her grief, permitted that Proserpine should pass one half of the year in the infernal regions with Pluto, and the other half with her mother on earth.

Cicero speaks of a temple of Ceres at Catanea in Sicily, where was a very ancient statue of that goddess, but entirely concealed from the sight of men, every thing being performed by matrons and virgins.

CERET, a town of France in Rousillon, with a magnificent bridge of a single arch. It is seated near the river Tec, in E. Long. 2. 46. N. Lat. 42. 23.

CEREUS, in *Botany*. See CACTUS.

CERIGO, an island in the Archipelago, anciently called *Cytherea*; noted for being the birthplace of Helen and of Venus. It is now one of the seven isles constituting the Ionian republic. At present there is nothing very delightful in the place; for the country is mountainous, and the soil dry. It abounds in hares, quails, turtle, and excellent falcons. It is about 50 miles in circumference, and produces corn, wine, flax, oil, and cotton. The town of the same name is strong both by art and nature, being seated on a craggy rock. The inhabitants, who are Greek Christians, were about 10,000 in number in 1806.

CERINES, a town in the island of Cyprus, with a good castle, a harbour, and a bishop's see. E. Long. 33. 35. N. Lat, 35. 22.

CERINTHE, HONEYWORT. See BOTANY *Index*.

CERINTHIANS, ancient heretics, who denied the deity of Jesus Christ.—They took their name from Cerinthus, one of the first heresiarchs in the church, being contemporary with St John. See CERINTHUS.

They believed that Jesus Christ was a mere man, born of Joseph and Mary; but that, in his baptism, a celestial virtue descended on him in form of a dove; by means whereof he was consecrated by the Holy Spirit, and made Christ. It was by means of this celestial virtue, therefore, that he wrought so many miracles; which, as he received it from heaven, quitted him after his passion, and returned to the place whence it came; so that Jesus, whom they called a *pure man*, really died and rose again; but that Christ, who was distinguished from Jesus, did not suffer at all. It was partly to refute this sect that St John wrote his gospel. They received the gospel of St Matthew, to countenance their doctrine of circumcision, from Christ's being circumcised; but they omitted the genealogy. They discarded the epistles of St Paul, because that apostle held circumcision abolished.

CERINTHUS, a heresiarch, cotemporary with the apostles, ascribed the creation not to God, but to angels. He taught that Jesus Christ was the son of Joseph, and that circumcision ought to be retained under the gospel. He is looked upon as the head of the converted Jews, who raised in the church of Antioch the tumult of which St Luke has given the history in the 15th chapter of the Acts. Some authors ascribe the book of the Apocalypse to Cerinthus; adding, that he put it off under the name of St John, the better to authorize his reveries touching Christ's reign upon earth: and it is even certain that he published some works of this kind under the title of *Apocalypse*. See APOCALYPSE.

CEROPEGIA. See BOTANY *Index*.

CERTHIA, in *Ornithology*, the CREEPER or OX-EYE, a genus belonging to the order of picæ. See ORNITHOLOGY.

CERTIFICATE, *Trial by*, in the law of England, a species of trial allowed in such cases where the evidence of the person certifying is the only proper criterion of the point in dispute *. For when the fact in question lies out of the cognizance of the court, the judges must rely on the solemn averment or information of persons in such a station as affords them the most clear and competent knowledge of the truth. As therefore such evidence, if given to a jury, must have been conclusive, the law, to save trouble and circuity, permits the fact to be determined upon such certificate merely. Thus, 1. If the issue be whether A was absent with the king in his army out of the realm in time of war, this shall be tried by the certificate of the mareschal of the king's host in writing under his seal, which shall be sent to the justices. 2. If, in order to avoid an outlawry, or the like, it was alleged that the defendant was in prison, *ultra mare*, at Bourdeaux, or in the service of the mayor of Bourdeaux, this should have been tried by the certificate of the mayor, and the like of the captain of Calais. But when this was law, those towns were under the dominion of the crown of England. And therefore, by a parity of reason, it should now hold, that in similar cases arising at Jamaica or Minorca, the trial should be by certificate from the governor of those islands. We also find that the certificate of the queen's messengers, sent to summon home a peeress of the realm, was formerly held a sufficient trial of the contempt in refusing to obey such summons. 3. For matters within the realm; the customs of the city of London shall be tried by the certificate of the mayor and aldermen, certified by the mouth of their recorder, upon a surmise from the party alleging it, that the custom ought to be thus tried; else it must be tried by the country: As, the custom of distributing the effects of freemen deceased; of enrolling apprentices, or that he who is free of one trade may use another; if any of these, or other similar points come in issue. 4. The trial of all customs and practice of the courts shall be by certificate from the proper officers of those courts respectively; and

* See *Trial*.

Blackst. Comment.

and when returned was made on a writ by the sheriff or under sheriff, shall be only tried by his own certificate.

CERTIORARI, in *Law*, a writ which issues out of the chancery, directed to an inferior court, to call up the records of a cause there depending, in order that justice may be done. And this writ is obtained upon complaint, that the party who seeks it has received hard usage, or is not likely to have an impartial trial in the inferior court. A certiorari is made returnable either in the king's bench, common pleas, or in chancery.

It is not only used out of the court of chancery, but likewise out of the king's bench; in which last mentioned court it lies where the king would be certified of a record. Indictments from inferior courts, and proceedings of the quarter-sessions of the peace, may also be removed into the king's bench by a certiorari: and here the very record must be returned, and not a transcript of it; though usually in chancery, if a certiorari be returnable there, it removes only the tenor of the record.

CERTITUDE, considered in the things or ideas which are the objects of our understanding, is a necessary agreement or disagreement of one part of our knowledge with another: as applied to the mind, it is the perception of such agreement or disagreement: or such a firm well-grounded assent, as excludes not only all manner of doubt, but all conceivable possibility of a mistake.

There are three sorts of certitude, or assurance, according to the different natures and circumstances of things. 1. A physical or natural certitude, which depends upon the evidence of sense; as that I see such or such a colour, or hear such or such a sound; nobody questions of the truth of this, where the organs, the medium, and the object, are rightly disposed. 2. Mathematical certitude is that arising from mathematical evidence: such as, that the three angles of a triangle are equal to two right ones. 3. Moral certitude is that founded on moral evidence, and is frequently equivalent to a mathematical one; as that there was formerly such an emperor as Julius Cæsar, and that he wrote the commentaries which pass under his name; because the historians of these times have recorded it, and no man has ever disproved it since: this affords a moral certitude, in common sense so great, that one would be thought a fool or madman for denying it.

CERTOSA, a celebrated Carthusian monastery, in the territory of the Pavese, in the duchy of Milan, four miles from Pavia: its park is surrounded with a wall 20 miles in circumference; but there are several small towns and villages therein.

CERVANTES. See SAAVEDRA.

CERVERA, a town of Spain in Catalonia, seated on a small river of the same name, in E. Long. 1. 9. N. Lat. 41. 28.

CERVIA, a sea-port town of Italy, in Romagna, with a bishop's see, seated on the gulf of Venice, in E. Long. 13. 5. N. Lat. 44. 16.

CERVICAL NERVES, are seven pair of nerves, so called, as having their origin in the *cervix*, or neck.

Cervical Vessels, among anatomists, denote the arteries, veins, &c. which pass through the *vertebræ* and muscles of the neck up to the skull.

CERVIX, in *Anatomy*, properly denotes the hind part of the neck; as contradistinguished from the fore part, which is called *jugulum*, or the throat.

CERVIX of the *Scapula*, denotes the head of the shoulder blade, or that upper process whose *sinus* receives the head of the *humerus*.

Cervix of the Uterus, the neck of the *uterus*, or that oblong canal or passage between the internal and external orifices, which receives and encloses the *penis* like a sheath, whence it is also called VAGINA.

CERUMEN, a thick, viscous, bitter, excrementitious humour, separated from the blood by proper glands placed in the *meatus auditorius*, or outer passage of the ear.

CERUSS, WHITE LEAD, a sort of calx of lead, made by exposing plates of that metal to the vapour of vinegar. See CHEMISTRY *Index*.

Ceruss, as a medicine, is used externally, either mixed in ointments or by sprinkling in on old gleeting and watery ulcers, and in many diseases of the skin. If, when it is reduced into a fine powder, it is received in with the breath in inspiration, and carried down into the lungs, it causes incurable asthmas. Instances of the very pernicious effects of this metal are too often seen among those persons who work lead in any form, but particularly among the workers in white lead.

The painters use it in great quantities; and that it may be afforded cheap to them, it is generally adulterated with common whiting.

CERVUS, or DEER, in *Zoology*, a genus of quadrupeds belonging to the order of Pecora. See MAMMALIA *Index*.

Servus Volans, in *Natural History*, a name given by authors to the stag-fly, or horned beetle, a very large species of beetle with horns sloped, and something like those of the stag.

CERYX, in antiquity. The ceryces were a sort of public criers, appointed to proclaim or publish things aloud in assemblies. The *ceryx* among the Greeks answered to the *præco* among the Romans. Our criers have only a small part of their office and authority.

There were two kinds of ceryces, *civil* and *sacred*. The former were those appointed to call assemblies, and make silence therein; also to go on messages, and do the office of our heralds, &c. The sacred ceryces were a sort of priests, whose office was to proclaim silence in the public games and sacrifices, publish the names of the conquerors, proclaim feasts, and the like. The priesthood of the ceryces was annexed to a particular family, the descendants of Ceryx, son of Eumolpus. To them it also belonged to lead solemn victims to slaughter. Before the ceremonies began, they called silence in the assembly, by the formula, Συφημειτε σιγε πας εςω λαως; answering to the *favete linguis* of the Romans. When the service was over, they dismissed the people with this formula, Λαων αφεσις, *Ite, missa est.*

CESARE, among logicians, one of the modes of the second figure of syllogisms; the minor proposition of which is an universal affirmative, and the other two universal negatives: thus,

CE No immoral books ought to be read;
SA But every obscene book is immoral;
RE Therefore no obscene books ought to be read.

arotti ‖ sion.

CESAROTTI, MELCHIOR, an Italian poet. See SUPPLEMENT.

CESENA, a town of Romagna in Italy, with a bishop's see, subject to the pope, and seated on the river Savio, in E. Long. 12. 46. N. Lat. 44. 8.

CESPITOSÆ PLANTÆ (from *cespes*, turf or sod), are those plants which produce many stems from one root, and thence form a close thick carpet on the surface of the earth.

CESPITOSÆ Paludes, turf bogs.

CESSATION, the act of intermitting, or discontinuing, the course of any thing, work, or action.

CESSATION of Arms, an armistice or occasional truce. See TRUCE.

When the commander of a place finds things reduced to an extremity, so that he must either surrender, or sacrifice the garrison and inhabitants to the mercy of the enemy, he plants a white flag on the breach, or beats the chamade; on which a cessation of arms commences, to give room for a capitulation.

CESSIO BONORUM, in *Scots Law*, the name of that action by which an insolvent debtor may apply for liberation from prison, upon making over his whole real and personal estate to his creditors.

CESSION, in *Law*, an act by which a person surrenders and transmits to another person a right which belonged to himself. Cession is more particularly used in the civil law for a voluntary surrender of a person's effects to his creditors to avoid punishment. See the article BANKRUPT.

In several places the cession carried with it a mark of infamy, and obliged the person to wear a green cap or bonnet; at Lucca, an orange one; to neglect this was to forfeit the privileges of the *Cession*. This was originally intended to signify that the cessionary was become poor through his own folly. The Italian lawyers describe the ceremony of cession to consist in striking the bare breech three times against a stone, called *Lapis Vituperii*, in presence of the judge. Formerly it consisted in giving up the girdles and keys in court; the ancients using to carry at their girdles the chief utensils wherewith they got their living; as the scrivener his escritoire, the merchant his bag, &c. The form of cession among the ancient Gauls and Romans was as follows: The cessionary gathered up dust in his left hand from the four corners of the house, and standing on the threshold, holding the door-post in his right hand, threw the dust back over his shoulders; then stripping to his shirt, and quitting his girdle and bags, he jumped with a pole over a hedge; hereby letting the world know that he had nothing left, and that when he jumped, all he was worth was in the air with him. This was the cession in criminal matters. In civil cases it was sufficient to lay a broom, a switch, or a broken straw, on the threshold: this was called *chrenecruda per durpillum et festucam*.

Cession ‖ Ceterach.

CESSION, in the ecclesiastical law, is when an ecclesiastical person is created a bishop, or when a parson of a parish takes another benefice, without dispensation, or being otherwise qualified. In both these cases their first benefices become void by cession, without any resignation; and to these livings that the person had, who was created bishop, the king may present for that time, whosoever is patron of them; and in the other case the patron may present: but by dispensation of retainder, a bishop may retain some or all the preferments he was entitled to before he was made bishop.

CESTRUM, BASTARD JASMINE. See BOTANY *Index*.

CESTUI, a French word, signifying *he* or *him*, frequently used in the English law writings. Thus, *Cestui qui trust*, a person who has lands, &c. committed to him for the benefit of another; and if such person does not perform his trust, he is compellable to it in chancery. *Cestui qui vie*, one for whose life any lands, &c. are granted. *Cestui qui use*, a person to whose use any one is infeoffed of lands or tenements. Formerly the feoffees to uses were deemed owners of the land, but now the possession is adjudged *in cestui qui use*.

CESTUS, among ancient poets, a fine embroidered girdle said to be worn by Venus, to which Homer ascribes the power of charming and conciliating love. The word is also written *cestum* and *ceston*: it comes from κεϱος, *a girdle* or other thing embroidered or wrought with a needle; derived, according to Servius, from κεντειν, *pungere*; whence also *incestus*, a term used at first for any indecency by undoing the girdle, &c. but now restrained to that between persons near a-kin. See INCEST.

CETACEOUS, an appellation given to the fishes of the whale kind. See CETOLOGY.

CETE, the name of Linnæus's seventh order of mammalia, comprehending the MONODON, BALÆNA, PHYSETER, and DELPHINUS. See CETOLOGY.

CETERACH, the trivial name of a species of ASPLENIUM. See ASPLENIUM, BOTANY *Index*.

CETOLOGY.

1 [...]nition [...]e title.

UNDER this general title is comprehended the history of that division of marine animals, which in the Linnæan arrangement constitutes the seventh order of the class mammalia. This is the order *cete* or *whales*. Ray and Willoughby have included this order of animals under the class of fishes. Ray, in his arrangement of fishes, divides them into two principal sections. The one comprehends those fishes which are furnished with lungs for respiration; and the other, those which breathe by means of gills, and may be considered as truly fishes. In the former section are included the cetaceous fishes; and the reasons which he assigns for arranging them in this manner are, that they agree in external form with fishes; that they are entirely naked, or covered only with a smooth skin; and that they live entirely in the water, and have all the actions of fishes. Although this tribe of animals resembles fishes, not only in manners and habits, but also in being inhabitants of the same element, Linnæus thought proper to class them with the mammalia, on

2 A[...]nge- m[...] of fi[...] by R[...]

3 Of whales by Linnæus,

Introduction.

on account of the similarity of their internal structure, having a double heart and warm blood, and respiring like them by means of lungs.

4 by Pennant.

Mr Pennant, in his British Zoology, has objected to the classification of cetaceous animals with the mammalia, as Linnæus has done, because, "to have preserved the chain of beings entire, he says that Linnæus should have made the genus *phocæ* or *seals*, and that of the *trichecus* or *manati*, immediately precede the whale, those being the links that connect the mammalia or quadrupeds with the fish; for the seal is in respect to its legs the most imperfect of the former class; and in the *manati* the hind feet coalesce, assuming the form of a broad horizontal tail." On this account, Mr Pennant has arranged the cetaceous order of animals under his class of fishes, including them under the first division

5 Treated of separately.

of that class. For the same reasons we have separated them from the class of fishes; but although they resemble the quadrupeds, which compose chiefly the class mammalia, in being warm-blooded, and in the functions of circulation and respiration; yet, as they possess characters so totally distinct from any of the mammalia, we judged it more natural to separate them also from this class, and to treat of them in the present article.

6 Their history important,

This tribe of animals is also entitled to a separate treatise, both on account of the interest to be derived from their natural history, and on account of their importance in a commercial view.

7 but deficient.

The history of cetaceous animals, as well as that of the other inhabitants of the ocean, cannot be expected to be complete. They are beyond the reach of the naturalist, from the nature of the element in which they live; and even when he is favoured with a transient glimpse, the rapidity of their motions precludes the possibility of obtaining much accurate knowledge

8 Reasons.

of their manners and habits. But the abode of the whale is the most inaccessible parts of the ocean. The frozen regions of the north and south are his chief retreat—regions so inhospitable, as to forbid the approach of the most hardy naturalist with all his zeal and ardour, and to be visited only by the adventurous fisherman, prompted by the hope of gain. To the latter, chiefly, we are indebted for what knowledge we possess of this tribe of animals. And from men who had a very different object in view, who, in this hazardous trade, had to struggle with the severest seasons, in a climate where the rigour of winter rarely relaxes, information on this subject could neither be accurate nor extensive.

9 Sources of information.

This, however, was the principal source from which the earlier writers on this department of natural history derived their information. Such were Sibbald, Martens, Dudley, Clein, and Anderson, who composed their descriptions from the relations and memoirs which were communicated to them by fishermen and voyagers. Hence have originated these erroneous and inaccurate details which have been introduced into the works of naturalists.

10 Name limited.

The name of *Cete*, as the word which is derived from the Greek language originally signifies, was given indiscriminately to all marine animals of extraordinary size. It has been limited by later naturalists to that tribe of fishes which are distinguished from other fishes by the functions of respiration and circulation, and by being viviparous. These are now included under the general term *cetaceous* fishes. Beside the discriminative marks of respiration, circulation, and being viviparous, others may be mentioned.

Introduction.

11 Difference from other fishes,

In the cetaceous fishes the skin is not covered with scales as in other fishes; there are one or two orifices in the upper part of the head for discharging water; the lateral fins are furnished with articulations as in the human hand, and the tail is horizontal.

12 in fat,

There is another remarkable difference between the cetaceous and other fishes, in the greater quantity of blood, and the thick covering of fat or *blubber*, for which the former are distinguished. And considering the temperature of the climate, and the element in which these animals live, this seems to be a wise and necessary provision of nature.

13 and quantity of blood.

The great quantity of blood produces a greater degree of heat, and the spongy porous mass of blubber, being from its nature a slow conductor of heat, is an excellent defence against the rigour of the seasons in the polar regions.

In the following treatise we propose to lay before our readers, 1st, The Classification and Natural History of Cetaceous Fishes; 2d, Their Anatomy and Physiology; and, lastly, The History of the Whale Fishery as an object of trade. These shall be the subjects of three chapters.

Chap. I. *Of the Classification and Natural History of Cetaceous Fishes.*

14 Classes four.

Cetaceous fishes have been divided into four classes, the characters of which are taken from the want of teeth, from the structure of the teeth, and from their position in one or both jaws. The following table exhibits the characters of these classes, with a translation opposite for the sake of the English reader.

1st, Balæna, or *Whale*.

Dentium loco laminæ corneæ in maxilla superiore.	In place of teeth there are horny plates in the upper jaw.

2d, Monodon, or *Unicorn Fish*.

Dens unicus aut duo in parte antica maxillæ superioris horizontaliter exserti.	One or two teeth horizontally inserted in the anterior part of the upper jaw.

3d, Physeter, or *Spermaceti Whale*.

Dentes veri in maxilla inferiore; aliquot vero plani, vix conspicui in maxilla superiore.	Teeth in the lower jaw, but scarcely conspicuous in the upper jaw.

4th, Delphinus, or *Dolphin*.

Dentes in utraque maxilla.	Teeth in both jaws.

15 Genera.

Each of the four classes which we have now enumerated and characterised, comprehends only a single genus, the characters of which are as follows:

Generic Characters.

1st Genus, Balæna, or *Whale*.

Maxilla superior dentium loco, laminis corneis instructa; fistula duplex in vertice.	The upper jaw is furnished with horny plates in place of teeth, and there are two blow-holes on the top of the head.

2d,

ssifica-n, &c.

2d Genus, Monodon, or *Unicorn-Fish.*

Dens unicus aut duo, longi aut breves, recti vel recurvi, in parte antica maxillæ superioris exserti; fistula in occipite.	In the anterior part of the upper jaw there is one or two teeth which are either straight or curved, long or short; the spout in the back part of the head.

3d Genus, Physeter, or *Spermaceti Whale.*

Dentes veri et visibiles in maxilla inferiore, in quibusdam vero maxilla superior dentibus planis vix conspicuis instructa; fistula in angulo superiore rostri.	The teeth distinctly seen in the lower jaw, but scarcely visible in the upper jaw; the spout in the upper part of the forehead.

4th Genus, Delphinus, or *Dolphin.*

Maxilla utraque dentata: fistula in fronte.	Both jaws are furnished with teeth; the spout in the forehead.

Class I. BALÆNA.

Genus 1st, Balæna, or *Whale.*

16 eric racters. The body is naked, elliptical, or of an oblong conical shape, and of a black or brownish colour.

The head is very long, laterally compressed, and diminishing towards the beak. The opening of the mouth is very large. The jaws are nearly equal, and without teeth; but in place of teeth, the upper jaw is furnished on both sides with horny plates, transversely disposed. The lower jaw is anteriorly of an oval or roundish form, broader than the upper jaw, and having a furrow on the margin for receiving the horny plates. The eyes are small; they are placed near the insertion of the lateral fins. The ears are also small, and are situated behind the eyes.

In some of the species the anterior part of the body is plicated or folded underneath.

The penis is enclosed in a sheath. The female is furnished with two mammæ; and the organs of generation are placed between them. Behind them is the anus.

There are three or four fins; two lateral fins, one at the extremity of the tail, which is placed horizontally. The dorsal fin is often wanting.

* *Species which have no Dorsal Fin.*

eCXL. g. 1. 1. Balæna Mysticetus, the *Greenland*, or *large Whalebone Whale.*

French, *Baleine Franche. Baleine de grande baie;* Spaniards, *Vallena; Whallfesch*, by the Germans; *Whallvisek*, Dutch; *Hvafisch, Sletback*, by the Norwegians; *Hvalfisk*, by the Swedes; *Slitcheback, Sandhual*, by the Danes; *Vatuskalr*, by the Icelanders; and *Arbek, Arbavirksoak*, by the Greenlanders.

17 acters. In this species the jaws are nearly of equal length; the lower is of an oval form, and broad in the middle; the back is spotted, black and white.

18 crip- This is the largest of animals known. The body, from a side view, appears of an elliptical form. The head is very nearly equal to one-third of the whole length of the body. It is as it were composed of two inclined planes joined together under a larger or smaller angle, and has something the appearance of the roof of a small house.

Classification, &c.

In the middle of the line formed by the junction of the two inclined planes, there rises a large tubercle, in which are situated the spouts or blow-holes opposite to each other, and curved in the shape of the letter S. The jaws are nearly equal in length; the lower is broader towards the middle of its length than the upper; and besides it spreads out and has membranous coverings, which terminate in a broad deep furrow, which is destined to receive the horny teeth of the upper jaw. When the jaws are close, the opening of the mouth folds upwards towards the orbit of the eyes, and exhibits by its inflection the curved form of a sickle. 19 Blow-holes.

The want of teeth is supplied by about 500 horny laminæ. This is the substance called *whalebone.* They are attached to the upper jaw on both sides, and supported at the base by a kind of bone which extends the whole length of the roof of the mouth. They are arranged transversely, and in an oblique direction. Each of them is from three to five feet long, is thickest at the base, tapers towards the point, is a little curved, and terminates in a fringe of long hair which hangs about the tongue. Towards the two extremities of each row, there are besides many other small laminæ, which are of a square form, of the thickness of a writing quill, and about four inches long. These latter are arranged in the same direction as the former; but are of a softer substance, and do not come so close to each other. 20 Whalebone.

The tongue is soft and spongy, strongly attached to the lower jaw, and rounded at the extremity. On the upper side it is white, but on the sides it is marked with black spots. It is often 10 feet broad and 18 feet long. 21 Tongue.

The eyes are placed very low, at the broadest part of the head, just above the angles of the mouth, and very near the origin of the lateral fins. They are furnished, as the means of defence, with eyelids and eyelashes; and resemble in form and magnitude those of an ox. The crystalline lens, which is white and transparent, is not larger than a pea. The external organ of hearing, consists of a small hole of the diameter of a quill, which is placed immediately behind the eyes. 22 Eyes. 23 Ear.

The back forms a gentle curvature from the tubercle on the top of the head; towards the middle of the trunk it is again elevated, and then tapers gradually to the tail. The lower part of the body diminishes in the same proportion. The lateral fins have their origin near the angle of the mouth. They are two large thick masses, of an oval irregular form, and are often 10 feet long. The tail fin is divided into two oval fleshy lobes, which terminate in a point. 24 Fins.

The male is furnished with a penis which is eight feet long, and surrounded with a double skin, which gives it something of the appearance of a knife in its sheath. The female has two mammæ, which are placed on each side of the organs of generation.

The skin of the whale is divided into the epidermis or scarf-skin, the true skin, the fat or blubber, and the muscle or flesh. The epidermis is as thin as parchment, 25 Skin.

Classification, &c. ment, and very easily separated, when the process of putrefaction first commences. The true skin is an inch thick, and covers a layer of fat of 15 inches.

26 Colour. The back of the whale is usually of a fine black, marked with whitish rays, which have some resemblance to the veins of wood; and in the thickest, as well as the finest of these traces, there pass other veins of a dirty white. This mixture of colours presents an agreeable appearance, especially when the back of the fish is illuminated with the rays of the sun. The different changes of colour from white to yellow then exhibit the splendour and brilliancy of silver.

The under part of the trunk, and of the lower jaw, is of a bright white. But these colours are subject to considerable variation, according to the age of the fish. Some have been observed to be entirely black; others spotted with white, yellow, and brown. Martens assures us, that he observed on the tail of a whale, the number 1222, as neatly traced as if it had been executed by the hand of a painter. But probably the resemblance to those figures was helped out by the aid of fancy.

Ellis and some other naturalists assert, that the whale is found perfectly white in the western parts of the northern ocean. It is not uncommon to see the young whale spotted with brown; and old whales marked on the back with a transverse band, which extends to the belly. Sometimes, however, the spots observed on the whale have been undoubtedly occasioned by wounds; for it is certain, that a white scar always remains on the place which has been wounded.

27 Size. The size of the whale has not been very accurately ascertained. Some have been taken of 80, and even of 100 feet long, and almost as much in circumference. The female is in general larger than the male. The period of pregnancy is nine or ten months; and one, very rarely two, is brought forth at a time. The young whale is 20 feet long at birth.

28 Haunts. This species of whale is very common towards the north pole, in the seas of Greenland and Spitzbergen, and especially in that part of the arctic sea which lies under the 76th degree of latitude.

29 Food. The principal food of the whale is a species of *helix* and different species of actiniæ. It is not a little surprising that the whale, of such immense size, should feed on such small animals, and should acquire such a quantity of fat as to yield above 150 tons of oil. But according to the testimony of those employed in the whale fishery, these worms are found in such abundance in the seas about Spitzbergen, that the whale has only to open his mouth to receive thousands at once, and then rejecting the water through the fringe or beard attached to the jaws, these little animals remain behind, taken as it were in a net. And indeed there seems to be a wise provision of nature for the subsistence of this monstrous animal, in impressing on these worms and insects, which are to be his food, a kind of instinct, which guides them to sport about the fringes of the jaws, in the very gulf which is to swallow them up. Linnæus says that the whale also feeds on *medusæ*. But to this it has been objected, that the medusæ are not in sufficient abundance in the northern seas, to furnish the necessary quantity of food for so large an animal. It seems not improbable, however, that the medusæ as well as the actiniæ may form part of its food. Classification, &c.

The excrement of the whale has some degree of solidity, and it is of a yellow colour, approaching somewhat to the colour of saffron.

The whale fishery, or rather it might be termed the chase of the whale, constitutes one of the principal occupations of the inhabitants of Greenland. The capture of a single whale is sufficient for the subsistence of a whole family for a long time. The flesh is eaten raw, baked, or after being half rotten, or dried in the heat of the sun; and according to Horrebow, it has a very good taste. The skin, the tail, and the fins, undergo no kind of preparation; for it seems these parts furnish, in the raw state, a very delicate morsel to the Greenlanders. The fat is either eaten, or burnt for the purpose of giving light. The intestines are employed to shut up the doors and windows of their habitations; and the tendons furnish thread for sewing, or for the construction of nets. Of the bones the Greenlanders make stools or chairs, and instruments that are used in hunting and fishing. The best lines are made of the hair that terminates the horny plates of the upper jaw. 30 Fishery by the Greenlanders. 31 Uses.

The following are the dimensions of a whale taken towards the north pole, and recorded by M. de Pages in the account of his voyage round the world.

	Ft.	Inch.
Total length,	48	0
Circumference of the head, which is the thickest part of the body,	26	5
Length of the head, about	18	0
Length of the jawbones,	18	0
Diameter of the orbit of the eyes,	0	3
Opening of the eyelids,	0	5
Distance of the eyes from the opening of the breathing holes,	6	0
Length of the cavity, which includes the penis,	4	0
Depth of this cavity,	0	8
Distance of this cavity from the anus,	1	0
Diameter of each mamma,	0	6
Length of the papilla,	0	2
Diameter of it,	0	$1\frac{1}{4}$
Distance of the two lobes of the tail fin, about	17	0
Depth of the hollow which separates the two lobes,	2	6
Length of the lateral fins,	8	0
Breadth of the same, about	7	0

2. Balæna Glacialis, *Iceland Whale.*

French, *Le Nord Caper, Baleine de Sarde;* German, *Nordkaper;* Norwegian, *Sildqual, Nordkaper.*

In this species, the jaws are nearly of equal length. The under jaw is rounded, and broader towards the middle of its length. There is no dorsal fin. The back is whitish. 32 Specific character.

The Iceland whale differs from the former only in the colour and dimensions of the body. The head and horny laminæ of the upper jaw are much smaller. The trunk of the body is more slender, and is of a light 33 Body.

assification, &c. light brown colour. It has been observed, that the lower jaw of this species is more elongated and rounder than that of the common whale.

34 ode of ting by Icelanders. As it is very dangerous to harpoon this species of whale, on account of its extreme agility, it is mentioned by Anderson, that the Icelanders have a very ingenious method of taking it. When they perceive the whale in chase of the herrings, they instantly launch their canoes furnished with harpoons, spears, and knives, and endeavour to get between the whale and the ocean. They continue the pursuit by rowing, and approach as near as possible. If the wind blow towards the shore, they pour on the sea a quantity of blood, with which they are always provided, and as it is carried by the waves to the coast, they endeavour to direct it as near to the shore as they can. The whale perceiving himself pursued, attempts to regain the ocean, but when he approaches the blood he is alarmed, and rather than swim across it, he makes his escape to the shores, where he often throws himself on the rocks. But if the wind blow from the land, the fishermen endeavour to get between the whale and the ocean, as in the other case; and when he attempts to make for the deep, they throw stones from their canoes, and shout and make a noise, so that the whale is terrified and is driven on shore. This, however, is contradicted by Horrebow, who remained two years in Iceland, and had good opportunities of being well informed of every thing relating to the whale-fishery. He says, that the Icelanders are neither hardy enough to make this hazardous attempt, nor so fortunate or dexterous as to take the whale so easily. The only method which is practised there, he says, is the following: When the boat approaches the whale, the harpooner discharges his harpoon, and the boat instantly retreats. The harpoon is known by having the mark of the proprietor, and when the whale has been successfully wounded, he dies and is thrown ashore. A certain portion belongs to the person who was so fortunate as to inflict the wound, and the remainder is claimed, according to a law of the country, as the right of the person on whose property he lands. According to this author, this is the whole art practised by the inhabitants of Iceland in the whale-fishery.

The Iceland whale yields only from 10 to 30 tons of blubber.—The food of this whale consists of some species of *helix*, *medusæ*, and herrings.

This whale inhabits the northern ocean, about the coasts of Norway and Iceland.

Klein has made two varieties of this whale, distinguishing them by names derived from that part of the ocean where they are found. 1. Var. *Australis*, which is found in the southern ocean, has the back very flat. 2. Var. *Occidentalis*, found in the western ocean, which has the back more elevated. The same naturalist has distinguished the *Balæna glacialis* by the name *borealis*.

*** Species which have a Fin or Bunches on the Back.*

3. Balæna Physalus, or *Fin Fish*.

French *Le Gibbar;* German, *Finnfisch;* Dutch, *Vinvisch;* Norwegian, *Ror-hual*, *Finne-fisk;* Greenland, *Tummilik;* Iceland, *Hunfubaks*.

35 Characters. The jaws are equal and pointed; the horny laminæ of the upper jaw are short, and of a bluish colour. There is one fin on the back. Classification, &c.

36 Description. According to the fishermen, the fin fish is as long but not so thick as the common whale. When the jaws are shut, the head resembles a cone, which constitutes nearly one-third part of the whole length of the whale, and terminates in a sharp snout. On the top of the head are two respiratory orifices divided longitudinally. This whale, it is said, ejects the water with much greater force than the common whale. The horny laminæ of the upper jaw are fringed and disposed in the same manner as those of the preceding. They differ in being shorter, and of a blue colour. The length is from 10 to 12 inches. The long hair which terminates the laminæ, is so twisted that the edges of the upper jaw seem covered with a thick cord interwoven together. The eyes are placed very low, nearly in the direction of the angles of the mouth. Towards the posterior extremity of the back, there arises a triangular fin, about 3 or 4 feet high, having the summit bent backwards. The lateral fins are of an oval figure, from 6 to 7 feet long. The tail fin is divided into two lobes which form nearly a right angle.

This species lives on the herring, the mackerel, a kind of salmon frequent in the northern sea, and other small fish. 37 Food.

The upper part of the body is of a shining brown colour. The belly and the under part of the lower jaw are of a splendid white.

This species of whale is found in the Greenland seas, in the European seas, in the Indian ocean, and in the new world. In March 1673, Martens mentions that he saw a whale of this species in the straits of Gibraltar. As the mass of the body constitutes the third or the fourth of that of the common whale, the fat is less thick. It yields, it is said, only ten tons of oil. This whale is therefore less an object of the fisherman's pursuit, for the produce of oil is not equivalent to the expence, the risk, and the danger that attend it.

It has been remarked, that as soon as the fin fish makes its appearance in the seas round Spitzbergen, the common whale is no longer to be seen.

In Greenland the flesh, the fins, the skin, and the tendons, are employed as food by the poorer inhabitants; and the bones are applied to a great many domestic uses. It is said that the flesh has the same taste as that of a sturgeon. 38 Uses.

4. Balæna Nodosa, *the Bunch* or *Humpback Whale*.

French, *Baleine-tampon;* German, *Plock-fish;* Dutch, *Pen-fish*.

The lateral fins are white. There is a bunch near the tail larger than the head of a man. 39 Characters.

Of this species less is known than of the others. In place of the dorsal fin, there is a bunch near the tail which declines posteriorly. It is about a foot high, and a little thicker than the human head. The lateral fins are white, placed near the middle of the body, and are 18 feet long. The blubber of the bunch-whale resembles that of the fin fish. According to Klein, the beard of this species is not held in much estimation, though it is more valued than that of the latter species. It is a native of the seas of New England. 40 Description.

 5. Balæna

Classification, &c.

5. Balæna Gibbosa, the *Scrag-whale.*

French, *La Baleine à six bosses;* German, *Knotenfisch;* Dutch, *Knobbelfisch.*

41 Characters. The horny laminæ of the upper jaw in this species are white; and there are six bunches on the back.

42 Description. In external form this species resembles the common whale. It is nearly of the same colour, and yields an equal quantity of blubber. It seems difficult to reconcile this with the specific name given by Klein, viz. *Balæna macra*, or lean whale. But it has been supposed that this refers to the muscular parts, which are of smaller size.

The dorsal fin is wanting. Its place seems to be supplied by six bunches or knots towards the tail. The laminæ are white, and are found to split with much difficulty.

Like the former, it inhabits the seas of New England.

*** *Species which have a Protuberance in form of a Fin on the Tail, and Folds on the Belly.*

6. Balæna Boops, the *Pike-headed Whale.*

French, *La Jubarte;* Greenland, *Keporkak;* Iceland, *Hrafin, Reydus.*

43 Characters. The lower jaw is a little shorter and narrower than the upper. The protuberance on the back is curved and stretching to the tail.

44 Description. M. O. Fabricius, who was present and assisted at the capture of a whale of this species, has given the following description of it. The body is round and very thick near the lateral fins. It gradually diminishes to the end of the tail, the thickness of which is not greater than what a man can embrace. The head is oblong, inclining, and terminates in a broad obtuse snout. Towards the middle of the head is the protuberance, in the middle of which are the two respiratary orifices, which are so close to each other as to appear to be only one. Before the orifices there are three rows of circular protuberances, of which the use is not known. The lower jaw is shorter and narrower than the upper. The eyes are placed on the sides of the head behind the orifices. The external opening of the organ of hearing forms two holes immediately behind the orbits of the eyes, but are almost imperceptible. The horny laminæ of the upper jaw are black, and scarcely a foot in length. They are disposed in the same manner as in the common whale, but the interstices in the fore part of the jaw are not filled up with small laminæ. The tongue is large, fat, and spongy; its colour resembles that of the liver. It is covered with a loose skin, which stretches towards the gullet, where it forms a kind of operculum or covering.

The lateral fins are large, oval, interiorly entire, rounded, and notched posteriorly, and a little hollowed externally. The tail fin is hollowed or notched in form of a crescent, and terminates in a point. From the lower part of the mouth to the region of the anus, the inferior surface of the body is marked with folds or furrows which unite in pairs, and form angles at the two extremities. The two external furrows are always of the greatest length; and it would appear that the whale has the power of dilating and contracting them at pleasure.

The colour of the upper part of the body is black; the lower part of the mouth and the lateral fins are white; the cavity of the furrows is of a blood red; the interior folds, the belly, and the tail fin, are marked with black and white spots. Under the epidermis is the skin which covers the fat, which in this species is but a thin layer, and consequently yields less oil than the preceding.

When the pike-headed whale takes in food, it opens its capacious mouth, and swallows a great quantity of water along with its prey. It is then that the folds of the skin on the belly are observed to dilate considerably; and then too the contrast between the fine red in the cavity of the furrows, the black colour of the laminæ of the jaw, and the bright white on the under part of the mouth, produces a very striking effect.

At every attempt at progressive motion, this species ejects the water by the respiratory orifices, but with less violence than other whales. The moment after, it disappears under the water. And when it plunges and shews the tail fin, it is considered as a sign that it is going to descend to a great depth, and that it will remain a longer time under the surface. When the sea is calm, it is seen asleep on the surface of the water; and the moment it awakes, it performs a number of different motions with inconceivable rapidity. Sometimes it lies on its sides; in an instant it strikes the water with the lateral fins with prodigious force, and then turns on its back. It springs up into the air, and returns to the water in a whirling motion, at a considerable distance from the place from which it arose.

The food of the pike-headed whale consists of a species of *helix*, a small species of salmon which frequents the northern ocean, and the sand-eel. It has only a single young one at a time. The young whale follows its mother till another is brought forth; but this does not happen every year. 45 Food.

The slightest wound is observed to occasion the death of this species of whale; for the wound very soon runs into gangrene. The animal often goes to a great distance from the spot where it received the fatal blow. The surest method seems to be to strike with the spear immediately behind the lateral fins; and if it happen that the intestines are wounded, the whale instantly plunges into the ocean.

This species frequents chiefly the Greenland seas, between the 61st and 65th degree of latitude. In winter it appears only in the open seas, but in summer it approaches the shores, and enters the great bays.

The length varies from 50 to 54 feet. Sibbald has given a description of a young one which was thrown ashore on the coast of Scotland. The following are the dimensions of the principal parts of the body:

	Ft.	In.
From the end of the snout to the extremity of the tail,	46	0
The greatest thickness at the lateral fins,	20	0
The greatest thickness at the dorsal fin,	12	0
Greatest breadth of the lower jaw,	4	6
Length of the opening of the mouth,	10	0

Breadth

Cl fica- ti &c.

	Ft.	In.
Breadth of the mouth,	4	0
Length of the tongue,	5	0
Breadth of this organ at the root,	3	0
Length of the pectoral fins,	5	0
Breadth of ditto,	1	6
Breadth of the tail fin,	9	6
Length of the penis,	2	0

7. Balæna Musculus, the *Round-lipped Whale*.

French and Greenland, *Rorqual;* Iceland, *Steipe, Reydus.*

5 Ch cters. In this species the lower jaw is longest and broadest. The protuberance on the back is straight, triangular, and stretches to the tail.

7 De ip- tio This species resembles the preceding in the form of the body. In both there is a prodigious enlargement of the side of the head, which gradually diminishes towards the tail. The structure of the lower jaw furnishes the principal characteristic distinction. In the pike-headed whale it is pointed; but in this species it is rounded, which gives the head an obtuse shape. The opening of the mouth is so wide, that it will admit fourteen men standing upright at the same time. The upper jaw is narrower than the lower; it is also more pointed at the extremity, and is received into the lower jaw. The tongue is composed of a soft spongy substance; and is covered with a fine membrane or skin. At the base of the tongue, on each side, there is a fleshy mass of a red colour, which shuts up the entrance of the gullet so closely that only small fish can be admitted. The whole palate is covered with black laminæ, which terminate at their extremity in a silky hair which hangs over the tongue. The laminæ and the hair are of unequal length and breadth. Those which are attached to the anterior part of the jaw are 3 feet long, and 12 inches broad; while those near the entrance to the gullet are scarcely six inches long by one inch broad.

The eyes are placed above the angle of the mouth; they resemble those of the ox. Above the eyes, in the middle of the head, are situated the two respiratory orifices, which are of a pyramidal form.

The pectoral fins are large, a little oval, and tapering; and situated opposite to the angle of the mouth. The dorsal fin is placed directly opposite to the opening of the anus. It tapers a little, and is curved backward. The tail fin is divided into two lobes, which are curved like a scythe, and end in a point.

From the end of the lower jaw to the navel, the under part of the body is covered with rugæ or folds, which are two inches broad, having the cavities by which they are separated of the same breadth. The sides are covered with a layer of fat or blubber, 4 inches thick; and on the head and neck, where the fat is more abundant, it is a foot in thickness. The upper part of the body is black, the belly is white.

3 Fo The herring is the food of this species of whale.

In the month of September 1692, a whale of this species was thrown ashore on the coast of Scotland, as we find it recorded by Sibbald. For twenty years before the fishermen had observed it occasionally in pursuit of the herrings; and they recognised it in consequence of a wound which it had received from a musket. The ball had pierced through the dorsal fin. Classification, &c. The following are the principal dimensions, by the same author.

	Ft.	In.
Whole length of the body, from the snout to the extremity of the tail,	78	0
Circumference of the body at its greatest thickness,	35	0
Length of the lower jaw,	13	2
Length of the tongue,	15	7
Breadth of ditto,	15	0
Length of the pectoral fins,	10	0
Greatest breadth of ditto,	2	6
Length of the dorsal fin,	2	0
Height of ditto,		
Distance between the extremity of the lobes of the tail,	18	6
Length of the penis,	5	0

8. Balæna Rostrata, the *Piked Whale*.

French, *La Baleine à Bec.*

The jaws are long, narrow, and pointed; the lower jaw is longest. The protuberance which is placed on the extremity of the back, is roundish at the apex. 49 Characters.

A side view of this species of whale presents a lengthened oval form, which has the greatest transverse diameter towards the middle of the body. The head constitutes a fourth part of the length of the body, and is of a conical form. The jaws are larger, narrower, and more pointed than in the other species. The upper jaw is the shortest. The eyes are placed little above the angles of the mouth, and the blowholes are on the top of the head. The laminæ of the upper jaw, according to Fabricius, are white and very short. 50 Description.

The lateral fins occupy the middle of the height of the sides; they are broad, nearly oval, and rounded. The dorsal fin is opposite to the anus. It is rounded at the top, inclining towards the tail. The tail fin is divided into two lobes, which form by their junction a crescent, the horns of which are directed behind.

The under part of the body, from the point of the lower jaw to the middle of the trunk, is covered with rugæ or folds in parallel rows, which stretch on both sides to the insertion of the pectoral fins. The back is black; but this gradually diminishes towards the belly, which is pure white, varied with a mixture of reddish shades.

This species of whale swims with extraordinary velocity. The fat or blubber is very compact, and yields but a small quantity of oil. The fishermen are therefore not very eager in the pursuit of it. But as the inhabitants of Greenland consider the flesh very delicate food, they are often employed in taking this whale. They never approach so near as to strike it with the harpoon; but discharge arrows from a distance, the wounds of which almost always prove mortal.

The food of this whale is the same as of some of the other species; chiefly, the small species of salmon of the northern seas, and the other small fish, which it pursues with such avidity, that they are often seen leaping from the sea to avoid the pursuit. This is the smallest species of whale. 51 Food.

It

Classification, &c.

52 Where found.

It is found most frequently in the Greenland seas; and often also in the European. One which was taken on the Dogger bank, measured 17 feet in length. It had lost the dorsal fin, and by some other accident the jaws were so swelled, that the head formed a mass specifically lighter than water, and therefore did not sink in that element.

Class II. MONODON.

Genus 1st, Monodon, *Unicorn-fish*, or *Sea-Unicorn*.

53 Generic characters.

The body is naked, oval, oblong, round and spotted. The head is small, and not easily distinguished from the rest of the body. There is only one respiratory orifice, which is placed on the top of the head, and shut up by a covering cut in form of a comb. The opening of the mouth is small. There are no teeth in the mouth; but from the upper jaw there proceeds, inclining sometimes to the right side, and sometimes to the left, one long tooth which is twisted in a spiral form. There are rarely two; but when that is the case, they are nearly of the same length; and there is only one species which has the teeth curved at the extremity. The eyes and ears are very small. The penis of the male is enclosed in a kind of sheath; and the female has two mammæ on the belly, between which are the organs of generation.

There are three or four fleshy fins; two pectoral fins; one at the extremity of the tail; and that of the back is often replaced by a projection which runs its whole length.

Species.

Plate CXL. fig. 2.

I. Monodon Monoceros, the *Narhwal*, or *Unicorn-Fish.*

French, *Narhwal*, *Licorne de mer;* Norwegian, *Lighual;* Iceland, *Narhwal;* Greenland, *Tauvar.*

54 Characters.

One tooth in shape of a horn, inserted in the upper jaw, and spirally twisted; there are rarely two. There is no tail fin.

55 Description.

The body of the narhwal is oblong and oval; the back broad, convex, and tapering towards the tail; the head is round, small, enlarged at the top, and terminates in an obtuse rounded snout. There are no teeth; but a long twisted tooth, which is attached to the upper jaw. It was long supposed that this bony instrument of defence was the horn of a very rare quadruped, and consequently it was sold at a very high price. Each tooth is from nine to ten feet in length, and possesses some of the properties of ivory. It is however easy to distinguish them. The fibres of the tooth of the unicorn-fish are finer than ivory; it is more compact, heavier, and less apt to become yellow. The narhwal is rarely furnished with more than one tooth, but under the common skin of the head on the other side, the rudiments of another may be observed. There have been, however, different examples of two teeth, and both nearly of the same length. In the year 1604, a female having two teeth was taken, and the bones of the head, with the teeth inserted, were brought to Hamburgh. The two teeth proceeded in a right line from the anterior part of the skull. At the place of insertion they were only two inches asunder, but gradually diverging, they were separated at the extremity 18 inches. The left tooth was 9 inches in circumference, and 7 feet 5 inches long. The right was 7 feet long, and 8 inches in circumference at the base. Both teeth entered 13 inches into the bones of the head, which was 2 feet long, and 18 inches broad.

The opening of the mouth is in general very small; not larger, according to some, than to admit the hand of a man. The tongue is nearly of the same size. The head ends in a rounded snout. The lower lip is thin, and shorter than the upper.

The eyes are placed opposite to the opening of the mouth; and they are surrounded by a kind of eye-lid. On the top of the head there is one respiratory orifice, which may be shut and opened at pleasure by means of a fringed covering.

The pectoral fins are about a foot long, and eight inches broad. The fin of the tail is divided into two obtuse oval lobes. In place of the dorsal fin, there is a ridge or projection about nine inches high, which extends from the breathing hole on the head to the base of the fin, which terminates the trunk of the body, and diminishes gradually in height as it approaches to the tail.

The skin is about one inch in thickness. The colour is of a grayish white, marked with a great number of black spots which seem to penetrate the substance of the skin. The skin of the belly is of a shining white, and soft as velvet to the touch.

The oil which the unicorn-fish yields is in small quantity, but is considered to be of a superior quality to that of the Greenland or common whale. The food of this fish is one of the species of the *Pleuronectes*, and some species of *helix*. 56 Food.

The length of the unicorn-fish is from 20 to 22 feet, the circumference about 12 feet. According to some authors indeed, some fish have been found 60 feet long. It inhabits chiefly the northern seas of Europe and America, about Davis straits, and the coasts of Iceland.

It would be difficult to take this fish singly and in the open sea; for they are excellent swimmers, and move with astonishing velocity by means of the tail fin. But as they live in very cold climates, and cannot remain long under water without respiring, they frequent the bays that are free of ice. In these places they crowd together in such numbers, that they force their teeth into the body of each other; and in this situation they can neither plunge into the deep water, nor avoid the pursuit and blows of the fishermen.

There is no part of this fish which is not applied to some useful purpose by the inhabitants of Greenland. 57 Uses.
They are extremely fond of the flesh, which they eat roasted or dried in the smoke. The intestines also are regarded as a very delicate food. They are also roasted. The fat affords an oil for burning. From the gullet they obtain bags or bladders which they employ in fishing. The tendons are made into excellent thread or small cords. Of the teeth they make several instruments which are used in the chase, or stakes for the construction of their huts.

The kings of Denmark have a most magnificent throne, which is entirely composed of the teeth of the unicorn-fish. It is preserved in the castle of Rosenberg; and it is esteemed of greater value than if it were made of gold. 58 Magnificent throne of the teeth.

It has been affirmed by some naturalists, that there have

Classification, &c.

have been found, individuals of the unicorn fish having protuberances on the back, and that in others the teeth were not spirally twisted, but smooth from the base to the extremity. Should these differences turn out to be uniform and constant, other species beside those already known must be admitted.

2. Monodon Spurius, the *Spurious Narhwal* or *Unicorn-fish.*

French, *L'Anarnak.*

Characters. In this species there are two small curved teeth in the upper jaw, and one fin on the back.

Description. This species, which has been described by Fabricius in his *Fauna Greenlandica*, properly belongs to the genus monodon, at least the characters correspond more nearly to this genus than any other. The body is oblong, rounded, and of a black colour. There are no teeth in the mouth; but to the upper jaw are attached two small teeth which are of a conical form, a little curved at the extremity, and about one inch long. Beside the two pectoral fins, there is a small one on the back.

This species is one of the smallest fishes belonging to this class. It respires like the other cetaceous fishes by a breathing hole on the top of the head.

It rarely happens that the tail fin is seen when it plunges into the water; but when it respires the air, it rises above the surface of the sea as high as the insertion of the pectoral fins.

The flesh and fat are found to have a violently purgative effect. From this property the Greenlanders have given it the name of *Anarnak*, which is adopted by the French naturalists.

It inhabits chiefly the open sea, and very rarely approaches the shores. It is most commonly found in the Greenland seas.

Class III. PHYSETER.

Genus 1st, Physeter, *Spermaceti Whale.*

Generic characters. The body is naked, sometimes oval, and sometimes in the form of a lengthened cone. The head is very thick, anteriorly truncated, and occupying nearly one half or one third of the whole length of the body. There is only one breathing hole, which is placed on the snout. The jaws are unequal. The lower is shorter and narrower, and it is furnished with teeth which are sometimes of a conical form, and sometimes blunt; sometimes straight, but often curved in form of a sickle. In the upper jaw there are corresponding cavities. It is also furnished with teeth, but they are flat, lie horizontally, and are scarcely visible.

The eyes are small, and are situated near the insertion of the pectoral fins. The external opening of the organ of hearing is very small, and not easily detected.

The penis, as in the other classes, is included in a sheath. The female has two mammæ situated in the abdomen, and between them are placed the parts of generation, near which is the external opening of the anus.

There are three fleshy fins. Two of these are the pectoral; and the third is at the extremity of the tail. The place of the dorsal fin is occupied by a false fin, and often by a kind of callosity.

Species.

1. Physeter Macrocephalus, *the Large Spermaceti Whale.*

French, *Cachalot;* Germ. *Pottfisch;* Dutch, *Potvisch;* Norweg. *Kaskelot, Potfisk, Trold Hual.* Plate CLX. fig. 3.

62 Characters. There is a spurious fin on the back. The teeth are curved and a little pointed at the extremity.

63 Description. Of all the species belonging to this genus, this, on account of its great bulk, is entitled to the first place. The head, which occupies the third part of the body, is a large mass of a square form angular at the sides, and truncated before. The upper is of much greater length than the lower. It is also broader, its edges forming a very considerable projection, and folded back towards the centre, where there is an oval longitudinal cavity destined to receive the lower jaw. The lower jaw is furnished on each side with a row of strong conical teeth, a little curved towards the mouth, and projecting from the alveolar process about one and a half inch. The two teeth at the anterior extremity of the jaw, and the four which terminate on each side the two rows, are smaller and more pointed. The colour of them externally approaches to that of ivory: but internally they are less hard and compact, and are of an ash colour. It has been supposed that the teeth become longer, thicker, and more curved, in proportion to the age of the animal. The ordinary length is about six inches, and three inches in circumference at the base. The upper jaw is furnished with as many cavities as there are teeth in the lower jaw; but, in the interstices which separate these cavities, there are about 20 small teeth placed horizontally, and raised a little above the flesh. These teeth are sharp on the side opposite to the place of insertion, but present a smooth, plain, and oblique surface, which fills up the interval that separates the cavities. This oblique surface is only visible; the rest of the tooth is covered with flesh. And from not attending to the form and disposition of these teeth, it has been generally said that the spermaceti whale had none in the upper jaw.

The tongue is a mass of flesh of a square form, and of a livid red colour, which fills almost the whole of the bottom of the mouth.

The breathing holes, passing diagonally through the head, unite into one at the superior extremity of the snout, where the opening is about six inches diameter.

The eyes are black, very small when compared to the bulk of the body, and surrounded with a strong short hair, which is not very perceptible. The opening of the ears is not easily detected. It is placed behind the orbit of the eyes, on a cutaneous excrescence between the eyes and the pectoral fins.

The head is separated from the trunk by a transverse groove, which extends to the place of insertion of the pectoral fins. These fins are of an oval form, three or four feet long, and three inches thick.

On the back there is a callosity which extends two-thirds of the whole length. It rises several inches above the surface, and is slightly inclined. Where it terminates behind it is truncated.

The organs of generation resemble those of quadrupeds. The penis of the male is enclosed in a sheath. On

Classification, &c.

On each side of the same organs in the female are placed the mammæ, which are four or five inches long.

The tail, which is small for the size of the fish, terminates in a fin, which is divided into two lobes, hollowed out in form of a sickle.

The back is black, or of a slate blue, spotted with white. The belly is also white. The fat or blubber, which lies immediately under the skin, is about five or six inches thick on the back, and rather less on the belly. The flesh is of a pale red, like that of pork. The head, though very large, is the least fleshy part of the body. But it yields the substance called *spermaceti*, in great abundance. This seems to vary in colour according to the climate in which the whale has lived.

The food of the spermaceti whale is the dog-fish and the lump-fish.

This whale swims with great velocity; and he often appears on the surface of the water. It is at this time that the fishermen take the opportunity of striking him with their spears; and it often happens that the parts of the body which have been wounded become gangrenous, and fall off before the death of the animal.

The flesh, the skin, the fat, and the intestines, are applied to the same purposes as those of the unicorn-fish. The tongue, roasted, is reckoned excellent food; and of the different bones of the body beside the teeth, instruments for the chase are made.

This whale inhabits chiefly the Greenland seas and Davis straits; but occasionally is found on the European shores to the southward. In the year 1784, in the month of March, 31 of these fishes came on shore on the western coast of Audierne in Lower Brittany in France. The following are the dimensions of one of these taken at the time.

	Ft.	In.

2. Physeter Catodon, *the small Spermaceti Whale.*

French *Le Petit Cachalot;* Norwegian, *Swine-Hual;* Greenland, *Kegutilik.*

64 Characters. In this species, there is a rough spurious fin on the back. The teeth are curved and blunt.

65 Description. Without attending to the form and disposition of the teeth in the cetaceous fishes, the characteristic marks are often ambiguous. All naturalists agree that the characters taken from the teeth are the most certain, because they are most constant and uniform in structure and appearance, and less subject to those variations which age and climate seem to produce. This species is, in this manner, easily distinguished from the others. The head is of a round form; the opening of the mouth is of a moderate size; the lower jaw is longer, but not so broad as the upper. It is furnished with a row of teeth on each side; and these correspond to the cavities in the upper jaw, which receive them. There is a peculiar structure of the teeth in this species. That part of the tooth which rises above the gum has a greater thickness than where it is inserted into the jaw; and besides, each tooth is flat at the top, and marked with concentric lines. The longest teeth are two inches in length, and about an inch in circumference at the greatest thickness.

Sibbald has mistaken the breathing holes for nostrils; and this seems to have arisen from the position of the breathing holes near the snout of the fish.

This species is chiefly an inhabitant of the northern seas.

Towards the end of the 17th century, 102 of this species came on shore at Cairston in the Orkney islands. The longest was 24 feet.

3. Physeter Trumpo, the *Spermaceti Whale.*

French, *Le Cachalot de la Nouvelle Angleterre; Le Trumpo.*

This species is distinguished by a bunch on the back, and having the head straight and pointed. 66 Charact.

The head of this species is of an immense size. It divides the body nearly into two equal parts. The upper jaw is much longer and thicker than the lower, which is furnished with 18 teeth, straight and pointed, about three inches distant from each other; and when the mouth is shut, they are received into cavities of the upper jaw. 67 Description.

The eyes are small. The breathing hole is at least a foot in diameter, and it is placed at the superior extremity of the snout.

The thickest part of the body is near the insertion of the pectoral fins. These are very small, and that of the tail is divided into two lobes. In place of the dorsal fin, there is a bunch on the back which is more than a foot thick. It is placed nearly opposite to the parts of generation.

The skin is of a grayish colour, and very soft to the touch. The length of this whale varies from 48 to 60 feet.

It is chiefly an inhabitant of the seas which wash the shores of New England.

An individual of this species landed in the year 1741, near Bayonne in France. It yielded ten tons of spermaceti, which was reckoned of a superior quality to that of the large spermaceti whale. In the stomach of the same whale was found a round mass of seven pounds weight, which was taken for ambergrease.

The substance called *spermaceti* is lodged in particular cells in the head near the seat of the brain. It is extracted by making a hole in the skull. 68 Spermaceti.

It has been observed by some naturalists that this whale is more agile and more dangerous than any other of the species. When it is wounded, it is said that it throws itself on its back, and defends itself with its mouth.

Mr Pennant has described this under the name of the *blunt-headed whale* (Physeter Microps, Lin.). But if we attend to the form of the body, the structure of the

Classification, &c. the head, the number and structure of the teeth, it seems to constitute a distinct species.

4. Physeter Cylindricus, the *Round Spermaceti Whale.*

69 Characters. There is a bunch on the back; the teeth are curved and pointed at the top; the breathing hole is in the middle of the snout.

70 Description. The form and relative situation of the trunk and head, the position of the breathing-hole, the relative length of the jaws, the number and structure of the teeth, and especially the size of the dorsal fin, present differences which sufficiently distinguish this from the following species. The body is cylindrical, from the extremity of the snout to a line drawn perpendicular to the place where the penis is inserted, and from thence to the tail fin it gradually diminishes. The head is at least the third of the whole length of the body. The profile of the head presents a kind of parallelogram. The jaws are nearly of equal length. On each side of the lower jaw there is a row of 25 curved, sharp-pointed teeth. The breathing-hole is placed at the superior extremity of the snout. The dorsal fin is replaced by a bunch, 18 inches high, and four and a half inches long at the base. The tail fin is divided into two lobes, forming a kind of crescent.

One of this species is described by Anderson, which was 48 feet long, 12 of perpendicular height, and 36 in circumference, at its greatest thickness.

5. Physeter Microps, the *Black-headed Spermaceti Whale* or *Cachalot.*

French, *Cachalot Microps, Cachalot à dents en Faucille;* Norwegian, *Staur-Hyming;* Greenland, *Tisagusik.*

71 Characters. In this species there is a long straight fin on the back. The teeth are curved, the point is at first directed to the mouth, and then turns outwards.

72 Description. The descriptions of naturalists who have treated of this species of whale are greatly confused; and this probably arises from not having attended sufficiently to the form of the teeth. According to Fabricius, there are only 22 teeth in the lower jaw, 11 on each side. All these teeth are curved, having the concave side towards the mouth, and are sunk in the jaw-bone, two-thirds of their whole length. The external part of the teeth is white as ivory, of a conical form; and the point which is sharp inclines a little outwardly. That part of the tooth which is sunk in the jaw is compressed on two sides, and furrowed on that side next to the gullet. The Greenlanders say that this whale has teeth in the upper jaw: but this is not clearly ascertained. Perhaps they are only flatted teeth, similar to what we have described in the great spermaceti whale. Classification, &c. Each tooth extends to a finger length, and is about one and a half inch broad. The longest occupy the middle part of the jaw. The smaller are at the extremities. The snout ends in a blunt surface; and, according to most naturalists, the upper jaw is the longest.

The pectoral fins are about four feet long. What occupies the place of a fin on the back is of considerable height, and has been by some naturalists compared to a long needle.

This whale is the declared enemy of some of the other whales, as the pike-headed whale and the porpoise, which it pursues as its prey. In Greenland the flesh of this whale is greatly esteemed, even more than that of any of the other species. It is rarely taken with the harpoon.

It inhabits chiefly the northern ocean.

6. Physeter Mular.

French, *La Cachalot Mular.*

This species is distinguished by a very elevated fin on the middle of the back. The teeth are slightly curved and obtuse. 73 Characters.

This species resembles the former in the general structure of the body. It differs in the form of the teeth, which are less curved, and are obtuse. The longest, which are eight inches in length, and nine inches in circumference, occupy the front of the jaw. The others are only six inches long. Sometimes the teeth are found to be hollow, and sometimes they are solid. Is this owing to the difference of age in the individuals in which it has been observed? Beside the pectoral fins, that which is placed on the back is very remarkable on account of its length. Sibbald compares it to the mizzen mast of a vessel. 74 Description.

According to Anderson, this species is farther distinguished by having three bunches or protuberances towards the extremity of the back: the first is 18 inches high; the second, six inches; and the last only three inches. The same historian has observed, that he was informed by the captain of a ship, that he saw on the coast of Greenland a great number of this species of whale, at the head of which was one of 100 feet long, which seemed to be the leader; and which, at the appearance of the ship, gave such a terrible shout, spouting water at the same time, as to shake the vessel. At this signal, the whole made a precipitate retreat.

This species is gregarious, and frequents the seas about the North Cape. They are but rarely taken; for they are very wild and difficult to wound. It appears, that the harpoon can only pierce them in one or two places near the pectoral fins.

The fat or blubber is very tendinous, and yields but a small proportion of oil.

Class IV. DELPHINUS.

Genus 1st, Delphinus, the *Dolphin.*

The body is naked, oval, or of an oblong conical shape, of a blue colour, inclining to black. The head is conical, diminishing gradually towards the snout. The 75 Generic characters.

Classification, &c. The breathing hole, which is on the top of the head, is in form of a crescent, the horns of which are directed towards the snout. The jaws are of equal length, sometimes beaked, and sometimes rounded. They are furnished with teeth, which are conical or compressed, pointed or obtuse, and in some species notched.

The eyes are placed near the angles of the mouth. The pupil of the eye is black, and the iris white. The external opening of the ears is situated behind the eyes. The nostrils terminate in the snout.

The penis of the male is included in a sheath; and the mammæ of the female are attached to the belly; and between them are the organs of generation.

There are four fins; two are pectoral; there is one on the back, and one at the extremity of the tail. In one species only the dorsal fin is wanting.

Species.

1. Delphinus Phocæna, the *Porpoise* or *Porpesse*.

French, *Le Marsouin;* Spanish, *Marsopa:* Dutch, *Bruinvisch;* German, *Meerschwein, Braunfisch;* Danes, *Marswin, Tumler;* Norweg. *Nise;* Greenland, *Nisa.*

76 Characters. The form of the body is conical. The dorsal fin is triangular. The snout is pointed. The teeth are enlarged at the summit, rounded and cutting.

77 Description. The body of this fish is round, thick, and diminishes towards the tail. The head resembles an obtuse cone. It is swelled out towards the top above the orbits of the eyes. It then gradually diminishes, and ends in a sharp snout.

The eyes are placed opposite to the opening of the mouth; and the pupil of the eye, which is black, is surrounded with a white iris. Behind the eyes there is a small round hole, about one inch in diameter: This is the organ of hearing. The nostrils are placed between the breathing hole and the extremity of the snout. The breathing hole is situated on the top of the head, in a line perpendicular to the interval between the eyes and the angles of the mouth.

The pectoral fins are attached to the edges of the lower surface of the body. The dorsal fin is triangular, and is situated very nearly on the middle of the trunk. Directly under the dorsal fin on the belly are the parts of generation. The anus is situated at an equal distance between the parts of generation and the tail fin.

The length of the porpoise is from four feet to six and eight. This fish is an excellent swimmer. When it rises to the surface to respire, the back only appears; the head and tail are kept under water. But when it is dead, it becomes straight.

78 Food. It feeds on small fishes, and pursues them with inconceivable rapidity.

79 Manners. The porpoise is generally gregarious; this is particularly the case in the time of copulation in the month of August. It is not unusual to see at that time 15 males in pursuit of one female; and so eager are they in the chase, that they are often thrown ashore. The female goes with young 10 months, and brings forth one at a time. At birth the young one is of considerable size, and it constantly follows the mother till it is weaned. When a pregnant female is killed, it has been observed that the tail of the fœtus is seen thrust through the navel of the mother. This is supposed to be occasioned by the spasmodic contraction, produced by the efforts of the mother in the struggles of death. Classification, &c.

The flesh of the porpoise has a disagreeable oily taste. It is however used as food by the inhabitants of Lapland and of Greenland. In Greenland they suffer it to undergo some degree of putrefaction to make it tender, and then they prepare it by roasting or boiling. They use the skin, the fat, and the entrails for this purpose. The Dutch and the Danes take the porpoise only for the extraction of the oil. 80 Uses.

The porpoise inhabits those places which are sheltered by rocks and bays, and is oftener seen in summer than in winter.

2. Delphinus Delphis, the *Dolphin*, or *Bottle-nosed Whale.*

French, *Dauphin;* German, *Meerschwein, Tummler;* Dutch, *Dolphin Taymelaar;* Norwegian, *Springer;* Iceland, *Leipter.*

The body is nearly oval. The dorsal fin is curved at the top. The snout is flattened and sharp. The teeth are cylindrical and pointed. 81 Characters.

The greatest thickness of the dolphin is at the insertion of the pectoral fins; from which the body gradually diminishes towards the head and tail, and thus has the oval form. The head enlarges at the top like that of the porpoise; but, in the dolphin, it diminishes in thickness, and ends in a flatted beak, like that of a goose. The jaws are of equal length, and furnished on each side with a row of cylindrical teeth, a little pointed at the end, and projecting near one and a half inches above the gum. It would appear that the number of teeth varies according to the age and sex. Klein has reckoned 96 in the upper jaw, and 90 in the under. Mr Pennant, on the contrary, mentions that he saw 19 teeth in the latter, and 21 in the former. Forty-seven teeth have been observed by others in each jaw. 82 Description.

The eyes are placed almost in the same line with the opening of the mouth. The breathing hole is on the top of the head, opposite to the orbit of the eyes. It appears in form of a crescent, the horns of which are directed towards the snout.

The pectoral fins are oval, and inserted at the under part of the breast. The dorsal fin occupies the middle of the body. It is curved backwards at the extremity. The tail fin is divided into two lobes, the one of which folds over the other.

The upper surface of the body is black; the breast is white. From under the eyes on each side passes a white ray, which stretches towards the pectoral fins.

The dolphin is almost always an inhabitant of the open seas, and very rarely approaches the shore. His motions are inconceivably swift; and hence he has been named by the mariners, the *arrow of the sea.*

The length of the dolphin varies from five to nine or ten feet.

The description which has now been given, has little relation to the fanciful accounts which have been detailed of this fish, or to the imaginary representations by the ancient painters and engravers. On the pieces of money which were in circulation in the time of Alexander the Great, and are preserved by Belon, as well as on other medals, the dolphin is represented with 83 Fabulous history.

sifica-, &c. with a very large head, a spacious open mouth, and the tail raised above the head.

No animal has been more celebrated by the ancient poets and historians than the dolphin. From the earliest ages he was considered as consecrated to the gods, and honoured as the benefactor of man. Pliny, Ælian, and other ancient authors, speak highly of his attachment to mankind. The younger Pliny has written a charming story of the loves of a dolphin for Hippus; and Ovid relates, with all the beauties of poetry, the story of the musician Arion, who being pursued by pirates and thrown into the sea, was rescued and saved by this kind animal.

Inde (fide majus) tergo delphina recurvo,
Se memorant onere supposuisse novo.
Ille sedens citharamque tenet, pretiumque vehendi
Cantat, et æquoreas carmine mulcet aquas.
Di pia facta vident. Astris delphina recepit
Jupiter; et stellas jussit habere novem.

OVID. Fasti, lib. ii. 117.

But (past belief) a dolphin's arched back
Preserved Arion from his destined wreck.
Secure he sits, and with harmonious strains
Requites his bearer for his friendly pains.
The gods approve: the dolphin heaven adorns,
And with nine stars a constellation forms.

But after all these fabulous accounts of the dolphin by the ancients, and the presages drawn by the modern sailors from their movements, it does not appear that this species of fish is endowed with more sagacity than any other of the cetaceous fishes, or discovers greater attachment to man. What may have been the foundation of these fables, it is not our present object to inquire. It is true, that the dolphin and others of the cetaceous fishes accompany ships for several days together. But this seems to be in search of food, on account of the offals of animal matters that are thrown overboard.

3. DELPHINUS TURSIO.

Greenland, *Nesarnak;* French, *Le Nesarnak.*

84 Characters. The form of the body is conical. The dorsal fin is curved. The snout is compressed above. The teeth are straight and blunt.

85 Description. The greatest thickness of this species is between the dorsal and pectoral fins. From this to the extremity of the tail the body becomes gradually more slender.

The breathing hole, which is placed above the orbits of the eyes, is about $1\frac{1}{2}$ inch in diameter. The anterior part of the head is inclined and rounded, and terminates in a flat beak. The lower jaw is the longest. Both jaws are furnished with 42 cylindrical teeth, which are disposed in a single row.

The pectoral fins are very low, and are of a falciform shape. The dorsal fin rises like an inclined plane, and is incurvated behind. At the posterior base of the latter fin there arises a projection which stretches to the tail. The tail fin is divided into two lobes in form of a crescent.

The upper part of the body is black; the belly is white.

It has been observed by some naturalists, that when this species rises to the surface to respire, a great part of the body appears above water. It inhabits the open seas, and is consequently taken with difficulty. The flesh, the fat, and the entrails, are eaten in the same way as the porpoise. Classification, &c.

DELPHINUS ORCA, *the Grampus.*

Plate CXL. fig. 4.

French, *Epaulard;* Norwegian, *Spek-Hugger; Hoval-Hund;* Dutch, *Botskop;* Iceland, *Huyding;* Swedes, *L'Opare.*

The body is nearly oval. The dorsal fin is very high. The teeth are conical and slightly curved. 86 Characters.

The profile of the grampus is oval and oblong. The greatest thickness is about the middle of the trunk, from which it gradually diminishes towards both extremities. The snout is short and round. The lower jaw is broader than the upper. Both jaws are furnished with conical teeth, which are unequal and curved at the top, and are from 20 to 30 in number in each jaw. 87 Description.

The eyes are situated in the same line with the opening of the mouth.

But the most distinguishing mark of the grampus is the dorsal fin, which rises from the middle of the back in the form of a cone, and is nearly four feet in height. The pectoral fins are very broad, and nearly oval. The tail fin is divided into two lobes in the form of a crescent. The penis is three feet in length.

The upper part of the body is black; the belly is white. Sometimes white spots are observed on the head and back.

The grampus is the largest fish belonging to the genus. Some have been seen of 25 feet in length by 12 or 13 in circumference. One of 24 feet long was taken in the mouth of the river Thames in the year 1759.

All naturalists agree in describing the grampus as the most cruel and voracious of the family of the dolphin. Its ordinary food is the seal and some species of flat fish. But it is said that it will attack the porpoise, and even the large whale. The latter, so far from defending himself, is struck with terror, utters dreadful shouts, and, to escape from the enemy, quits the open seas, and retires towards the coasts, which is perhaps the reason that the whale is sometimes thrown ashore. The grampus, however, is often the victim of its voracity. It is at this time that the fishermen watch the opportunity of striking him with the harpoon.

When the emperor Claudius was engaged in the construction of the harbour of Ostia, a grampus, attracted by some skins which had been sunk in a shipwreck, came upon the coast. There he remained for several days; and forming a kind of canal to receive his huge body in the sand, was protected from the agitation of the sea. While in pursuit of his prey, one day, he was driven ashore by the violence of the waves. The back appeared above the surface of the sea, and resembled a ship with its bottom upwards. The emperor caused strong nets to be stretched across the mouth of the harbour to prevent the escape of the fish, in case he should again get into the water. He then advanced in person, accompanied with his pretorian bands, and exhibited a very amusing spectacle to the Romans. The soldiers embarked in boats were ordered to attack him with spears and other missile weapons. One of the boats was filled with water, and sunk

Classification, &c. sunk in consequence of the fish spouting with great violence.

a. A variety of the grampus is described by the late Mr John Hunter, in the Philosophical Transactions for 1787. It is distinguished particularly by having a very large belly, which diminishes suddenly towards the region of the anus. The dorsal fin reaches nearer the tail. It has the form of a rectangular triangle, and is longer, but less elevated than the first described. The lower part of the body is not perfectly white, but is marked with brown and black spots.

5. Delphinus Gladiator, the *Sea-Sword.*

88 Characters. The form of the body of this species is conical. The dorsal fin resembles a sabre. The teeth are small and sharp.

89 Description. This species comes very near the grampus in the form of the head; but it is chiefly distinguished by the dorsal fin, which is three or four feet high, and about 18 inches broad at the base. It becomes slender toward the summit, and is incurvated towards the tail. This fin seems to be an offensive instrument; for with it they strike and wound the whale. The length is from 23 to 25 feet.

This species is gregarious. They are found together in small bodies, which attack the whale with great fury, and tear off large masses from his body. When he becomes warm and fatigued, he lolls out his tongue, which is instantly seized by the watchful enemy. They even enter the mouth and tear out the tongue entirely, which seems with them to be a delicate morsel. The delphinus gladiator possesses immense strength. They have been known to seize upon a dead whale that was dragged by a number of boats, and carry it to the bottom.

They are found near Spitzbergen, in Davis straits, and on the coasts of New England, and even so far north as the 79° of latitude. They are very fat, and the oil which they yield is esteemed very good.

6. Delphinus Leucas.

Beluga, Pennant's Quadrup.: *Whittfisch*, Anderson's Iceland.

90 Characters. The form of the body is conical. There is no dorsal fin. The teeth are short and blunt.

91 Description. This species has been arranged by some naturalists among the whales, but having teeth in both jaws makes it properly come under this genus. The body resembles a lengthened cone, having the base at the pectoral fins, and the vertex at the tail. The head is short, and ends in an obtuse snout, on the top of which is a protuberance in which is the blow-hole, which terminates in an oblique direction towards the posterior part of the body. The jaws are nearly equal. The lower jaw is furnished with nine small obtuse teeth on each side, which resemble in structure the grinding teeth of quadrupeds. The teeth in the fore part of the jaw are the smallest. In the upper jaw the number of teeth is the same, but they are more pointed and slightly curved.

The eyes are not larger than those of the hog. The opening of the mouth is small, and the tongue is strongly attached to the lower jaw. Behind the eyes is the external opening of the ear, but it is scarcely visible.

The pectoral fins are broad and of an oval figure. The dorsal fin is wanting, but in its place there is an angular protuberance. The tail fin is divided into two rounded lobes. Classification, &c.

The penis of the male is bony, of a white colour, and inclosed in a sheath. The mammæ of the female are placed on each side of the organs of generation.

The whole body is white, and marked in young fishes with brown and blue spots. The skin is an inch thick, and covers a layer of fat of three inches. It is said that the flesh of this species has a reddish colour like that of pork.

It lives on different fishes, particularly the cod and the soal fish. And as the throat is of small capacity, it is sometimes suffocated in attempting to swallow fish of too large size. The female has one young at a time, which at birth is of a greenish colour, but becomes afterwards bluish, and as it advances in age is white. The females are gregarious, and the young follow at their sides, imitating all their motions. This species is often observed following ships, and exhibiting by a thousand different motions an amusing spectacle.

It quits the open sea during the rigour of winter, and enters the bays that are free from ice. It is seldom an object of trade, on account of the little advantage from the fat. Their arrival, however, is considered by the whale fishers as the fortunate presage of an abundant fishery. The length is from 12 to 18 feet.

7. Delphinus Bidentatus.

The body is conical. The dorsal fin is spear-shaped. The snout is slender and flat. There are two sharp teeth in the lower jaw. 92 Characters.

This species in some of its characters resembles the *delphinus tursio*, but in others is so different that it may properly be regarded as a distinct species. The forehead is convex and rounded. The upper jaw is flat, and ends in a beak like that of a duck; but there are only two sharp teeth at the anterior extremity of the lower jaw. The pectoral fins, which are of an oval form and small for the size of the body, are placed opposite to the angles of the mouth. The place of the dorsal fin corresponds to the origin of the tail, is spear-shaped, pointed, and inclines backward. The tail fin is divided into lobes, forming by their union a crescent. The lower part of the body is of a light brown colour, the upper part is brownish black. This species is supposed to be from 30 to 40 feet long. 93 Description.

8. Delphinus Butskopf, *Bottle-headed* or *Beaked Whale.*

The form of the body is conical. The dorsal fin is incurvated towards the tail. The snout is flat and slender. The upper jaw and the palate are furnished with small teeth. 94 Characters.

The body represents a cone whose summit is towards the tail. The head is of a greater height than breadth. The front, which is full and round, becomes suddenly narrow, and ends in a flat beak rounded at the extremity. The breathing-hole is on the top of the head, opposite to the orbit of the eyes; it forms a crescent whose horns are turned towards the tail. This is the characteristic 95 Description.

sifica-tion, &c. characteristic mark between this and other species of *delphinus*. In place of teeth the surface of the palate and upper jaw are covered with small points, which are unequal and hard. The tongue adheres to the lower jaw, and is notched at the edges. The edge of the upper jaw is also notched.

The eyes are convex as in quadrupeds. They are surrounded with eyelids, and are placed nearly in the middle of the side of the head.

The pectoral fins are attached to the lower part of the breast; they are small in proportion to the size of the fish. The dorsal fin is nearer the tail than the snout: the summit is incurvated backward. The tail-fin is divided into two lobes in form of a sickle.

The whole body excepting the belly is of a leaden colour.

In the *Journal de Physique* for the year 1789, M. Baussard has published an account of two cetaceous fishes which were taken near Honfleur in September of the preceding year. The largest was $23\frac{1}{2}$ feet long, and the smallest $12\frac{1}{2}$. The fishers of Honfleur perceived them at a distance struggling on the strand. When they approached they found the smallest stuck on the sand in shallow water. The mother made many attempts to move her young one into deep water, and not only failed but stuck fast by the head, the heaviest part of the body. The fishermen first took possession of the young one, secured it with ropes; and by their own exertions, aided by a horse and the flowing of the sea, succeeded in bringing it on shore. They then went into the water up to the middle to secure the mother; and having made above 50 wounds with knives on the head and back, and a large wound in the belly, at which the fish seemed to be in great pain, by uttering groans like those of a hog, they were driven off by the violent motion of the tail. A small anchor was then brought, which was introduced into the breathing hole, and a rope was fastened round the tail. The fish finding herself thus entangled, made such violent efforts, that she broke a thick rope, disengaged herself from the anchor, and taking the advantage of the rising tide, escaped and launched into the deep, at the same instant throwing up an immense quantity of water mixed with blood to the height of 12 feet. She was found next day floating on the water quite dead, at the distance of three leagues from Honfleur.

The following are the principal dimensions of the young fish and the mother,

	Young one. Feet	Inches.	*Mother.* Feet.	Inches.

Bonna-terre, Encycloped. Method.

9. Delphinus Feres.

96 Characters. In this species there is one fin on the back. The head is rounded. The teeth are oval and obtuse.

The head is nearly of the same height as the length. It is very thick at the top, and suddenly diminishing towards the anterior part ends in a short round snout. The jaws are equal; they are covered with membranous lips, and furnished internally with a row of teeth; 20 have been reckoned in each jaw. The form of the teeth constitutes the distinctive character of the species. The large and the small teeth are equal in number. The largest are above an inch long by half an inch broad. The small teeth are only five or six lines in length. Classification, &c. 97 Description.

The skeleton of one of this species is preserved in the cabinet of natural history at Frejus in France. The length is 14 feet. The bones of the skull are 1 foot 10 inches long, and 1 foot 5 inches broad.

This species is found in the Mediterranean sea.

Chap. II. *Of the Anatomy and Physiology of Cetaceous Fishes.*

It has fallen to the lot of few anatomists to have an opportunity of examining with accuracy the structure of cetaceous fishes. The same difficulties which have retarded the progress of their natural history, operate perhaps still more powerfully in preventing the acquisition of information with regard to their anatomical structure. They are not inhabitants of those parts of the world where this knowledge is in that improved state to render such investigations successful: and when they are accidentally found on the shores of civilized countries, the anatomist, whose skill and dexterity only could be advantageously employed in the examination, is not always at hand, and they are too large to be transported to the dissecting-room, where the nature and structure of the different parts could be patiently traced and faithfully demonstrated. Several of the species of this tribe of fishes have been dissected by the late Mr John Hunter, the detail of which he has given in a paper on the Structure and Economy of Whales, in the Philosophical Transactions for the year 1787, and to this paper we must acknowledge ourselves indebted for the principal part of the anatomical knowledge which we propose to lay before our readers in the present chapter. 98 Difficulties in acquiring a knowledge of their structure.

We have already mentioned the characters which distinguish the whale tribe from fishes in general. They have indeed nothing peculiar to fish, except that they live in the same element, and have the same powers of progressive motion as those fish, which from their nature must move with great velocity. This seems to be the case with all fish which come to the surface of the water, as the whales must do for the purpose of respiration. It has also been observed that they are more closely allied to quadrupeds than to fish. They have in many respects the peculiar structure and economy of parts which belong to this class of animals. They are furnished with lungs, breathe air, and have warm blood. 99 Distinctive characters. 100 Allied to quadrupeds.

This tribe of animals is peculiarly fitted by their external form for dividing the water in progressive motion, and for moving with considerable velocity. And, on account of the uniformity of the element in which they live, the form of their bodies is more uniform than in animals of the same class that live on land. 101 Fitted for rapid motion.

The

Anatomy and Physiology.

102 Form of the head;

The form of the head is commonly a cone or inclined plane. The spermaceti whale is an exception to this, in which it terminates in a blunt surface. The head is larger in proportion to the body than in quadrupeds, and swells out laterally at the articulation of the lower jaw. This seems to be of advantage to the animal in catching its prey, as there is no motion of the head on the body.

103 of the body.

Behind the pectoral fins, at the insertion of which the circumference is greatest, the body gradually diminishes to the spreading of the tail. The body is flattened laterally; and it would appear that the back is sharper than the belly, which is nearly flat.

104 Power of the tail.

The progressive motion of the animal is performed by the tail, which moves the broad termination or lobes, operating in the same manner as an oar in sculling a boat. And for the purpose of preventing any obstruction in moving through the water, it may be observed that all the external parts of the class mammalia, that live on land, are either entirely wanting, or are concealed under the skin in cetaceous fishes.

Sect. I. *Of the Bones.*

105 The skeleton gives no idea of the general form.

The bones alone, Mr Hunter observes, when properly united into the skeleton, in many animals give the general shape and character. But this is not so decidedly the case in this order of animals. In them the head is immensely large, the neck small, there are few ribs, in many a very short sternum, and no pelvis, with a long spine terminating in a point, so that these bones being merely joined together do not afford any idea of the regular shape of the animal. The different parts of the skeleton are so enclosed, and the projecting spaces between the parts so filled up, that they are altogether concealed, and give to the animal externally an uniform and elegant form.

106 Bones of the head;

The great size of the bones of the head leave but a small cavity for the brain. In the spermaceti whale it is not easy to discover where the cavity of the skull lies. This is also the case with the large whalebone and bottle-nose whale. In the porpoise, the skull constitutes the principal part of the head: for the brain is found to be considerably larger in proportion to the size of the animal. The bones of one genus differ very much from those of another. In the spermaceti and bottle-nose whales, the grampus and the porpoise, the lower jaws, especially at the posterior ends, resemble each other; but in others it is very different. The number of particular bones is also observed to vary very much.

107 of the neck and back;

Vertebræ.—The piked whale has seven vertebræ in the neck, 12 in the back, and 27 to the tail. This makes the whole number 46. In the porpoise the cervical vertebræ are seven in number. There is one common to the neck and back, 14 proper to the back, and 30 to the tail, making in whole 51. The cervical vertebræ of a bottle-nose whale, were the same in number as those of the porpoise. There were 17 in the back and 37 in the tail, which make the whole number 60. Four of the vertebræ of the neck in the porpoise are anchylosed, or have grown together. The atlas in every one of this order of animals that has been examined is the thickest of the vertebræ. It seems to be composed of two. There is no articulation between the first and second vertebræ of the neck to admit of rotatory motion. The vertebræ of the neck are very thin, so that the distance between the head and shoulders is as short as possible.

108 of the breast.

Sternum or *Breastbone.*—This is very flat in the piked whale, and consists of a single very short bone. The breastbone of the porpoise is considerably longer; it is composed of three bones, which are of some length in the small bottle-nose whale. The first rib of the piked whale, and the three first of the porpoise, are articulated to the sternum.

109 Ribs

Ribs.—The small bottle-nose whale, dissected by Mr Hunter, had 18 ribs on each side; and the porpoise had 16. Fifteen ribs have been reckoned in the skeleton of the dolphin. A large whalebone whale had 15 ribs on each side, which were 21 feet long and 18 inches in circumference. The spermaceti whales which were thrown ashore on the coast of Brittany in France, had only 8 ribs on each side. They were 5 feet long and 6 inches in circumference.

110 articulate with two vertebræ.

The ends of the ribs that have two articulations, in the whole of this tribe, Mr Hunter observes, are articulated with the body of the vertebræ above, and with the transverse processes below, by the angles, so that there is one vertebra common to the neck and back. In the large whalebone whale the first rib is bifurcated, and consequently is articulated with two vertebræ.

111 Pectoral fins similar to the extremities of quadrupeds.

Pectoral or *lateral fins.*—These are analogous, and somewhat similar in construction to the anterior extremities of quadrupeds. They are composed of a scapula or shoulder-blade, os humeri, ulna, radius, carpus, and metacarpus, which last may include the fingers, the number of bones being such as may be reckoned fingers, although they are included in one general covering. The number of bones in each is different, the fore-finger has five, the middle and ring-finger has seven, and the little finger has four. These bones are not articulated by capsular ligaments as in quadrupeds, but by intermediate cartilages attached to each bone. These cartilages are nearly equal in length to one-half of the bone. This construction gives firmness and a considerable degree of pliability to the whole.

112 Teeth

Teeth.—Of this tribe of animals some have teeth in both jaws, some have them only in one, while there are others which have none at all. The teeth cannot be divided into classes as in quadrupeds. They are all pointed teeth, and are pretty much similar in form and size. Each tooth is a double cone, one part of which is fastened in the jaw, and the other projects above the gum. In some, indeed, the fang is flattened and thin at the extremity; and in others it is curved.

113 formed differently from quadrupeds.

The formation of the teeth, and their progress afterwards, seems to be different from that of quadrupeds: For they seem to form in the gum, so that they must either extend and sink into the jaw, or the alveoli must rise to enclose them. Mr Hunter thinks this last the most probable, since the depth of the jaw is increased, so that the teeth seem to sink deeper and deeper in it. This mode of formation is observed in jaws that are not fully grown; for, as happens in other animals, the teeth increase in number as the jaw lengthens.

114 Are not shed.

It does not appear that they shed their teeth, or have

Anatomy and Physiology.

have new ones formed similar to the old. This indeed seems scarcely possible from the situation in which they are originally formed.

15 Peculiar substance.

Whalebone.—This is a substance peculiar to the whale. It is of the same nature as horn. It is therefore entirely composed of animal matter, and is extremely elastic. The name of bone is undoubtedly improper, as it has no earthy matter in its composition; but as it has been commonly employed we shall still retain it.

16 Two kinds.

There are two kinds of whalebone. One kind is got from the large whale; the other from a smaller species. It is placed in the inside of the mouth, and is attached to the upper jaw. It consists of thin plates of different sizes in different parts of the mouth. The length and the breadth of the whalebone, although not always, in general correspond pretty nearly; those plates that are longest being also the broadest.

17 Arrangement.

These plates are arranged in several rows on the outer edge of the upper jaw, similar to the teeth in other animals, and stand parallel to each other, one edge being towards the circumference of the mouth, and the other towards the inside. They are placed at unequal distances in different parts of the mouth. In the piked whale, they are only one-fourth of an inch asunder at the greatest distance. In the great whale the distances are greater.

18 Outer row.

The longest plates are in the outer row; and the length is proportioned to the different distances between the different parts of the jaws. Some of them are 14 or 15 feet long, and 12 or 15 inches broad. Towards the anterior and posterior part of the mouth they are very short. They rise for half a foot or more of the same breadth, and afterwards shelve off from the inside till they come nearly to a point at the outer. The exterior of the inner rows are the longest, corresponding to the termination of the declivity of the outer, and become shorter and shorter, till they hardly rise above the gum.

19 Inner row.

The inner rows are closer than the outer, rise almost perpendicularly from the gum, are longitudinally straight, and have less declivity than the other. The plates of the outer row make a serpentine line laterally, and in the piked whale the outer edge is the thickest. Round the line made by their outer edge runs a small white bead, which is formed along with the whalebone, and wears down with it; both edges of the smaller plates are of nearly the same thickness. In all

20 H.

of the plates, the termination is in a kind of hair, as if the plate were divided into innumerable small parts. The exterior plates have the strongest and also longest.

The whole surface of the mouth resembles the skin of an animal covered with strong hair; and under this surface the tongue lies when the mouth is shut. In the piked whale the projecting whalebone remains entirely on the inside of the lower jaw, when the mouth is shut, because the jaws meet everywhere along their surface. Mr Hunter is at a loss to explain how this is effected in large whales, in which the lower jaw is straight, forming a horizontal plane; but the upper jaw being an arch, cannot be hid by the former. He therefore supposes that a broad upper lip reaches to the lower jaw and covers the whole.

The formation of the whalebone is in one respect similar to that of horn, hair, &c. but it has another mode of growth and decay which is peculiar. The plates form upon a thin vascular substance, which does not immediately adhere to the jaw-bone; but which has a more dense vascular substance between. From this substance thin broad processes, corresponding to each plate, are sent out; and on these processes the plate is formed, in the same way as the horn on the bony cone, or the tooth on the pulp. Each plate is necessarily hollow at the growing end, and the first part of the growth takes place on the inside of the hollow. But besides this mode of growth, it receives additional layers on the outside, which are formed on the vascular substance extended along the surface of the jaw. This part also forms upon it a kind of horny substance between each plate, which is very white, rises with the whalebone, and becomes even with the outer edge of the jaw, and the termination of its outer part forms the bead above mentioned. This intermediate substance fills up the space between the plates, as high as the jaw, and is similar to the alveolar processes, keeping them firm in their places.

121 Formation peculiar.

As both the whalebone and the intermediate substance are constantly growing, a determined length must be supposed necessary, so that there must be a regular mode of decay established, which does not depend entirely on chance or accidental circumstances. In its growth there seems to be a formation of three parts; one from the rising cone, which is the centre, a second on the outside, and a third being the intermediate substance. These appear to have three stages of duration; for that which forms on the cone, it is supposed, makes the hair; and that on the outside makes principally the plate of the whalebone; and this, when got a certain length, breaks off, leaving the hair projecting, becoming at the termination very brittle; and the third or intermediate substance, by the time it rises as high as the edge of the skin of the jaw, decays and softens away.

Plate CXLI. Fig. 3, 4, 5.

The use which has been ascribed to the whalebone, is principally for the retention of the food till it is swallowed; for it is supposed that the fish which are taken by the species of whale having this peculiar construction of the mouth, are small when compared with its size.

Sect. II. *Of the Skin and Muscles.*

122 Cuticle.

The cuticle, or scarf skin, in this order of animals, is similar to that on the sole of the foot in the human species. It seems to be composed of a number of layers, which may be separated by slight putrefaction. Mr Hunter suspects that this arises from a succession of cuticles being formed. The fibres of the cuticle appear to have no particular direction. It has no elasticity, but is easily torn asunder. The internal layer is tough and thick, and in the spermaceti whale, the external surface resembles coarse velvet. The cuticles gives the colour to the animal. In parts that are dark, a dirty coloured substance has been washed away in separating the cuticle from the true skin. This seems to be the *rete mucosum.*

123 True skin.

The cutis or true skin in cetaceous fishes is extremely villons in the external surface, corresponding to the rough surface of the cuticle, and forming ridges in some

Anatomy and Physiology.

some parts. The villi, which are soft and pliable, float in water, and are observed to be longer or shorter in proportion to the eyes of the animal. In some they are one-fourth of an inch in length, and in all they are very vascular.

The cutis seems to be the termination of the cellular membrane of the body more closely united, having smaller interstices, and becoming more compact. In fat animals the distinction between skin and cellular membrane is small, the gradation from the one to the other being almost imperceptible; for the cells of both membrane and skin being loaded with fat, the whole seems to be one uniform substance. A loose elastic skin would appear to be improper in this tribe of animals; it is therefore always on the stretch by the adipose membrane being loaded with fat. In some places, indeed, where it seems to be necessary, it possesses considerable elasticity, as at the setting on of the fins, and under the jaw, round the opening of the prepuce, the nipples, &c. to allow free motion of these parts, where it is observed that there is more reticular and less adipose membrane.

In the piked whale there is a very singular instance of an elastic cuticular contraction. The whole skin of the fore part of the neck and breast, and as far down as the middle of the belly, is extremely elastic; but it receives an increased lateral elasticity by being ribbed longitudinally. It is not easy to say why this part which covers the thorax should possess so much elasticity, for this part of the body cannot be increased in size.

124 Muscles.

The fleshy or muscular parts of cetaceous fishes resemble that of most quadrupeds. Perhaps it comes nearer to that of a bull or a horse than to that of any other animal. Some of the fleshy parts are very firm; and about the breast and belly they are mixed with tendons.

125 Tendons

The body and tail of this tribe of animals are composed of a series of bones connected together, and moved as in fish; but the movements are produced by long muscles, with long tendons. This renders the body thicker, and the tail at its stem smaller, than any other swimming animal.

The depressor muscles of the tail, which are similar in situation to the psoæ, make two very large ridges on the lower part of the cavity of the belly, rising much higher than the spine, and the lower part of the aorta passes between them. These two large muscles go to the tail, which may be considered as the two posterior extremities united in one.

The muscles of cetaceous animals lose their fibrous structure a very short time after death, and become as uniform a texture as a mass of clay, and even softer. This change no doubt arises from incipient putrefaction, although no evidence of this process being begun is to be had from any offensive smell. This change is most remarkable in the large muscles, as those of the back and the psoæ muscles.

The Tail.—The construction of the tail affords an instance of a singular piece of mechanism. It is composed of three layers of tendinous fibres, which are covered with the cutis and cuticle. Two of these layers are external: the other is internal. The direction of the fibres of the external layers is the same as in the tail, forming a stratum about one-third of an inch thick; but varying, as the tail is thicker or thinner. The middle layer is composed entirely of tendinous fibres, passing directly across between the two external layers, their length being in proportion to the thickness of the tail. This structure gives amazing strength to this part of the animal. 126 very stro

The substance of the tail is so firm and compact, that the vessels remain in their dilated state, even when they are cut across. This section consists of a large vessel, surrounded by as many small ones as can come in contact with its external surface. The fins are merely covered with a strong condensed adipose membrane.

Sect. III. *Of the Organs of Digestion and Excretion.*

In the whale, the œsophagus begins at the fauces, as in other animals. At the beginning it is circular, but is soon divided into two passages by the epiglottis crossing it. Passing down in the posterior mediastinum, to which it is attached by a broad part of the same membrane, its anterior surface makes the posterior part of a cavity behind the pericardium. Having passed through the diaphragm, it enters the stomach, and is lined with a very thick, white, and soft cuticle, which is continued into the first cavity of the stomach. The inner or true coat of the œsophagus is white, and of considerable density, but it is not muscular; for it is thrown into large longitudinal folds, by the contraction of the muscular fibres. This coat is very glandular; many orifices of glands, especially near the fauces, are visible. The œsophagus is larger than it is in quadrupeds, in proportion to the bulk of the animal, but of less size than it usually is in fish. One in the piked whale that was measured, was three inches and a half wide. 127 Gullet.

The stomach, as in other animals, lies on the left side of the body, and terminates on the pylorus towards the right. The duodenum passes down on the right side, as in the human body, lies on the right kidney, and then passes to the left side, behind the ascending part of the colon and root of the mesentery, comes out on the left side, and getting on the edge of the mesentery, becomes a loose intestine, forming the jejunum. In this course behind the mesentery, it it exposed as in most quadrupeds. The jejunum and ileum pass along the edge of the mesentery downwards, to the lower part of the abdomen. The ileum, near the lower end, makes a turn towards the right side, mounts upwards round the edge of the mesentery, passes a little way on the right, as high as the kidney, and there enters the colon or cæcum. The cæcum, which is about seven inches long, and resembles that of the lion or seal, lies on the lower end of the kidney, considerably higher than in the human body; and this renders the ascending part of the colon short. The colon passes obliquely up the right side, a little towards the middle of the abdomen; and when as high as the stomach, crosses to the left, and acquires a broad mesocolon. It lies here on the left kidney, and in its passage down inclines more and more to the middle line of the body. When it has reached the lower part of the abdomen, it passes behind the uterus, and along the vagina in the female; between the two testicles, and behind the bladder and root of the penis, in the male; bending down, to open on what is called the belly of the animal. In its whole course 128 Stomach and intestines.

course it is gently convoluted. In those which have no cæcum, and, therefore, can hardly be said to have a colon, the intestine, before its termination in the rectum, makes the same kind of sweep round the other intestines, as the colon does where there is a cæcum.

For the size of the animal, the intestines are not large. In those of 18 or 24 feet long, they are not larger than in the horse; the colon is very short, and has little more capacity than the jejunum and ileum. This is a circumstance common to carnivorous animals. In the piked whale, the length from the stomach to the cæcum is $28\frac{1}{2}$ yards, the length of the cæcum seven inches, and of the colon to the anus, two yards and three quarters.

The teeth, in the ruminating tribe of animals, point out the kind of stomach, cæcum, and colon; but in others, as the horse, lion, &c. the appearances of the teeth only indicate the kind of colon and cæcum. In the cetaceous tribe of fishes, whether they have teeth or not, the stomachs vary little, and the circumstance of cæcum seems not to depend on either teeth or stomach.

The stomach, in all the subjects examined by Mr Hunter, consisted of several bags continued from the
129 first on the left, towards the right, where the last terminates in duodenum. The number and size of the stomachs differ considerably. In the porpoise, grampus, and piked whale, there are five; in the bottle-nose whale, seven. The two first stomachs in the porpoise, bottle-nose, and piked whale, are the largest;

Number of stomachs.

130 the others are smaller, but not uniformly so.

First.

The first stomach has very much the shape of an egg with the small end downwards, and is lined with a continuation of the cuticle from the œsophagus. In some,
131 the œsophagus enters the upper end of the stomach; in others, it enters posteriorly and obliquely. The second stomach in the piked whale is very large, and rather longer than the first, is of the shape of the Italic letter *S*, and passes out from the upper end of the first on its right side, by nearly as large a beginning as the body of the bag. In the porpoise, where this second stomach begins, the cuticle of the first ends. The inside of the second stomach has unequal rugæ like an irregular honey-comb. In the piked whale the rugæ are longitudinal, and in many places deep, some of them being united by cross bands: in the porpoise the folds are thick, massy, and indented into each other. This stomach opens into the third by a round contracted orifice.

Second.

132 The third stomach is the smallest, appears only to be a passage between the second and fourth, has no peculiar internal structure, and terminates in as large an open-
133 ing as at its beginning. It is from one to five inches long. The fourth stomach is less than either the first or second. It seems to be flattened between the second and fifth; and in some, as the porpoise, it is long, and passes in a serpentine course like an intestine. The
134 internal surface is regular and villous, and opens on its right side into the fifth. The fifth stomach is round in the piked whale; in the porpoise it is oval: it is small, and terminates in the pylorus without any appearance of a valvular structure. Its coats are thinner than those of the fourth; the internal surface is even, and it is commonly tinged with bile. In some, as the piked whale and the large whalebone whale, there is a cæcum; in others, as the porpoise, grampus, and bottle-nose whale, it is wanting.

Third.

Fourth.

Fifth.

The structure of the inner surface of the intestine is very singular. The inner surface of the duodenum of the piked whale has longitudinal rugæ or valves, at some distance from each other, and receiving lateral folds. The inner coat of the ileum and jejunum appears in irregular folds, which may vary according to the action of the muscular coat of the intestine, yet do not seem to depend entirely on this contraction. In some the whole tract of the intestine is thrown into large cells, which are subdivided into smaller. These cells have the appearance of pouches with the mouths downwards, and act like valves when any thing is attempted to be passed in a contrary direction.

Liver.—In this tribe of animals there is a consider- 135
able degree of uniformity in the liver, which in shape bears a near resemblance to the human liver, but is probably less firm in its texture. The right lobe is the largest and thickest, and there is a large fissure between the two lobes, in which the round ligament passes. Toward the left the liver is much attached to the stomach. The gall-bladder is wanting; but the hepatic duct, which enters the duodenum about seven inches beyond the pylorus, is large.

Resembles the human.

Pancreas.—The pancreas is a long flat body, hav- 136
ing its left end attached to the right side of the first cavity of the stomach. It crosses the spine at the root of the mesentery, joins the hollow curve at the duodenum near to the pylorus, adheres to that intestine, and its duct enters that of the liver near the termination in the gut.

Situation.

Spleen.—The spleen, which is involved in the epi- 137
ploon, is small for the size of the animal. In some of the tribe, as in the porpoise, there are one or two small ones, not larger in size than a nutmeg, and sometimes smaller. They are placed in the epiploon behind the others.

Small.

Kidney.—The kidneys in this whole tribe of ani- 138
mals are conglomerated. They are made up of smaller parts, which are connected only by cellular membrane, blood-vessels, and ducts. The smaller portions are of a conical figure; the apex is placed towards the centre of the kidney, and the base forms the external surface. Each portion is composed of a cortical and tubular substance, the tubular terminating in the apex, which apex makes the mamilla. Each mamilla has an infundibulum, which is long, and at its beginning wide, embracing the base of the mamilla, and becoming smaller. These infundibula at last unite and form the ureter.

Conglomerated.

Ureters and Bladder.—The ureter comes out of the 139
kidney at the lower end, and passes along to the bladder, which it enters very near to the urethra. The bladder, which is of an oblong shape, is small for the size of the animal. In the female the urethra passes along to the external sulcus or vulva, and opens just under the clitoris, as in the human subject. The *capsulæ renales*, when compared to the human, are small for the size of the animal. They are flat and of an oval figure. They are composed of two substances; of an external substance, which has the direction of its fibres towards the centre; and of an internal substance, which is more uniform and has less of the fibrous appearance.

Small.

Anatomy and Physiology.

Sect. IV. *Of the Organs of Circulation and Respiration.*

140 Heart large.

1. Circulation.—The heart and blood-vessels, especially the veins, are probably larger in proportion to their size than in the quadruped. The heart is enclosed in its pericardium, and is attached to the diaphragm as in the human body. It is composed of two auricles and two ventricles, is flatter than in the quadruped, and adapted to the shape of the chest. The auricles have a greater number of fasciculæ, passing more across the cavity from side to side, than in many other animals; and besides have considerable muscularity and elasticity. There is nothing peculiar in the structure of the ventricles of the heart, in their valves, in the arteries, or in their distribution, all which have a similarity to other animals whose parts are nearly similar.

141 Structure not peculiar.

142 Blood in great proportion.

Animals of this tribe have a greater proportion of blood than any other yet known; and some arteries are apparently intended as reservoirs, where a great quantity of blood is required in any part. There is a network of arteries, formed of the intercostal arteries, and running between the pleura, ribs, and their muscles. The spinal marrow is surrounded with a net-work of arteries in the same manner, especially where it passes out from the brain, where a thick substance is formed by their ramifications and convolutions.

In examining particular parts which bear any relation to the size of the animal, if we have been accustomed to see them in the middle-sized animals, we must behold them with astonishment in animals like the whale, which so far exceed the common bulk. The heart and aorta of the spermaceti whale, for instance, appear of immense size, when we make this kind of comparison. The latter measures a foot in diameter; and the former was too large to be contained in a wide tub. Considering the quantity of circulating fluid in so large a vessel, that probably 10 or 15 gallons of blood are thrown out at a single stroke, and the great velocity with which it moves, the mind must be filled with wonder.

143 Circulation astonishing.

144 Veins.

The veins seem to have nothing peculiar in their structure, if we except the veins in the folds on the skin of the breast, as in the piked whale, where, and in similar places, it was necessary to have the elasticity increased.

145 Red globules in great proportion.

The blood of this order of animals is similar to that of quadrupeds. Mr Hunter seems to think that the quantity of red globules is in larger proportion; and he supposes that this increased quantity of red particles may have some effect in aiding to keep up the animal heat; for as they live in a very cold climate, or atmosphere, compared with the heat of their bodies, it is readily carried off, and therefore some help of this kind becomes necessary.

The quantity of blood in this tribe of animals is comparatively greater than in the quadruped, and therefore it is probable that it amounts to more than in any known animal. In them too the red blood is carried to the extreme parts of the body, similar to what happens in the quadruped, but different from fish.

2. Respiration.—Some parts of the organs of respiration in animals that live on land seem to be fitted for a compound action, as for instance the larynx, which is adapted both for respiration, deglutition, and sound; but in the whale tribe it seems to be adapted only for respiration.

146 Varieties.

Larynx.—The larynx varies much in structure and size in the different species. It is composed of the os hyoides, thyroid, cricoid, and two arytenoid cartilages. The os hyoides was larger, while the cartilages were much smaller, in the bottle-nose whale of 24 feet long than in the piked whale of 17 feet. In the bottle-nose the os hyoides is composed of three bones, with two whose ends are attached to it, making five in all. In the porpoise it consists of only one bone slightly bent: it has no attachment to the head, as in many quadrupeds.

The thyroid cartilage, in the piked whale, is broad from side to side, and has two lateral processes which are long, and pass down the outside of the cricoid, near to its lower end, and are joined to it, as in the human subject. The cricoid cartilage is broad and flat, making the posterior and lateral part of the larynx, and is much deeper behind and laterally than before. The two arytenoid cartilages project much, and are united to each other till near their ends; they are articulated on the upper edge of the cricoid, cross the cavity of the larynx obliquely, and make the passage at the upper part a groove between them. In several of the tribe, the epiglottis makes a third part of the passage, and completes the glottis by forming it into a canal. No thyroid gland has been discovered.

147 Not divided into lobes.

Lungs.—The lungs are two oblong bodies, one on each side of the chest, but are not divided into smaller lobes as in the human subject. They are of considerable length, but not so deep as in the quadruped, from the heart being broad and flat, and filling up the chest. They are increased in size by rising higher up in the chest, and passing farther down on the back. The lungs are extremely elastic in their substance, and have the appearance and consistence of the spleen of an ox. The branches of the bronchiæ which ramify into the lungs, have the cartilages rounded, which seems to admit of greater motion between them.

148 Very elastic.

The pulmonary cells are smaller than in the quadruped, and communicate with each other, which those of the quadruped do not; for by blowing into one branch of the trachea, the whole lungs may be filled.

149 Diaphragm.

The diaphragm has not the same attachments as in the quadruped; because the ribs in this tribe do not complete the cavity of the thorax. The diaphragm is therefore unconnected forwards to the abdominal muscles, which are very strong, being a mixture of muscular and tendinous fibres. The chest is longest in the direction of the animal at the back, by the diaphragm passing obliquely backwards, and reaching low on the spine. The parts immediately concerned in respiration are very strong. This is particularly the case with the diaphragm. This seems necessary, as the animal must enlarge the chest in so dense a medium as water, the pressure of which must be greater than the counter-pressure from the air inspired. And for the same reason, expiration must be easily performed, for the pressure of the water and the natural elasticity of the parts are greater than the resistance of the internal air, so that

that it may be produced without any immediate action of muscles. In these animals the diaphragm seems to be the principal agent in inspiration.

Blow-hole, or passage for the air.—In animals breathing air, the nose is the passage for the air, and the seat of the organ of smelling; but in some of the cetaceous

150 strils edy intended for piration. tribe, this sense seems to be wanting; in them, therefore, the nostrils are intended merely for respiration. The membranous portion of the posterior nostrils is one canal; but in the bony part, in most of them, it is divided into two. In those which have it divided, it is in some continued double through the anterior soft parts, and opens by two orifices; but, in others, it unites again in the membranous part, making externally only one orifice, as in the porpoise, grampus, and bottle-nose whale. At its beginning in the fauces, it is a roundish hole, surrounded by a strong sphincter muscle, which grasps the epiglottis: the canal beyond this enlarges, and opens into the two passages in the bones of the head. In the spermaceti whale, in which the canal is single, it is thrown a little to the left side. After these canals emerge from the bones near the external opening, they become irregular, and have sulci passing out laterally, of irregular forms, with corresponding eminences; and the structure of these eminences is muscular and fatty.

CXLI. g. 1, 2. Where there is only one external opening, it is transverse, as in the porpoise, grampus, bottle-nose, and spermaceti whale; but when it is double, it is longitudinal, as in the large whalebone whale, and in the piked whale. These openings form a passage for the air to and from the lungs; for it would be impossible for these animals to breathe through the mouth.

151 ening ll fitted respira- n. In the whale tribe, the situation of the opening on the upper surface of the head is well adapted for the purpose of respiration; for it is the first part that comes to the surface of the water in the natural progressive motion of the animal. The animals of this order do not live in the medium which they breathe. This requires a particular construction of the organs which conduct the air to the lungs, that the water in which they live may not interfere with the air they breathe. The projecting glottis passes into the posterior nostrils, by which means it crosses the fauces, and divides them into two passages.

The beginning of the posterior nostrils, which answers to the *palatum molle* in the quadruped, has a sphincter which grasps the glottis, by which its situation is rendered still more secure, and the passages through the head, across the fauces and along the trachea, are rendered one continued canal. This union of glottis and epiglottis with the posterior nostril making only a kind of joints, admits of motion, and of a dilatation and contraction of the fauces in deglutition, from the epiglottis moving more in or out of the posterior nostril. This tribe of animals having no projecting tongue, and therefore wanting its extensive motion, and the power of sucking things into the mouth, may perhaps require this peculiarity of construction to render the communication between the air and lungs more perfect. But how far this is the case, in the present state of our knowledge of the structure and economy of these respiratory organs, it is not easy to say.

Sect. V. *Of the Brain and Organs of Sense.*

The brain.—In the different genera of the cetaceous tribe of animals, the brain differs much, and also in the proportion it bears to the bulk of the animal. The porpoise has the largest brain, and thus comes nearest to the human subject. The whole brain is compact. The anterior part projects less forward than in the quadruped; the *medulla oblongata* is less prominent, and lies on the hollow made by the lobes of the cerebellum. 152 Not in proportion to the bulk.

The brain is composed of distinctly marked cortical and medullary substances. The medullary substance is very white; the cortical like the tubular substance of the kidney; and these two substances, seem to be in the same proportion as in the human brain. The lateral ventricles are large. They pass close round the ends of the *thalami nervorum opticorum*. The thalami are large: the *corpora striata* small. Most of the other parts have a great resemblance to similar parts in the human brain.

The substance of the brain is more visibly fibrous than in any other animal. The fibres pass from the ventricles as from a center to the circumference, and continue through the cortical substance. The brain of the piked whale weighed four pounds 10 ounces. 153 Substance fibrous.

The spinal marrow in this tribe of animals is proportionally smaller than in the human species. It is largest in the porpoise where the brain is largest, bearing some proportion to the quantity of brain. But this is not always the case; for in the spermaceti whale, where the brain is small, the spinal marrow is proportionally largest. It terminates about the twenty-fifth vertebra, beyond which is the *cauda equina*; the dura mater is no farther continued. The nerves that go off from the spinal marrow in its course are more uniform in size than in the quadruped; the parts being more equal, and no extremities, except the fins, to be supplied. The structure of the spinal marrow is more fibrous than in other animals; when separated longitudinally, it tears with a fibrous appearance, but when separated transversely, it breaks irregularly. 154 Spinal marrow.

The skull is lined with the dura mater, and in some forms the three processes corresponding to the divisions of the brain, as in the human subject; but in others this division is bony. Where the dura mater covers the spinal marrow, it differs from what takes place in other animals, for it encloses the marrow closely, and the nerves immediately passing out through it at the lower part, as they do at the upper, so that the cauda equina as it forms is on the outside of the dura mater.

The nerves going out from the brain are similar to those of the quadruped, excepting in those that want olfactory nerves, as the porpoise. As the organs of sense are variously formed in different animals, fitted for the different modes of impression, in this tribe the construction is varied according to the economy of the animal. The senses of touch and taste seem to be adapted to every mode; but those of smell, sight, and hearing, probably require to be varied or modified according to circumstances; and according to these circumstances the senses are formed. 155 Nerves.

Sense of touch.—The skin in this tribe of animals appears in general to be well calculated for sensation. The 156 Skin the seat of sensation.

The whole surface is covered with villi, which are so many vessels, and it must be supposed also nerves. Whether this structure be only necessary for acute sensation, or whether it be necessary for common sensation, is not known. But it may be observed, that where the sense of touch is required to be acute, the villi are usually thick and long; and this is probably necessary, because in these parts of the body where the sensations of touch are acute, such parts are covered with a thick cuticle. This is remarkably the case in the ends of our fingers and toes, and in the foot of the hoofed animals. Mr Hunter seems to think that the sense of touch possesses greater acuteness in water.

157
Tongue not merely the organ of taste.

Sense of taste.—The tongue in most animals is not only the organ of taste, but is also intended for mechanical purposes. For this latter purpose it is perhaps less so than in any other animal. In some it has more freedom of motion than in others; and the reason of this is probably the difference in the mode of catching the food and of swallowing. In those with teeth it projects most, which seems less necessary in others which merely open the mouth to receive the food along with the water, or swim upon it. In the porpoise and grampus, the tongue is firm in texture; but in the spermaceti whale it resembles a feather bed. It is composed of muscle and fat; and in some is pointed and serrated on the edges.

158
Wanting in some.

Sense of smelling.—In many of this tribe there is no organ of smell at all; and in those which have such an organ, it is not that of a fish, and therefore, like theirs, it is probably not calculated to smell water. It becomes a matter of difficulty to account for the manner in which such animals smell water, and why others have no such organ, which is supposed to be peculiar to the large and small whalebone whales. Mr Hunter is of opinion that the air retained in the nostril out of the current of respiration, which by being impregnated with the odoriferous particles contained in the water during the act of blowing, is applied to the organ of smell. It might be supposed, he observes, that they would smell the air on the surface of the water by every inspiration as animals do on land; but admitting this to be the case, it will not give them the power to smell the odoriferous particles of their prey in the water at any depth; and as their organ is not fitted to be affected by the application of water, and as they cannot suck water into the nostrils without the danger of its passing into the lungs, it cannot be by its application to this organ that they are enabled to smell. Some have the power of throwing the water from the mouth through the nostril, and with such force as to raise it 30 feet high. This no doubt answers some very important purpose, although not very obvious. Mr Hunter, supposing that smelling the external air could be of no use as a sense, thinks that they do not smell in inspiration; for the organ of smell is out of the direct road of the current of air in inspiration, and it is also out of the current of water when they spout; may it not then be supposed, he asks, that this sinus contains air, and as the water passes in the act of throwing it out, that it impregnates this reservoir of air, which immediately affects the sense of smell? This operation is conjectured to be performed in the act of expiration; because then the water is said to be very offensive. Mr Hunter adds, that if this solution be well founded, those only can spout which have the organ of smell. But as some animals of this order are entirely deprived of this organ, and as the organ in those which have it is extremely small, as well as the nerve which receives the impression, it would appear to be less necessary in them than in those which live in air.

159
Similar quadru-peds.

Sense of hearing.—The internal ear in general has nearly the same construction as that of quadrupeds. The bones, the cavities, the cartilages, and the nerves are the same, their disposition and arrangement varying in some of the species; and from this there arises a difference of structure in these organs, and perhaps also a difference in the sensation. According to some anatomists, the semicircular canals are wanting in some of this tribe of animals; while they have been described by others. Some have described the form of the vestibulum as in the spermaceti whale, others have denied its existence altogether. It is perhaps owing to their being less easily detected, that they have been supposed not to exist at all. According to the relations of fishermen, the cetaceous tribe have the sense of hearing as acute as that of quadrupeds.

160
Is small

Sense of seeing.—The organ of light in this tribe seems to have a very close analogy with the same organ in quadrupeds. There is the same relative connection between the choroid coat, the retina, and the crystalline humour. In some circumstances, however, they differ, by which probably the eye in this tribe is better adapted to see in the medium through which the light is to pass. The eye for the size of the animal is small; from which it is conjectured that their power of motion is not great. As no observations have yet been made on the form, size, and density of the different humours of the eye, any thing we could add would be mere conjecture founded on vague analogy.

SECT. VI. *Of the Organs of Generation, &c.*

161
Structure similar to those of ruminating animals.

If the cetaceous tribe of animals come near to fishes in some point of resemblance, they are very different in those of others. This is remarkably the case in the structure of the organs of generation, in which they come nearer in form to those of ruminating animals, than of any other; and this similarity is more striking in the female than in the male; for the situation must vary in the latter on account of external circumstances.

162
Male.

In the male the testicles remain in the situation in which they were formed, as in those quadrupeds in which they never come down into the scrotum. They are situated near the lower part of the abdomen, one on each side, upon the two great depressors of the tail; and at this part they come in contact with the abdominal muscles anteriorly. The vasa deferentia pass directly from the epididymis behind the bladder, or between it and the rectum, into the urethra. The vesiculæ seminales are wanting. The structure of the penis is nearly the same as that of the quadruped. The erectores penis, which have a similar insertion to those of the human subject, as well as the accelcratores, are very strong muscles.

163
Female.

These organs in the female consist of the external opening of the vagina, the two horns of the uterus, Fallopian tubes, fimbriæ, and ovaria. The external opening is a longitudinal slit, whose edges meet in two opposite

Anatomy and Physiology.

opposite points, forming a kind of sulcus. The vagina passes upwards and backwards in a diagonal direction, respecting the cavity of the abdomen, and then divides into the two horns, one on each side of the loins. These afterwards terminate in the Fallopian tubes, to which the ovaria are attached. The inside of the vagina is smooth for about one-half of its length, and then begins to form something similar to valves projecting towards the mouth of the vagina, each like an *os tincæ*. Those are from six to nine in number. These hardly go quite round where they first begin to form, but the last make complete circles; and at this place the vagina becomes smaller, and continues gradually to decrease in width to its termination. From the last projecting part the passage is continued up to the opening of the two horns: and at this place the inner surface forms longitudinal rugæ, which stretch into the horns.

The Fallopian tubes, at their termination in the uterus, are for some inches remarkably small, they then begin to dilate suddenly; and this dilatation increases, till at the mouth they are five or six inches in diameter. Through their whole length they are full of longitudinal rugæ. The ovaria are oblong bodies about five inches in length; one end is attached to the end of the Fallopian tube, and the other to the horn of the uterus. They are irregular in the external surface, and have no capsule but what is formed by the Fallopian tube.

In what position the act of copulation is performed, does not seem to be precisely ascertained. The Greenland fishermen say, that they are then erect in the water, the heads being above the surface, and embracing each other with the fins. M. de St Pierre, during the course of a voyage to the isle of France, asserts, that he saw them several times in this position. Others as confidently affirm, that the female throws herself on her back; but it would appear, that this position must interfere with the act of respiration, which cannot be for any length of time suspended; and, therefore, that it is less probable.

164 Bring forth only once in two years.

It is conjectured, that the female admits the male only once in two years, and that the time of gestation is nine or ten months. It is probable, too, that having only two nipples, they bring forth only a single young one at a time.

165 Mammæ.

The glands for the secretion of milk, or the breasts, are two, one on each side of the middle line of the belly at its lower part. The posterior ends, from which the nipples proceed, are on each side of the opening of the vagina in small furrows. They are flat bodies lying betweent he external layer of fat and the abdominal muscles, and are of considerable length, but only one-fourth of that in breadth. There is a large trunk which runs through the whole length of the gland, and appears to serve the purpose of a reservoir for the milk. Into this trunk the lateral and smaller ducts enter, some with the course of the milk, some in a contrary direction. The trunk terminates in a projection externally, which incloses the nipple.

166 Process of sucking.

It seems difficult at first sight to conceive in what way the process of sucking is performed; so that both the mother and the young one may at the same time respire freely. According to the relations of the Greenland fishermen, the mother throws herself on her side, and the young one then seizes the nipple. In this position, the smallest motion of the body permits the mother or the young one to enjoy the advantage of respiration. The art of sucking must be different from that of land animals, for in them it is performed by drawing the air from the mouth backward into the lungs, which the fluid follows by the pressure of the external air on its surface; but, in the cetaceous tribe, the lungs have no connection with the mouth. The operation of sucking must therefore be performed by the action of the mouth itself, and by its having the power of expansion.

167 Milk rich.

The milk of the whale is supposed to be very rich. In the one which was taken near Berkeley with its young one, the milk was tasted by Mr Jenner and Mr Ludlow. By their account, it had the richness of cows milk to which cream had been added.

The young whale, according to Dudley, continues to suck for a year. They are then called *short-heads* by the fishermen, and are extremely fat, some yielding 50 tons of fat. The mothers, at the same period, are very lean. At the age of two years, they are called *stunts*, because they are supposed to be dull after being weaned. The quantity of fat which they then yield, is from 24 to 28 tons. After this period, they come under the denomination of *skull-fish*, when their age can only be guessed at by the length of hair at the terminations of the whalebone.

168 Affection for its young.

The affection and attachment which the whale discovers for its young, have been much celebrated by naturalists. Perhaps it is magnified by the comparison between the whale and fishes living in the same element, the care of whose offspring is totally disregarded by the parent, and left, which indeed is all that is necessary, to the influence of heat and air to bring forth from the ova or spawn deposited by the mother. This attachment is probably, after all, not more remarkable than in other animals which suckle their young, and bring forth a small number, or only one at a time.

Sect. VII. *Of the Food of the Whale; the Size, Abode, Fat, &c.*

169 Different kinds of fish.

Food.—The food of the whole cetaceous tribe is supposed by naturalists to be fish, each probably having some particular kind. Some hundreds of the beaks of cuttle-fish were found by Mr Hunter, in the stomach of the bottle-nose whale; in the stomach of the piked-whale, bones of different fish, but particularly those of the dog-fish; and, in the grampus, the tail of a porpoise.

Considering the capacity of the œsophagus, we must conclude, that they do not swallow fish so large in proportion to their size as many fish do; for it is observed, that fish often attempt to swallow more at a time than what the stomach will hold; so that part must remain in the œsophagus till the rest is digested.

170 Of the large whale.

The food of the large whalebone whale is supposed to be small fish, sometimes crab-fish and shell-fish. It may appear strange, that so large an animal should be able to find a quantity of food sufficiently great for its subsistence, and to preserve with it such a covering of fat as they are generally found to have. But this wonder ceases, when it is considered that the very food they

Anatomy and Physiology.

they seek after, is found in the greatest abundance in those regions which they usually inhabit. In the economy of the whalebone whale, this substance, from which it derives its name, seems to be of particular use; for as it appears that they live on small fish, which they probably receive into the mouth in great numbers, it was necessary that there should be some contrivance to retain them in the mouth till they are swallowed; and this purpose is fully answered by the whalebone.

171 Northern whale.

The northern whale, or the north-caper, lives on mackerel, herrings, cod fish, and tunny fish. Horrebow mentions, that the Icelanders found in the stomach of an individual of this species, which came on shore in pursuit of its prey, no less than 600 living cod-fish, besides a great number of pilchards, and some aquatic birds. This account is probably exaggerated, at least with regard to the number of fish in the stomach being alive. The other species belonging to this genus usually feed on the herring, the arctic salmon, and the sand-eel.

172 Narhwal.

The narhwal, or unicorn whale, is said to live chiefly on the different species of actinia. It is unprovided with teeth to seize its prey; but, according to some naturalists, it can employ the long tooth which proceeds from the upper jaw to entangle these fishes; and having collected them in this manner to the edge of the lips, it sucks them into the mouth and destroys them, by constantly stretching the tongue along the lips.

173 Spermaceti whale.

The spermaceti whales pursue the seal, the dolphin, and the pike-headed whale. The large spermaceti whale pursues, with great avidity, the shark, which is said to be his ordinary food; and this animal, otherwise so formidable, is seized with such a panic at the sight of this terrible enemy, that he conceals himself in the mud, or under the sand; sometimes seeing himself so assailed on all sides, he darts across the rocks, and strikes them with such force and violence as to occasion his own death. This terror, according to Fabricius, is so strongly impressed, that the shark, which is so greedy of the carcases of the other cetaceous fishes, dares not even approach the dead body of the large spermaceti whale.

174 Blackheaded spermaceti whale.

The physeter microps is said to prey chiefly on the seal. When the seals are in number together, and find themselves attacked by their enemy, they make a precipitate retreat. Some gain the shore; while others climb on a piece of ice; and then, if the whale be alone, he conceals himself under the ice, and waits till the seal return to the water, when he seizes his prey. But if several whales have joined in the pursuit, as frequently happens, it is said they surround the mass of ice, and overturn it in the water.

175 Dolphin.

The dolphin genus feed on cod fish, flat fish, such as the turbot, and many other kinds of fish of moderate size. The grampus is the boldest, the strongest, and the most voracious of any belonging to this tribe of animals. It is agreed by almost all naturalists, that the grampus will even attack the great whale, and put him to flight, which is said to be the reason that they are sometimes thrown ashore on our coasts.

176 Sixty feet.

Size of the whale.—The whale is now rarely seen to exceed 60 feet in length, by 36 feet in circumference. A whale, which landed in the island of Corsica in 1620, was one of the largest which has been known for some centuries. It measured 100 feet in length. But although this be an enormous bulk, it falls far short of the magnitude of the whale, as it has been described by ancient naturalists, existing in their time. But probably these relations will gain little faith, even from the most credulous of the present day, in which Pliny speaks of the whale being 960 feet long; and in another place, the same naturalist says, that Juba writes to C. Cæsar, the son of Augustus, that some whales of 600 feet in length, and 360 in circumference, had entered the rivers of Arabia.

177 Former larger.

But whatever credit is to be given to these stories, there is little doubt that the whales in the northern ocean were formerly of much greater bulk than they now are: and the reason seems to be, that being less disturbed when this fishery was less frequented, they arrived at a greater age, and consequently acquired a greater size.

178 Reason.

179 More frequent in the ocean formerly.

Abode of the whale.—According to the testimony of the ancient naturalists, the whale was more frequently seen in the ocean than at present; for, on account of being disturbed by the numerous fleets traversing the ocean, they have retired to the regions of the north, where they are less exposed to the noise of the mariners, less harassed by the fishermen, and enjoy that tranquillity which is no longer to be found in their former haunts.

180 Chiefly the northern seas.

The large whalebone whale is most frequently found in the Greenland seas, Davis straits, and the coasts of Spitzbergen, Iceland, and Norway; on the coasts of Labrador, in the gulf of St Lawrence, and round Newfoundland. This whale is also found among the Philippine islands, near Socotora, an island on the coast of Arabia Felix, and on the coasts of Ceylon. The whale also frequents the Chinese seas; and, if the reports of voyagers are to be implicitly admitted, is found there of an immense size. The usual retreat of the spermaceti whale is the northern ocean, towards Davis straits, the North Cape, and the coasts of Finmark. Of all the cetaceous fish, this indeed seems to lead the most wandering life. In the year 1787, this whale was discovered in great numbers in an extensive bay in the southern peninsula of Africa, at the distance of 40 leagues from the Cape of Good Hope.

The dolphin family is found in all seas; in the ocean, the Mediterranean, the gulf of Messina, and the Adriatic sea, from whence they go into the lagoons of Venice, and to the coasts of Galicia. On the coasts of Cochin China very considerable fisheries are established, which produce a great quantity of oil.

181 Largest fishes in northern regions.

We may conclude, that, in general, the great whale and the unicorn fish usually frequent the seas towards the poles, between the 68th and 79th degrees of latitude; and that the other families are found diffused more or less in the seas of more temperate regions. It would appear, from this account of the places which are the ordinary haunt of the whale, that the productions of nature are disposed somewhat in a contrary order; since we find all the large terrestrial animals, such as the elephant and rhinoceros, in countries within the torrid zone; while the huge inhabitants of the ocean have fixed their abode in the polar regions.

182 Largest land animals in the torrid zone.

Migration

Anatomy and Physiology.

Causes of.

Migration of the whale.—Although the abode of the whale be generally determined and fixed, yet particular causes force them to leave their usual and natural haunts. The season of their amours, a furious storm, the pursuit of a harassing enemy, the want of food, or excessive cold, often oblige them to migrate. Sometimes they appear solitary, sometimes in considerable numbers, according to the nature of the causes which have disturbed and driven them from their ordinary retreats. According to the information of voyagers who have visited these regions, the great whale every year, in the month of November, leaves Davis straits, enters the river St Lawrence, and there brings forth her young, between Camourasca and Quebec; and from thence, in the month of March following, they regularly return to the polar seas.

It appears, that the whale constantly remains in the northern ocean, and never leaves it but when the female is to bring forth, or when they are driven away by an enemy. In this last case they are most commonly found solitary, at least not more than the male and female, or the mother and the young one.

The spermaceti whales, however, seem frequently to change their habitation, and to roam about in strange seas. This appears from considerable numbers having been thrown ashore or left dry by the retreating tide at different times. In the year 1690, 200 of this species were landed near Cairston in the Orkneys; and, in the year 1784, 31 large spermaceti whales came on shore on the west coast of Audierne in Lower Brittany in France.

Black-headed whale.

Enemies of the whale.—The greatest and most terrible enemy of the small whale is the physeter microps, or black-headed spermaceti whale. As soon as he perceives the pike-headed whale, the porpoise, and some others, he darts upon them, and tears them to pieces with his crooked fangs.

Unicorn-fish.

It is said, that there exists a continual and settled enmity between the unicorn-fish and the great whale; and that they never meet without engaging in combat, in which the whale receives so many severe, and often deadly wounds, as often to occasion its death. When the unicorn-fish strikes its tooth or horn into the side of ships, it is supposed that it is through mistake, taking the vessel for its enemy, the whale.

White bear.

The white bear, so common in Greenland and Spitzbergen, is extremely fond of the flesh of the cetaceous and other fishes. He remains constantly on the watch for his prey, on a mass of ice, or on the sea shore; and as soon as he perceives it, he throws himself into the water, and plunges to attack it. The large and the small whales are equally the objects of his eager pursuit; but he is not successful till after they have lost a great deal of blood from the wounds which he has inflicted, or they have been exhausted with fatigue.

Saw-fish.

Between the saw-fish and the whale there exists a constant warfare. It is related by all the fishermen, that the whale and saw-fish, whenever they meet, join in combat, and that the latter is always the aggressor. Sometimes two or more individuals combine to attack a single whale; and it is inconceivable with what fury they make the attack. The whale, whose only defence is his tail, endeavours to strike his enemy with it; and a single blow would prove mortal. But the saw-fish, with astonishing agility, shuns the dreadful stroke, bounds into the air, and returns upon his huge adversary, plunging the rugged weapon, with which he is furnished, into his back. The whale is still more irritated by this wound, which only becomes fatal when it penetrates the fat. The engagement ceases not but with the death of one of the combatants. Martens relates an account of one of these combats between the Iceland whale (Balæna Glacialis) and the saw-fish. It seemed to be extremely dangerous to approach the field of battle. It was therefore at some distance, that he saw them pursuing and striking each other, dealing such violent blows that the water rose in foam as if agitated by a storm. He was prevented from seeing the issue of the struggle by the weather becoming thick and hazy; but he was informed by the sailors, that such combats were frequent; that they generally kept at a distance till the whale was vanquished; and that the saw-fish, only eating the tongue, relinquished the rest of the body, which they take possession of.

Forskal informs us, that the Arabians believe that some species of the scarus, a fish found in the Red sea, enter the blow-holes of the whale, and destroy it with their sharp spines; and, in confirmation of this fact, it is mentioned, that one of these fishes was found in the blow-hole of a dead whale. 188

Birds.

The whale is even harassed with aquatic birds, which alight in great numbers on its back, in search of the testaceous animals and small insects, which have made it their habitation. And, like most other animals, the whale is tormented with a species of louse, peculiar to itself, which adheres so strongly to the skin, that it may sooner be torn asunder than be made to let go its hold. The fins, the lips, the parts of generation, and other parts of the body, which are most protected from friction, are chiefly infested with this insect. The bite is extremely painful, and they are most troublesome in that season when the whale is in heat. 189

Not so old as formerly.

Age of the whale.—If the time necessary for the growth or increase of the body were in proportion to the period of life, there could be little doubt of the whale being, of all animals known, the most remarkable for longevity. It is well known, that the whales which were taken when this fishery first became an object of trade, that is, between 200 and 300 years ago, were of much greater bulk than they are found to be in the present day. The largest now taken rarely exceed 60 feet long; while, at that time, some reached the astonishing size of 100 in length. The reason of this difference of size seems to be, that, when the fishery first commenced, whales which had probably reached their utmost growth were frequently met with. These, on account of being the largest, were constantly harassed, pursued, and destroyed; so that none which have attained their full growth are now to be found in those seas resorted to by the fishermen. From this circumstance, that no large whales are now to be seen in the places which they commonly frequent, it is concluded, that the period of the life of the whale is very long; and that they cannot arrive at the huge size for which the first whales were so remarkable, since they are not permitted to live undisturbed the requisite length of time to attain that bulk. According to Buffon, a whale may live 1000 years, since a carp has been known to reach the age of 200. But,

Anatomy and Physiology.

But, reasoning from analogy, with regard to the structure and economy of the whale, we have seen in many instances, by no means holds; and it is perhaps equally inapplicable to the growth and age of this order of animals.

190 Oil. *The fat* or *oil of cetaceous fishes.*—The fat of this order of animals is usually called *oil.* It is the most fluid of animal fats, for it does not coagulate in our atmosphere. It is found in considerable quantity, principally on the outside of the muscles, and immediately under the skin; and is rarely to be met with in any of the cavities, or in the interstices of the muscles. This substance is enclosed in a reticular membrane, apparently composed of fibres passing in all directions, which seem to confine its extent, and allow it little or no motion on itself; for the whole, when distended, forms almost a solid body. In some of the animals of this order there is a different distribution of the fat. Under the head or neck of the bottle-nose whale, it is confined in large cells which admit of motion. In some this reticular membrane is very fine, in others it is coarse and strong, and it varies in different parts of the same fish. In the porpoise, spermaceti, and large whalebone whale, it is very fine; in the grampus and small whalebone whale, it is coarse. In all of them it is finest on the body, becoming coarser as it reaches and covers the fins and tail, which latter is composed of fibres without any fat.

The internal fat is the least fluid in this order of animals. It is nearly of the consistence of hogs lard. The external fat is the common train-oil. It is the adipose covering from all of the whale kind, which is brought home in square pieces called *flitches;* and this, which is commonly known under the name of *blubber,*

191 Of two kinds. after being boiled, yields the oil by expression, leaving the cellular membrane. When these flitches or masses of fat become putrid, there issue two kinds of oil. The one is pure; but the other seems to have a considerable mixture of other animal matters, which, from the state of putridity, are readily dissolved in the purer oil, and form a kind of butter. It feels unctuous to the touch, and ropy, coagulates with cold, swims on water, and the pure oil separates and rises to the top. The substance which remains after all the oil is extracted, is almost entirely convertible into glue, and is sold to be applied to the same purposes.

192 In every part of the body. *Spermaceti.*—The substance called *spermaceti* is found in every part of the body, mixed with the common fat of the animal; but to this it bears a small proportion. In the head this substance is also mixed with the common fat; but here the proportions of the two substances are reversed: the spermaceti is by far in greatest quantity. And, from this circumstance of its being found in such abundance, in what, from a slight view, would appear to be the cavity of the skull, it has been by some supposed to be the brain.

193 Most abundant in the head. The two kinds of fat in the head are contained in cells or in cellular membrane, similar to what takes place in other animals; but, besides these, there are larger cells, or ligamentous parts going across, the better to support the vast load of oil of which the bulk of the head is principally composed. There are two places in the head in which this oil lies. These are situated along the upper and lower part of it, and are divided by the nostrils and a great number of tendons which pass from the nose and the different parts of the head. The cells which are of the smallest size, and are the least ligamentous, are observed to contain the purest spermaceti. These cells resemble those which contain the fat in other parts of the body nearest the skin, and they lie above the nostril, along the upper part of the head, immediately under the skin and common cellular membrane. The spermaceti, which lies above the roof of the mouth, or between it and the nostril, is more intermixed with a ligamentous cellular membrane; and it is contained in chambers whose partitions are perpendicular. Near the nose these chambers are smallest; but they become larger towards the back part of the head, and in these last the spermaceti is purest. About the nose Mr Hunter discovered a great number of vessels which had the appearance of a plexus of veins, some of which were as large as a finger. They were loaded with spermaceti and oil, and some of them had corresponding arteries. He thinks it probable that they were lymphatics, and that their contents were absorbed from the cells of the head; for many of these cells or chambers were found empty.

The numerous useful purposes to which the common oil of the whale and the spermaceti are applied, the latter sometimes in medicine, and both in many of the arts and in domestic economy, are to well known to be particularly pointed out.

194 Doubts and opinions of its origin. *Ambergris.*—This substance, the origin of which was long a matter of doubt and uncertainty among naturalists, is now pretty well ascertained to be the production of some of the cetaceous tribe of animals. By some it was supposed to be the excrement of the whale, and by others, that it was the dung of birds. According to some, it is composed of honey and wax, consolidated by the heat of the sun and the action of sea water; while, in the opinion of others, it is a bituminous substance, which flows from the bowels of the earth into the waters of the ocean, where it becomes hard and firm.

195 The production of the spermaceti whale. But, in the opinion of later naturalists, it is a substance which has an origin and formation similar to that of musk, and is a production of the spermaceti whale. This opinion has been rendered more probable by the same substance having been found in some whales of this species, and particularly in one which came on shore on the coast of Bayonne in France, in 1741. In the latter it was found in rounded masses from three to 12 inches in diameter, which weighed from $1\frac{1}{2}$ lb. to 20lb. It was contained in an oval bag from three to four feet long, and from two to three feet broad, which was suspended immediately above the testicles. This bag terminated in two tubes, one of which becoming narrower, reached to the penis; the other proceeded from the kidneys, and terminated in the other extremity. The bag was almost entirely filled with a yellow-coloured fluid, not quite so thick as oil, exhaling a similar but stronger odour than the masses of ambergris which floated in it. Each mass was composed of concentric layers. The number of masses found in one bag never exceeded four. One was found which weighed 20lb.; but there was no other in the same bag. It has been supposed that the ambergris is only found in old whales, and in the males. Some naturalists think that this substance is an oily concretion

tion which exhales the odour of the fluid in which it is formed; and that the bag which contains these fragrant masses is the urinary bladder.

But if this be the usual mode in which ambergris is produced, it appears difficult to account for the large masses which are found floating in the waters of the ocean in different parts of the world, as among the islands in the torrid zone, and in the Indian and African seas.

According to the information collected by Dr Swediaur, and which the reader will find more fully detailed under the word Ambergris, it appears that it is generally considered by the New England fishermen as a production of the spermaceti whale. Sometimes they find it floating in the sea; and when this happens they search for the whale, supposing that it has been voided by this animal. Sometimes they cut it out from a swelling or protuberance on the belly of the dead whale. And from all the information which Dr Swediaur could obtain, he concludes, that ambergris is generated in the bowels of the spermaceti whale (*Physeter Macrocephalus*, Lin.), and that it is there mixed with the beaks of the *sepia octopodia*, which is the principal food of this whale.

96 Supposed to indicate disease.

He therefore considers this substance to be the fæces of the animal preternaturally indurated, mixed with the indigestible relics of the food. See Ambergris.

Later information has verified some part of the doctor's opinion, as well as some of the conjectures of earlier naturalists. Mr Coffin, master of a ship employed in the southern whale fishery, brought home, in the year 1791, 362 ounces of ambergris taken from the body of a female spermaceti whale on the coast of Guinea. Part was found floating in the sea, and part was seen coming from the anus while the people were employed in cutting up the blubber. More was found in the intestines, and the rest in a bag communicating with them. This whale was lean, sickly, and old, and yielded but a small proportion of oil. When the spermaceti whale is struck, she generally voids her excrement; and, if she does not, it is conjectured that she has no ambergris. Mr Coffin supposes, that the production of this substance is either the cause or the effect of some disease, as he thinks it is most likely to be found in sickly fish, as was the case with the fish which

97 Probably a preternatural substance.

yielded him so large a quantity. Perhaps it may be found by future and more accurate investigation to be a natural production of the animal, secreted to answer some important purpose in its economy; and that it is preternaturally increased in quantity, either by the excessive or the diminished action of the vital powers in age or disease, and then it is excreted, or discovered in the body of the fish after death.

98 Used as a perfume.

Ambergris is one of the most fragrant perfumes; and for this purpose, it is chiefly employed in this as well as in most other countries. In Asia, and in some parts of Afica, it is also used in medicine and cookery. It is bought up in considerable quantities by the pilgrims who travel to Mecca, by whom it is supposed to be used in fumigations in religious ceremonies, in the same manner as the burning frankincense or other fragrant perfumes makes part of the religious rites of other countries.

Chap. III. *Of the Whale Fishery.*

199 Power of man in subduing the largest animals.

Nothing, perhaps, displays in a more striking manner the power and dexterity of man than the facility and success with which he conquers and destroys the most enormous and the most formidable of the animated productions of nature. The elephant and the whale, the largest animals known, the one seemingly secure in the midst of the huge icy mountains of the polar regions, and the other roaming at pleasure in the almost inaccessible wilds and deep woods of the torrid zone, yield to his power, or fall beneath his all-subduing arm. The swiftest and the most ferocious, as well as the most sagacious, and the most cunning and artful, escape not the toils and snares which he contrives, or the deadly aim of the instruments of his invention.

Whether man was originally urged by necessity, as is most probable, to attack so huge a monster as the whale, or whether it was indirectly to gratify the artificial demands of luxury that he first attempted and still continues to persevere in an occupation so full of of danger and fatigue, it must be allowed to be one of the boldest and most daring enterprises that can be conceived. And indeed were it not quite familiar to us, we should still behold with dread and astonishment so feeble a creature as man preparing to attack this monster of the deep, whose strength, were it properly directed, no power could resist; nor would our wonder be diminished, when we find that he seldom fails to succeed in the attempt. But knowledge is power; and the triumphs of intellectual power are equally conspicuous, in accommodating the most unwieldy and most unmanageable parts either of the inanimate or animated creation to the supply and gratification of human wants and desires, in guiding through the trackless ocean the ship from which the spear is launched for the destruction of the whale, or in digging from the bowels of the earth the metal with which the compass and the harpoon are constructed.

200 Norwegians first acquainted with this fishery.

So early as the 9th century, in the time of Alfred the Great, it appears that the Norwegians were acquainted with the whale fishing. This prince received an account of the discoveries of a Norwegian about the North Cape, in which he speaks of his having been as far north as the places to which the whale-hunters resort; which is considered as a proof of its antiquity; although it is supposed that it was pursued merely on account of the oil, the use of the whalebone not being then known *.

* *Anderson's Hist. of Comm.* i. 84.

201 Biscayans most expert.

But the people who are recorded in history as having prosecuted this fishery with success, were the Biscayans. The spermaceti whale, as well as the whalebone whale, were at that time frequently seen in these latitudes. The first attempts were made in the bay of Biscay, and in the gulf of Gascony. Ships were fitted out, instruments were constructed, and an establishment was formed for carrying on the fishery. It was observed that the whale only appeared at certain seasons of the year, which led the new fishers to suppose that his residence in other seas was more permanent. And discovering that they retreated towards the polar regions, ships were fitted out and manned

with

Whale Fishery.

with the most experienced seamen, to pursue them northward. At this time the Biscayans carried on this trade, both for the sake of the oil and the whalebone.

202 The English first engage in it.

Towards the end of the 16th century, the English first engaged in the whale fishery. But at this time they were so little acquainted with it, that "the request of an honest merchant, by letter to a friend of his, to be advised and directed in the course of killing the whale," is recorded by the historians of that age. The answer was, that a ship of two hundred tons must be fitted out, and provided with all kinds of proper utensils and instruments. But it appears to have been necessary to send to *Biskaie for men skilful in catching the whale and ordering of the oil, and one cooper skillful to set up the staved cask.*

Hakluyt's Voyage, 414.

In the year 1594, some English ships made a voyage to Cape Breton, at the entrance of the bay of St Lawrence, some for the morse fishing, and others for the whale fishing. This seems to have been among their first attempts in this trade. The fishing proved unsuccessful; but they found in an island 800 whale fins or whalebone, part of the cargo of a Biscayan ship wrecked there three years before, which they put on board and brought home. This was the first time that this substance was imported into England.

203 Whalebone first introduced.

204 Ships fitted out from Hull.

The town of Hull, in 1598, first fitted out ships from England for the Greenland whale fishery, a branch of trade which has since become very considerable, and has frequently received the protection and encouragement of the legislature. A premium of six shillings for each ton of oil, and five shillings for each ton of whalebone, was at first granted by government in 1672. But this encouragement appearing insufficient for the success of the fishery, or the enterprise being considered too great for the stock of individuals, a company was incorporated in 1692, and established by royal authority, with peculiar privileges. Their capital amounted to 40,000l. sterling. The subscriptions in a few years increased to 82,000l. sterling; but in 1701 the company was dissolved, and the trade made free to all adventurers.

205 Premium granted.

206 Company established.

207 English very successful.

The English were now become the most successful adventurers in this fishery. By their skill, their industry, and perseverance, and the aid and encouragement granted by the legislature, they carried on the whale fishery on more advantageous terms than the Biscayans, the first adventurers, whose efforts became less enterprising, as their success was more precarious. In the year 1730, they fitted out for this fishery only 33 ships; about the year 1735, the number was diminished to ten or twelve; and continuing to decrease till the war in 1744, the trade was finally abandoned.

208 New English Company.

The English still persevered in the trade, a new company was establishad, and a fund of 50,000l. sterling was provided, with power to the company to make all necessary and proper regulations. And for the farther encouragement of the fishery, a duty of 17l. or 18l. sterling was imposed on the ton of all oil imported, and a premium or bounty, to the same amount, was paid for every ton of oil exported which was the produce of the national fishery. Other encouragements were also given; rewards were bestowed on the most successful; the sailors employed in the trade were exempted from the impress service; adventurers were indemnified for all losses which they sustained in their first enterprise; and they were granted the privilege of providing, duty free, all those articles which were needed in this fishery, and were the subjects of taxation.

209 Fishery encouraged.

Still farther to encourage and extend the fishery, which now had become an important national concern, parliament granted in 1779 a premium to five ships which should bring home the greatest quantity of oil: for the first greatest quantity, 500l. sterling; for the next, 400l.; and for the third, fourth, and fifth, 300l. 200l. and 100l. sterling.

In North America, while that continent was subject to Britain, the whale fishery was carried on to a very considerable extent. A society was established at New York, and numbers of ships were equipped for this trade in different parts of the colonies, by enterprising adventurers, and it has been long extremely successful and lucrative.

210 Fishery North America.

The advantages derived to the nation from the whale fishery, are no doubt very considerable. Beside being an excellent nursery for hardy seamen, it is the foundation of great commercial concerns, by introducing articles which become the sources of an important trade. In this view it has often been an object of legislative discussion, and has often experienced the liberal encouragement and protection of government. According to a law passed in favour of ships employed in this trade, every British vessel of 200 tons or upwards, bound to the Greenland seas, on the whale fishery, if found to be duly qualified agreeable to the act, obtained a licence from the commissioners of the customs to proceed on such voyage; and on the ship's return, the master and mate declaring on oath that they were on such voyage, that they used all their endeavours to take whales, and that all the whale-fins, blubber, oil, &c. imported in their ship, were taken by their crew in those seas, there was allowed 40s. for every ton according to the admeasurement of the ship.

211 Advantages of the fishery.

212 Regulations.

It was afterwards found, however, that so great a bounty was neither necessary to the success of the trade nor expedient with regard to the public. In 1786, therefore, the acts conferring the said emoluments being upon the point of expiring, the subject was brought under the consideration of parliament; and it was proposed to continue the former measures, but with a reduction of the bounty from 40s. to 30s. In proposing this alteration, it was stated, "that the sums which this country had paid in bounties for the Greenland fishery amounted to 1,265,461l.; that, in the last year, we had paid 94,858l.; and that, from the consequent deduction of the price of the fish, the public at present paid 60 per cent. upon every cargo. In the Greenland fishery there were employed 6000 seamen, and these seamen cost government 13l. 10s. per man per annum, though we were never able to obtain more than 500 of that number to serve on board our ships of war. Besides, the vast encouragement given to the trade had occasioned such a glut in the market, that it was found necessary to export considerable quantities; and thus we paid a large share of the purchase money, for foreign nations, as well as for our own people, besides supplying them with the materials of several important manufactures." This proposition was opposed by several members, but was finally carried; and the propriety of the measure became very soon

213 State of the trade in England.

Whale fishery.

soon apparent. At that time (1786) the number of ships employed from England in the whale fishery to Davis straits and the Greenland seas amounted to 139; besides 15 from Scotland. The proposed alteration took place the following year (1787); and notwithstanding the diminution of the bounty, the trade increased; the number of ships employed the same year from England amounting to 217, and the next year (1788) to 222. Their cargoes consisted of 5989 tons of clean oil; 7654 tons of whalebone, beside 13,386 seal skins.

214 Southern whale fishery,

For some years British capital has been employed in a southern whale fishery; and this has also been a very lucrative branch of trade. This fishery was first prosecuted with vigour about the commencement of the American war. In the year 1785, 18 ships which produced 29,000l. sterling were employed in it. Two years afterwards the number of ships was doubled, and the returns increased in a much greater proportion, which is a proof of the flourishing state of the trade. The number of ships in 1787 was 38, and the produce amounted to 107,000l. sterling.

215 ...ied on Ameri- settled Milford Haven.

Some American families, when the war broke out in that country, emigrated to Nova Scotia, where they proposed to carry on the whale fishery; but being discouraged from particular circumstances, on the invitation of the honourable Mr Greville, they settled at Milford in Milford Haven, and fitted out a ship, which had a very successful voyage. The number of ships soon increased to four, and at present (1803), that number is doubled, so that 8 ships are now employed in the southern whale fishery from this port, with a capital afloat of no less than 80,000l. sterling. This fact is stated by Mr Barrow in his Travels in Southern Africa; and "I mention it (says he), as a striking instance to show the importance of the South sea fishery, and as a proof that, contrary to the generally received opinion, it may be carried on with skill and management, and without the adventitious aid of trading, so as fully to answer the purpose of those who are properly qualified to embark in the undertaking. For where men, by industry in their profession, rise from small beginnings into affluence, such profession may be followed with a greater certainty of success than many others which appear to hold out more seducing prospects. The American fishermen never set out with a capital, but invariably work themselves into one; and the South sea fishery from England may succeed on the same principle, as the above example clearly shews, under every disadvantage, when properly conducted.

216 ...tially ...ourag-

"It is difficult to point out the grounds of justice or policy in giving tonnage bounties to the Greenland fishery, and only premiums to successful adventurers in the southern fishery. A voyage to Greenland is four months, the outfit of which is covered by the tonnage bounty, and if wholly unsuccessful, the same ship can make a second voyage the same year to some of the ports of the Baltic. A voyage to the South sea is from 12 to 18 months, and must depend solely on the success in fishing. A Greenland ship sets out on a small capital, and builds on a quick return; but a South sea whaler must expend a very considerable capital in making an outfit, for which he can reckon on no returns for at least 18 months. Hence the usual practice of sending them out in the double capacity of fishers and contraband traders, in order that the loses they may sustain by ill success in fishing may be made good by smuggling.

Whale Fishery.

"If by extending the fishery we should be enabled to supply the continent of Europe, two objects should never be out of the view of the legislature—the exemption from duty of all the produce of the fisheries, and particularly spermaceti, which, if manufactured into candles, and subject only to the same duty as tallow candles, would produce much more to the revenue than when taxed as it now is, as wax. I have heard it asserted that the extension of the premium system, by doubling its present amount, which never could exceed 30,000l. a-year, would be adequate encouragement to supply the home-market with spermaceti and black whale oil, and that the bonding of foreign oil in Great Britain would throw the whole agency of American fishery on England with greater advantage to both countries than by any other system. 217

Cape of Good Hope a convenient station

"But when we consider that the home market is necessarily secured to British subjects by high duties on foreign oil, we should also consider that every means to lessen the charges of outfit should strengthen our adventure in this lucrative branch of trade. Among others that would seem to have this tendency, are the facilities that might be afforded by the happy position of the Cape of Good Hope. If at this station was established a kind of central depot for the southern whale-fishery, it might, in time, be the means of throwing into our hands exclusively the supply of Europe with spermaceti oil. To the protection of the fisheries on the east and west coasts of southern Africa, the Cape is fully competent, and the fisheries on these coasts would be equally undisturbed in war as in peace. From hence they would, at all times, have an opportunity of acquiring a supply of refreshments for their crews, and of laying in a stock of salt provisions at one-fourth part of the expence of carrying them out from England." 218

Dutch early engaged in the fishery.

The Dutch were very early engaged in the Greenland whale-fishery, which soon became one of the most important objects of their trade. In 1611 a company was established at Amsterdam for carrying on the whale-fishery on the coasts of Spitzbergen and Nova Zembla. This branch of trade has in general succeeded better with the Dutch than with any other nation. The principal reason which has been assigned for this success is the greater economy and frugality of this people, in this as in all their concerns, by which they are able to undersell others in oil and whalebone. The mode of fitting out all their ships is also mentioued as a cause of their prosperity in this fishery. The ship-builder, the rope-maker, the baker, the brewer, and other tradesmen, employed in fitting out these ships, commonly take a share in the voyage. When it proves fortunate, they are double gainers; but when it is unsuccessful, the loss which they sustain is probably not greater than if they had merely furnished the articles without having a chance of the profit; and in this respect have the advantage of mere merchants. It is observed by De Witt that this fishery, since it fell into the hands of individuals, has seldom failed to be profitable; but while it was monopolized by the Dutch Greenland company, the profit was inconsiderable. Some idea may be formed of the extent to which the Dutch have carried this trade, by stating that 219

Extent of their fishery.

Whale Fishery.

that for a period of 46 years preceding the year 1722, 5886 ships were employed in it, and in this period they took 32,907 whales. Each whale, at an average, valued at 500l. makes the total amount above 16 millions sterling.

The following table affords at one view a brief record of the Dutch whale fishery from 1661 to 1788. The number of ships employed for each year, and the number of whales taken, are stated in separate columns.

221

This table is interesting, as it shews us the precarious nature of this fishery. But it would have been still more valuable, if some other circumstances had been stated, such as the nature of the seasons when the fishery was less successful; whether the preceding winter was unusually long or severe; whether the short summer of these regions was not remarkable for extremes or sudden changes of heat and cold, sudden changes and variations of the wind, the prevalence of particular winds; or other facts which might enable us to trace the causes of the extraordinary failure and success of the fishery.

222 Attemp[t of] the Fre[nch] to reviv[e it.]

The French made an attempt to revive this branch of trade in 1784. Six ships fitted out at Dunkirk at the expence of the late king, made some successful voyages both in the northern and southern whale fishery. The advantages of the trade were obvious, and the French government was eager to improve them. In the year 1786, some of the inhabitants of the island of Nantucket, near Halifax in North America, were invited to settle at Dunkirk to carry on the fishery. Several families accepted the invitation, and to encourage them to prosecute the trade, they were permitted to enjoy peculiar privileges and immunities. Ships were sent out to different seas, and had prosperous voyages. But this trade, as well as every other branch of French commerce, has probably been completely interrupted by the late revolution, and the particular circumstances in which that nation has been with regard to foreign powers.

223 Other n[a]tions en[]gage in [it.]

Besides the nations which we have mentioned, who have been most deeply concerned in this fishery, the inhabitants of other countries have also embarked in it. Some ships were equipped at Embden in 1768 by order of the king of Prussia; the Swedish government in 1774 granted to a company established at Gottenburgh the exclusive privilege of the Davis straits and Greenland fishery for 20 years; and Denmark in 1775 attempted to take a share in the benefits of that fishery, which many of the nations of Europe, more enterprising or more industrious, had long successfully enjoyed on the shores of the Danish dominions.

224 Time of [the] fishery.

The whale fishery commences in May. It is about this time that the whales are seen in great numbers between

Whale Fishery.

between the 76th and 79th degrees of north latitude; and at a distance they exhibit the appearance of the smoke rising from the chimneys of a great town by the water which is thrown into the air by their spouting or blowing. The fishery continues for the months of June and July, when it must be abandoned whether it has been successful or unprosperous; because it is necessary to be clear of the ice by the end of August. The ships return home at farthest in the month of September. But if the fishery happen to begin early in May, and prove abundant, they sometimes return in June or July.

225 Mode of taking the whale by Europeans.

We shall now conclude this article with a short account of the different modes that are practised in taking the whale. The following is employed in the Greenland fishery by Europeans. Every ship is provided with six boats, to each of which belong six men for rowing the boat, and a harpooner, whose business it is to strike the whale with his harpoon. Two of these boats are kept constantly on the watch at some distance from the ship, fastened to pieces of ice, and are relieved by others every four hours. As soon as a whale is perceived, both the boats set out in pursuit of it, and if either of them can come up before the whale finally descends, which is known by his throwing up his tail, the harpooner discharges his harpoon at him. There is no difficulty in choosing the place where the whale is to be struck, as some have asserted: for these animals only come up to the surface in order to breathe, or *blow*, as the fishermen term it, and therefore always keep the soft and vulnerable part of their bodies above water. A late improvement was made in the method of discharging the harpoon; namely, by shooting it out of a kind of swivel or musquetoon: but it does not appear, that since this improvement was made the whale fishing ships have had better success than before. As soon as the whale is struck, the men set up one of their oars in the middle of the boat as a signal to those in the ship. On perceiving this, the watchman alarms all the rest with the cry of *fall! fall!* upon which all the other boats are immediately sent out to the assistance of the first.

The whale finding himself wounded, swims off with prodigious velocity. Sometimes he descends perpendicularly, and sometimes goes off horizontally at a small depth below the surface. The rope which is fastened to the harpoon is about 200 fathoms long, and properly coiled up, that it may freely be given out as there is a demand for it. At first the velocity with which this line runs over the side of the boat is so great, that it is wetted to prevent its taking fire: but in a short time the strength of the whale begins to fail, and the fishermen, instead of letting out more rope, strive as much as possible to pull back what is given out already, although they always find themselves necessitated to yield at last to the efforts of the animal, to prevent its sinking the boat. If he runs out the 200 fathoms of line contained in one boat, that belonging to another is immediately fastened to the end of the first, and so on; and there have been instances where all the rope belonging to the six boats has been necessary, though half that quantity is seldom required. The whale cannot stay long below water, but again comes up to blow; and being now much fatigued and wounded, stays longer above water than usual. This gives another boat time to come up with him, and he is again struck with a harpoon. He again descends, but with less force than before; and when he comes up again, is generally incapable of descending, but suffers himself to be wounded and killed with long lances which the men are provided with for that purpose. He is known to be near death when he spouts up the water deeply tinged with blood.

The whale being dead, is lashed alongside the ship. They then lay it on one side, and put two ropes, one at the head, and the other in the place of the tail, which, together with the fins, is struck off as soon as he is taken, to keep these extremities above water. On the off-side of the whale are two boats, to receive the pieces of fat, utensils, and men, that might otherwise fall into the water on that side. These precautions being taken, three or four men, with irons at their feet to prevent slipping, get on the whale, and begin to cut out pieces of about three feet thick and eight long, which are hauled up at the capstan or windlass. When the fat is all got off, they cut off the whalebone of the upper jaw with an axe. Before they cut, they are all lashed to keep them firm; which also facilitates the cutting, and prevents them from falling into the sea; when on board, five or six of them are bundled together, and properly stowed; and after all is got off, the carcase is turned adrift, and devoured by the white bears, who are very fond of it. In proportion as the large pieces of fat are cut off, the rest of the crew are employed in slicing them smaller, and picking out all the lean. When this is prepared, they stow it under the deck, where it lies till the fat of all the whales taken during the fishery is on board; then cutting it still smaller, they put it up in tubs in the hold, cramming them full and close. At the end of the season they return home, where the fat is boiled and pressed to give out the oil.

226 By the people of Kamtschatka.

But a different method is practised by the rude inhabitants of the different nations on the coasts of the Frozen ocean. On some parts of the sea coasts of Kamtschatka, the return of the fishing season is celebrated with a grand festival and great rejoicings in their subterraneous winter habitations, in which many superstitious ceremonies are performed. In one part of the ceremonies dogs are sacrificed with beating of drums and other rude musical instruments. The priests who attend and conduct the festival, transport with great solemnity and pomp a figure of a whale, made of wood, from the summer habitation to the winter cottage. As the ceremonies proceed, the whole company assembled shout with a great noise, that the whale has made its escape from the cottage to the sea; and they pretend even to show the traces of the whale, in its course, as if it had really made its way through the opening in the cottage. These ceremonies being ended, the men prepare their nets, and embark in their canoes. The nets are set at the openings of bays, where fish, which are the food of the whale, are abundant, and in the pursuit of which entering the bays he is taken. When this is observed by the people in the canoes, they approach and secure their prize with ropes and straps of leather. This event is again celebrated by their wives and children on shore with dancing, singing, and other demonstrations of joy. But after the whale is sufficiently secured, he is not brought on shore

Whale-Fishery.

shore till another ceremony is performed. They put on their best clothes, and with similar solemnity, transport the image of the whale in wood from the winter to a new summer habitation. A lamp is there lighted up, and an attendant is appointed to watch and keep it burning from the spring to the autumn. The whale is then cut up, and furnishes for a long time what is considered by the natives of those regions a very delicate food.

228 By the people of the Kurile islands.

Among the Kurile islands, which are situated near the southern extremity of the peninsula of Kamtschatka, the whales are most abundant about the beginning of autumn. At that time the inhabitants embark in their canoes, and search for them in places where they generally find them asleep on the surface of the water. When they are so fortunate as to find one in this situation, they approach with the least possible noise; and, when they have come within the proper distance, they pierce him with poisoned arrows. And although these wounds seem extremely slight, they are said in a short time to occasion great pain. The whale thus wounded moves about furiously, blows with great violence, and soon dies.

229 Of Iceland.

We have already mentioned the mode of taking the whale which is practised by the Icelanders, in giving the natural history of the *balæna glacialis*, or Iceland whale. It is, according to Anderson, by throwing blood into the sea, when they get between the whale and the shore. They then endeavour to drive him towards the shore; but the whale finding himself pursued, attempts to regain the ocean, and approaching the blood, is alarmed; and rather than swim across it, returns towards the land, where he is often thrown on shore. But this is contradicted by Horrebow, who says, that the usual method of killing the whale in Iceland is with the harpoon.

230 Of Greenland.

When the whale returns to the coasts of Greenland, the fishermen put on their large skin coats, and furnish themselves with a large knife, and a stone to sharpen it. They provide also harpoons, spears, and arrows, with a number of large skins of the sea-dog inflated. Thus equipped, they launch their canoes, and embark with their wives and children. The harpoon which they generally employ is pointed with bone, or a sharp stone. Some indeed have harpoons of iron, which they procure from the Danes by barter for the oil or fat of the whale. The scarcity of wood and iron makes these articles extremely valuable to Greenlanders, and has excited their ingenuity to avoid the risk of losing them. For this purpose an inflated bladder of the skin of the sea-dog is attached to the harpoon, so that in case it should not reach the whale when they attempt to strike, it may float on the water, and be recovered. Thus equipped they launch out into the ocean in their small canoes, and, with great intrepidity, attack the largest whales. They approach them, says Anderson, with astonishing boldness, and endeavour to fix, by means of their harpoon, which they throw at his body, some of the skins inflated with air. For, notwithstanding the enormous bulk of this animal, two or three of these skins, by the resistance which they make to the water, on account of their diminished specific gravity, greatly impede his attempts at plunging into the deep. Having by this means succeeded in arresting his progress, they approach nearer; and, with their lances, pierce his body, till he become languid and feeble with the loss of blood, and at last dies. The fishermen then plunge into the sea with their skin-jackets filled with air, and swim to their prize; and, floating on the surface of the water, they cut off with their knives from every part of the whale the fat or blubber, which is thrown into the canoes. And, notwithstanding the rudeness and imperfection of their instruments, their dexterity is such, that they can extract from the mouth the greatest, or at least the best part of the whalebone.

231 Astonishing mode by the Floridan Indians.

But the mode of fishing the whale, the boldest and most astonishing, is that which is practised by the Indians on the coast of Florida. When a whale appears, they fasten to their bodies two pieces of wood and a mallet; and these instruments, with their canoe, constitute the whole of their fishing equipage. When they approach the whale, they throw themselves into the water, swim directly towards him, and have the address to get upon his neck, taking care to avoid the stroke of his fins or tail. When the whale first spouts, the Indian introduces one of the pieces of wood into the opening of one of the blow-holes, and drives it home with the mallet. The whale thus attacked, instantly plunges, and carries the Indian along with him, who keeps fast hold of the animal. The whale, which has now only one blow-hole, soon returns to the surface of the water to respire: and, if the Indian succeeds in fixing the other piece of wood into the second blow-hole, the whale again descends to the bottom, but a moment after reappears on the surface, where he remains motionless, and immediately expires by the interruption of the function of respiration.

EXPLANATION OF PLATES.

232 Plates explained.

Plate CXL.—Fig. 1. The large whalebone or Greenland whale, is from 40 to 60 feet long, and more than one half the length in circumference at the thickest part. This whale is taken on account of the oil and the whalebone.

Fig. 2. The narhwal or unicorn-fish, yields a small quantity of oil, but it is said to be of a superior quality. The horns or teeth are much valued, and are in some respects preferable to ivory. They are from 9 to 10 feet long. The flesh is greatly esteemed by the inhabitants of Greenland.

Fig. 3. The large spermaceti whale, which is taken on account of the oil, and also on account of the more valuable substance, spermaceti, which is found chiefly in cells within the skull. The figure here given is taken from one of the 31 which came on shore in 1784, near Audierne in France. The length was 44 feet.

Fig. 4. The grampus. This figure was taken from one caught at the mouth of the Thames in 1759. It was 24 feet long.

Plate CXLI.—Fig. 1. and 2. exhibit a view of the course of the blow-hole in the cetaceous fishes.

Fig. 1. shews the blow-hole of the whalebone and spermaceti whale. In the whalebone whale it is double, and the course of it is marked by the dotted line ABCD. It is single in the spermaceti whale, and marked by the dotted lines AEFD.

Fig. 2. shews that of the monodon and delphinus. That of the monodon, which is single, is shewn by the dotted line ABCD, terminating at the back part of the

the head; and that of the class delphinus by the dotted line AEFD, terminating at the top of the head.

Fig. 3. A perpendicular section of several plates of whalebone in their natural situation in the gum. The inner edges or shortest terminations are removed, and the cut edges seen from the inside of the snout. A, the upper part, shews the distance of the plates from each other. C, the lower part, shews the white substance on which they grow, and the basis on which they stand.

Fig. 4. A side view of one of the plates of whalebone. A, the part which projects beyond the gum, B, the portion which is sunk in the gum. CC, a white substance which surrounds the whalebone, forming there a projecting bead, and also passing between the plates to form their external lamellæ. DD, the part analogous to the gum. E, a fleshy substance covering the jaw-bone, on which the inner lamella of the plate is formed. F, the termination of the whalebone in the hair.

Fig. 5. An outline to shew the mode of growth of the plates, and of the white intermediate substance. A, the middle layer of the plate, which is formed upon a pulp or cone that passes up in the centre of the plate. The termination of this layer forms the hair. B, one of the outer layers, which is formed from the intermediate white substance. CCCC, the intermediate white substance, the laminæ of which are continued along the middle layer, and form the substance of the plate of whalebone. D, the outline of another plate of whalebone. E, the basis on which the plates are formed which adheres to the jaw-bone.

Cette || Ceuta.

CETTE, a maritime town of France, in Languedoc, seated at the place where the canal of Languedoc begins, between Montpelier and Agde, on the bay of Maguelona, in the Mediterranean sea. Population in 1815, 8000. E. Long. 3. 15. N. Lat. 43. 25.

CETUS, in *Astronomy*, the whale; a large constellation of the southern hemisphere, under Pisces, and next the water of Aquarius. The stars in the constellation Cetus, in Ptolemy's catalogue, are twenty-two; in Tycho's twenty-one; in Hevelius's forty-five; in the Britannic catalogue ninety-seven.

Cetus is represented by the poets as the sea monster which Neptune, at the suit of the nymphs, sent to devour Andromeda for the pride of her mother, and which was killed by Perseus. In the mandible of Cetus is a variable star which appears and disappears periodically, passing through the several degrees of magnitude, both increasing and diminishing, in about 333 days. See ASTRONOMY.

CEVA, a strong town of Piedmont in Italy, seated on the river Tanero, with a strong fort, and containing 5000 inhabitants. E. Long. 3. 8. N. Lat. 44. 20.

CEVENNES, mountains of Languedoc in France, remarkable for the frequent meetings of the Protestants there as a place of security against the tyranny of their governors. In Queen Anne's reign there was an attempt made to assist them by an English fleet in the Mediterranean; but to no purpose, for the French had occupied the passages.

CEUTA, a maritime town of Barbary in Africa, and in the kingdom of Fez, seated on the straits of Gibraltar, opposite that place, in W. Long. 6. 25. N. Lat. 36. 35. John king of Portugal took it from the Moors in 1415, but it now belongs to Spain. In 1697 it sustained a vigorous siege by the Moors.

Ceuta, Ceylon.

CEYLON, a large island in the East Indies, which lies between 6° and 10° north latitude: and between 78° and 82° east longitude. It is situated at the entrance of the bay of Bengal, by which it is bounded on the north. On the north-west it is separated from the Coromandel coast by the gulf of Manaar, a narrow strait full of shoals, and impassable by large ships; and is distant about 60 leagues from Cape Comorin, the southern part of the peninsula of India. Its circumference is computed to be about 900 miles; and its length from Point Pedro at the northern extremity to Donderhead at the southern is about 300 miles. Its breadth is very unequal, being in some parts only from 40 to 50 miles, while in others it extends to 60, 70, and even 100.

The appearance of the eastern coast is bold and rocky, and a few reefs of rocks run out into the sea on the south-east between Point de Galle and Batocolo. The deep water on the eastern shores admits the approach of the largest vessels in safety; and if that side of the island be the least fertile, its other defects are amply compensated by the harbours of Trincomalee and Batocolo. The north and north-west coast from Point Pedro to Columbo is flat, and everywhere indented with inlets of the sea. The largest of them extends almost quite across the island from Mullipatti to Jafnapatam on the north-west point of the island; and forms the peninsula of Jafnapatam. Several of these inlets form small harbours.

The interior of the island abounds with steep and lofty mountains, covered with thick forests, and full of of almost impenetrable jungles. The woods and mountains completely surround the dominions of the king of Candy, and seem destined by nature to defend him against those foreign enemies, whose superior skill and power have deprived him of the open tracts on the sea-coast. The most lofty range of mountains divides the island nearly into two parts, and so completely separates them from each other, that both the climate and seasons on either side are essentially different. These mountains also obstruct completely the effect of the monsoons, which set in periodically from opposite sides of them; so that not only the opposite sea-coast, but the whole country in the interior, suffers very little from these storms.

The monsoons in Ceylon are connected with those on the Coromandel and Malabar coasts; but they set in much sooner on the western than the eastern side of the island. On the west side, where Columbo lies, the rains prevail in the months of May, June, and July, the season when they are felt on the Malabar coast. This monsoon is usually extremely violent, being accompanied with dreadful storms of thunder and lightning, together with vast torrents of rain, and violent south-west winds. During its continuance, the northern parts of the island are very little affected, and are even generally dry. In the months of October and November, when the opposite monsoon sets in on the Coromandel coast, it is the north of Ceylon which is affected, and scarcely any impression of it is felt in the southern parts.

These monsoons pass slightly over the interior, and seldom occasion any considerable inconvenience. But this part of the island is not altogether freed from the dreadful storms which so terribly ravage the tropical climates. During its own periodical season, which happens in March and April, the rain pours down in torrents, and the thunder and lightning are terrible.

From the situation of this island, so near the equator, the days and nights are nearly of equal length; the variation during the two seasons not exceeding 15 minutes. The seasons are more regulated by the monsoons than the course of the sun; for although the island lies to the north of the line, the coolest season is during the summer solstice, while the western monsoon prevails. Their spring commences in October; and the hottest season is from January to the beginning of April. The heat, during the day, is nearly the same throughout the whole year; the rainy season, however, renders the nights much cooler, from the dampness of the earth, and the prevalence of winds during the monsoons. The climate, upon the whole, is much more temperate than on the continent of India. This temperate climate, however, is chiefly confined to the coast where the sea-breezes have room to circulate. In the interior of the country, owing to the thick and close woods, and the hills which crowd upon each other, the heat is in many degrees greater than on the sea-coast, and the climate often extremely sultry and unhealthy.

The principal harbours in the island for large ships are Trincomalee and Point de Galle; they also come to anchor, and at certain seasons of the year moor securely, in the roads of Columbo. There are several other inferior ports round the island, which afford shelter to the smaller coasting vessels.

The two principal rivers are the Malivagonga and the Mulivaddy. The former takes its rise among the hills to the south-east of Candy, and nearly surrounds that city. After a variety of circuitous windings among the mountains, it at last discharges itself into the sea at Trincomalee. This river is so deep as to be fordable only towards the source; but the rocks, which everywhere break its course, prevent it from being navigated. The Mulivaddy rises from the foot of a very high mountain, known to Europeans by the name of Adam's Peak, and situated about sixty miles to the north-east of Columbo. This river falls into the sea by several branches: the largest of these empties itself about three miles from the fort of Columbo, after having nearly surrounded a large tract of the level country, of which it forms a peninsula.

Besides the rivers with which Ceylon abounds, there are many lakes and canals communicating with them, particularly in the neighbourhood of Columbo and Nigumbo. They are often of considerable extent, and of great utility to the inhabitants in their neighbourhood, who have thus an opportunity of readily transporting their several articles of trade; and it is by this means also that the towns on the coast are supplied with the greatest abundance of fresh-water fish.

The internal communications by land through the island have scarcely passed the first stage of improvement. Along the sea-coasts indeed there are roads and stations for travellers: but these roads are in many places rugged and steep.

The soil in general is sandy, with a small mixture of clay. In the south-west parts, particularly about Columbo, there is a great deal of marshy ground, very rich and productive. This tract, however, is chiefly occupied with cinnamon plantations, and the rest of the island, in its present state of cultivation, does not produce a sufficient quantity of rice for the consumption of its inhabitants.

Ceylon was originally divided into a number of distinct petty kingdoms, separated by the several rivers and mountains which are dispersed over the face of the island, and subject each to its own independent sovereign. In process of time, however, the whole country was reduced under the dominion of the king of Candy, and divided by him into a few great provinces, from which several of the numerous titles he still retains were derived. These provinces were Candy, Coitu, Matura, Dambadar, and Sittivacca, which included the rich districts on the west coast. The chief of these provinces was Candy, situated in the centre of the island, and honoured with the royal residence. The king holds his court there to this day; and though all the other provinces have been more or less encroached upon, no part of Candy has ever been reduced to permanent subjection under a foreign power. The great divisions of the island now are reduced to two; the one comprehending those parts under the dominion of Europeans, and the other those which still remain to the natives.

Little was known of the island of Ceylon previous to the arrival of the Portuguese in 1505, who were admitted by the king of the country in a friendly manner, and received from him an annual tribute for their protection against external invasion, particularly against the attacks of the Arabs, who had long harassed and oppressed

Ceylon.

oppressed the Ceylonese. The inhabitants at that time, as at present, consisted of two distinct races, the Bedahs, who lived in the forests, particularly in the northern parts, and the Cinglese, who inhabited the sea coast. Columbo, now the European capital at Ceylon, was at that time the royal residence. Cinnamon was even then the chief product and staple commodity of the country. Two hundred and fifty thousand pounds weight were annually delivered by the king to the Portuguese in name of tribute. The inhabitants suffered great cruelties and oppression under the Portuguese, and were glad of an opportunity of throwing off the yoke and putting themselves under the protection of the Dutch. In 1632, a strong armament was sent out by the latter to act in concert with the native prince; and after a bloody struggle, the Portuguese were at last expelled from the island. Columbo surrendered to the Dutch arms in 1656, and this terminated the dominion of the Portuguese in the island. In the year 1795, the island was reduced by a body of British troops. Subsequently to that period the native princes in the interior have been subdued.

The chief towns in Ceylon are Trincomalee and Columbo. Trincomalee lies in latitude 8° 30′. It runs in a north-east direction along one branch of the bay. The country around it is mountainous and woody; the soil uncultivated and rather barren, and the whole appearance wild.

Trincomalee, from its situation and construction, is naturally strong. It occupies more ground than Columbo, but contains a much smaller number of houses, and those inferior in size and appearance to those which are to be met with in several towns on the south-west coast. The circumference of Trincomalee, within the walls, is about three miles; within this space is also included a hill or rising point, immediately over the sea, and covered with brushwood.

The fort is strong, and commands the principal bays; and, in particular, the entrance into the grand harbour, or inner bay, which affords at all seasons, and in every variety of weather, a secure shelter to ships of all descriptions, being land-locked on all sides, and sufficiently deep and capacious to receive any number of the largest vessels.

This harbour, from its nature and situation, is that which stamps Ceylon one of our most valuable acquisitions in the East Indies. As soon as the violent monsoons commence, every vessel which is caught by them in any other part of the bay of Bengal, is obliged immediately to put to sea to prevent inevitable destruction. At these seasons Trincomalee and Bombay alone, of all the ports on the different coasts of the peninsula of India, are capable of affording a safe retreat. The incalculable advantages to be derived from such a harbour, are increased by its proximity and easy access to our settlements in the bay of Bengal.

Columbo is the capital of Ceylon and the seat of government. Although Trincomalee, on account of its situation and harbour, be of more consequence to this nation to retain, yet Columbo in every other respect is greatly superior. The number of its inhabitants is much greater; its fort and black town are much larger; the country where it is situated is far more fertile, and the rich district depending upon it much wider, being not less than 20 leagues in length, and 10 in breadth. It is situated in the west, or rather towards the south-west part of the island, in about 7° north latitude and 78° east longitude from London.

The plan of Columbo is regular. It is nearly divided into four equal quarters by two principal streets, which cross each other, and extend the whole length of the town. To these, smaller ones run parallel, with connecting lanes between them. At the foot of the ramparts on the inside is a broad street or way, which goes round the whole fort, and communicates with the bastions and soldiers barracks; and also affords, at the different angles, open spaces for their private parading.

Besides the European inhabitants of Ceylon, the natives are quite distinct from each other in manners and civilization. The Cinglese, who inhabit the low lands and parts contiguous to the coasts, live entirely under the dominion of whatever European nation has been able to acquire possession of that part of the island. The nature of the country they inhabit indeed leaves them hardly any alternative but unconditional submission, unless they could either meet the Europeans in open battle, or consent to quit their plentiful fields for the barren mountains of the interior.

They are a quiet, inoffensive people; exceedingly grave, temperate, and frugal. Their bodies partake of the indolence of their minds, and it is with reluctance they are roused to any active exertion. When, however, they are obliged to apply themselves to any work, such as agriculture, they are capable of undergoing a great deal of labour.

The milder virtues form the most prominent features of the Cinglese character. They are gentle, charitable, and friendly, and have scarcely any of the false, treacherous, and designing arts which are often found among the Candians. With much less smoothness and courteousness of face and manner than the latter, they have much sincerer hearts. On examining the countenances and carriage of these two classes of Ceylonese, it is easy to perceive the difference arising from the respective circumstances in which they are placed. The countenance of the Candian is erect, his look haughty, his mein lofty, and his whole carriage marked by the pride of independence.

The looks of the Cinglese even denote a degree of effeminacy and cowardice, which excites the contempt of the Candians; although the latter, with all their boasted spirit, can never venture to attack an European but by the same method as the Cinglese, and are equally cautious in waiting the convenient moment of assaulting him from the bushes, in which they have concealed themselves.

The most singular part of the inhabitants of Ceylon are the Bedahs or Vaddahs. The origin of the Bedahs or Vaddahs, who inhabit the deepest recesses of the Ceylonese forests, has never been traced, as no other race can be found in the eastern world which corresponds with them. Conjecture has, indeed, been busy on the occasion, as it usually is where real information is wanting. The Bedahs are generally supposed to have been the aboriginal inhabitants of the island, who, upon being overwhelmed by their Cinglese invaders, preferred the independence of savages to a tame submission. A current tradition, however,

ever, assigns them a different origin. It is related that they were cast away on the island, and chose to settle there; but refusing, upon a certain occasion, to assist the king in his wars against some foreign enemies, they were driven out from the society of the natives, and forced to take up their abode in the most unfrequented forests. Some imagine that the Bedahs are merely a part of the native Candians, who chose to retain their ancient savage freedom, when their brethren of the plains and valleys submitted to the cultivation of the earth, and the restraints of society. This opinion rests entirely on those Bedahs, who are most known, speaking a broken dialect of the Cinglese. It is, however, by no means ascertained that this is the universal language of the Bedahs; nor is any account of their origin supported by the slightest shadow of proof.

Among the animals of Ceylon, and at the head of the class of quadrupeds, is the elephant, which is considered as superior to those found in any other part of the world. The oxen are of very small size, scarcely exceeding that of calves of a year old. They are of that species which have the hump on the shoulder; but are inferior in quality, as well as in size, to any found on the Indian continent. The beef is sometimes of a good quality, and forms the chief food of the European soldiers. Buffaloes are found in great numbers in the island, both in a wild and tame state. They are wild and untractable; and even when tamed and trained to the draught, for which, being stronger and larger than the oxen, they are well adapted, they retain a good deal of their original manners. A variety of deer and elks are found in Ceylon; especially the gazelle, a very small species, about the size of our hare, which is caught by the natives and brought to market in cages, where they are sold for about 1s. a piece. Hares, similar to the European, abound in every part of the island; a small species of tyger, the tyger cat, the leopard, the jackal, porcupines, racoons, squirrels, and sometimes, but rarely, the hyena, and the bear, are found in Ceylon. Birds, insects, serpents, and other reptiles, such as are usually to be met with in the larger islands of the Indian ocean, or on the neighbouring continent, are common on this island.

Ceylon abounds in all the vegetables and fruits which are found within the tropical regions. But among the vegetable productions of Ceylon, the most valuable, and what may be reckoned the staple commodity of the island, is the cinnamon.

The principal woods, or gardens, as they are called, where the cinnamon is procured, lie in the neighbourhood of Columbo. The grand garden near the town is so extensive as to occupy a tract of country from 10 to 15 miles in length, and stretching along from the north-east to the south of the district. Nature has here concentrated both the beauty and the riches of the island. Nothing can be more delightful to the eye than the prospect which stretches around Columbo. The low cinnamon trees which cover the plain allow the view to reach the groves of evergreens, interspersed with tall clumps, and bounded everywhere with extensive ranges of cocoa-nut and other large trees. The whole is diversified with small lakes and green marshes, skirted all around with rice and pasture fields. In one part the intertwining cinnamon trees appear completely to clothe the face of the plain; in another, the opening made by the intersecting footpaths just serve to shew that the thick underwood has been penetrated.

The soil best adapted for the growth of the cinnamon is a loose white sand. Such is the soil of the cinnamon gardens around Columbo, as well as in many parts around Nigumbo and Caltura, where this spice is found of the same superior quality. Of late years little is procured from the interior; and what is brought thence is coarser and thicker in the appearance, and of a hot pungent taste.

As this spice constitutes the wealth of Ceylon, great pains are taken to ascertain its quality, and to propagate the choicest kinds. The prime sort, and that which grows in the gardens around Columbo, is procured from the *laurus cinnamomum*. This is a tree of a small size, from four to ten feet in height: the trunk is slender, and like several of our shrubs, a number of branches and twigs shoot out from it on every side. The wood is soft, light, and porous, in appearance much resembling that of our osier; and when barked it is chiefly fit for fuel, to which use it is commonly converted. It is, however, sometimes sawed into planks, and manufactured into caddies and other pieces of furniture; but its scent does not secure it from the attacks of the worms.

The cinnamon tree produces a species of fruit resembling an acorn, but not so large, which ripens about the latter end of autumn, and is gathered by the natives for the purpose of extracting the oil. The process they employ is to bruise the fruit, boil it, and skim off the oil: this they use for their hair and body on great occasions, and also for burning in their lamps. When mixed with cocoa-nut oil, it gives extremely good light. The kings of Candy use it for this purpose, and formerly commanded their subjects to bring them a certain quantity as a yearly tribute. When any ambassadors are sent to these princes, they always burn this oil during the time of audience.

The pearl-fishery in the bay of Condatchy, during the season, exhibits one of the most interesting scenes in Ceylon. The banks, where it is carried on, extend several miles along the coast from Manaar southward, off Arippo, Condatchy, and Pomparipo. The principal bank is opposite to Condatchy, and lies out at sea about 20 miles. The first step, previous to the commencement of the fishery, is to have the different oyster banks surveyed, the state of the oysters ascertained, and a report made on the subject to government. If it has been found that the quantity is sufficient, and that they are arrived at a proper degree of maturity, the particular banks to be fished that year are put up for sale to the highest bidder, and are usually purchased by a black merchant. Government sometimes judges it more advantageous to fish the banks on its own account, and to dispose of the pearls afterwards to the merchants. When this plan is adopted, boats are hired for the season on account of government, from different quarters; the price varies considerably, according to circumstances; but is usually from 500 to 800 pagodas for each boat.

As neither the season, nor the convenience of the persons attending, would permit the whole of the banks to be fished in one year, they are divided into three or four different portions, which are fished one portion annually in succession. The different portions are completely distinct, and are set up separately to sale, each

Ceylon. each in the year in which it is to be fished. By this means a sufficient interval is given to the oysters to attain their proper growth; and as the portion first used has generally recovered its maturity by the time the last portion has been fished, the fishery becomes almost regularly annual, and may thus be considered as yielding a yearly revenue. The oysters are supposed to attain their completest state of maturity in seven years; for, if left too long, it is said that the pearl becomes so large and inconvenient to the fish, that it throws it out of the shell.

The fishing season commences in February, and ends about the beginning of April. The period allowed to the merchant to fish the banks is six weeks, or two months at the utmost; but there are several interruptions, which prevent the fishing days from exceeding more than about thirty. If it happens to be a very bad season, and many stormy days intervene during the period allotted, the purchaser of the fishery is often allowed a few days more as a favour.

During the season, all the boats regularly sail and return together. A signal gun is fired at Arippo, about ten o'clock at night, when the whole fleet sets sail with the land breeze. They reach the banks before daybreak; and at sunrise commence fishing. In this they continue busily occupied till the sea breeze, which rises about noon, warns them to return to the bay. As soon as they appear within sight, another gun is fired, and the colours hoisted, to inform the anxious owners of their return. When the boats come to land, their cargoes are immediately taken out, as it is necessary to have them completely unloaded before night. Whatever may have been the success of their boats, the owners seldom wear the looks of disappointment; for, although they may have been unsuccessful one day, they look with the most complete assurance of better fortune to the next; as the Brahmins and conjurors, whom they implicitly trust in defiance of all experience, understand too well the liberality of a man in hopes of good fortune, not to promise them all they can desire.

Each of the boats carries 20 men, with a tindal or chief boatman, who acts as pilot. Ten of the men row and assist the divers in re-ascending. The other ten are divers; they go down into the sea by five at a time; when the first five come up the other five go down, and by this method of alternately diving, they give each other time to recruit themselves for a fresh plunge.

In order to accelerate the descent of the divers, large stones are employed; five of these are brought in each boat for the purpose; they are of a reddish granite, common in this country, and of a pyramidal shape, round at top and bottom, with a hole perforated through the smaller end sufficient to admit a rope. Some of the divers use a stone shaped like a half-moon, which they fasten round the belly when they mean to descend, and thus keep their feet free.

The people are accustomed to dive from their very infancy, and fearlessly descend to the bottom in from four to ten feet fathom water, in search of the oysters. The diver, when he is about to plunge, seizes the rope to which one of the stones we have described is attached, with the toes of his right foot, while he takes hold of a bag of net-work with those of his left; it being customary among all the Indians to use their toes in working or holding as well as their fingers, and such is the power of habit that they can pick up even the smallest thing from the ground with their toes as nimbly as an European could do with his fingers. The diver thus prepared, seizes another rope with his right hand, and holding his nostrils shut with the left, plunges into the water, and by the assistance of the stone speedily reaches the bottom. He then hangs the net round his neck, and with much dexterity, and all possible dispatch, collects as many oysters as he can while he is able to remain under water, which is usually about two minutes. He then resumes his former position, makes a signal to those above by pulling the rope in his right hand, and is immediately by this means drawn up and brought into the boat, leaving the stone to be pulled up afterwards by the rope attached to it.

The exertion undergone during this process is so violent, that upon being brought into the boat, the divers discharge water from their mouth, ears, and nostrils, and frequently even blood. But this does not hinder them from going down again in their turn. They will often make from 40 to 50 plunges in one day; and at each plunge bring up about 100 oysters. Some rub their bodies over with oil, and stuff their ears and noses to prevent the water from entering; while others use no precautions whatever. Although the usual time of remaining under water does not much exceed two minutes, yet there are instances known of divers who could remain four and even five minutes. The longest instance ever known was that of a diver who came from Anjango in 1797, and who absolutely remained under water full six minutes.

The boat-owners and merchants are very apt to lose many of the best pearls while the boats are on their return to the bay from the banks, as the oysters when alive and left for some time undisturbed frequently open their shells of their own accord; a pearl may then be easily discovered, and the oyster prevented by means of a bit of grass or soft wood from again closing its shell, till an opportunity offers of picking out the pearl. Those fellows who are employed to search among the fish also commit many depredations, and even swallow the pearls to conceal them; when this is suspected, the plan followed by the merchants is to lock the fellows up, and give them strong emetics and purgatives, which have frequently the effect of discovering the stolen goods.

As soon as the oysters are taken out of the boats, they are carried by the different people to whom they belong, and placed in holes or pits dug in the ground to the depth of about two feet, or in small square places cleared and fenced round for the purpose; each person having his own separate division. Mats are spread below them to prevent the oysters from touching the earth; and here they are left to die and rot. As soon as they have passed through a state of putrefaction, and have become dry, they are easily opened without any danger of injuring the pearls, which might be the case if they were opened fresh, as at that time to do so requires great force. On the shell being opened, the oyster is minutely examined for the pearls: it is usual even to boil the oyster, as the pearl, though commonly found in the shell, is not unfrequently contained in the body of the fish itself.

The pearls found at this fishery are of a whiter colour than those got in the gulf of Ormus on the Arabian

bian coast, but in other respects are not accounted so pure or of such an excellent quality; for though the white pearls are most esteemed in Europe, the natives prefer those of a yellowish or golden cast. Off Tutucoreen, which lies on the Coromandel coast, nearly opposite to Condatchy, there is another fishery; but the pearls found there are much inferior to the two species now mentioned, being tainted with a blue or grayish tinge.

In preparing the pearls, particularly in drilling and stringing them, the black people are wonderfully expert. The instrument they employ in drilling is a machine made of wood, and of a shape resembling an obtuse inverted cone, about six inches in length, and four in breadth, which is supported upon three feet, each 12 inches long. In the upper flat surface of this machine, holes or pits are formed to receive the larger pearls, the smaller ones being beaten in with a little wooden hammer. The drilling instruments are spindles of various sizes according to that of the pearls; they are turned round in a wooden head by means of a bow-handle to which they are attached. The pearls being placed in the pits which we have already mentioned, and the point of the spindle adjusted to them, the workman presses on the wooden head of the machine with his left hand, while his right is employed in turning round the bow-handle. During the process of drilling, he occasionally moistens the pearl by dipping the little finger of his right hand in a cocoa-nut filled with water, which is placed by him for that purpose; this he does with a dexterity and quickness which scarcely impedes the operation, and can only be acquired by much practice.

They have also a variety of other instruments, both for cutting and drilling the pearls. To clean, round, and polish them to that state in which we see them, a powder made of the pearls themselves is employed. These different operations in preparing the pearls occupy a great number of the black men in various parts of the island. In the black town of Columbo, in particular, many of them may every day be seen at this work.

Putallom is remarkable for its salt-pans. This place, before the arrival of Europeans on the island, supplied the natives with salt; and on account of its convenient situation, was pitched upon by the Dutch for manufacturing the salt with which they supplied the king of Candy's dominions, according to the articles of their treaty with him. The salt-pans are formed by an arm of the sea which overflows part of the country between Putallom and Calpenteen. A very large quantity of salt was manufactured here by the Dutch; they looked upon it as of the highest importance to their interests in the island, and the most formidable weapon which it was in their power to employ against the native king, as it was impossible for him to procure any but through their means. The Dutch enacted severe laws to prevent individuals from manufacturing or trading in this article, the government taking upon itself the management of the works and the care of supplying both its own subjects and the Candians. In order to keep a constant check on the latter, the Dutch were careful not to allow them too great a quantity at once; and whatever remained at Putallom after supplying the demands of each year they destroyed, that it might not be seized upon by surprise. But this manufacture has been of late greatly neglected. See CEYLON, SUPPLEMENT.

CHACE. See CHASE.

CHACO, a large country of South America, situated between 19° and 37° S. Lat. It belongs to the Spaniards, by whom it was conquered in 1536. It is not naturally fruitful; but abounds in gold mines, which are so much the more valuable that they are easily worked. The works are carried on by about 8000 blacks, who deliver every day to their masters a certain quantity of gold; and what they can collect above this belongs to themselves; as well as what they find on those days that are consecrated to religion and rest, upon condition that during the festival they maintain themselves. This enables many of them to purchase their liberty; after which they intermarry with the Spaniards.

CHADCHOD, in Jewish antiquity. Ezekiel mentions *chadchod* among the several merchandises which were brought to Tyre. The old interpreters, not very well knowing the meaning of this term, continued it in their translation. St Jerome acknowledges that he could not discover the interpretation of it. The Chaldee interprets it pearls; others think that the onyx, ruby, carbuncle, crystal, or diamond, is meant by it.

CHÆRONEA, in *Ancient Geography*, the last town, or rather the last village, of Bœotia, towards Phocis; the birth-place of Plutarch; famous for the fatal defeat of the confederate Greeks by Philip of Macedon. This place was considered by Philip as well adapted to the operations of the Macedonian phalanx; and the ground for his encampment, and afterwards the field of battle, were chosen with equal sagacity; having in view on one side a temple of Hercules, whom the Macedonians regarded as the author of their royal house, and the high protector of their fortune; and on the other the banks of the Thermodoon, a small river flowing into the Cephissus, announced by the oracles of Greece as the destined scene of desolation and woe to their unhappy country. The generals of the confederate Greeks had been much less careful to avail themselves of the powerful sanctions of superstition. Unrestrained by inauspicious sacrifices, the Athenians had left the city at the exhortation of Demosthenes, to wait no other omen but the cause of their country. Regardless of oracles, they afterwards advanced to the ill-fated Thermodoon, accompanied by the Thebans, and the scanty reinforcements raised by the islands and states of Peloponnesus which had joined their alliance. Their army amounted to 30,000 men, animated by the noblest cause for which men can fight, but commanded by the Athenians Lysicles and Chares; the first but little, and the second unfavourably known; and by Theagenes the Theban, a person strongly suspected of treachery; all three creatures of cabal and tools of faction, slaves of interest or voluptuousness, whose characters (especially as they had been appointed to command the only states whose shame, rather than virtue, yet opposed the public enemy) are alone sufficient to prove that Greece was ripe for ruin.

When the day approached for abolishing the tottering independence of those turbulent republics, which their own internal vices, and the arms and intrigues of Philip,

Philip, had been gradually undermining for 22 years, both armies formed in battle array before the rising of the sun. The right wing of the Macedonians was headed by Philip, who judged it proper to oppose in person the dangerous fury of the Athenians. His son Alexander, only 19 years of age, but surrounded by experienced officers, commanded the left wing, which faced the Sacred Band of the Thebans. The auxiliaries of either army were posted in the centre. In the beginning of the action, the Athenians charged with impetuosity, and repelled the opposing divisions of the enemy; but the youthful ardour of Alexander obliged the Thebans to retire, the Sacred Band being cut down to a man. The young prince completed their disorder, by pursuing the scattered multitude with his Thessalian cavalry.

Meantime the Athenian generals, too much elated with their first advantage, lost the opportunity to improve it; for having repelled the centre and right wing of the Macedonians, except the phalanx, which was composed of chosen men, and immediately commanded by the king, they, instead of attempting to break this formidable body by attacking it in flank, pressed forward against the fugitives, the insolent Lysicles exclaiming in vain triumph, "Pursue, my brave countrymen! let us drive the cowards to Macedon." Philip observed this rash folly with contempt; and saying to those round him, "Our enemies know not how to conquer," commanded his phalanx, by a rapid evolution, to gain an adjacent eminence, from which they poured down, firm and collected, on the advancing Athenians, whose confidence of success had rendered them totally insensible to danger. But the irresistible shock of the Macedonian spear converted their fury into despair. Above a thousand fell, two thousand were taken prisoners; the rest escaped by a precipitate and shameful flight. Of the Thebans more were killed than taken. Few of the confederates perished, as they had little share in the action, and as Philip, perceiving his victory to be complete, gave orders to spare the vanquished, with a clemency unusual in that age, and not less honourable to his understanding than his heart; since his humanity thus subdued the minds, and gained the affections of his conquered enemies.

According to the Grecian custom, the battle was followed by an entertainment; at which the king, presiding in person, received the congratulations of his friends, and the humble supplications of the Athenian deputies, who craved the bodies of their slain. Their request, which served as an acknowledgment of their defeat, was readily granted; but before they availed themselves of the permission to carry off their dead, Philip, who with his natural intemperance had protracted the entertainment till morning, issued forth with his licentious companions to visit the field of battle; their heads crowned with festive garlands, their minds intoxicated with the insolence of wine and victory; yet the sight of the slaughtered Thebans, which first presented itself to their eyes, and particularly the sacred band of friends and lovers, who lay covered with honourable wounds on the spot where they had been drawn up to fight, brought back these insolent spectators to the sentiments of reason and humanity. Philip beheld the awful scene with a mixture of admiration and pity; and, after an affecting silence, denounced a solemn curse against those who basely suspected the friendship of such brave men to be tainted with criminal and infamous passions.

But this serious temper of mind did not last long; for having proceeded to that quarter of the field where the Athenians had fought and fallen, the king abandoned himself to all the levity and littleness of the most petulant joy. Instead of being impressed with a deep sense of his recent danger, and with dutiful gratitude to Heaven for the happiness of his escape, and the importance of his victory, Philip only compared the boastful pretensions with the mean performances of his Athenian enemies; and, struck by this contrast, rehearsed, with the insolent mockery of a buffoon, the pompous declaration of war lately drawn up by the ardent patriotism and too sanguine hopes of Demosthenes. It was on this occasion that the orator Demades at once rebuked the folly, and flattered the ambition of Philip, by asking him, Why he assumed the character of Thersites when fortune assigned him the part of Agamemnon?

Whatever might be the effect of this sharp reprimand, it is certain that the king of Macedon indulged not, on any future occasion, a vain triumph over the vanquished. When advised by his generals to advance into Attica, and to render himself master of Athens, he only replied, "Have I done so much for glory, and shall I destroy the theatre of that glory?" His subsequent conduct corresponded with the moderation of this sentiment. He restored without ransom the Athenian prisoners; who, at departing, having demanded their baggage, were also gratified in this particular; the king pleasantly observing, that the Athenians seemed to think he had not conquered them in earnest. Soon afterwards he dispatched his son Alexander, and Antipater, the most trusty of his ministers, to offer them peace on such favourable terms as they had little reason to expect. They were required to send deputies to the isthmus of Corinth, where, to adjust their respective contingent of troops for the Persian expedition, Philip purposed assembling early in the spring a general convention of all the Grecian states: they were ordered to surrender the isle of Samos, which actually formed the principal station of their fleet, and the main bulwark and defence of all their maritime or insular possessions; but they were allowed to enjoy, unmolested, the Attic territory, with their hereditary form of government.

CHÆROPHYLLUM, Chervil. See Botany *Index*.

CHÆTODON. See Ichthyology *Index*. This fish is a native of the East Indies, where it frequents the sides of the sea and rivers in search of food; from its singular manner of obtaining which it receives its name. When it spies a fly sitting on the plants that grow in shallow water, it swims to the distance of four, five, or six feet; and then, with a surprising dexterity, it ejects out of its tubular mouth a single drop of water, which never fails striking the fly into the water, where it soon becomes its prey.

CHAFF, in *Husbandry*, the husks of the corn, separated by screening or winnowing it. It signifies also the rind of corn, and straw cut small for the use of cattle.

Chaff-cutter, a machine for making chaff to feed horses.

horses.—The advantages of an easy and expeditious method of cutting straw into chaff, by an engine which could be used by common labourers, have been long acknowledged; and various attempts have been made to bring such an engine to perfection. But the objections to most of them have been their complicated structure, their great price, and the noise they make in working; all which incoveniences seem to have been lately removed by an invention of Mr James Pike, watchmaker at Newton Abbot in Devonshire. Of his engine, which is of a simple and cheap construction, the following description, and figure referred to, are extracted from the Transactions of the Society of Arts, for 1787.

The engine is fixed on a wooden frame, which is supported with four legs, and on this frame is a box for containing the straw, four feet six inches long, and about ten inches broad; at one end is fixed across the box two rollers inlaid with iron, in a diagonal line, about an eighth of an inch above the surface; on the ends of these rollers are fixed two strong brass wheels, which take one into the other. On one of these wheels is a contract wheel, whose teeth take in a worm on a large arbor; on the end of this arbor is fixed a wooden wheel, two feet five inches diameter and three inches thick; on the inside part of this wheel is fixed a knife, and every revolution of the wheel the knife passes before the end of the box and cuts the chaff, which is brought forward between the rollers, which are about two inches and a half asunder; the straw is brought on by the worm taking one tooth of the wheel every round of the knife; the straw being so hard pressed between the rollers, the knife cuts off the chaff with so great ease, that 22 bushels can be cut within the hour, and makes no more noise than is caused by the knife passing through the chaff.

Plate CXVII. *A* is the box into which the straw is put. *B*, the upper roller, with its diagonal projecting ribs of iron, the whole moving by the revolution of the brass wheel *C* on the axis of which it is fixed. *D*, a brass wheel, having upon it a face wheel, whose teeth take into the endless screw on the arbor *E*, while the teeth on the edge of this wheel enter between those on the edge of the wheel *C*. On the axis of the wheel *D* is a roller, with iron ribs similar to *B*, but hid within the box. *E*, the arbor, one of the ends of which being made square and passing through a mortise in the centre of the wooden wheel *F*, is fastened by a strong screw and nut; the other end of this arbor moves round in a hole within the wooden block *G*. *H*, the knife, made fast by screws to the wooden wheel *F*, and kept at the distance of nearly three quarters of an inch from it by means of a strip of wood of that thickness, of the form of the blade, and reaching to within an inch of the edge. *I*, the handle mortised into the outside of the wooden wheel *F*.

CHAFFER, in *Zoology*, a species of beetle. See SCARABÆUS, ENTOMOLOGY *Index*.

CHAFFERCONNERS, in commerce, printed linens manufactured in the Great Mogul's dominions. They are imported by the way of Surat, and are of the number of those linens prohibited in France.

CHAFFERY, in the iron works, the name of one of the two principal forges. The other is called the *finery*. When the iron has been brought at the finery into what is called an ancony, or square mass, hammered into a bar in its middle, but with its two ends rough, the business to be done at the chaffery is the reducing the whole to the same shape, by hammering down these rough ends to the shape of the middle part.

Chaffery ‖ Chain.

CHAFFINCH, the English name of a species of FRINGILLA. See ORNITHOLOGY *Index*.

CHAGRE, a fort of America, in the province of Darien, at the mouth of a river of the same name. It has been taken several times by the Buccaneers, and last of all by Admiral Vernon in 1740. W. Long. 82. 7. N. Lat. 9. 50.

CHAIN (*Catena*) a series of several rings or links, fitted into one another.

There are chains of divers matters, sizes, forms, and for divers uses.—Ports, rivers, streets, &c. are closed with iron chains; rebellious cities are punished by taking away their chains and barriers.

The arms of the kingdom of Navarre are, *Chains Or, in a field of Gules*. The occasion hereof is referred to the kings of Spain leagued against the Moors; who, having gained a celebrated victory against them in 1212, in the distribution of the spoils the magnificent tent of Miralmumin fell to the king of Navarre, as being the first that broke and forced the chains thereof.

A Gold CHAIN is one of the ornaments or badges of the dignity of the chief magistrates of a city, as the mayor of London, the provost and bailies of Edinburgh, &c.—Something like this obtained among the ancient Gauls: the principal ornament of their persons in power and authority was a gold chain, which they wore on all occasions; and even in battle, to distinguish them from the common soldiers.

CHAIN also denotes a kind of string, of twisted wire; serving to hang watches, tweeser cases, and other valuable toys upon. The invention of this piece of curious work is owing to the English; whence, in foreign countries, it is denominated the *English chain*. These chains are usually either of silver or gold, some of gilt copper; the thread or wire of each kind to be very fine.—For the fabric, or making of these chains, a part of the wire is folded into little links of an oval form; the longest diameter about three lines; the shortest one. These, after they have been exactly soldered, are again folded into two; and then bound together or interwoven, by means of several other little threads of the same thickness; some whereof, which pass from one end to the other, imitate the warp of a stuff; and the others, which pass transverse, the woof. There are at least four thousand little links in a chain of four pendants; which are by this means bound so equally, and withal so firmly together, that the eye is deceived, and takes the whole to consist of one entire piece.

CHAIN is also a kind of measure in France, in the trade of wood for fuel. There are chains for wood by tale, for wood by the rope, for faggots, for cleft wood, and for round sticks. There are also chains for measuring the sheaves of all sorts of corn, particularly with regard to the payment of tithes; for measuring pottles of hay, and for measuring horses. All these are divided into feet, inches, hands, &c. according to the use they are designed for.

CHAIN,

Chain.

CHAIN, in surveying, is a measure, consisting of a certain number of links of iron wire, usually a hundred; serving to take the dimensions of fields, &c. This is what Mersenne takes to be the arvipendium of the ancients.

The chain is of various dimensions, as the length or number of links varies: that commonly used in measuring land, called Gunter's chain, is in length four poles or perches; or sixty-six feet, or a hundred links; each link being seven inches $\frac{92}{100}$. Whence it is easy to reduce any number of those links to feet, or any number of feet to links.

This chain is entirely adapted to English measure; and its chief convenience is in finding readily the numbers contained in a given field. Where the proportions of square feet and acres differ, the chain, to have the same advantage as Gunter's chain, must also be varied. Thus, in Scotland, the chain ought to be of 74 feet, or 24 Scotch ells, if no regard be had to the difference between the Scotch and English foot; but if regard be had to this difference, the Scotch chain ought to consist of $74\frac{1}{3}$ English feet, or 74 feet four inches and $\frac{4}{5}$ of an inch. This chain being divided into an hundred links, each of these will be $\frac{928}{1000}$ inches.

That ordinarily used for large distances, is in length 100 feet; each link one foot. For small parcels, as gardens, &c. is sometimes used a small chain of one pole, or 16 feet and a half length; each link one inch $\frac{98}{100}$.

Some in lieu of chains use ropes; but these are liable to several irregularities, both from the different degrees of moisture, and of the force which stretches them. Schwenterus, in his Practical Geometry, tells us, he has observed a rope sixteen feet long reduced to fifteen in an hour's time, by the mere falling of a hoar-frost. To obviate these inconveniences, Wolfius directs, that the little strands whereof the rope consists be twisted contrariwise, and the rope dipped in boiling hot oil, and when dry, drawn through melted wax. A rope thus prepared will not get or lose any thing in length, even though kept under water all day.

CHAIN-Pump. See PUMP.

CHAIN-Shot, two bullets with a chain between them. They are used at sea to shoot down yards or masts, and to cut the shrouds or rigging of a ship.

Top CHAIN, on board a ship, a chain to sling the sail yards in time of battle, in order to prevent them from falling down when the ropes by which they are hung happen to be shot away or rendered incapable of service.

Plate CXXXVII.

CHAIN Wales, or *Channels*, of a ship, (*porteboissoirs*,) are broad and thick planks projecting horizontally from the ship's outside, abreast of and somewhat behind the masts. They are formed to extend the shrouds from each other, and from the axis or middle line of the ship, so as to give a greater security and support to the masts, as well as to prevent the shrouds from damaging the gunwale, or being hurt by rubbing against it. Every mast has its chain wales, which are either built above and below the second deck ports in a ship of the line; they are strongly connected to the side by knees, bolts, and standards, besides being confined thereto by the chains, whose upper ends pass through notches on the outer edge of the chain wales, so as to unite with the shrouds above.

Cha || Cha

CHAINS, in *Ship-Building*, are strong links or plates of iron, the lower ends of which are bolted through the ship's side to the timbers.

Hanging in CHAINS, a kind of punishment inflicted on murderers. By stat. 25 Geo. II. c. 37. the judge shall direct such to be executed on the next day but one, unless Sunday intervene, and their bodies to be delivered to the surgeons to be dissected and anatomized; and he may direct them afterwards to be hung in chains. During the interval between sentence and execution, the prisoner shall be kept alone, and sustained only with bread and water. The judge, however, hath power to respite the execution, and relax the other restraints of the act.

CHAIN Island, an island lately discovered by Captain Wallis in the South sea. It seemed to be about five miles long and as much broad, lying in the direction of north-west and south-east. It appeared to be a double range of woody islands joined together by reefs, so as to compose one island of an oval figure, with a lake in the middle. The trees are large, and from the smoke that issued from the woods, it appeared to be inhabited. W. Long. 145. 54. S. Lat. 17. 23.

CHAJOTLI, or CHAYOTI, a Mexican fruit of a round shape, and similar in the husk with which it is covered to the chesnut, but four or five times larger, and of a much deeper green colour. Its kernel is of a greenish white, and has a large stone in the middle, which is white, and like it in substance. It is boiled, and the stone eaten with it. This fruit is produced by a twining perennial plant, the root of which is also good to eat.

CHAIR (*Cathedra*), was anciently used for the pulpit, or suggestum, whence the priest spoke to the people.

It is still applied to the place where professors and regents in universities deliver their lectures, and teach the sciences to their pupils; thus, we say, the professor's chair, the doctor's chair, &c.

Curule CHAIR, was an ivory seat placed on a car, wherein were seated the prime magistrates of Rome, and those to whom the honour of a triumph had been granted.

Sedan CHAIR, a vehicle supported by poles, wherein persons are carried; borne by two men. There are 200 chairs allowed by act of parliament; and no person is obliged to pay for a hackney chair more than the rate allowed by the act for a hackney coach driven two-third parts of the said distance. 9 Ann. c. 23. § 8. Their number is since increased by 10 Ann. c. 19. and 12 Geo. I. c. 12. to 400. See *Hackney COACHES*.

CHAIR is also applied by the Romanists to certain feasts, held anciently in commemoration of the translation of the see, or seat, of the vicarage of Christ, by St Peter.

The perforated chair, wherein the new elected pope is placed, F. Mabillon observes, is to be seen at Rome; but the origin thereof he does not attribute, as is commonly done, to the adventure of Pope Joan; but says there is a mystery in it; and it is intended,

tended, forsooth, to explain to the pope those words of Scripture, that *God draws the poor from out of the dust and mire.*

CHAIRMAN, the president, or speaker of an assembly, company, &c. We say, the chairman of a committee, &c.

CHAISE, a sort of light open chariot, or calash.

Aurelius Victor relates, that Trajan first introduced the use of post-chaises; but the invention is generally ascribed to Augustus; and was probably only improved by Trajan and succeeding emperors.

CHALAZA, among naturalists, a white knotty sort of a string at each end of an egg, formed of a plexus of the fibres of the membranes, whereby the yolk and white are connected together.

CHALCAS. See BOTANY *Index*.

CHALCEDON, or CALCEDON, anciently known by the names of *Procerastis* and *Colbusa;* a city of Bithynia, situated at the mouth of the Euxine, on the north extremity of the Thracian Bosphorus, over against Byzantium. Pliny, Strabo, and Tacitus, call it *The city of the Blind;* alluding to the answer which the Pythian Apollo gave to the founders of Byzantium, who, consulting the oracle relative to a place where to build a city, were directed to choose that spot, which lay opposite "to the habitation of the blind;" that is, as was then understood, to Chalcedon; the Chalcedonians well deserving that epithet for having built their city in a barren and sandy soil, without seeing that advantageous and pleasant spot on the opposite shore, which the Byzantines afterwards chose.—Chalcedon, in the Christian times, became famous on account of the council which was held there against Eutyches. The emperor Valens caused the walls of this city to be levelled with the ground, for siding with Procopius, and the materials to be conveyed to Constantinople, where they were employed in building the famous Valentinian aqueduct. Chalcedon is at present a poor place, known to the Greeks by its ancient name, and to the Turks by that of *Cadiaci*, or "the Judges' Town."

CHALCEDONY, in *Natural History*, a genus of the semipellucid gems. They are of an even and regular, not tabulated structure; of a semi-opaque crystalline basis, and variegated with different colours, but those ever disposed in form of mists or clouds, and, if nicely examined, found to be owing to an admixture of various coloured earths, but imperfectly blended in the mass, and often visible in distinct moleculæ. It has been doubted by some whether the ancients were at all acquainted with the stone we call *chalcedony;* they having described a Chalcedonian carbuncle and emerald, neither of which can at all agree with the characters of our stone; but we are to consider that they have also described a Chalcedonian jasper, which seems to have been the very same stone as they describe by the word *turbida*, which extremely well agrees with our chalcedony.

There are four known species of the chalcedony. 1. A bluish white one. This is the most common of all, and is found in the shape of our flints and pebbles, in masses of two or three inches or more in diameter. It is of a whitish colour, with a faint cloud of blue diffused all over it, but always in the greatest degree near the surface. This is a little less hard than the oriental onyx. The oriental chalcedonies are the only ones of any value; they are found in vast abundance on the shores of rivers in all parts of the East Indies, and frequently come over among the ballast of the East India ships. They are common in Silesia and Bohemia, and other parts of Europe also; but with us are less hard, more opaque, and of very little value. 2. The dull milky-veined chalcedony. This is a stone of little value; and is sometimes met with among our lapidaries, who mistake it for a kind of nephritic stone. It is of a somewhat yellowish white or cream colour, with a few milk-white veins. This is principally found in New Spain. 3. The third is a brownish, black, dull, and cloudy one, known to the ancients by the name of smoky jasper, or jaspis capnitis. This is the least beautiful stone of all the class: it is of a pale brownish white, clouded all over with a blackish mist, as the common chalcedony is with a blue. It is common both in the East and West Indies, and in Germany; but is very little valued, and is seldom worked into any thing better than the handles of knives. 4. The yellow and red chalcedony is greatly superior to all the rest in beauty; and is in great repute in Italy, though very little known among us. It is naturally composed of an admixture of red and yellow only, on a clouded crystalline basis; but is sometimes found blended with the matter of common chalcedony, and then is mixed with blue. It is all over of the misty hue of the common chalcedony. This is found only in the East Indies, and there not plentifully. The Italians make it into beads, and call these *cassidonies;* but they are not determinate in the use of the word, but call beads of several of the agates by the same name. All the chalcedonies readily give fire with steel, and make no effervescence with aquafortis.

Chalcedony, Chalcidene.

CHALCIDENE, or CHALCIDICE, in *Ancient Geography*, an inland country of Syria, having Antiochia or Seleucia to the west, Cyrrhestica to the north, to the south Apamene and Cœlosyria, and to the east Chalybonites; being so called from its principal city Chalcis. This province, one of the most fruitful in Syria, was seized by Ptolemy the son of Mennæus, during the troubles of Syria, and by him made a separate kingdom. Ptolemy himself is styled by Josephus and Hegesippus only prince of Chalcis, but his son Lysanias is honoured both by Josephus and Dio with the title of king. Upon the death of Antiochus Dionysius king of Syria, Ptolemy attempted to make himself master of Damascus and all Cœlosyria; but the inhabitants having an utter aversion to him on account of his cruelty and wickedness, chose rather to submit to Aretas king of Arabia, by whom Antiochus and his whole army had been cut off. He opposed Pompey on his entering Syria; but was by him defeated, taken prisoner, and sentenced to death; which, however he escaped by paying a thousand talents, and was left also in possession of his kingdom. After Aristobulus king of Judea had been poisoned by the friends of Pompey, and Alexander his son beheaded at Antioch, he sent Philippion his son to Ascalon, whither the widow of Aristobulus had retired with her other children, to bring them all to Chalcis; proposing, as he was in love with one of the daughters named Alexandra, to maintain them in his own kingdom in a manner suitable to their rank; but Philippion likewise being

ing in love with Alexandra, married her on the way; for which presumption Ptolemy put him to death on his return, and then took her to wife. On account of this affinity, he supported to the utmost of his power Antigonus the younger son of Aristobulus, who took the field at the head of a considerable army, but on his entering Judea was entirely defeated by Herod. Ptolemy soon after died, and was succeeded by his son Lysanias, who, espousing the cause of the Asmonæan family with great warmth, promised to Barzapharnes who commanded the Parthian troops in Syria, and to Pacorus the king's son, a thousand talents and five hundred women, provided they should put Antigonus in possession of the kingdom of Judea, and depose Hyrcanus. He was not long after put to death by Mark Antony, at the instigation of Cleopatra; who, in order to have his dominions, accused him falsely of having entered into an alliance with the Parthians.

CHALCIDIC, Chalcidicum, or Chalcedonium, in the ancient architecture, a large magnificent hall belonging to a tribunal or court of justice. Festus says, it took its name from the city Chalcis; but he does not give the reason. Philander will have it to be the court or tribunal where affairs of money and coinage were regulated; so called from χαλκος, *brass*, and δικη, *justice*. Others say, the money was struck in it; and derive the word from χαλκος, and οικος, *house*. In Vitruvius, it is used for the auditory of a basilica: in others of the ancient writers for a hall or apartment where the heathens imagined their gods to eat.

CHALCIDICE, in *Ancient Geography*, an eastern district of Macedonia, stretching northwards between the Sinus Toronæus and Singiticus. Formerly a part of Thrace, but invaded by Philip of Macedon. Named from the city Chalcis near Olynthus.

CHALCIDIUS, a famous Platonic philosopher in the third century, who wrote a commentary, which is esteemed, on the Timæus of Plato. This work has been translated from the Greek into Latin.

CHALCIS, in *Ancient Geography*, a city of Chalcidice. See Chalcidice. Another of Ætolia, near the mouth of the river Evenus, on the Ionian sea, at the foot of a cognominal mountain; and therefore called by some *Hypochalcis*. Another of Eubœa, (Strabo), on the Euripus, the country of Lycophron the poet, one of the seven which formed the constellation Pleiades. Now *Negroponte*. E. Long. 24. 30. N. Lat. 38. 30. A fourth, the capital of Chalcidene in Syria; distinguished by the name *ad Belum*, a mountain or a river; and *ad Libanum*, from its situation (Pliny).

CHALCITIS, one of the divisions or districts of Mesopotamia, to the south of Anthemusia, the most northern district, next to Armenia, and situated between Edessa and Carræ. *Chalcitis* (Pliny), an island opposite to Chalcedon.

CHALCONDYLAS, Demetrius, a learned Greek, born at Constantinople, left that city after its being taken by the Turks, and afterwards taught Greek in several cities in Italy. He composed a Greek grammar; and died at Milan in 1513.

Chalcondylas, *Laonicus*, a famous Greek historian of the 15th century, was born at Athens; and wrote an excellent history of the Turks, from Ottoman, who reigned about the year 1300, to Mahomet II. in 1453.

CHALDEA, in *Ancient Geography*, taken in a larger sense, included Babylonia; as in the prophecies of Jeremiah and Ezekiel. In a restricted sense, it denoted a province of Babylonia, towards Arabia Deserta; called in Scripture *The land of the Chaldeans*. Named from Chaled the fourth son of Nahor. See Babylonia.

CHALDEE language, that spoken by the Chaldeans or people of Chaldea. It is a dialect of the Hebrew.

Chaldee Paraphrase, in the rabbinical style, is called Targum. There are three Chaldee paraphrases in Walton's Polyglot; viz. that of Onkelos, that of Jonathan son of Uzziel, and that of Jerusalem.

CHALDRON, a dry English measure, consisting of thirty-six bushels, heaped up according to the sealed bushel kept at Guildhall, London; but on shipboard, twenty-one chaldrons of coals are allowed to the score. The chaldron should weigh two thousand pounds.

CHALICE, the cup or vessel used to administer the wine in the sacrament, and by the Roman Catholics in the mass.

The use of the chalice, or communicating in both kinds, is by the church of Rome denied to the laity, who communicate only in one kind, the clergy alone being allowed the privilege of communicating in both kinds.

CHALK (*Creta*), is a white earth found plentifully in Britain, France, Norway, and other parts of Europe, said to have been anciently dug chiefly in the island of Crete, and thence to have received its name of *Creta*. They have a very easy way of digging chalk in the county of Kent in England. It is there found on the sides of hills; and the workmen undermine it so far as appears proper; then digging a trench at the top, as far distant from the edge as the undermining goes at bottom, they fill this with water, which soaks through in the space of a night, upon which the whole flake falls down at once. In other parts of the kingdom, chalk generally lies deeper, and they are forced to dig for it at considerable depths, and draw it up in buckets.

Chalk is of two kinds; hard, dry, and firm, or soft and unctuous; both of which are adapted to various purposes. The hard and dry kind is much the properest for burning into lime; but the soft and unctuous chalk is the best for using as a manure for lands. Chalk, whether burnt into lime or not, is in some cases an excellent manure.

Pure chalk melts easily with alkali and flint into a transparent colourless glass. With alkaline salts it melts somewhat more difficultly, and with borax somewhat more easily than with flint or sand. It requires about half its weight of borax and its whole weight of alkali to fuse it. Sal mirabile, and sandiver, which do not vitrify at all with the crystalline earths, form, with half their weight of chalk, the first a yellowish black, the latter a greenish glass. Nitre, on the other hand, one of the most active fluxes for flint, does not perfectly vitrify with chalk. This earth notably promotes the vitrification of flint; a mixture of the two requiring less alkali than either of them separately. If glass made from flint and alkali is further saturated with the flint, so as to be incapable of bearing

bearing any further addition of that earth without becoming opaque and milky, it will still in a strong fire take up a considerable proportion, one-third or one-fourth of its weight, of chalk, without injury to its transparency: hence chalk is sometimes made use of in compositions for glass, as a part of the salt may then be spared. Chalk likewise has a great effect in melting the stony matters intermixed with metallic ores, and hence might be of use in smelting ores; as indeed limestone is used for that purpose. But it is remarkable, that chalk, when deprived of its fixed air, and converted into limestone, loses much of its disposition to vitrify. It is then found to melt very difficultly and imperfectly, and to render the glass opaque and milky.

Chalk readily imbibes water; and hence masses of it are employed for drying precipitates, lakes, earthy powders that have been levigated with water, and other moist preparations. Its economical uses in cleaning and polishing metalline or glass utensils are well known. In this case it is powdered and washed from any gritty matter it may contain, and is then called *whiting*.—In medicine it is one of the most useful absorbents, and is to be looked upon simply as such. The astringent virtues which some have attributed to it have no foundation, unless in as far as the earth is saturated with an acid, with which it composes a saline concrete manifestly subastringent. For the further properties of chalk, see CHEMISTRY *Index*.

Black CHALK, a name given by painters to a species of earth with which they draw on blue paper, &c. It is found in pieces from two to ten feet long, and from four inches to twenty in breadth, generally flat, but somewhat rising in the middle, and thinner towards the edges, commonly lying in large quantities together. While in the earth, it is moist and flaky: but being dried, it becomes considerably hard and very light, but always breaks in some particular direction; and if attentively examined when first broken, appears of a striated texture. To the touch it is soft and smooth, stains very freely, and by virtue of its smoothness makes very neat marks. It is easily reduced into an impalpable soft powder, without any diminution of its blackness. In this state it mixes easily with oil into a smooth paste; and being diffused through water, it slowly settles in a black slimy or muddy form; properties which make its use very convenient to the painters, both in oil and water colours. It appears to be an earth quite different from common chalk, and rather of the slaty bituminous kind. In the fire it becomes white with a reddish cast, and very friable, retaining its flaky structure, and looking much like the white flaky masses which some sorts of pitcoal leave in burning. Neither the chalk nor these ashes are at all affected by acids.

The colour shops are supplied with this earth from Italy or Germany; though some parts of England afford substances nearly, if not entirely, of the same quality, and which are found to be equally serviceable both for marking and as black paints. Such particularly is the black earth called *killow*, said by Dr Merret, in his *Pinax Rerum Britannicarum*, to be found in Lancashire, and by Mr Da Costa, in his History of Fossils, to be plentiful near the top of Cay-Avon, a high hill in Merionethshire.

Red CHALK, an earth much used by painters and artificers, and common in the colour shops. It is properly an indurated clayey ochre, and is dug in Germany, Italy, Spain, and France, but in greatest quantity in Flanders. It is of a fine, even, and firm texture; very heavy, and very hard; of a pale red on the outside, but of a deep dusky chocolate colour within. It adheres firmly to the tongue, is perfectly insipid to the taste, and makes no effervescence with acids.

CHALK *Land*. Barley and wheat will succeed very well on the better sort of chalky land, and oats generally do well on any kind of it. The natural produce of this sort of land in weeds, is that sort of small vetch called the *tine-tare*, with poppies, may-weed, &c. Sainfoil and hope-clover will generally succeed tolerably well on these lands; and where they are of a better sort, the great clover will do. The best manure is dung, old rags, and the sheep dung left after folding them.

CHALK-*Stones*, in *Medicine*, signify the concretions of calcareous matter in the hands and feet of people violently afflicted with the gout. Leeuwenhoek has been at the pains of examining these by the microscope. He divides them into three parts. The first is composed of various small parcels of matter looking like white grains of sand; this is harder and drier, and also whiter, than the rest. When examined with large magnifiers, those are found to be composed of oblong particles laid closely and evenly together: though the whole small stones are opaque, these component parts of them are pellucid, and resemble pieces of horse-hair cut short, only that they are somewhat pointed at both ends. These are so extremely thin, that Mr Leeuwenhoek computes that 1000 of them placed together would not amount to the size of one hair of our heads. The whole stones in this harder part of the chalk are not composed of these particles, but there are confusedly thrown in among them some broken parts of other substances, and in a few places some globules of blood and small remains of other juices. The second kind of chalky matter is less hard and less white than the former, and is composed of fragments or irregular parts of those oblong bodies which compose the first or hardest kind, and these are mixed among tough and clear matter, and interspersed with the small broken globules of blood discoverable in the former, but in much greater quantity. The third kind appears red to the naked eye; and, when examined with glasses, is found to be a more tough and clammy white matter, in which a great number of globules of blood are interspersed; these give it the red appearance it has.

CHALLENGE, a cartel or invitation to a duel or other combat *. A challenge either by word or letter, or to be the bearer of such a challenge, is punishable by fine and imprisonment on indictment or information.

* See *Duel*.

CHALLENGE, among hunters. When hounds or beagles, at first finding the scent of their game, presently open and cry, they are said to challenge.

CHALLENGE, in the *Law of England*, is an exception made to jurors †; and is either in civil or criminal cases.

† See the article *Trial*.

1. In *civil* cases challenges are of two sorts; challenges to the array, and challenges of the poll.

Challenge. 1. Challenges to the array are at once an exception to the whole panel, in which the jury are arrayed, or set in order by the sheriff in his return; and they may be made upon account of partiality or some default in the sheriff or his under-officer who arrayed the panel. Also, though there be no personal objection against the sheriff, if yet he arrays the panel at the nomination, or under the direction of either party, this is good cause of challenge to the array. Formerly, if a lord of parliament had a cause to be tried, and no knight was returned upon the jury, it was a canse of challenge to the array; also by the policy of the ancient law, the jury was to come *de vicineto*, from the neighbourhood of the vill or place where the cause of action was laid in the declaration: and therefore some of the jury were obliged to be returned from the hundred in which such vill lay; and, if more were returned, the array might be challenged from defect of hundreders. For, living in the neighbourhood, these were supposed to know beforehand the characters of the parties and witnesses; and therefore they better knew what credit to give to the facts alleged in evidence. But this convenience was overbalanced by another very natural and almost unavoidable inconvenience; that jurors, coming out of the immediate neighbourhood, would be apt to intermix their prejudices and partialities in the trial of right. And this the law was so sensible of, that it for a long time has been gradually relinquishing this practice; the number of necessary hundreders in the whole panel, which in the reign of Edward III. was constantly six, being in the time of Fortescue reduced to four; afterwards by statute 26 Eliz. c. 6. to two; and at length, by statute 4 and 5 Anne, c. 16. it was entirely abolished upon all civil actions, except upon penal statutes, and upon those also by the 24 Geo. II. c. 18. the jury being now only to come *de corpore comitatus*, from the body of the country at large, and not *de vicineto*, or from the particular neighbourhood. The array by the ancient law may be also challenged, if an alien be party to the suit, and upon a rule obtained by his motion to the court for a jury *de medietate linguæ*, such a one be not returned by the sheriff pursuant to the statute 28 Edward III. c. 13. enforced by 8 Hen. VI. c. 29. which enacts, that where either party is an alien born, the jury shall be one half denizens and the other aliens (if so many be forthcoming in the place), for the more impartial trial; a privilege indulged to strangers in no other country in the world; but which is as ancient in England as the time of King Ethelred, in whose statute *de monticolis Walliæ* (then aliens to the crown of England), c. 3. it is ordained, that "duodeni legales homines, quorum sex Walli et sex Angli erunt, Anglis et Wallis jus dicunto."

2. Challenges to the polls, *in capita*, are exceptions to particular jurors; and seem to answer to the *recusatio judicis* in the civil and canon laws; by the constitutions of which a judge might be refused upon any suspicion of partiality. By the laws of England also, in the times of Bracton and Fleta, a judge might be refused for good cause; but now the law is otherwise, and it is held that judges or justices cannot be challenged. For the law will not suppose a possibility of bias or favour in a judge who is already sworn to administer impartial justice, and whose authority greatly depends on that presumption and idea. And, should the fact at any time prove flagrantly such, as the delicacy of the law will not presume beforehand, there is no doubt but that such misbehaviour would draw down a heavy censure from those to whom the judge is accountable for his conduct. But challenges to the polls of the jury (who are judges of fact) are reduced to four heads by Sir Edward Coke: *propter honoris respectum; propter defectum; propter affectum;* and *propter delictum.* 1. *Propter honoris respectum;* as, if a lord of parliament be impannelled on a jury, he may be challenged by either party, or he may challenge himself. 2. *Propter defectum;* as, if a juryman be an alien born, this is defect of birth; if he be a slave or bondman, it is defect of liberty, and he cannot be a *liber et legalis homo.* Under the word *homo* also, though a name common to both sexes, the female is however excluded, *propter defectum sexus:* except when a widow feigns herself with child in order to exclude the next heir, and a supposititious birth is suspected to be intended; then upon the writ *de ventre inspiciendo,* a jury of women is to be impannelled to try the question whether with child or not. But the principal deficiency is defect of estate sufficient to qualify him to be a juror, which depends upon a variety of statutes*. 3. Jurors may be challenged *propter affectum,* for suspicion of bias or partiality. This may be either a principal challenge, or to the favour. A *principal* challenge is such, where the cause assigned carries with it, *prima facie,* evident marks of suspicion either of malice or favour; as, that a juror is of kin to either party within the ninth degree; that he has an interest in the cause; that there is an action depending between him and the party; that he has taken money for his verdict, &c. which if true cannot be overruled; for jurors must be *omni exceptione majores.* Challenges *to the favour* are where the party hath no principal challenge; but objects only some probable circumstances of suspicion, as acquaintance, and the like; the validity of which must be left to the determination of *triors,* whose office is to decide whether the juror be favourable or unfavourable. 4. Challenges *propter delictum,* are for some crime or misdemeanour that affects the juror's credit, and renders him infamous: As for a conviction of treason, felony, perjury, or conspiracy; or if for some infamous offence, he hath received judgment of the pillory or the like.

* See Blackst. Commen iii. 362.

II. In *criminal* cases, challenges may be made either on the part of the king, or on that of the prisoner; and either to the whole array, or to the separate polls, for the very same reasons that they may be in civil causes. For it is here at least as necessary as there, that the sheriff or returning officer be totally indifferent; that, where an alien is indicted, the jury should be *de medietate,* or half foreigners, if so many are found in the place (which does not indeed hold in treasons, aliens being very improper judges of the breach of allegiance; nor yet in the caso of Egyptians under the statute 22 Hen. VIII. c. 10.); that on every panel there should be a competent number of hundreders; and that the particular jurors should be *omni exceptione majore,* not liable to objections either *propter honoris respectum, propter defectum, propter affectum,* or *propter delictum.*

Challenges

Challenge || Chaloner.

Challenges on any of the foregoing accounts are styled challenges *for cause;* which may be without stint in both civil and criminal trials. But in criminal cases, or at least in capital ones, there is, *in favorem vitæ*, allowed to the prisoner an arbitrary and capricious species of challenge to a certain number of jurors, without showing any cause at all; which is called a peremptory challenge: a provision full of tenderness and humanity to prisoners for which our laws are justly famous. This is grounded on two reasons: 1. As every one must be sensible what sudden impressions and unaccountable prejudices we are apt to conceive upon the bare looks and gestures of another; and how necessary it is that a prisoner, when put to defend his life, should have a good opinion of his jury, the want of which might totally disconcert him; the law wills not that he should be tried by any one man against whom he has conceived a prejudice, even without being able to assign a reason for such his dislike. 2. Because upon challenges for cause shown, if the reason assigned prove insufficient to set aside the juror, perhaps the bare questioning his indifference may sometimes provoke a resentment; to prevent all ill consequences from which, the prisoner is still at liberty, if he pleases, peremptorily to set him aside.

This privilege of peremptory challenges, though granted to the prisoner, is denied to the king by the statute 33 Edward I. stat. 4. which enacts, that the king shall challenge no jurors without assigning a cause certain, to be tried and approved by the court. However, it is held that the king need not assign his cause of challenge till all the panel is gone through, and unless there cannot be a full jury without the persons so challenged. And then, and not sooner, the king's counsel must show the cause, otherwise the juror shall be sworn.

The peremptory challenges of the prisoner must, however, have some reasonable boundary, otherwise he might never be tried. This reasonable boundary is settled by the common law to the number of 35; that is, one under the number of three full juries. For the law judges, that 35 are fully sufficient to allow the most timorous man to challenge through mere caprice; and that he who peremptorily challenges a greater number, or three full juries, has no intention to be tried at all. And therefore it deals with one who peremptorily challenges above 35, and will not retract his challenge, as with one who stands mute or refuses his trial; by sentencing him to the *pein forte et dure* in felony, and by attainting him in treason. And so the law stands at this day with regard to treason of any kind. But by statute 22 Hen. VIII. c. 14. (which, with regard to felonies, stands unrepealed), no person arraigned for felony can be admitted to make more than 20 peremptory challenges.

CHALONS-SUR-SAONE, a ancient town of France, in Burgundy, and capital of the Chalonnois, with a citadel and bishop's see. It is seated on the river Saone, in E. Long. 5. 7. N. Lat. 46. 47.

CHALONS-sur-Marne, a large episcopal town of France, in Champagne. It carries on a considerable trade in shalloons and other woollen stuffs. It is seated between two fine meadows on the rivers Marne, Mau, and Nau, in E. Long. 4. 37. N. Lat. 48. 57.

CHALONER, SIR THOMAS, a statesman, soldier, and poet, descended from a good family in Denbigh in Wales, was born at London about the year 1515. Having been educated in both universities, but chiefly at Cambridge, he was introduced at the court of Henry VIII. who sent him abroad in the retinue of Sir Henry Knevet, ambassador to Charles V. and he had the honour to attend that monarch on his fatal expedition against Algiers in 1541. Soon after the fleet left that place, he was shipwrecked on the coast of Barbary in a very dark night: and having exhausted his strength by swimming, he chanced to strike his head against a cable, which he had the presence of mind to catch hold of with his teeth; and, with the loss of several of them, was drawn up by it into the ship to which he belonged. Mr Chaloner returned soon after to England, and was appointed first clerk of the council, which office he held during the rest of that reign. On the accession of Edward VI. he became a favourite of the duke of Somerset, whom he attended to Scotland, and was knighted by that nobleman after the battle of Musselburgh, in 1547. The protector's fall put a stop to Sir Thomas Chaloner's expectations, and involved him in difficulties. During the reign of Queen Mary, being a determined Protestant, he was in some danger; but having many powerful friends, he had the good fortune to escape. On the accession of Queen Elizabeth, he appeared again at court; and was so immediately distinguished by her majesty, that she appointed him ambassador to the emperor Ferdinand I. being the first ambassador she nominated. His commission was of great importance; and the queen was so well satisfied with his conduct, that soon after his return, she sent him in the same capacity to Spain; but Sir Thomas was by no means satisfied with this instance of her majesty's confidence: the courts of England and Spain being at this time extremely dissatisfied with each other, he foresaw that his situation would be very disagreeable, and so it proved; but Elizabeth must be obeyed. He embarked for Spain in 1561, and returned to London in 1564, in consequence of a request to his sovereign, in an elegy written in imitation of Ovid. After his return, he resided in a house built by himself in Clerkenwell close, where he died in the year 1565, and was buried in St Paul's. Sir William Cecil assisted as chief mourner at his funeral.

So various were the talents of Sir Thomas Chaloner, that he excelled in every thing to which he applied himself. He made a considerable figure as a poet. His poetical works were published by William Malim, master of St Paul's school, in 1579. His capital work was that "Of restoring the English republic, in ten books," which he wrote when he was ambassador in Spain. It is remarkable, that this great man, who knew how to transact as well as write upon the most important affairs of states and kingdoms, could descend to compose a *dictionary for children*, and to translate from the Latin a book *Of the office of Servants*, merely for the utility of the subjects.

CHALONER, *Sir Thomas*, the younger, though inconsiderable as an author, deserved to be recorded as a skilful naturalist, in an age wherein natural history was very little understood in this or any other country; and particularly as the founder of the alum works in Yorkshire, which have since proved so exceedingly advantageous

vantageous to the commerce of this kingdom. He was the only son of Sir Thomas Chaloner mentioned in the last article, and was born in the year 1559. Being very young at the time of his father's death, the lord treasurer Burleigh, taking charge of his education, sent him to St Paul's school, and afterwards to Magdalen college in Oxford, where, like his father, he discovered extraordinary talents for Latin and English poetry. About the year 1580, he made the tour of Europe, and returned to England before 1584; for in that year, we find him a frequent attendant in the court of Queen Elizabeth. About this time he married the daughter of Sir William Fleetwood, recorder of London. In 1591 he was knighted; and, some time after, discovered the alum mines on his estate at Gisborough, near the river Tees in Yorkshire (A).

Towards the latter end of the queen's reign, Sir Thomas visited Scotland; and returning to England in the retinue of King James I. found such favour in the sight of his majesty, that he was immediately appointed governor to Prince Henry, whom he constantly attended, and, when his royal pupil visited Oxford, was honoured with the degree of master of arts. How he was employed after the death of the prince is not known. Some years before that event, he married a second wife, the daughter of Mr William Blount of London, by whom he had some children. He died in the year 1615, and was buried at Chiswick in Middlesex. His eldest son William was created a baronet in 18th of James, anno 1640. The title was extinct in 1681. He wrote, 1. Dedication to Lord Burleigh of his father's poetical works, dated 1579. 2. The virtue of nitre, wherein is declared the sundry cures by the same effected. Lond. 1584, 4to.

CHALYBEAT, in *Medicine*, an appellation given to any liquid, as wine or water, impregnated with particles of iron or steel. See MINERAL WATERS.

CHALYBES, in *Ancient Geography*, an ancient people of the Hither Asia. Their situation is differently assigned: Strabo placing them in Paphlagonia, to the east of Synope; Apollonius Rhodius and Stephanus, on the east of the Thermodon, in Pontus; called *Halizones*, by Homer. They either gave their name to, or took it from, their iron manufactures (Xenophon, Val. Flaccus), their only support, their soil being barren and ungrateful, (Dionysius Periegetes).

CHAM, or KHAN, the title given to the sovereign princes of Tartary.

The word, in the Persian, signifies *mighty lord;* in the Sclavonic, *emperor.* Sperlingius, in his dissertation on the Danish term of *majesty, koning, king*, thinks the Tartarian *cham* may be well derived from it; adding, that in the north they say *kan, konnen, konge, konning*, &c. The term *cham* is also applied, among the Persians, to the great lords of the court, and the governors of provinces.

CHAM, in *Geography*, a town of the Bavarian palatinate, situated on a river of the same name, about 25 miles north-east of Ratisbon. E. Long. 13. N. Lat. 49. 15.

CHAMA, in *Zoology*, a genus of shell fish belonging to the order of vermes testaceæ. The shell is thick, and has two valves; it is an animal of the oyster kind. Linnæus enumerates 14 species, principally distinguished by the figure of their shells.

CHAMADE, in *War*, a certain beat of a drum, or sound of a trumpet, which is given the enemy as a signal to inform them of some propositions to be made to the commander, either to capitulate, to have leave to bury their dead, make a truce, or the like. Menage derives the word from the Italian *chiamata*, of *clamare*, "to cry."

CHAMÆDRYS. See VERONICA, BOTANY *Index*.

CHAMÆPITHYS. See TEUCRIUM, BOTANY *Index*.

CHAMÆROPS. See BOTANY *Index*.

This plant the Americans call *thatch*, from the use to which the leaves are applied.—Under the name of palmetto, however, Mr Adanson describes a species of palm which grows naturally at Senegal, whose trunk rises from 50 to 60 feet in height: from the upper end of the trunk issues a bundle of leaves, which, in turning off, form a round head: each leaf represents a fan of five or six feet in expansion, supported by a tail of the same length. Of these trees some produce male flowers, which are consequently barren; others are female, and loaded with fruit, which succeed each other uninterruptedly almost the whole year round. The fruit of the large palmettos, Mr Adanson affirms to be of the bigness of an ordinary melon, but rounder; it is enveloped in two skins, as tough as leather, and as thick as strong parchment; within the fruit is yellowish, and full of filaments, fastened to three large kernels in the middle. The negroes are very fond of this fruit, which, when baked under the ashes, is said to taste like a quince.

CHAMANIM, in the Jewish antiquities, is the Hebrew name for that which the Greeks call *Pyreia* or *Pyrateria;* and St Jerome in Leviticus has translated *simulachra*, in Isaiah, *delubra*. These chamanim were, according to Rabbi Solomon, idols exposed to the sun upon the tops of houses. Abenezoa says they were portable chapels or temples made in the form of chariots, in honour of the sun. What the Greeks call Pyreia were temples consecrated to the sun and fire, wherein a perpetual fire was kept up. They were built upon eminences; and were large enclosures without

(A) Sir Thomas, during his residence in Italy, being particularly fond of natural history, spent some time at Puzzoli, where he was very attentive to the art of producing alum. This attention proved infinitely serviceable to his country, though of no great benefit to himself or his family, his attempt being attended with much difficulty and expence. It was begun about the year 1600, in the reign of Queen Elizabeth; but was not brought to any degree of perfection till some time in the reign of Charles I. by the assistance of one Russel a Walloon, and two other workmen brought from the alum works at Rochelle. By one of the arbitrary acts of Charles, it was then deemed a mine royal, and granted to Sir Paul Pindar. The long parliament adjudged it a monopoly, and justly restored it to the original proprietors.

Chamanim ‖ Chamber.

out covering, where the sun was worshipped. The Guebres, or worshippers of fire, in Persia and the East Indies, have still these Pyreia. The word *chamanim* is derived from *chaman*, which signified to warm or burn.

CHAMARIN, a word which occurs in several places of the Hebrew Bible, and is generally translated the *priests of the idols*, or the *priests clothed in black*, because *chamar* signifies "black," or "blackness." St Jerome, in the second book of Kings, renders it *aruspices*. In Hosea and Zephaniah, he translates it *œditui* or church-wardens. But the best commentators are of opinion, that by this word we are to understand the priests of the false gods, and in particular the worshippers of fire: because they were, as they say, dressed in black; or perhaps the Hebrews gave them this name in derision, because, as they were continually employed in taking care about the fuel, and keeping up the fire, they were always as black as smiths or colliers. We find priests, among those of Isis, called *melanephori*, that is to say, that wear black; but whether this may be by reason of their dressing in black, or whether it were because they wore a certain shining black veil in the processions of this goddess, is not certain. *Camar*, in Arabic, signifies the "moon." Isis is the same deity. Grotius thinks the Roman priests, called *camilli*, came from the Hebrew *chamarin*. Those among the heathens who sacrificed to the infernal gods were dressed in black.

CHAMBER, in building, a member of a lodging, or piece of an apartment, ordinarily intended for sleeping in; and called by the Latins *cubiculum*. The word comes from the Latin *camera*; and that, according to *Nicod*, from the Greek καμαρα, *vault* or *curve*; the term *chamber* being originally confined to places arched over.

A complete apartment is to consist of a hall, antichamber, *chamber*, and cabinet.

Privy CHAMBER. Gentlemen of the privy chamber are servants of the king, who are to wait and attend on him and the queen at court, in their diversions, &c. Their number is forty-eight, under the lord chamberlain, twelve of whom are in quarterly waiting, and two of these lie in the privy chamber.

In the absence of the lord chamberlain, or vice chamberlain, they execute the king's orders: at coronations, two of them personate the dukes of Aquitain and Normandy; and six of them, appointed by the lord chamberlain, attend ambassadors from crowned heads to their audiences, and in public entries. The gentlemen of the privy chamber were instituted by Henry VII.

CHAMBER, in policy, the place where certain assemblies are held; also the assemblies themselves. Of these some are established for the administration of justice, others for commercial affairs.

Of the first kind are, 1. Star chamber, so called because the roof was painted with stars; the authority, power, and jurisdiction of which, are absolutely abolished by the statute 17 Car. I. 2. Imperial chamber of Spire, the supreme court of judicatory in the empire, erected by Maximilian I. This chamber has a right of judging by appeal; and is the last resort of all civil affairs of the states and subjects of the empire, in the same manner as the aulic council of Vienna. Nevertheless it is restrained in several cases: it takes no notice of matrimonial causes, these being left to the pope; nor of criminal causes, which either belong to particular princes of towns in their respective territories, or are cognizable by all the states of the empire in a diet. By the treaty of Osnaburg, in 1648, fifty assessors were appointed for this chamber, whereof 24 were to be Protestants, and 26 Catholics; besides five presidents, two of them Protestants, and the rest Catholics. 3. Chamber of accounts, a sovereign court in France, where accounts are rendered of all the king's revenues, inventories and avowals thereof registered, oaths of fidelity taken, and other things relating to the finances transacted. There are nine in France: that of Paris is the chief; it registers proclamations, treaties of peace, naturalizations, titles of nobility, &c. All the members wear long black gowns of velvet, of satin, or damask, according to their places. 4. Ecclesiastical chambers in France, which judge by appeal of differences about collecting the tythes. 5. Chamber of audience, or grand chamber, a jurisdiction in each parliament of France, the counsellors of which are called *jugeurs*, or judges, as those of the chamber of inquests are called *raporteurs*, reporters of processes by writing. 6. Chamber of the edict, or miparty, a court established by virtue of the edict of pacification in favour of those of the reformed religion. This chamber is now suppressed. 7. Apostolical chamber of Rome, that wherein affairs relating to the revenues of the church and the pope are transacted. This council consists of the cardinal camerlinga, the governor of the rota, a treasurer, an auditor, a president, one advocate-general, a solicitor-general, a commissary, and twelve clerks. 8. Chamber of London, an apartment in Guildhall, where the city-money is deposited.

Of the last sort are, the chambers of commerce; the chambers of assurance; and the royal or syndical chamber of booksellers in France.

1. The chamber of commerce is an assembly of merchants and traders, where the affairs relating to trade are treated of. There are several established in most of the chief cities of France; and in our own country we have lately seen chambers of this kind erected, particularly in London, Edinburgh, and Glasgow. 2. Chamber of assurance, in France, denotes a society of merchants and others for carrying on the business of insuring: but in Holland it signifies a court of justice, where causes relating to insurances are tried. 3. Chamber of booksellers in Paris, an assembly consisting of a syndic and assistants, elected by four delegates from the printers, and twelve from the booksellers, to visit the books imported from abroad, and to search the houses of sellers of marble paper, printsellers, and dealers in printed paper for hangings, who are prohibited from keeping any letters proper for printing books. In the visitation of books, which ought to be performed by three persons at least from among the syndic and assistants, all libels against the honour of God, and the welfare of the state, and all books printed either within or without the kingdom in breach of their regulations and privileges, are stopt, even with the merchandises that may happen to be in the bales with such libels or other prohibited books.

The

The days appointed for this chamber to meet are Tuesdays and Fridays, at two o'clock in the afternoon.

CHAMBER, in military affairs. 1. Powder chamber, or bomb chamber; a place sunk under ground for holding the powder, or bombs, where they may be out of danger, and secured from the rain. 2. Chamber of a mine; the place, most commonly of a cubical form, where the powder is confined. 3. Chamber of a mortar; that part of the chase, much narrower than the rest of the cylinder, where the powder lies. It is of different forms; sometimes like a reversed cone; sometimes globular, with a neck for its communication with the cylinder, whence it is called a bottled chamber; but most commonly cylindrical, that being the form which is found by experience to carry the ball to the greatest distance.

CHAMBERLAIN, an officer charged with the management and direction of a chamber. See CHAMBER in *Policy*.

There are almost as many kinds of chamberlains as chambers; the principal whereof are as follows:

Lord CHAMBERLAIN *of Great Britain*, the sixth great officer of the crown; to whom belong livery and lodging in the king's court; and there are certain fees due to him from each archbishop or bishop when they perform their homage to the king, and from all peers at their creation or doing their homage. At the coronation of every king, he is to have forty ells of crimson velvet for his own robes. This officer, on the coronation day, is to bring the king his shirt, coif, and wearing clothes; and after the king is dressed, he claims his bed, and all the furniture of his chamber, for his fees: he also carries, at the coronation, the coif, gloves, and linen, to be used by the king on that occasion; also the sword and scabbard; the gold to be offered by the king, and the robes royal and crown: he dresses and undresses the king on that day, waits on him before and after dinner, &c. To this officer belongs the care of providing all things in the house of lords, in the time of parliament; to him also belongs the government of the palace of Westminster; he disposes likewise of the sword of state, to be carried before the king, to what lord he pleases.

The great chamberlain of Scotland was ranked by King Malcolm, as the third great officer of the crown, and was called *Camerarius Domini Regis*. Before a treasurer was appointed, it was his duty to collect the revenue of the crown; and he disbursed the money necessary for the king's expences, and the maintenance of the king's household. From the time that a treasurer was appointed, his province was limited to the boroughs throughout the kingdom, where he was a sort of justice general, as he had a power for judging of all crimes committed within the borough, and of the crime of forestalling. He was to hold chamberlain ayres every year. He was supreme judge: nor could any of his decrees be questioned by any inferior judicatory. His sentences were put in execution by the magistrates of the boroughs. He also regulated the price of provisions within the borough, and the fees of the workmen in the mint house. His salary, was only 200l. a-year. The smallness of his salary, and his great powers, had no doubt been the causes much oppression in this officer, and the chamberlain ayre was called rather a legal robbery than a court of justice; and when the combined lords seized King James VI. August 24. 1582, and carried him to Ruthven Castle, they issued a proclamation in the king's name, discharging the chamberlain ayres to be kept. The chamberlain had great fees arising from the profits of escheats, fines, tolls, and customs. This office was granted heritably to the family of Stuart duke of Lenox: and when their male line failed, King Charles II. conferred it in like manner upon his natural son, whom he created duke of Monmouth, and on his forfeiture it went to the duke of Lenox; but that family surrendered the office to the crown in 1703.

Lord CHAMBERLAIN *of the Household*, an officer who has the oversight and direction of all officers belonging to the king's chambers, except the precinct of the king's bedchamber.

He has the oversight of the officers of the wardrobe at all his majesty's houses, and of the removing wardrobes, or of beds, tents, revels, music, comedians, hunting, messengers, &c. retained in the king's service. He moreover has the oversight and direction of the serjeants at arms, of all physicians, apothecaries, surgeons, barbers, the king's chaplains, &c. and administers the oath to all officers above stairs.

Other chamberlains are those of the king's court of exchequer, of North Wales, of Chester, of the city of London, &c. in which case this officer is generally the receiver of all rents and revenues belonging to the place whereof he is chamberlain.

In the exchequer there are two chamberlains, who keep a controlment of the pells of receipts and exitus, and have certain keys of the treasury, records, &c.

CHAMBERLAIN *of London* keeps the city money, which is laid up in the chamber of London: he also presides over the affairs of masters and apprentices, and makes free of the city, &c.

His office lasts only a year; but the custom usually obtains to re-choose the same person, unless charged with any misdemeanour in his office.

CHAMBERLAYNE, EDWARD, descended from an ancient family, was born in Gloucestershire, 1616, and made the tour of Europe during the distractions of the civil war. After the Restoration, he went as secretary with the earl of Carlisle, who carried the order of the Garter to the king of Sweden; was appointed tutor to the duke of Grafton, natural son of Charles II. and was afterwards pitched on to instruct Prince George of Denmark in the English tongue. He died in 1703, and was buried in a vault in Chelsea churchyard: his monumental inscription mentions six books of his writing; and that he was so desirous of doing service to posterity, that he ordered some copies of his books to be covered with wax, and buried with him. That work by which he is best known, is his *Angliæ Notitiæ*, or *the Present State of England*, which has been often since printed.

CHAMBERLAYNE, *John*, son to the author of "The Present State of England," and continuator of that useful work, was admitted into Trinity College, Oxford, 1685; but it doth not appear that he took any degree. Beside the *Continuation* just mentioned, he was author of "Dissertations, historical, critical, theological, and moral, on the most memorable events of the Old and New Testaments, with Chronological Tables;" one vol.

vol. folio; and translated a variety of works from the French, Dutch, and other languages. He likewise was F. R. S. and communicated some pieces, inserted in the Philosophical Transactions. It was said of him that he understood sixteen languages; but it is certain that he was master of the Greek, Latin, French, High and Low Dutch, Portugnese, and Italian. Though he was qualified for employment, he had none but that of gentleman-usher to George prince of Denmark. After a useful and well-spent life, he died in the year 1724. He was a very pious and good man, and earnest in promoting the advancement of religion, and the interest of true Christianity; for which purpose he kept a large correspondence abroad.

CHAMBERRY, a considerable and popnlous town of Italy, in Savoy, with a castle. It is capital of the duchy, and well built, but has no fortifications. It is watered by several streams, which have their sources in St Martin's hill, and run through several of the streets. There are piazzas under most part of the houses, where people may walk dry in the worst weather. It hath large and handsome suburbs; and in the centre of the town is the royal palace. The parliament meets here, which is composed of four presidents, and a pretty large number of senators, being the supreme tribunal of the whole duchy. The population in 1815 was 11,763. The Jesuits college is the most magnificent of all the monasteries. E. Long. 5. 50. N. Lat. 45. 25.

CHAMBERS, David, a Scots historian, priest, and lawyer, was born in the shire of Ross, about the year 1530, and educated in the university of Aberdeen. From thence he went to France and Italy, where he continued some time, particularly at Boulogne, where, in 1556, he was a pupil of Marianus Sozenus.

After his return to Scotland, he was appointed, by Queen Mary, parson of Suddy and chancellor of Ross. He was soon after employed in digesting the laws of Scotland, and was principally concerned in publishing the acts of parliament of that kingdom by authority in 1566. He was also appointed one of the lords of session, and continued her majesty's faithful servant till her declining fortune obliged her adherents to seek for refuge in other kingdoms. Chambers went first to Spain, where he was graciously received by King Philip; and thence he travelled to Paris, where he was no less kindly received by Charles IX. of that kingdom, to whom, in 1572, he presented his history of Scotland, &c. He died at Paris in the year 1592, much regretted (says Mackenzie) by all who knew him. His writings were chiefly calculated to assist his royal mistress, and to extol the wisdom of the Scots nation.

Chambers, *Ephraim*, author of the Scientific Dictionary which goes under his name, was born at Milton, in the county of Westmoreland. His parents were dissenters of the Presbyterian persuasion, and his education no other than that common one which is intended to qualify a youth for trade and commerce. When he became of a proper age, he was put apprentice to Mr Senex the globe-maker, a business which is connected with literatnre, and especially with astronomy and geography. It was during Mr Chambers's residence with this skilful mechanic, that he contracted that taste for science and learning which accompanied him through life, and directed all his pursuits. It was even at this time that he formed the design of his grand work, the "Cyclopædia;" and some of the first articles of it were written behind the counter. Having conceived the idea of so great an undertaking, he justly concluded that the execution of it would not consist with the avocations of trade; and therefore he quitted Mr Senex, and took chambers at Gray's Inn, where he chiefly resided during the rest of his days. The first edition of the *Cyclopædia*, which was the result of many years intense application, appeared in 1728, in two vols. folio. It was published by subscription, the price being 4l. 4s.; and the list of subscribers was very respectable. The dedication, which was to the king, is dated October 15. 1727. The reputation that Mr Chambers acquired by his execution of this undertaking, procured him the honour of being elected F. R. S. November 6. 1729. In less than 10 years time a second edition became necessary; which accordingly was printed, with corrections and additions, in 1738; and was followed by a third the very next year.

Although the Cyclopædia was the grand business of Mr Chambers's life, and may be regarded as almost the sole foundation of his fame, his attention was not wholly confined to this undertaking. He was concerned in a periodical publication, entitled, "The Literary Magazine," which was begun in 1735. In this work he wrote a variety of articles, and particularly a review of Morgan's "Moral Philosophy." He was engaged likewise, in conjunction with Mr John Martyn, F. R. S. and professor of botany at Cambridge, in preparing for the press a translation and abridgment of the "Philosophical History and Memoirs of the Royal Academy of Sciences at Paris, or an Abridgment of all the Papers relating to Natural Philosophy, which have been published by the Members of that illustrious Society." This undertaking, when completed, was comprised in five volumes, 8vo, which did not appear till 1742, some time after our author's decease, when they were published under the joint names of Mr Martyn and Mr Chambers. Mr Martyn, in a subsequent publication, had passed a severe censure upon the share which his fellow-labourer had in the abridgment of the Parisian papers. The only work besides, that we find ascribed to Mr Chambers, is a translation of the *Jesuit's Perspective*, from the French; which was printed in 4to, and hath gone through several editions. Mr Chambers's close and unremitting attention to his studies at length impaired his health, and obliged him occasionally to take a lodging at Canonbury-house, Islington. This not having greatly contributed to his recovery, he made an excursion to the south of France, but did not reap that benefit from it which he had himself hoped and his friends wished. Returning to England, he died at Canonbury-house, and was buried at Westminster; where the following inscription, written by himself, is placed on the north side of the cloisters of the Abbey:

Multis pervulgatis,
Paucis notus;
Qui vitam, inter lucem et umbram,
Nec eruditus, nec idiota,

Literis deditus, transegit; sed ut homo
Qui humani nihil a se alienum putat.
Vita simul, et laboribus functus,
Hic requiescere voluit,
Ephraim Chambers, R. S. S.
Obiit xv Maii. MDCCXL.

After the author's death two more editions of his Cyclopædia were published. A supplement, which extended to two volumes more, was afterwards compiled; and in the year 1778 was published an edition of both, incorporated into one alphabet, by Dr Rees, which was completed in four volumes folio. Another edition which is now (1803) going on, and is to extend to 20 vols. 4to, has been undertaken by the same gentleman.

CHAMBRE, Martin Cureau de la, physician in ordinary to the French king, was distinguished by his knowledge in medicine, philosophy, and polite learning. He was born at Mons, and was received into the French academy in 1635, and afterwards into the academy of sciences. He wrote a great number of works; the principal of which are, 1. The characters of the passions. 2. The art of knowing men. 3. On the knowledge of beasts, &c. He died at Paris in 1669.

CHAMELEON. See Lacerta, Erpetology *Index*.

CHAMFERING, in *Architecture*, a phrase used for cutting any thing aslope on the under side.

CHAMIER, Daniel, an eminent Protestant divine, born in Dauphiny. He was many years preacher at Montellimart; from whence he went in 1612 to Montaubon, to be professor of divinity in that city, and was killed by a cannon-ball during the siege in 1621. The most considerable of his works is his *Panstratia Catholica*, or "Wars of the Lord," in four volumes folio; in which he treats very learnedly of the controversies between the Protestants and Roman Catholics.

CHAMOIS, or Chamois Goat, in *Zoology*. See Capra, Mammalia *Index*.

CHAMOMILE. See Anthemis, Botany *Index*.

CHAMOS, or Chemosh, the idol or god of the Moabites.

The name of *chamos* comes from a root which, in Arabic, signifies to *make haste;* for which reason many believe Chamos to be the sun, whose precipitate course might well procure it the name of swift or speedy. Others have confounded Chamos with the god *Hammon*, adored not only in Libya and Egypt, but also in Arabia, Ethiopia, and the Indies. Macrobius shows that Hammon was the sun; and the horns, with which he was represented, denoted his rays. Calmet is of opinion that the god Hamonus, and Apollo Chomeus, mentioned by Strabo and Ammianus Marcellinus, was the very same as Chamos or the sun. These deities were worshipped in many of the eastern provinces. Some who go upon the resemblance of the Hebrew term *chamos* to that of the Greek *comos*, have believed Chamos to signify the god Bacchus, the god of drunkenness, according to the signification of the Greek *comos*. St Jerome, and with him most other interpreters, take Chamos and Peor for the same deity. But it seems that Baal Peor was the same as Tammuz or Adonis; so that Chamos must be the god whom the heathens call the sun.

CHAMOUNI, one of the elevated valleys of the Alps, situated at the foot of Mont Blanc. See Alps and Blanc.

The first strangers whom a curiosity to visit the glaciers drew to Chamouni (M. Saussure observes), certainly considered this valley as a den of robbers; for they came armed cap-a-pee, attended with a troop of domestics armed in the same manner; they would not venture into any house; they lived in tents which they had brought along with them; fires were kept burning, and centinels on guard, the whole night over. It was in the year 1741 that the celebrated traveller Pocock, and another English gentleman called Wyndham, undertook this interesting journey. It is remembered by the old men of Chamouni, and they still laugh at the fears of the travellers, and at their unnecessary precautions. For 20 or 25 years after this period, the journey was made but seldom, and then chiefly by Englishmen, who lodged with the curate; for, when I was there in 1760, and even for four or five years afterwards, there was no habitable house except one or two miserable inns, like those in villages that are little frequented. But now that this expedition has gradually become so fashionable, three large and good inns, which have been successively built, are hardly sufficient to contain the travellers that come during the summer from all quarters.

This concourse of strangers, and the money they leave behind them at Chamouni, have somewhat affected the ancient simplicity of the inhabitants, and even the purity of their manners. Nobody, however, has any thing to fear from them; the most inviolable fidelity is observed with respect to travellers; they are only exposed to a few importunate solicitations, and some small artifices dictated by the extreme eagerness with which the inhabitants offer their services as guides.

The hope of obtaining this employment brings together, round a traveller, almost all the men in every village through which he passes, and makes him believe that there are a great many in the valley; but there are very few at Chamouni in summer. Curiosity, or the hope of making money, draws many to Paris and into Germany; besides, as the shepherds of Chamouni have the reputation of excelling in the making of cheese, they are in great request in the Tarentaise, in the valley of Aoste, and even at greater distances; and they receive there, for four or five months in summer, very considerable wages. Thus the labours of the field devolve almost entirely on the women, even such as in other countries fall solely on the men; as mowing, cutting of wood, and thrashing; even the animals of the same sex are not spared, for the cows there are yoked in the plough.

The only labours that belong exclusively to the men are the seeking for rock crystal and the chase. Happily they are now less employed than formerly in the first of these occupations; I say happily, for many of them perished in this pursuit. The hope of enriching themselves quickly by the discovery of a cavern filled with fine crystals, was so powerful a motive, that they exposed themselves in the search to the most alarming dangers; and hardly a year passed without some of them perishing in the snows, or among the precipices.

The principal indication of the grottoes or crystal ovens as they are here called, are veins of quartz, which appear mouni. appear on the outside of the rocks of granite, or of the laminated rock. These white veins are seen at a distance, and often at great heights, on vertical and inaccessible places. The adventurers endeavour to arrive at these, either by fabricating a road across the rocks, or by letting themselves down from above suspended by ropes. When they reach the place, they gently strike the rock; and if the stone returns a hollow sound, they endeavour to open it with a hammer, or to blow it up with powder. This is the principal method of searching: but young people, and even children, often go in quest of these crystals over the glaciers, where the rocks have lately fallen down. But whether they consider these mountains as nearly exhausted, or that the quantity of crystal found at Madagascar has too much lowered the price of this fossil, there are now but few people that go in search of it, and perhaps there is not a single person at Chamouni that makes it his only occupation. They go however occasionally, as to a party of pleasure.

But the chase of the chamois goat, as dangerous, and perhaps more so than the seeking for crystal, still occupies many inhabitants of the mountains, and carries off, in the flower of their age, many men whose lives are most valuable to their families. And when we are informed how this chase is carried on, we will be astonished that a course of life, at once so laborious and perilous, should have irresistible attractions for those who have been accustomed to it.

The chamois hunter generally sets out in the night, that he may reach by break of day the most elevated pastures where the goats come to feed, before they arrive. As soon as he discovers the place where he hopes to find them, he surveys it with his glass. If he finds none of them there, he proceeds, always ascending; whenever he descries any, he endeavours to get above them, either by stealing along some gully, or getting behind some rock or eminence. When he is near enough to distinguish their horns, which is the mark by which he judges of the distance, he rests his piece on a rock, takes his aim with great composure, and rarely misses. This piece is a rifle-barrelled carabine, into which the ball is thrust, and these carabines often contain two charges, though they have but one barrel; the charges are put one above another, and are fired in succession. If he has wounded the chamois, he runs to his prey, and for security he hamstrings it; then he considers his way home; if the road is difficult, he skins the chamois, and leaves the carcase; but, if it is practicable, he throws the animal on his shoulders, and bears him to his village, though at a great distance, and often over frightful precipices; he feeds his family with the flesh, which is excellent, especially when the creature is young; and he dries the skins for sale.

But if, as is the most common case, the vigilant chamois perceives the approach of the hunter, he immediately takes flight among the glaciers, through the snows, and over the most precipitous rocks. It is particularly difficult to get near these animals when there are several together; for then one of them, while the rest are feeding, stands as a centinel on the point of some rock that commands a view of the avenues leading to the pasture; and as soon as he perceives any object of alarm, he utters a sort of hiss; at which the others instantly gather round him to judge for themselves of the nature of the danger: if it is a wild beast, or a hunter, the most experienced puts himself at the head of the flock, and away they fly, ranged in a line, to the most inaccessible retreats. Chamouni.

It is here that the fatigues of the hunter begin; instigated by his passion for the chase, he is insensible to danger: he passes over snows, without thinking of the horrid precipices they conceal; he entangles himself among the most dangerous paths, and bounds from rock to rock, without knowing how he is to return. Night often surprises him in the midst of his pursuit; but he does not for that reason abandon it; he hopes that the same cause will arrest the flight of the chamois, and that he will next morning overtake them. Thus he passes the night, not at the foot of a tree, like the hunter of the plain; nor in a grotto, softly reclined on a bed of moss; but at the foot of a rock, and often on the bare points of shattered fragments, without the smallest shelter. There, all alone, without fire, without light, he draws from his bag a bit of cheese, with a morsel of oaten bread, which make his common food; bread so dry, that he is sometimes obliged to break it between two stones, or with the hatchet he carries with him to cut out steps in the ice. Having thus made his solitary and frugal repast, he puts a stone below his head for a pillow, and goes to sleep, dreaming on the route which the chamois may have taken. But soon he is awakened by the freshness of the morning; he gets up, benumbed with cold; surveys the precipices which he must traverse, in order to overtake his game; drinks a little brandy, of which he is always provided with a small portion, and sets out to encounter new dangers. Hunters sometimes remain in these solitudes for several days together, during which time their families, their unhappy wives in particular, experience a state of the most dreadful anxiety; they dare not go to rest for fear of seeing their husbands appear to them in a dream; for it is a received opinion in the country, that when a man has perished, either in the snow, or on some unknown rock, he appears by night to the person he held most dear, describes the place that proved fatal to him, and requests the performance of the last duties to his corpse.

"After this picture of the life which the chamois hunters lead, could one imagine that this chase would be the object of a passion absolutely unsurmountable! I knew a well-made handsome man, who had just married a beautiful woman:—'My grandfather,' said he to me, 'lost his life in the chase; so did my father; and I am persuaded that I too shall die in the same manner; this bag which I carry with me when I hunt I call my grave clothes, for I am sure I will have no other; yet, if you should offer to make my fortune on condition of abandoning the chase of the chamois, I could not consent.' I made some excursions on the Alps with this man: His strength and address were astonishing: but his temerity was greater than his strength; and I have heard, that two years afterwards, he missed a step on the brink of a precipice, and met with the fate he had expected.

Voyages dans les Alpes, par M. Saussure, tom. iii.

"The few who have grown old in this employment bear upon their faces the marks of the lives they have led. A savage look, something in it haggard and wild, makes them be known in the midst of a crowd, even when

Chamouni.

when they are not in their hunting dress. And undoubtedly it is this ill look which makes some superstitious peasants believe that they are sorcerers, that they have dealings with the devil in their solitudes, and that it is he who throws them down the rocks. What then can be the passionate inducement to this course of life? It is not avarice, at least it is not an avarice consistent with reason: the most beautiful chamois is never worth more to the person that kills it than a dozen of francs, even including the value of its flesh: and now that the number is so much diminished, the time lost before one can be taken is much more than its value. But it is the very dangers that attend the pursuit, those alternations of hope and fear, the continual agitation and exercise which these emotions produce in the mind, that instigate the hunter: they animate him as they do the gamester, the warrior, the sailor, and even to a certain degree, the naturalist of the Alps; whose life, in some measure, pretty much resembles that of the hunter, whose manners we have described."

But there is another kind of hunting, which is neither dangerous nor laborious, nor fatal to any one but to the poor animals that are the objects of it.—These are the marmots, animals that inhabit the high mountains; where in summer they scoop out holes, which they line with hay, and retire to at the beginning of autumn. Here they grow torpid with the cold, and remain in a sort of lethargy, till the warmth of the spring returns to quicken their languid blood, and to recal them to life. When it is supposed that they have retired to their winter abodes, and before the snow has covered the high pastures where their holes are made, people go to unharbour them. They are found from 10 to 13 in the same hole, heaped upon one another, and buried in the hay. Their sleep is so profound, that the hunter often puts them into his bag, and carries them home without their awaking. The flesh of the young is good, though it tastes of oil, and smells somewhat of musk; the fat is used in the cure of rheumatisms and pains, being rubbed on the parts affected; but the skin is of little value, and is sold for no more than five or six sols. Notwithstanding the little benefit they reap from it, the people of Chamouni go in quest of this animal with great eagerness, and its numbers accordingly diminish very sensibly.

It has been said, that marmots, in order to transport the hay into their holes, use one of their number laid on his back as a cart; but this is fabulous, for they are seen carrying the hay in their mouths. Nor is it for food that they gather it, but for a bed, and in order to shut out the cold, and to guard the avenues of their retreat from enemies. When they are taken in autumn, their bowels are quite empty, and even as clean as if they had been washed with water; which proves that their torpidity is preceded by a fast, and even by an evacuation; a wise contrivance of nature for preventing their accumulated fæces from growing putrid or too dry, in the long lethargy they are exposed to. They also continue a few days after their revival without eating, probably to allow the circulation and digestive power to recover their activity. At first leaving their holes, they appear stupid and dazzled with the light; they are at this time killed with sticks, as they do not endeavour to fly, and their bowels are then also quite empty. They are not very lean when they awake, but grow more so for a few days after they first come abroad. Their blood is never congealed, however profound their sleep may be; for at the time that it is deepest, if they are bled, the blood flows as if they were awake.

Chamouni, Champagne.

In these countries the period is so short between the dissolution of the snow and its return, that grain has hardly time to come to maturity. M. Saussure mentions a very useful and ingenious practice, invented by the mountaineers of Argentiere, for enlarging this period, "I observed (says he) in the middle of the valley, several large spaces where the surface of the snow exhibited a singular appearance, somewhat resembling a piece of white cloth spotted with black. While I was endeavouring to divine the cause of this phenomenon, I discovered several women walking with measured pace, and sowing something in handfuls that was black; and which being scattered, regularly diverging on the surface of the snow, formed that spotted appearance that I had been admiring. I could not conceive what seed should be sown on snow six feet deep; but my guide, astonished at my ignorance, informed me that it was black earth spread upon the snow to accelerate its melting; and thus to anticipate, by a fortnight or three weeks, the time of labouring the fields, and sowing. I was struck with the elegant simplicity of a practice so useful, the effects of which I already saw very evidently in places which had not been thus treated above three days.

"As to the inhabitants of Chamouni, the men, like those of most high valleys, are neither well made nor tall; but they are nervous and strong, as are also the women. They do not attain to a great age: men of 80 are very rare. Inflammatory diseases are the most fatal to them; proceeding, no doubt, from obstructed perspiration, to which the inconstant temperature of the climate exposes them.

"They are in general honest, faithful, and diligent, in the practice of religious duties. It would, for instance, be in vain to persuade them to go anywhere on a holiday before hearing mass. They are economical, but charitable. There are amongst them neither hospitals nor foundations for the poor; but orphans and old people, who have no means of subsistence, are entertained by every inhabitant of a parish in his turn. If a man is prevented by age or infirmities from taking charge of his affairs, his neighbours join among themselves and do it for him.

"Their mind is active and lively, their temper gay, with an inclination to raillery: they observe, with singular acuteness, the ridiculous in strangers, and turn it into a fund of very facetious merriment among themselves; yet they are capable of serious thinking: many of them have attacked me on religious and metaphysical subjects; not as professing a different faith from theirs, but on general questions, which showed they had ideas independent of those they were taught."

CHAMPAGNE, a considerable province of France, about 162 miles in length, and 112 in breadth, bounded on the north by Hainault and Luxembourg, on the east by Lorrain and the Franche Compte, on the south by Burgundy, and on the west by the Isle of France

France and Soissonnois. It has a great number of rivers, the principal of which are the Meuse, the Seine, the Marne, the Aube, and the Aine. Its principal trade consists in excellent wine, all sorts of corn, linen cloth, woollen stuffs, cattle, and sheep. It is also divided into the higher and lower; and Troyes is the capital town. Its subdivisions are Champagne Proper, and Rhemois, the Retolois, the Pertois, the Village, Basigni, the Senonois and the Brie Champenois. It now forms the departments of Ardennes, Aube, Marne, and Upper Marne.

Champagne Proper, is one of the eight parts of Champagne, which comprehends the towns of Troyes, Chalons, St Menehould, Eperney, and Vertus.

CHAMPAIN, or *Point Champain*, in *Heraldry*, a mark of dishonour in the coat of arms of him who kills a prisoner of war after he has cried quarter.

CHAMPERTRY, in *Law*, a species of MAINTENANCE, and punished in the same manner; being a bargain with the plaintiff or defendant *campum partire*, " to divide the land," or other matter sued for, between them, if they prevail at law; whereupon the champertror is to carry on the party's suit at his own expence. This *champart*, in the French law, signifies a similar division of profits, being a part of the crop annually due to the landlord by bargain or custom. In our sense of the word, it signifies the purchasing of a suit or right of suing; a practice so much abhorred by our law, that it is one main reason why a *chose* in action, or thing of which one hath the right but not the possession, is not assignable in common law; because no man should purchase any pretence to sue in another's right. These pests of civil society, that are perpetually endeavouring to disturb the repose of their neighbours, and officiously interfering in other men's quarrels even at the hazard of their own fortunes, were severely animadverted on by the Roman law, and were punished by the forfeiture of a third part of their goods, and perpetual infamy. Hitherto also must be referred the provisions of the statute 32 Henry VIII. c. 9. that no one shall sell or purchase any pretended right or title to land, unless the vender hath received the profits thereof for one whole year before such grant, or hath been in actual possession of the land, or of the reversion or remainder; on pain that both purchaser and vender shall each forfeit the value of such land to the king and the prosecutor.

CHAMPION, a person who undertakes a combat in the place or quarrel of another; and sometimes the word is used for him who fights in his own cause.

It appears that champions, in the just sense of the word, were persons who fought instead of those that, by custom, were obliged to accept the duel, but had a just excuse for dispensing with it, as being too old, infirm, or being ecclesiastics. and the like. Such causes as could not be decided by the course of common law were often tried by single combat; and he who had the good fortune to conquer, was always reputed to have justice on his side. See the article BATTLE.

Champion of the King (*campio regis*), is an ancient officer, whose office is, at the coronation of our kings, when the king is at dinner, to ride armed *cap-a-pee* into Westminster-hall, and by the proclamation of a herald make a challenge, " That if any man shall deny the king's title to the crown, he is there ready to defend it in single combat, &c." which being done, the king drinks to him, and sends him a gilt cup with a cover full of wine, which the champion drinks, and hath the cup for his fee. This office at the coronation of King Richard II. when Baldwin Ferville exhibited his petition for it, was adjudged from him to his competitor Sir John Dymocke, (both claiming from Marmion), and hath continued ever since in the family of the Dymockes; who hold the manor of Sinvelsby in Lincolnshire, hereditary from the Marmions, by grand serjeantry, viz. that the lord thereof shall be the king's champion as aforesaid. Accordingly Sir Edward Dymocke performed this office at the coronation of King Charles II.; a person of the name of Dymocke performed at the coronation of his present majesty George III.

CHAMPLAIN, Samuel de, a celebrated French navigator, the founder of the colony of New France, or Canada. He built Quebec; and was the first governor of the colony in 1603. Died after 1649. See QUEBEC.

CHANANÆI, in *Ancient Geography*, the name of the ancient inhabitants of Canaan in general, descendants of Canaan; but peculiarly appropriated to some one branch; though uncertain which branch or son of Canaan it was, or how it happened that they preferred the common gentilitious name to one more appropriated as descendants of one of the sons of Canaan; unless from their course of life, as being in the mercantile way, the import of the name of *Canaan*; and for which their situation was greatly adapted, they living on the sea and about Jordan, and thus occupying the greater part of the Land of Promise.

CHANCE, a term we apply to events, to denote that they happen without any necessary or foreknown cause. See CAUSE.

Our aim is, to ascribe those things to *chance* which are not necessarily produced as the natural effects of any proper cause: but our ignorance and precipitancy lead us to attribute effects to *chance* which have a necessary and determinate cause.

When we say a thing happens *by chance*, we really mean no more than that its cause is unknown to us: not, as some vainly imagine, that *chance* itself can be the cause of any thing.

The case of the painter, who unable to express the foam at the mouth of a horse he had painted, threw his sponge in despair at the piece, and *by chance*, did that which he could not before do by design, is an eminent instance of the force of *chance*: yet, it is obvious, all we mean here by *chance* is, that the painter was not aware of the effect; or that he did not throw the sponge with such a view: not but that he actually did every thing necessary to produce the effect; insomuch, that considering the direction wherein he threw his sponge, together with its form, specific gravity, the colours wherewith it was smeared, and the distance of the hand from the piece, it was impossible, on the present system of things, the effect should not follow.

Chance is frequently personified, and erected into a chimerical being, whom we conceive as acting arbitrarily, Chance, Chance-Medley.

rily, and producing all the effects whose real causes do not appear to us; in which sense the word coincides with the τυχη, *fortuna*, of the ancients.

CHANCE is also used for the manner of deciding things, the conduct or direction whereof is left at large, and not reducible to any determinate rules or measures, or where there is no ground for preference: as at cards, dice, lotteries, &c.

For the laws of CHANCE, *or the Proportion of Hazard in Gaming*, see GAME.

The ancient *sortilege*, or *chance*, M. Placette observes, was instituted by God himself: and in the Old Testament we find several standing laws and express commands which prescribed its use on certain occasions. Hence the Scripture says, "The *lot*, or *chance*, fell on Matthias," when it was in question who should fill Judas's place in the apostolate.

Hence also arose the *sortes sanctorum*, or method of determining things, among the ancient Christians, by opening some of the sacred books, and pitching on the first verse they cast their eye on, as a sure prognostic of what was to befal them. The *sortes Homericæ, Virgilianæ, Prænestinæ*, &c. used by the heathens, were with the same view, and in the same manner. See SORTES.

St Augustine seems to approve of this method of determining things future, and owns that he had practised it himself; grounded on this supposition, that God presides over *chance;* and on Prov. xvi. 33.

Many among the modern divines hold *chance* to be conducted in a particular manner by Providence; and esteem it an extraordinary way which God uses to declare his will, and a kind of immediate revelation.

CHANCE-Medley, in *Law*, is where one is doing a lawful act, and a person is killed by chance thereby; for if the act be unlawful, it is felony. If a person cast, not intending harm, a stone, which happens to hit one, whereof he dies; or shoots an arrow in a highway, and another that passeth by is killed therewith; or if a workman, in throwing down rubbish from a house, after warning to take care, kills a person; or a schoolmaster in correcting his scholar, a master his servant, or an officer in whipping a criminal in a reasonable manner, happens to occasion his death; it is chance-medley and misadventure. But if a man throw stones in a highway where persons usually pass; or shoot an arrow, &c. in a market-place among a great many people; or if a workman cast down rubbish from a house in cities and towns where people are continually passing; or a schoolmaster, &c. correct his servant or scholar, &c. exceeding the bounds of moderation; it is manslaughter: and if with an improper instrument of correction, as with a sword or iron bar, or by kicking, stamping, &c. in a cruel manner, it is murder. If a man whips his horse in a street to make him gallop, and the horse runs over a child and kills it, it is manslaughter: but if another whips the horse, it is manslaughter in him, and chance-medley in the rider. And if two are fighting, and a third person coming to part them is killed by one of them without any evil intent, yet this is murder in him, and not manslaughter by chance-medley or misadventure. In chance-medley, the offender forfeits his goods; but hath a pardon of course.

Chancel, Chancellor.

CHANCEL, is properly that part of the choir of a church, between the altar or communion-table and the balustrade or rail that encloses it, where the minister is placed at the celebration of the communion. The word comes from the Latin *cancellus*, which in the lower Latin is used in the same sense, from *cancelli*, "lattices or cross bars," wherewith the chancels were anciently encompassed, as they now are with rails. The right of a seat and a sepulchre in the chancels is one of the privileges of founders.

CHANCELLOR, was at first only a chief notary or scribe under the emperors; and was called *cancellarius*, because he sat behind a lattice (in Latin *cancellus*), to avoid being crowded by the people: though some derive the word from *cancellare*, "to cancel." (See CHANCERY.) This officer was afterwards invested with several judicial powers, and a general superintendency over the rest of the officers of the prince. From the Roman empire it passed to the Roman church, ever emulous of imperial state: and hence every bishop has to this day his chancellor, the principal judge of his consistory. And when the modern kingdoms of Europe were established upon the ruins of the empire, almost every state preserved its chancellor with different jurisdictions and dignities, according to their different constitutions. But in all of them he seems to have had the supervision of all charters, letters, and such other public instruments of the crown as were authenticated in the most solemn manner: and therefore, when seals came in use, he had always the custody of the king's great seal.

Lord High CHANCELLOR *of Great Britain*, or *Lord Keeper of the Great Seal*, is the highest honour of the long robe, being created by the mere delivery of the king's great seal into his custody: whereby he becomes, without writ or patent, an officer of the greatest weight and power of any now subsisting in the kingdom. He is a privy counsellor by his office; and, according to Lord Chancellor Ellesmere, prolocutor of the house of lords by prescription. To him belongs the appointment of all the justices of the peace throughout the kingdom. Being in former times commonly an ecclesiastic (for none else were then capable of an office so conversant in writing), and presiding over the royal chapel, he became keeper of the king's conscience; visitor, in right of the king, of all hospitals and colleges of the king's foundation; and patron of all the king's livings under the value of 20l. per annum in the king's books. He is the general guardian of all infants, idiots and lunatics; and has the general superintendence of all charitable uses in the kingdom; and all this over and above the vast extensive jurisdiction which he exercises in his judicial capacity in the court of chancery. He takes a precedence of every temporal lord except the royal family, and of all others except the archbishop of Canterbury. See CHANCERY.

CHANCELLOR, in Scotland, was the chief in matters of justice. In the laws of King Malcolm II. he is placed before all other officers; and from these it appears that he had the principal direction of the chancery, or chancellary as it is called, which is his proper office. He had the custody of the king's seal; and he was the king's most intimate counsellor, as appears by an old law cited by Sir James Balfour: "The chancellar

Chancellor. chancellar sal at al tymes assist the king, in giving him counsall mhir secretly nor the rest of the nobility, to quais ordinances all officiaris, als well of the realme as of the kingis hous, sould answer and obey. The chancellar sal be ludgit neir unto the kingis grace, for keiping of his bodie, and the seill; and that he may be readie baith day and nicht at the king's command." By having the custody of the great seal, he had an opportunity of examining the king's grants, and other deeds which were to pass under it, and to cancel them if they appeared against law, and were obtained surreptitiously or by false suggestions.

King James VI. ordained the chancellor to have the first place and rank in the nation, *ratione officii;* by virtue whereof he presided in the parliament, and in all courts of judicature. After the restoration of King Charles II. by a particular declaratory law, parliament first, the lord chancellor was declared, by virtue and right of his office, president in all the meetings of parliament, or other public judicatures of the kingdom. Although this act was made to declare the chancellor president of the exchequer as well as other courts, yet in 1663 the king declared the treasurer to be president of that court.

The office of Lord Chancellor was abolished by the Union, there being no farther use for the judicial part of this office; and to answer all the other parts of the chancellor's office, a lord keeper of the great seal was erected, with a salary of 3000l. a-year.

Chancellor of a Cathedral, an officer that hears lessons and lectures read in the church, either by himself or his vicar; to correct and set right the reader when he reads amiss; to inspect schools; to hear causes; apply the seal; write and dispatch the letters of the chapter; keep the books; take care that there be frequent preachings, both in the church and out of it; and assign the office of preaching to whom he pleases.

Chancellor of the Duchy of Lancaster, an officer appointed chiefly to determine controversies between the king and his tenants of the duchy land, and otherwise to direct all the king's affairs belonging to that court. See *Duchy Court*.

Chancellor of the Exchequer, an officer who presides in that court, and takes care of the interest of the crown. He is always in commission with the lord-treasurer, for the letting of crown lands, &c. and has power with others, to compound for forfeitures of lands upon penal statutes. He has also great authority in managing the royal revenues, and in matters relating to the first fruits.

Chancellor of the order of the Garter and other Military orders, is an officer who seals the commissions and mandates of the chapter and assembly of the knights, keeps the register of their proceedings, and delivers acts thereof under the seal of their order.

Chancellor of an University, is he who seals the diplomas, or letters of degrees, provision, &c. given in the university.

The chancellor of Oxford is usually one of the prime nobility, chosen by the students themselves in convocation. He is their chief magistrate; his office is, *durante vita*, to govern the university, preserve and defend its rights and privileges, convoke assemblies, and do justice among the members under his jurisdiction.

Chancellor ‖ Chancery.

Under the chancellor is the vice-chancellor, who is chosen annually, being nominated by the chancellor, and elected by the university in convocation. He is always the head of some college, and in holy orders. His proper office is to execute the chancellor's power, to govern the university according to her statutes, to see that officers and students do their duty, that courts be duly called, &c. When he enters upon his office, he chooses four pro-vice chancellors out of the heads of the colleges, to execute his power in his absence.

The chancellor of Cambridge is also usually one of the prime nobility, and in most respects the same as that in Oxford; only he does not hold his office *durante vita*, but may be elected every three years. Under the chancellor there is a commissary, who holds a court of record for all privileged persons and scholars under the degree of master of arts, where all causes are tried and determined by the civil and statute law, and by the custom of the university.

The vice-chancellor of Cambridge is chosen annually by the senate, out of two persons nominated by the heads of the several colleges and halls.

Chancellor's Court. See *University Courts*.

CHANCERON, in *Natural History*, a name given by the French writers to the small caterpillar, that eats the corn, and does vast mischief in their granaries. See the the article *Corn-Butterfly*.

CHANCERY, the highest court of justice in Britain next to the parliament, and of very ancient institution. It has its name chancery (*cancellaria*) from the judge who presides here, the lord chancellor, or *cancellarius;* who, according to Sir Edward Coke, is so termed, *à cancellando*, from cancelling the king's letters patent when granted contrary to law, which is the highest point of his jurisdiction. In chancery there are two distinct tribunals; the one ordinary, being a court of common law; the other extraordinary, being a court of equity.

1. The *ordinary* legal court holds pleas of recognizances acknowledged in the chancery, writs of *scire facias*, for repeal of letters patent, writs of partition, &c. and also of all personal actions by or against any officer of the court. Sometimes a *supersedeas*, or writ of privilege, hath been here granted to discharge a person out of prison: one from hence may have a *habeas corpus* prohibition, &c. in the vacation; and here a *subpœna* may be had to force witnesses to appear in other courts, when they have no power to call them. But, in prosecuting causes, if the parties descend to issue, this court cannot try it by jury; but the lord chancellor delivers the record into the king's bench to be tried there; and after trial had, it is to be remanded into the chancery, and there judgment given; though if there be a demurrer in law, it shall be argued in this court. *Blackst. Comment.*

In this court is also kept the *officina justitiæ;* out of which all original writs that pass under the great seal, all commissions of charitable uses, sewers, bankruptcy, idiocy, lunacy, and the like, do issue; and for which it is always open to the subject, who may there at any time demand and have, *ex debito justitiæ*, any writ that his occasions may call for. These writs, relating to the business

business of the subject, and the returns of them, were, according to the simplicity of ancient times, originally kept in a hamper, *in hanaperio;* and the other (relating to such matters wherein the crown is mediately or immediately concerned) were preserved in a little sack or bag, *in parva baga;* and hence hath arisen the distinction of the *hanaper* office, and the *petty-bag* office, which both belong to the common law court in chancery.

2. The *extraordinary* court, or court of equity, proceeds by the rules of equity and conscience, and moderates the rigour of the common law, considering the *intention* rather than the *words* of the law. It gives relief for and against infants notwithstanding their minority, and for or against married women notwithstanding their coverture. All frauds and deceits for which there is no redress at common law; all breaches of trust and confidence; and accidents, as to relieve obligors, mortgagers, &c. against penalties and forfeitures, where the intent was to pay the debt, are here remedied: for in chancery, a forfeiture, &c. shall not bind, where a thing may be done after, or compensation made for it. Also this court will give relief against the extremity of unreasonable engagements entered into without consideration; oblige creditors that are unreasonable to compound with an unfortunate debtor; and make executors, &c. give security and pay interest for money that is to lie long in their hands. This court may confirm title to lands, though one hath lost his writings: and render conveyances defective through mistake, &c. good and perfect. In chancery, copy-holders may be relieved against the ill usage of their lords; enclosures of land that are common be decreed; and this court may decree money or lands given to charitable uses, oblige men to account with each other, &c. But in all cases where the plaintiff can have his remedy at law, he ought not to be relieved in chancery; and a thing which may be tried by a jury is not triable in this court.

The proceedings in chancery are, first to file the bill of complaint, signed by some counsel, setting forth the fraud or injury done, or wrong sustained, and praying relief: after the bill is filed, process of *subpœna* issues to compel the defendant to appear; and when the defendant appears, he puts in his answer to the bill of complaint, if there be no cause for the plea to the jurisdiction of the court, in disability of the person, or in bar, &c. Then the plaintiff brings his replication, unless he files exceptions against the answer as insufficient, referring it to a master to report whether it be sufficient or not; to which report exceptions may also be made. The answer, replication, rejoinder, &c. being settled, and the parties come to issue, witnesses are to be examined upon interrogatories, either in court or by commission in the country, wherein the parties usually join; and when the plaintiff and defendant have examined their witnesses, publication is to be made of the depositions, and the cause is to be set down for hearing; after which follows the decree. But it is now usual to appeal to the house of lords; which appeals are to be signed by two noted counsel, and exhibited by way of petition; the petition or appeal is lodged with the clerk of the house of lords, and read in the house, whereon the appellee is ordered to put in his answer, and a day fixed for hearing the cause; and after counsel heard, and evidence given on both sides, the lords will affirm or reverse the decree of the chancery, and finally determine the cause by a majority of votes, &c.

CHANDELIER, in fortification, a kind of moveable parapet, consisting of a wooden frame, made of two upright stakes, about six feet high, with cross planks between them; serving to support fascines to cover the pioneers.

CHANDERNAGORE, a French settlement in the kingdom of Bengal in the East Indies. It lies on the river Ganges, two leagues and a half above Calcutta. The district is hardly a league in circumference, and has the disadvantage of being somewhat exposed on the western side; but its harbour is excellent, and the air is as pure as it can be on the banks of the Ganges. Whenever any building is undertaken that requires strength, it must here, as well as in all other parts of Bengal, be built upon piles, it being impossible to dig three or four feet without coming at water.

CHANDLER, Mary, distinguished by her talent for poetry, was the daughter of a dissenting minister at Bath, and was born at Malmsbury in Wiltshire in 1687. She was bred a milliner; but from her childhood had a turn for poetry, and in her riper years applied herself to the study of the poets. Her poems, for which she was complimented by Mr Pope, breathe the spirit of piety and philosophy. She had the misfortune to be deformed, which determined her to live single; though she had great sweetness of countenance, and was solicited to marry. She died in 1745, aged 58.

Chandler, *Dr Samuel*, a learned and respectable dissenting minister, descended from ancestors who had heartily engaged in the cause of religious liberty, and suffered for the sake of conscience and nonconformity; was born at Hungerford in Berks, where his father was a minister of considerable worth and abilities. Being by his literary turn destined to the ministry, he was first placed at an academy at Bridgewater, and from thence removed to Gloucester under Mr Samuel Jones. Among the pupils of Mr Jones were Mr Joseph Butler, afterwards bishop of Durham, and Mr Thomas Secker, afterwards archbishop of Canterbury. With these eminent persons he contracted a friendship that continued to the end of their lives, notwithstanding the different views by which their conduct was afterwards directed, and the different situations in which they were placed.

Mr Chandler having finished his academical studies, began to preach about July 1714; and being soon distinguished by his talents in the pulpit, he was chosen in 1716 minister of the Presbyterian congregation at Peckham near London, in which station he continued some years. Here he entered into the matrimonial state, and began to have an increasing family, when, by the fatal South Sea scheme of 1720, he unfortunately lost the whole fortune which he had received with his wife. His circumstances being thereby embarrassed, and his income as a minister being inadequate to his expences, he engaged in the trade of a bookseller, and kept a shop in the Poultry, London, for about two or three years, still continuing to discharge the duties of the pastoral office. He also officiated as joint preacher with the learned Dr Lardner of a winter weekly evening lecture at the meeting house in the Old Jewry, London: in which meeting he was established assistant preacher about

Chandler. about the year 1725, and then as the pastor. Here he administered to the religious improvement of a very respectable congregation for 40 years with the greatest applause; and with what diligence and application he improved the vacancies of time from his pastoral duties, for improving himself and benefiting the world, will appear from his many writings on a variety of important subjects. While he was thus laudably employed, not only the universities of Edinburgh and Aberdeen gave him, without any application, testimonies of their esteem in diplomas, conferring on him the degree of D. D. but he also received offers of preferment from some of the governors of the established church, which he nobly declined. He had likewise the honour of being afterwards elected F. R. and A. SS.

On the death of George II. in 1760, Dr Chandler published a sermon on that event, in which he compared that prince to King David. This gave rise to a pamphlet, which was printed in the year 1761, entitled "The History of the Man after God's own Heart;" wherein the author ventured to exhibit King David as an example of perfidy, lust, and cruelty, fit only to be ranked with a Nero or a Caligula; and complained of the insult that had been offered to the memory of the late British monarch by Dr Chandler's parallel between him and the king of Israel. This attack occasioned Dr Chandler to publish in the following year "A Review of the History of the Man after God's own Heart; in which the Falsehoods and Misrepresentations of the Historian are exposed and corrected." He also prepared for the press a more elaborate work, which was afterwards published in two volumes 8vo, under the following title: "A Critical History of the Life of David; in which the principal Events are ranged in Order of time; the chief Objections of Mr Bayle and others against the Character of this Prince, the Scripture Account of him, and the Occurrences of his Reign, are examined and refuted; and the Psalms which refer to him explained." As this was the last, it was likewise one of the best, of Dr Chandler's productions. The greatest part of this work was printed off at the time of our author's death, which happened May 8. 1766, aged 73. During the last year of his life, he was visited with frequent returns of a very painful disorder, which he endured with great resignation and Christian fortitude. He was interred in the burying-ground at Bunhill-fields on the 16th of the month; and his funeral was very honourably attended by ministers and other gentlemen. He expressly desired, by his last will, that no delineation of his character might be given in his funeral sermon, which was preached by Dr Amory. He had several children; two sons and a daughter who died before him, and three daughters who survived him; two of whom are yet living, and both married, one of them to the Rev. Dr Harwood.

Dr Chandler was a man of very extensive learning and eminent abilities; his apprehension was quick and his judgment penetrating; he had a warm and vigorous imagination; he was a very instructive and animated preacher; and his talents in the pulpit and as a writer procured him very great and general esteem, not only among the dissenters, but among large numbers of the established church. He was principally instrumental in the establishment of the fund for relieving the widows and orphans of poor Protestant dissenting ministers: the plan of it was first formed by him; and it was by his interest and application to his friends that many of the subscriptions for its support were procured.

Chandler, Chang-tong.

In 1768, four volumes of our author's sermons were published by Dr Amory, according to his own directions in his last will; to which were prefixed a neat engraving of him, from an excellent portrait by Mr Chamberlin. He also expressed a desire to have some of his principal pieces reprinted in four volumes 8vo: proposals were accordingly published for that purpose, but did not meet with sufficient encouragement. But in 1777, another work of our author was published in one volume 4to, under the following title: "A Paraphrase and Notes on the Epistles of St Paul to the Galatians and Ephesians, with doctrinal and practical Observations: together with a critical and practical Commentary on the two Epistles of St Paul to the Thessalonians." Dr Chandler also left, in his interleaved Bible, a large number of critical notes, chiefly in Latin, which are now the property of Dr Kippis, Mr Farmer, Dr Price, and Dr Savage, and which have been intended to be published; but the design has not yet been executed. A complete list of Dr Chandler's works is given in the Biographia Britannica, vol. iii. p. 435.

CHANG-TONG, a province of China, bounded on the east by Petcheli and part of Honan, on the south by Kiang-nan, on the cast by the sea, and on the north by the sea and part of Petcheli. The country is well watered by lakes, streams, and rivers; but is nevertheless liable to suffer from drought, as rain falls here but seldom. The locusts also sometimes make great devastation. However, it abounds greatly in game; and there is perhaps no country where quails, partridges, and pheasants, are sold cheaper, the inhabitants of this province being reckoned the keenest sportsmen in the empire. This province is greatly enriched by the river Yun, called the *Grand Imperial Canal*, through which all the barks bound to Pekin must pass in their way thither. The duties on this canal alone amount to more than 450,000l. annually. The canal itself is greatly admired by European travellers on account of its strong and long dikes, the banks decorated with cut stone, the ingenious mechanism of its locks, and the great number of natural obstacles which have been overcome in the execution of the work. The province produces silk of the ordinary kind: and besides this, another from a sort of insect resembling our caterpillar. It is coarser than the ordinary silk, but much stronger and more durable; so that the stuffs made from it have a very extensive sale throughout the empire.

Chang-tong is remarkable for being the birth-place of the celebrated philosopher and lawgiver Confucius. His native city is called *Kio-feou*, where there are several monuments erected in honour of this great man. This province is divided into six districts, which contain six cities of the first class, and 114 of the second and third. Along the coast, also, are 15 or 16 villages of considerable importance on account of their commerce; there is likewise a number of small islands, most of which have harbours very convenient for the Chinese junks which pass from thence to Corea or Leatong. The most remarkable cities are, 1. Tsi-nan-fou, the

the capital, which stands south of the river Tsing-ho or Tsi. It is large and populous; but chiefly celebrated for having been the residence of a long series of kings, whose tombs rising on the neighbouring mountains, afford a beautiful prospect. 2. Yn-tcheu-fou, the second city of the province, situated between two rivers, and in a mild and temperate climate. Great quantities of gold are said to have been formerly collected in its neighbourhood. 3. Lin-tcin-tcheu, situated on the great canal, is much frequented by ships, and may be called a general magazine for every kind of merchandise. Here is an octagonal tower, divided into eight stories, the walls of which are covered on the outside with porcelain loaded with various figures neatly executed, and incrusted on the inside with variously coloured marble. A staircase, constructed in the wall, conducts to all the stories, from which there are passages that lead into magnificent galleries ornamented with gilt ballustrades. All the cornices and projections of the tower are furnished with little bells; which, says M. Grosier, when agitated by the wind, form a very agreeable harmony. In the highest story is an idol of gilt copper, to which the tower is dedicated. In the neighbourhood are some other temples, the architecture of which is exceedingly beautiful.

CHANGER, an officer belonging to the king's mint, who changes money for gold or silver bullion. See MINT.

Money-CHANGER, is a banker, who deals in the exchange, receipt, and payment of moneys. See BANKER.

CHANGES, in *Arithmetic*, &c. the permutations or variations of any number of quantities; with regard to their position, order, &c. See COMBINATION.

[*To find all the possible* CHANGES *of any number of Quantities, or how oft their Order may be varied.*] Suppose two quantities a and b. Since they may be either wrote ab or ba, it is evident their *changes* are $2=2.1$. Suppose three quantities abc: their *changes* will be as in the margin; as is evident by combining c first with ab, then with ba; and hence the number of *changes* arises $3.2.1=6$. If the quantities be 4, each may be combined four ways with each order of the other three; whence the number of changes arises $6.4=4.3.2.1.=24$. Wherefore, if the number of quantities be supposed n, the number of *changes* will be $n.n-1.n-2.n-3.n-4.$ &c. If the same quantity occur twice, the *changes* of two will be found bb; of three, bab, abb, bbc; of four, $cbab$, $bcab$, $babc$. And thus the number of *changes* in the first case will be $1=(2.1):2.1$; in the second, $3=(3.2.1):2.1$; in the third, $12=(4.3.2.1):2.1$.

c a b
a c b
a b c
——
c b a
b c a
b a c

If a fifth letter be added, in each series of four quantities, it will beget five *changes*, whence the number of all the *changes* will be $60=(5.4.3.2.)\ 1,:2.1.$ Hence if the number of quantities be n, the number of *changes* will be $(n.n-1.n-2.n-3.n-4.$ &c.$):2.2.$ From these special formulæ may be collected a general one, viz. if n be the number of quantities, and m the number which shows how oft the same quantity occurs; we shall have $(n.n-1.n-2.n-3.n-4.n-5.n-6.n-7.n-8.n-9.$ &c.$):(m-1.m-2.m-3.m-4.$ &c.$)$ the series being to be continued, till the continual subtraction of unity from n and m leave 0. After the same manner we may proceed further, till putting n for the number of quantities, and l, m, r, &c. for the number that shows how oft any of them is repeated, we arrive at an universal form. $(n.n-1.n-2.n-3.n-4.n-5.n-6.n-7.n-8.$ &c.$):(l.l-1.l-2.l-3.l-4.l-5.$ &c. $m.m-1.m-2.m-3.$ &c.$)\ r.r-1.r-2.r-3.r-4.r-5.$ &c.

Suppose, for instance, $n=6$, $l=3$, $r=0$. The number of *changes* will be $(6.5.4.3.2.1.):(3.2.1.3.2.1.)=(6.5.4.):(3.2=2.5.2=20)$.

Hence, suppose thirteen persons at a table, if it be required how oft they may *change* places; we shall find the number $13.12.11.10.9.8.7.6.5.4.3.2.1.=6227020800$.

In this manner may all the possible anagrams of any word be found in all languages, and that without any study: suppose, v. g. it were required to find the anagrams of the word *amor*, the number of *changes* will be

a	*oam*	*rmoa*	*maro*	*arom*
——	*aom*	*mroa*	*maor*	*aorm*
ma	*amo*	*mora*	——	*aomr*
am	——	*moar*	*raom*	——
——	*roma*	——	*oram*	*ramo*
oma	*orma*	*rmao*	*oarm*	*armo*
moa	*omra*	*mrao*	*oamr*	*amro*
mao	*omar*		——	*amor*
			roam	

The anagrams therefore of the word *amor*, in the Latin tongue, are *roma*, *mora*, *maro*, *ramo*, *armo*. See ANAGRAM.

Whether this new method of anagramatizing be like to prove of much service to that art, is left to the poets.

CHANNA, in *Zoology*, the name of a fish caught in great plenty in the Mediterranean, and brought to market in Italy and elsewhere, among the sea perch, which it so nearly resembles, that it would not be distinguishable from it, but that the sea perch is bigger, and has only broad transverse lines on its back, whereas the channa has them both transverse and longitudinal. It has a very wide mouth, and its lower jaw is longer than its upper; so that its mouth naturally falls open. Its eyes are small, and its teeth very sharp; its back is of a blackish red; it has several longitudinal lines of a reddish hue; and its tail is marked with reddish spots. There is an observation, that in all the fish of this kind which have been examined by naturalists, there have been found none but females. This is as old as the days of Aristotle. Whether this be true in fact, would require many observations. If it should prove so, the whole seems to end in this, that the channa is no distinct species, but only the female of some other fish. There is another fish not unlike this, called *cannadella*, or rather *channadella*, which at Marseilles is known by the name of *charina*.

CHANNEL, in *Geography*, an arm of the sea, or a narrow sea between two continents; or between a continent and an island. Such are the British channel, St George's channel, the channel of Constantinople, &c.

Channel of a Ship. See *Chain-Wales*.

CHAN-SI, a province of China, and one of the smallest in the empire, is bounded on the east by Petcheli, on the south by Honan, on the west by Chen-si, and on the north by the great wall. The climate is healthful

Chan-si, Chant.

healthful and agreeable, and the soil generally fertile, though the country is full of mountains. Some of these last are rough, wild, and uninhabited; but others are cultivated with the greatest care from top to bottom, and cut into terraces, forming a very agreeable prospect; while some have on their tops vast plains no less fertile than the richest low lands. These mountains abound with coal, which the inhabitants pound and make into cakes with water; a kind of fuel which, though not very inflammable, affords a strong and lasting fire when once kindled. It is principally used for heating their stoves, which are constructed with brick as in Germany; but the inhabitants of this province give them the form of small beds, and sleep upon them. The best grapes to be met with in this part of Asia grow in the province of Chan-si; so that good wine might be made; but the people choose rather to dry and sell them to the neighbouring provinces. The country abounds with musk, porphyry, marble, lapis lazuli, and jasper of various colours; and iron mines, as well as salt pits and crystal, are very common. Here are five cities of the first class, and eighty-five of the second and third: the most remarkable are, 1. Tai-youen-fou the capital, an ancient city about three leagues in circumference, but much decayed in consequence of being no longer the residence of the princes of the blood as it was formerly. Nothing now remains of the palaces of those princes but a few ruins; but their tombs are still to be seen on a neighbouring mountain. The burying-place is magnificently ornamented; and all the tombs are of marble or cut stone, having near them triumphal arches, statues of heroes, figures of lions and different animals, especially horses, and which are disposed in very elegant order. An awful and melancholy gloom is preserved around these tombs by groves of aged cypresses, which have never felt the stroke of the axe, placed chequer-wise. The principal articles of trade here are, hardware, stuffs of different kinds, particularly carpets in imitation of those of Turkey. 2. Ngan-y is situated near a lake as salt as the ocean, from which a great quantity of salt is extracted. 3. Fuen-tcheou-fou, an ancient and commercial city, built on the banks of the river Fuen-ho: it has baths and springs almost boiling hot, which, by drawing hither a great number of strangers, add greatly to its opulence. 4. Tai-tong-fou, situated near the wall, is a place of great strength, and important by reason of its situation, as being the only one exposed to the incursions of the Tartars. Its territories abound with lapis lazuli, medicinal herbs, and a particular kind of jasper called *yieche*, which is as white and beautiful as agate; marble and porphyry are also common; and a great revenue is produced from the skins which are dressed here.

CHANT, (*cantus*), is used for the vocal music of churches.

In church history we meet with divers kinds of *chant* or *song*. The first is the *Ambrosian*, established by St Ambrose. The second, the *Gregorian chant*, introduced by Pope Gregory the Great, who established schools of chantors, and corrected the church-song. This is still retained in the church under the name of *plain song*: at first it was called the *Roman song*. The *plain* or *Gregorian chant*, is where the choir and people sing in unison, or all together in the same manner.

Chantilly ‖ Chaos.

CHANTILLY, a village in France, about seven leagues from Paris, where there is a magnificent palace and fine forest formerly belonging to the duke of Bourbon.

CHANTOR, a singer of a choir in a cathedral. The word is almost grown obsolete, *chorister* or *singing-man* being commonly used instead of it. All great chapters have chantors and chaplains to assist the canons, and officiate in their absence.

CHANTOR is used by way of excellence for the precentor or master of the choir, which is one of the first dignities of the chapter. At St David's in Wales, where there is no dean, he is next in dignity to the bishop. The ancients called the chantor *primicerius cantorum*. To him belonged the direction of the deacons and other inferior officers.

Chantors, in the temple of Jerusalem, were a number of Levites, employed in singing the praises of God, and playing upon instruments before his altar. They had no habits distinct from the rest of the people; yet in the ceremony of removing the ark to Solomon's temple, the chantors appeared dressed in tunics of byssus or fine linen. 2 Chron. v. 12.

CHANTRY, or CHAUNTRY, was anciently a church or chapel endowed with lands, or other yearly revenue, for the maintenance of one or more priests, daily saying or singing mass for the souls of the donors, and such others as they appointed. Hence *chauntry-rents*, are rents paid to the crown by the tenants or purchasers of *chauntry-lands*.

CHAOLOGY, the history or description of the chaos. See CHAOS.

Orpheus, in his chaology, sets forth the different alterations, secretions, and diverse forms, which matter went through till it became inhabitable; which amounts to the same with what we otherwise call *cosmogony*. Dr Burnet, in his Theory of the Earth, represents the the chaos as it was at first, entire, undivided, and universally rude and deformed; or the *tohu bohu*: then shows how it came to be divided into its respective regions; how the homogeneous matter gathered itself apart from all of a contrary principle; and, lastly, how it hardened and became a solid habitable globe. See EARTH.

CHAOS, that confusion in which matter lay when newly produced out of nothing at the beginning of the world, before God, by his almighty word, had put it into the order and condition wherein it was after the six days creation. See EARTH.

Chaos is represented by the ancients as the first principle, ovum, or seed of nature and the world. All the sophists, sages, naturalists, philosophers, theologues, and poets, held that chaos was the eldest and first principle, το αρχαιον χαος. The Barbarians, Phœnicians, Egyptians, Persians, &c. all refer the origin of the world to a rude, mixed, confused mass of matter. The Greeks, Orpheus, Hesiod, Menander, Aristophanes, Euripides, and the writers of the Cyclic Poems, all speak of the first chaos; the Ionic and Platonic philosophers build the world out of it. The Stoics hold, that as the world was first made of a chaos, it shall at last be reduced to a chaos; and that its periods and revolutions in the mean time are only transitions from one chaos to another. Lastly, the Latins, as Ennius, Varro, Ovid, Lucretius, Statius, &c. are all of the same

same opinion. Nor is there any sect or nation whatever that does not derive their διακοσμησις, *the structure of the world*, from a chaos.

The opinion first arose among the Barbarians, whence it spread to the Greeks and from the Greeks to the Romans and other nations. Dr Burnet observes, that besides Aristotle and a few other Pseudo-Pythagoreans, nobody ever asserted that our world was always from eternity of the same nature, form, and structure, as at present; but that it had been the standing opinion of the wise men of all ages, that what we now call the *terrestrial earth*, was originally an unformed, indigested mass of heterogeneous matter, called *chaos;* and no more than the rudiments and materials of the present world.

It does not appear who first broached the notion of a chaos. Moses, the eldest of all writers, derives the origin of this world from a confusion of matter, dark, void, deep, without form, which he calls *tohu bohu;* which is precisely the chaos of the Greek and Barbarian philosophers. Moses goes no further than the chaos, nor tells us whence it took its origin, or whence its confused state; and where Moses stops, there precisely do all the rest. Dr Burnet endeavours to show that as the ancient philosophers, &c. who wrote of the cosmogony, acknowledged a chaos for the principle of their world; so the divines, or writers of the theogony, derive the origin or generation of their fabled gods from the same principle.

Mr Whiston supposed the ancient chaos, the origin of our earth, to have been the atmosphere of a comet: which though new, yet all things considered, is not the most improbable assertion. He endeavours to make it out by many arguments, drawn from the agreement which appears to be between them. So that, according to him, every planet is a comet, formed into a regular and lasting constitution, and placed at a proper distance from the sun, revolving in a nearly circular orbit: and a comet is a planet either beginning to be destroyed or re-made; that is, a chaos or planet unformed or in its primeval state, and placed as yet in an orbit very eccentrical.

Chaos, in the phrase of Paracelsus, imports the air. It has also some other significations amongst the alchemists.

Chaos, in *Zoology*, a genus of insects belonging to the order of vermes zoophyta. The body has no shell or covering, and is capable of reviving after being dead to appearance for a long time; it has no joints or external organs of sensation. There are five species, mostly obtained by infusions of different vegetables in water, and only discoverable by the microscope. See Animalculæ.

CHAPEAU, in *Heraldry*, an ancient cap of dignity worn by dukes, being scarlet-coloured velvet on the outside, and lined with a fur. It is frequently borne above a helmet instead of a wreath, under gentlemen's crests.

CHAPEL, a place of divine worship so called. The word is derived from the Latin *capella.* In former times, when the kings of France were engaged in war, they always carried St Martin's hat into the field, which was kept in a tent as a precious relick: from whence the place was called *capella;* and the priests, who had the custody of the tent, *capellani.* Afterwards the word *capella* became applied to private oratories.

In Britain there are several sorts of chapels. 1. Parochial chapels: these differ from parish churches only in name; they are generally small, and the inhabitants within the district few. If there be a presentation *ad ecclesiam* instead of *capellam*, and an admission and institution upon it, it is no longer a chapel, but a church. 2. Chapels, which adjoin to, and are part of the church: such were formerly built by honourable persons, as burying-places for themselves and their families. 3. Chapels of ease; these are usually built in very large parishes, where all the people cannot conveniently repair to the mother church. 4. Free chapels; such as were founded by kings of England. They are free from all episcopal jurisdiction, and only to be visited by the founder and his successors; which is done by the lord chancellor: yet the king may license any subject to build and endow a chapel, and by letters patent exempt it from the visitation of the ordinary. 5. Chapels in the universities, belonging to particular colleges. 6. Domestic chapels, built by noblemen or gentlemen for the private service of God in their families. See Chaplain.

Chapel is also a name given to a printer's workhouse; because, according to some authors, printing was first actually performed in chapels or churches; or, according to others, because Caxton, an early printer, exercised the art in one of the chapels in Westminster Abbey. In this sense they say, *the orders or laws of the chapel*, *the secrets of the chapel*, &c.

Knights of the Chapel, called also *Poor Knights of Windsor*, were instituted by Henry VIII. in his testament. Their number was at first thirteen, but has been since augmented to 26. They assist in the funeral services of the kings of England: they are subject to the office of the canons of Windsor, and live on pensions assigned them by the order of the Garter. They bear a blue or red cloak, with the arms of St George on the left shoulder.

CHAPELAIN, James, an eminent French poet, born at Paris in 1595, and often mentioned in the works of Balzac, Menage, and other learned men. He wrote several works, and at length distinguished himself by a heroic poem called *La Pucelle, ou France Delivrée*, which employed him several years; and which, raising the expectation of the public, was as much decried by some as extolled by others. He was one of the king's counsellors; and died in 1647, very rich, but was very covetous and sordid.

CHAPELET, in the manege, a couple of stirrup-leathers, mounted each of them with a stirrup, and joined atop in a sort of leather buckle, called the *head of the chapelet*, by which they were made fast to the pummel of the saddle, after being adjusted to the rider's length and bore. They are used both to avoid the trouble of taking up or letting down the stirrups every time that a gentleman mounts on a different horse and saddle, and to supply the place of the academy saddles, which have no stirrups to them.

CHAPELLE, Claudius Emanuel Luillier, the natural son of Francis Luillier, took the name of *Chapelle* from a village between Paris and St Denys, where he was born. He distinguished himself by writing small pieces of poetry, in which he discovered great delicacy,

delicacy, an easy turn, and an admirable felicity of expression. He was the friend of Gassendi and Moliere: and died in 1686.

CHAPERON, Chaperonne, or Chaperoon, properly signifies a sort of hood or covering for the head, anciently worn both by men and women, the nobles and the populace, and afterwards appropriated to the doctors and licentiates in colleges, &c. Hence the name passed to certain little shields, and other funeral devices, placed on the foreheads of the horses that drew the hearses in pompous funerals, and which are still called *chaperoons* or *shafferoons;* because such devices were originally fastened on the *chaperonnes*, or hoods, worn by those horses with their other coverings of state.

Chaperon of a bit-mouth, in the manege, is only used for scatch-mouths, and all others that are not cannon-mouths, signifying the end of the bit that joins to the branch just by the banquet. In scatch-mouths the chaperon is round, but in others it is oval: and the same part that in scatch and other mouths is called *chaperon*, is in cannon-mouths called *fronçeau*.

CHAPITERS, in *Architecture*, the same with Capitals.

Chapiters, in *Law*, formerly signified a summary of such matters as were inquired of, or presented before justices in eyre, justices of assize, or of the peace, in their sessions.

Chapiters, at this time, denotes such articles as are delivered by the mouth of the justice in his charge to the inquest.

CHAPLAIN properly signifies a person provided with a chapel, or who discharges the duty thereof.

Chaplain is also used for an ecclesiastical person, in the house of a prince, or a person of quality, who officiates in their chapels, &c.

In England there are 48 chaplains to the king, who wait four each month, preach in the chapel, read the service to the family, and to the king in his private oratory, and say grace in the absence of the clerk of the closet. While in waiting they have a table and attendance, but no salary. In Scotland the king has six chaplains, with a salary of 50l. each, three of them having in addition the deanery of the chapel-royal divided between them, making up above 100l. to each. The only duty at present is to say prayers at the election of peers for Scotland to sit in parliament.—According to a statute of Henry VIII. the persons vested with a power of retaining chaplains, together with the number each is allowed to qualify, is as follows: An archbishop, eight; a duke or bishop, six; marquis or earl, five; viscount, four; baron, knight of the Garter, or lord chancellor, three; a duchess, marchioness, countess, baroness, the treasurer and comptroller of the king's house, clerk of the closet, the king's secretary, dean of the chapel, almoner, and master of the rolls, each of them two; chief justice of the king's bench, and warden of the cinque-ports, each one. All these chaplains may purchase a license or dispensation, and take two benefices with cure of souls. A chaplain must be retained by letters testimonial under hand and seal; for it is not sufficient that he serve as chaplain in the family.

The first chaplains are said to have been those instituted by the ancient kings of France, for preserving the chape, or cape, with the other relicks of St Martin, which the kings kept in their palace, and carried out with them to the war. The first chaplain is said to have been Gul. de Mesmes, chaplain to St Louis.

Chaplain in the order of Malta, is used for the second rank or class in that order; otherwise called *diaco*.

The knights make the first class, and the chaplains the second.

Chaplains of the Pope, are the auditors, or judges of cause in the sacred palace; so called, because the pope anciently gave audience in his chapel, for the decision of cases sent from the several parts of Christendom. He hither summoned as assessors the most learned lawyers of his time; and they hence acquired the appellation of *capellani*, chaplains. It is from the decrees formerly given by these that the body of decretals is composed: their number Pope Sixtus IV. reduced to twelve.

Some say, the shrines of relicks were covered with a kind of tent-cape, or *capella*, i. e. little cape; and that hence the priests, who had the care of them, were called chaplains. In time these relicks were reposited in a little church, either contiguous to a larger or separate from it; and the same name, *capella*, which was given to the cover, was also given to the place where it was lodged: and hence the priest who superintended it came to be called chaplain.

CHAPLET, an ancient ornament for the head, like a garland or wreath: but this word is frequently used to signify the circle of a crown. There are instances of its being borne in a coat of arms, as well as for crests; the paternal arms for Lascelles are argent, three chaplets, gules.

Chaplet also denotes a string of beads used by the Roman Catholics, to count the number of their prayers. The invention of it is ascribed to Peter the hermit, who probably learned it of the Turks, as they owe it to the East Indians.

Chaplets are sometimes called *paternosters;* and are made of coral, of diamonds, of wood, &c. The common chaplet contains 50 ave-marias, and five paternosters. There is also a chaplet of our Saviour, consisting of 33 beads, in honour of his 33 years living on the earth, instituted by Father Michael the Camaldulian.

The Orientals have a kind of chaplets which they call *chains*, and which they use in their prayers, rehearsing one of the perfections of God on each link or bead. The Great Mogul is said to have 18 of these chains, all precious stones; some diamonds, others rubies, pearls, &c. The Turks have likewise chaplets, which they bear in the hand, or hang at the girdle: but Father Dandini observes, they differ from those used by the Romanists, in that they are all of the same bigness, and have not that distinction into decades, though they consist of six decades, or 60 beads. He adds, that the Mussulmans run over the chaplet almost in an instant, the prayers being extremely short, as containing only these words, "praise to God," or "glory to God," for each bead. Besides the common chaplet they have likewise a larger one consisting of 100 beads, where there is some distinction, as being divided by little threads into three parts; on one of which they repeat 30 times *soubhan Allah*, i. e. "God is worthy to be praised:" on another, *ellamh Allah*, "Glory be to God:" and on the third, *Allah echer*, "God is great." These thrice thirty times making only 90; to complete the number 100, they add other prayers for the beginning of the chaplet.—He adds, that the Mahometan chaplet appears to have had its rise from the *mea beracoth*, or "hundred benedictions," which the Jews are obliged to repeat daily, and which we find in their prayer books; the Jews and Mahometans having this in common, that they scarce do any thing without pronouncing some laud or benediction.

Menage derives the word *chaplet* from *chapeau*, "hat." The modern Latins call it *chapellina*, the Italians more frequently *corona*.

Chaplet, or *Chapelet*, in *Architecture*, a little moulding, cut or carved into round beads, pearls, olives, or the like.

CHAPMAN, George, born in 1557, a man highly esteemed in his time for his dramatic and poetic works. He wrote 17 plays; translated Homer and some other ancient poets; and was thought no mean genius. He died in 1634; and was buried in St Giles's in the Fields, where his friend Inigo Jones erected a monument to him.

CHAPPE, in *Heraldry*, the dividing an escutcheon by lines drawn from the centre of the upper edge to the angles below, into three parts, the sections on the sides being of different metal or colour from the rest.

CHAPPEL *in* FRITH, a market town of Derbyshire, about 26 miles north-west of Derby. W. Long. 1. 50. N. Lat. 53. 22.

Chappel, *William*, a learned and pious bishop of Cork, Cloyne, and Ross in Ireland, born in Nottinghamshire in 1582. When the troubles began under Charles I. he was prosecuted by the puritan party in parliament, and retired to Derby, where he devoted himself to study till his death in 1649. He wrote *Methodus Concionandi*, i. e. "the Method of Preaching:" and he is one of those to whom the *Whole Duty of Man* has been attributed. He left behind him also his own life written by himself in Latin, which has been twice printed.

CHAPTER, in ecclesiastical polity, a society or community of clergymen belonging to the cathedrals and collegiate churches.

It was in the eighth century that the body of canons began to be called a chapter. The chapter of the canons of a cathedral were a standing council to the bishops, and, during the vacancy of the see, had the jurisdiction of the diocese. In the earlier ages, the bishop was head of the chapter; afterwards abbots and other dignitaries, as deans, provosts, treasurers, &c. were preferred to this distinction. The deans and chapters had the privilege of choosing the bishops in England; but Henry VIII. got this power vested in the crown: and as the same prince expelled the monks from the cathedrals, and placed secular canons in their room, those he thus regulated were called deans and chapters of the new foundation; such are Canterbury, Winchester, Ely, Carlisle, &c. See Dean.

Chapter, in matters of literature, a division in a book for keeping the subject treated of more clear and distinct.

CHAR, in *Ichthyology*, a species of Salmo.

CHARA. See Botany *Index*.

CHARABON, a sea-port town on the northern coast of the island of Java in the East Indies. E. Long. 10. 8. S. Lat. 6.

CHARACENE, the most southern part of Susiana, a province of Persia, lying on the Persian gulf, between the Tigris and the Eulæus. It was so named from the city of Chorax, called first Alexandria, from its founder Alexander the Great; afterwards Antiochia, from Antiochus V. king of Syria, who repaired and beautified it; and lastly, Chorax Spasinæ, or Pasinæ, that is, the Mole of the Spasines, an Arabian king of that name having secured it against the overflowing of the Tigris, by a high bank or mole, extending three miles, which served as a fence to all that country. Dionysius Periegetes, and Isidorus, author of the Parthicæ Mansiones, were both natives of this city. The small district of Characene was seized by Pasines, the son of Sogdonacus, king of the neighbouring Arabs, during the troubles of Syria, and erected into a kingdom. Lucian calls him Hyspasines, and adds, that he ruled over the Characeni and the neighbouring people: he died in the 85th year of his age. The other kings of this country we find mentioned by the ancients are, Teræus, who died in the 92d year of his age, and after him Artabazus the seventh, as Lucian informs us, who was driven from the throne by his own subjects, but restored by the Parthians. And this is all we find in the ancients relating to the kings of Characene.

CHARACTER, in a general sense, signifies a mark or figure, drawn on paper, metal, stone, or other matter, with a pen, graver, chissel, or other instrument, to signify or denote any thing. The word is Greek, χαρακτηρ, formed from the verb, χαρασσων, *insculpere*, "to engrave, impress," &c.

The various kinds of characters may be reduced to three heads, viz. *Literal Characters*, *Numeral Characters*, and *Abbreviations*.

I. *Literal* Character, is a letter of the alphabet, serving to indicate some articulate sound, expressive of some idea or conception of the mind. See Alphabet.

1. These may be divided, with regard to their nature and use, into *Nominal Characters*, or those we properly call *letters;* which serve to express the names of things: See Letter. *Real Characters;* those that instead of names express things and ideas: See Idea, &c. *Emblematical* or *Symbolical Characters;* which have this in common with real ones, that they express the things themselves; but have thus further, that they in some measure personate them, and exhibit their form; such are the hieroglyphics of the ancient Egyptians. See Hieroglyphic, Symbol, &c.

2. *Literal* Characters may be again divided, with regard to their invention and use, into *particular* and *general* or *universal*.

Particular Characters, are those peculiar to this or that nation. Such are the Roman, Italic, Greek, Hebrew, Arabic, Gothic, Chinese, &c. *characters.*—See Hebrew, Gothic, Chinese, &c.

Universal CHARACTERS, are also *real characters*, and make what some authors call a *Philosophical Language*.

That diversity of *characters* used by the several nations to express the same idea, is found the chief obstacle to the advancement of learning; to remove this, several authors have taken occasion to propose plans of *characters* that should be universal, and which each people should read in their own language. The *character* here is to be real, not nominal: to express things and notions; not, as the common ones, letters or sounds: yet to be mute, like letters, and arbitrary; not emblematical, like hieroglyphics.

Thus, every nation should retain its own language, yet every one understand that of each other, without learning it; only by seeing a real or universal *character* which should signify the same things to all people, by what sounds soever each express it in their particular idiom. For instance, by seeing the *character* destined to signify *to drink*, an Englishman should read *to drink;* a Frenchman, *boire;* a Latin, *bibere;* a Greek πινειν; a Jew, שמת; a German, *trincken:* and so of the rest; in the same manner as seeing a horse, each people expresses it after their own manner; but all mean the same animal.

This real *character* is no chimera; the Chinese and Japanese have already something like it. They have a common *character*, which each of those nations understand alike in their several languages; though they pronounce them with such different sounds, that they do not understand one another in speaking.

The first and most considerable attempts for a *real character*, or philosophical language, in Europe, are those of Bishop Wilkins and Dalgarno: but these, with how much art soever they were contrived, have yet proved ineffectual.

M. Leibnitz had some thoughts the same way; he thinks those great men did not hit the right method. It was probable, indeed, that by their means, people who do not understand one another might easily have a commerce together: but they have not hit on true *real characters*.

According to him, the *characters* should resemble those used in algebra; which, in effect, are very simple, yet very expressive; without any thing superfluous or equivocal; and contain all the varieties required.

The *real character* of Bishop Wilkins has its just applause: Dr Hook recommends it, on his own knowledge and experience, as a most excellent scheme; and to engage the world to the study thereof, publishes some fine inventions of his own therein.

M. Leibnitz tells us, he had under consideration an *alphabet of human thoughts;* in order to a new philosophical language on his own scheme: but his death prevented its being brought to maturity.

M. Lodwic, in the Philosophical Transactions, gives us a plan of *an universal alphabet* or *character of* another kind: this was to contain an enumeration of all such single sounds, or letters, as are used in any language; by means whereof, people should be enabled to pronounce truly and readily any language; to describe the pronunciation of any language that shall be pronounced in their hearing, so as others accustomed to this language, though they had never heard the language pronounced, shall at first be able truly to pronounce it: and, lastly, this *character* to serve as a standard to perpetuate the sounds of any language. In the Journal Litteraire, an. 1720, we have a very ingenious project for an universal *character*. The author, after obviating the objections that might be made against the feasibleness of such schemes in the general, proposes his own: his *characters* are to be the common Arabic, or numeral figures. The combinations of these nine are sufficient to express distinctly an incredible quantity of numbers, much more than we shall need terms to signify our actions, goods, evils, duties, passions, &c. Thus is all the trouble of framing and learning any new *character* at once saved; the Arabic figures having already all the universality required.

The advantages are immense. For, 1*mo*, We have here a stable, faithful interpreter; never to be corrupted or changed, as the popular languages continually are. 2*do*, Whereas the difficulty of pronouncing a foreign language is such as usually gives the learner the greatest trouble, and there are even some sounds which foreigners never attain to, in the *character* here proposed this difficulty has no place: every nation is to pronounce them according to the particular pronunciation that already obtains among them. All the difficulty is, the accustoming the pen and the eye to affix certain notions to *characters* that do not, at first sight, exhibit them. But this trouble is no more than we find in the study of any language whatever.

The inflections of words are here to be expressed by the common letters. For instance, the same *character* shall express a *filly* or a *colt*, a *horse* or a *mare*, an *old horse* or an *old mare*, as accompanied with this or that distinctive letter, which shall show the sex, youth, maturity, or old age; a letter also to express the bigness or size of things; thus *v. g.* a man with this or that letter, to signify a *great man*, or a *little man*, &c.

The use of those letters belongs to the grammar; which, once well understood, would abridge the vocabulary exceedingly. An advantage of this grammar is, that it would only have one declension and one conjugation; those numerous anomalies of grammarians are exceeding troublesome; and arise hence, that the common languages are governed by the populace, who never reason on what is best; but in the *character* here proposed, men of sense having the introduction of it, would have a new ground, whereon to build regularly.

A new universal character has been proposed by Mr Northmore of London, by which different nations may communicate their sentiments to each other. His original plan was, to make the same numerical figure represent the same word in all languages. But he found afterwards that it might be improved, by using a figure not for every word, but every *useful* word. And even these he thinks might be abbreviated by adopting certain uniform fixed signs, the number of which would not exceed 20, for the various parts of speech. Words of negation, he proposed, to be expressed by a prefixed sign. A few instances will explain the author's meaning.

Suppose the number 5 to represent the word *see*,
6 - - *a man*,
7 - - *happy*,
8 - - *never*,
9 - - *I*,

Characters.

"I would then (says he) express the tenses, genders, cases, &c. *in all languages*, in some such *uniform* manner as the following:

(1)	5	=	*present tense*,	-	see,
(2)	$\cdot 5$	=	*perfect tense*,	-	saw,
(3)	$:5$	=	*perfect participle*,	-	seen,
(4)	$5:$	=	*present participle*,	-	seeing,
(5)	$5\cdot$	=	*future*,	-	will see,
(6)	$\underline{5}$	=	*substantive*,	-	sight,
(7)	$\underline{\underline{5}}$	=	*personal substantive*,	-	spectator,
(8)	6	=	*nominative case*,	-	a man,
(9)	$\ddot{6}$	=	*genitive*,	-	of a man,
(10)	$\dddot{6}$	=	*dative*, -	-	to a man,
(11)	$\overset{\frown}{6}$	=	*feminine*, -	-	a woman,
(12)	$+6$	=	*plural*, -	-	men,
(13)	7	=	*positive*, -	-	happy,
(14)	$\hat{7}$	=	*comparative*,	-	happier,
(15)	$\hat{\hat{7}}$	=	*superlative*,	-	happiest,
	$\underline{7}$	=	as above, No. 6.	-	happiness,
(16)	-7	=	*negation*, -	-	unhappy.

"From the above specimen, I should find no difficulty in comprehending the following sentence, though it were written in the language of the Hottentots:

$9, 8, \cdot 5, -\hat{7}, \overset{\frown}{6}$. *I never saw a more unhappy woman.*

"Those languages which do not use the pronoun prefixed to the verb, as the Greek and Roman, &c. may apply it, in a small character, simply to denominate the person; thus, instead of 9, 8, .5, *I never saw;* they may write, 8, $_9 5$, which will signify that the verb is in the first person, and will still have the same meaning."

Our author thinks, that according to this scheme of an universal character, about 20 signs, and less than 10,000 *chosen* words (synonyms being set aside), would answer all the ends proposed; and that foreigners, by referring to their numerical dictionary, would easily comprehend each other. He proceeds next to shew how appropriate sounds may be given to his signs, and an universal *living language* formed from the universal *characters*.

To attain this end, he proposes to distinguish the ten numerals by ten monosyllabic names of easy pronunciation, and such as may run without difficulty into one another. To illustrate his scheme, however, he calls them, for the present, by their common English names; but would pronounce each number made use of by uttering separately its component parts, after the manner of accountants. Thus, let the number 6943 represent the word *horse*, he would not, in the universal language, call a horse *six thousand nine hudred and forty-three*, but *six*, *nine*, *four*, *three*, and so on for all the words of a sentence, making the proper stop at the end of each. In the same manner, a distinct appellation must be appropriated to each of the prefixed signs, to be pronounced immediately after the numeral to which it is an appendage. Thus, if *plu* be the appellation or the sign of the plural number, *six*, *nine*, *four*, *three*, *plu* will be *horses*.

"Thus (says our author), I hope, it is evident that about 30 or 40 distinct syllables are sufficient for the above purpose; but I am much mistaken if *eleven* only will not answer the same end. This is to be done by substituting the first 20 or 30 numerals for the signs, and saying, as in algebra, that a term is in the power of such a number, which may be expressed by the simple word *under*. *Ex gr.* Let 6943 represent the word *horse;* and suppose 4 to be the sign of the plural number, I would write the word thus $\frac{4}{6943}$; and pronounce it, six, nine, four, three, in the power of or *under* four. By these means eleven distinct appellations would be sufficient, and time and use would much abbreviate the pronunciation."

But the difficulty is not in inventing the most simple, easy, and commodious *character*, but in engaging the several nations to use it; there being nothing they agree less in, than the understanding and pursuing their common interest.

3. Literal characters may again be divided, with respect to the nations among whom they have been invented, into Greek characters, Roman characters, Hebrew characters, &c. The Latin character now used through all Europe, was formed from the Greek, as the Greek was from the Phœnician; and the Phœnician, as well as the Chaldee, Syriac, and Arabic characters, were formed from the ancient Hebrew, which subsisted till the Babylonish captivity; for after that event the character of the Assyrians, which is the square Hebrew now in use, prevailed, the ancient being only found on some Hebrew medals, commonly called Samaritan medals. It was in 1091 that the Gothic characters, invented by Ulfilas, were abolished, and the Latin ones established in their room.

Medallists observe, that the Greek character, consisting only of majuscule letters, has preserved its uniformity on all medals, as low as the time of Gallienus, from which time it appears somewhat weaker and rounder: from the time of Constantine to Michael we find only Latin characters: after Michael, the Greek characters recommence; but from that time they began to alter with the language, which was a mixture of Greek and Latin. The Latin medals preserved both their characters and language, as low as the translation of the seat of the empire to Constantinople: towards the time of Decius the character began to lose its roundness and beauty; some time after, it retrieved and subsisted tolerably till the time of Justin, when it degenerated gradually into the Gothic. The rounder, then, and better formed a character is upon a medal, the fairer pretence it has to antiquity.

II. *Numerical Characters*, or characters used to express numbers, are either letters or figures.

The Arabic character, called also the common one, because it is used almost throughout Europe in all sorts of calculations, consists of these ten digits, 1, 2, 3, 4, 5, 6, 7, 8, 9, 0.

The Roman numeral character consists of seven majuscule letters of the Roman alphabet, viz. I, V, X, L, C, D, M. The I denotes one, V five, X ten, L fifty, C a hundred, D five hundred, and M a thousand. The I repeated twice makes two, II; thrice, three, Characters. three, III. Four is expressed thus, IV. as I before V or X takes an unit from the number expressed by these letters. To express six, an I is added to a V, VI.; for seven, two, VII.; and for eight, three, VIII. Nine is expressed by an I before X, thus, IX. The same remark may be made of the X before L or C, except that the diminution is by tens; thus, XL denotes forty, XC ninety, and LX sixty. The C before D or M diminishes each by a hundred. The number five hundred is sometimes expressed by an I before a C inverted, thus, IƆ; and instead of M, which signifies a thousand, an I is sometimes used between two C's, the one direct, and the other inverted, thus, CIƆ. The addition of C and Ɔ before or after raises CIƆ by tens; thus, CCIƆƆ expresses ten thousand, CCCIƆƆƆ a hundred thousand. The Romans also expressed any number of thousands by a line drawn over any numeral less than a thousand; thus, $\overline{V}$ denotes five thousand, $\overline{LX}$ sixty thousand; so likewise $\overline{M}$ is one milllion, $\overline{MM}$ is two millions, &c.

The Greeks had three ways of expressing numbers: 1. Every letter, according to its place in the alphabet, denoted a number, from α, one, to ω, twenty-four. 2. The alphabet was divided into eight units, α, one, β two, γ, three, &c.; into eight tens, ι ten, κ twenty, λ thirty, &c.; and eight hundreds, ρ one hundred, σ two hundred, τ three hundred, &c. 3. Ι stood for one, Π five, Δ ten, Η a hundred, Χ a thousand, Μ ten thousand; and when the latter Π enclosed any of these, except Ι, it showed the enclosed letter to be five times its value; as; |Δ| fifty, |Η| five hundred, |Χ| five thousand, |Μ| fifty thousand.

The French CHARACTERS used in the chamber of accounts, and by persons concerned in the management of the revenue, is, properly speaking, nothing else than the Roman numerals, in letters that are not majuscule; thus, instead of expressing fifty-six by LVI, they denote it by smaller characters, lvj.

III. CHARACTERS of Abbreviations, &c. in several of the arts, are symbols contrived for the more concise and immediate conveyance of the knowledge of things. For the

CHARACTERS *used in Algebra*. See ALGEBRA, Introduction.

Of the Aspects.

☌ or S Conjunction	△ Trine
SS Semisextile	Bq Biquintile
* Sextile	Vc Quincunx
Q Quintile	☍ Opposition
□ Quartile	☊ Dragon's head
Td Tredecile	☋ Dragon's tail

Of Time.

A. M. *ante meridiem*, before the sun comes upon the meridian.
O. or N. noon.
P. M. *post meridiem*, when the sun is past the meridian.

CHARACTERS *in Commerce.*

D° *ditto*, the same	S or *s* shillings
N° *numero*, or number	*d* pence or deniers
F° *folio*, or page	℔ pound weight
C or ⊕ hundred weight, or 112 pounds	R° *recto* } *folio*
q^{ts} quarters	V° *vero* } *folio*
L. or *l.* pounds Sterling	R^x rixdollar
p^r *per* or by, p^r *ann.* by the year, p^r *cent.*	D^t ducat
	P. S. postscript, &c.

Characters.

CHARACTERS *in Geometry and Trigonometry.*

‖ the character of parallelism	⩝ equiangular or similar
△ triangle	≛ equilateral
□ square	∠ an angle
▯ ▭ rectangle	∟ right angle
⊙ circle	⊥ perpendicular

° denotes a degree; thus 45° implies 45 degrees. ′ denotes a minute; thus, 50′ is 50 minutes. ″, ‴, ⁗, denote seconds, thirds, and fourths: and the same characters are used when the progressions are by tens, as it is here by sixties.

CHARACTERS *in Grammar, Rhetoric, Poetry, &c.*

( ) parenthesis	D. D. doctor in divinity
[ ] crotchet	V. D. M. minister of the word of God
- hyphen	LL. D. doctor of laws
' apostrophe	J. V. D. doctor of civil and common law
` emphasis or accent	M. D. doctor in physic
˘ breve	A. M. master of arts
·· dialysis	A. B. bachelor of arts
‸ caret and circumflex	F. R. S. fellow of the royal society
† ‡ and * references	
§ section or division	
¶ paragraph	
" quotation	

For the other characters used in Grammar, see COMMA, COLON, SEMICOLON.

CHARACTERS *among the ancient Lawyers, and in ancient Inscriptions.*

§ paragraph	C. Code
ff digests	C. C. consules
Scto. senatus consulto	T. titulus
E. extra	P. P. D. D. propria pecunia dedicavit
S. P. Q. R. senatus populusque Romanus	D. D. M. dono dedit monumentum.
P. P. pater patriæ	

CHARACTERS *in Medicine and Pharmacy.*

℞ recipe	M. manipulus, a handful
ā, āā or ana, of each alike	P. a pugil
℔ a pound, or a pint	P. Æ. equal quantities
℥ an ounce	S. A. according to art
ʒ a drachm	q. s. a sufficient quantity
℈ a scruple	q. pl. as much as you please
gr. grains	P. P. pulvis patrum, the Jesuits bark.
ß or ſs half of any thing	
cong. congius, a gallon	
coch. cochleare, a spoonful	

CHARACTERS *upon Tomb-stones.*

S. V. Siste viator, *i. e.* Stop traveller.
M. S. Memoriæ sacrum, *i. e.* Sacred to the memory.

Characters.

D. M. Diis manibus.

J. H. S. Jesus.

X. P. a character found in the catacombs, about the meaning of which authors are not agreed.

CHARACTERS used in Music, and of Musical Notes with their proportions, are as follows.

𝆶	character of a large	8	𝅘𝅥	crotchet	$\frac{1}{4}$
𝆷	a long	4	𝅘𝅥𝅮	quaver	$\frac{1}{8}$
𝅜	a breve	2	𝅘𝅥𝅯	semiquaver	$\frac{1}{16}$
𝅝	a semibreve	1	𝅘𝅥𝅰	demisemiquaver	$\frac{1}{32}$
𝅗𝅥	a minim	$\frac{1}{2}$			

♯ character of a sharp note; this character, at the beginning of a line or space, denotes that all the notes in that line are to be taken a semitone higher than in the natural series; and the same affects all the octaves above and below, though not marked: but when prefixed to any particular note, it shows that note alone to be taken a semitone higher than it would be without such a character.

♭ or *b*, character of a flat note: this is the contrary to the other above; that is, a semitone lower.

♮ character of a natural note: when in a line or series of artificial notes, marked at the beginning ♭ or ♯, the natural note happens to be required, it is denoted by this character.

𝄞 character of the treble cliff.

𝄡 character of the mean cliff.

𝄢 bass cliff.

$\frac{2}{4}$ or $\frac{4}{8}$, characters of common duple time, signifying the measure of two crotchets to be equal to two notes, of which four make a semibreve.

C ₵ Φ characters that distinguish the movements of common time, the first implying slow, the second quick, and the third very quick.

$\frac{1}{2}$, $\frac{1}{3}$, $\frac{3}{4}$, $\frac{3}{8}$, $\frac{1}{16}$, characters of simple triple time, the measure of which is equal to three semibreves, or to three minims.

$\frac{4}{6}$, $\frac{6}{8}$, or $\frac{6}{16}$, characters of a mixed triple time where the measure is equal to six crotchets, or six quavers.

$\frac{9}{4}$, or $\frac{9}{8}$, or $\frac{9}{16}$, or $\frac{9}{1}$, or $\frac{9}{2}$, characters of compound triple time.

$\frac{4}{12}$, $\frac{8}{12}$, $\frac{12}{16}$, or $\frac{1}{12}$, or $\frac{2}{12}$, characters of that species of triple time called the measure of twelve times.

CHARACTER, in human life, that which is peculiar in the manners of any person, and distinguishes him from all others.

Good CHARACTER, is particularly applied to that conduct which is regulated by virtue and religion; in an inferior but very common sense, it is understood of mere honesty of dealing between man and man. The importance of a good character in the commerce of life seems to be universally acknowledged.—To those who are to make their own way either to wealth or honours, a good character is usually no less necessary than address and abilities. To transcribe the observation of an elegant moralist: though human nature is degenerate, and corrupts itself still more by its own inventions; yet it usually retains to the last an esteem for excellence, But even if we are arrived at such an extreme degree of depravity as to have lost our native reverence for virtue; yet a regard to our own interest and safety, which we seldom lose, will lead us to apply for aid, in all important transactions, to men whose integrity is unimpeached. When we choose an assistant, a partner, a servant, our first inquiry is concerning his character. When we have occasion for a counsellor or attorney, a physician or apothecary, whatever we may be ourselves, we always choose to trust our property and persons to men of the best character. When we fix on the tradesmen who are to supply us with necessaries, we are not determined by the sign of the lamb, or the wolf, or the fox, nor by a shop fitted up in the most elegant taste; but by the fairest reputation. Look into a daily newspaper, and you will see, from the highest to the lowest rank, how important the characters of the employed appear to the employers. After the advertisement has enumerated the qualities required in the person wanted, there constantly follows, that none need apply who cannot bring an undeniable character. Offer yourself as a candidate for a seat in parliament, be promoted to honour and emolument, or in any respect attract the attention of mankind upon yourself, and if you are vulnerable in your character, you will be deeply wounded. This is a general testimony in favour of honesty, which no writings and no practices can possibly refute.

Young men, therefore, whose characters are yet unfixed, and who consequently may render them just such as they wish, ought to pay great attention to the first steps which they take on entrance into life. They are usually careless and inattentive to this object. They pursue their own plans with ardour, and neglect the opinions which others entertain of them. By some thoughtless action or expression, they suffer a mark to be impressed upon them, which scarcely any subsequent merit can entirely erase. Every man will find some persons, who, though they are not professed enemies, yet view him with an envious or a jealous eye, and who will gladly revive any tale to which truth has given the slightest foundation.

In this turbulent and confused scene, where our words and actions are often misunderstood, and oftener misrepresented, it is indeed difficult even for innocence and integrity to avoid reproach, abuse, contempt, and hatred. These not only hurt our interest and impede our advancement in life, but sorely afflict the feelings of a delicate and tender mind. It is then the part of wisdom first to do every thing in our power to preserve an irreproachable character, and then to let our happiness depend chiefly on the approbation of our own consciences, and on the advancement of our interest in a world where liars shall not be believed, and where slanders shall receive countenance from none but him who, in Greek, is called by way of eminence, *Diabolus*, or the calumniator.

CHARACTER, in *Poetry*, particularly the epopee and drama, is the result of the manners or peculiarities by which each person is distinguished from others.

The poetical character, says M. Bossu, is not properly any particular virtue or quality, but a composition of several which are mixed together, in a different degree, according to the necessity of the fable and the unity of the action: there must be one, however, to reign over all the rest; and this must be found, in some degree, in every part. The first quality in Achilles, is wrath; in Ulysses, dissimulation; and in Æneas, Character, Characteristic. Æneas, mildness; but as these characters cannot be alone, they must be accompanied with others to embellish them, as far as they are capable, either by hiding their defects, as in the anger of Achilles, which is palliated by extraordinary valour; or by making them centre in some solid virtue, as in Ulysses, whose dissimulation makes a part of his prudence; and in Æneas, whose mildness is employed in a submission to the will of the gods. In the making up of which union, it is to be observed, the poets have joined together such qualities as are by nature the most compatible; valour with anger, piety with mildness, and prudence with dissimulation. The fable required prudence in Ulysses, and piety in Æneas; in this, therefore, the poets were not left to their choice; but Homer might have made Achilles a coward without abating any thing from the justness of his fable; so that it was the necessity of adorning his character, that obliged him to make him valiant; the character, then, of a hero in the epic poem, is compounded of three sorts of qualities; the first essential to the fable; the second, embellishments of the first; and valour, which sustains the other two, makes the third.

Unity of character is as necessary as the unity of the fable. For this purpose a person should be the same from the beginning to the end; not that he is always to betray the same sentiments, or one passion; but that he should never speak nor act inconsistently with his fundamental character. For instance, the weak may sometimes sally into a warmth, and the breast of the passionate be calm, a change which often introduces in the drama a very affecting variety; but if the natural disposition of the former was to be represented as boisterous, and that of the latter mild and soft, they would both act out of character, and contradict their persons.

True characters are such as we truly and really see in men, or may exist without any contradiction to nature; no man questions but there have been men as generous and as good as Æneas, as passionate and as violent as Achilles, as prudent and wise as Ulysses, as impious and atheistical as Mezentius, and as amorous and passionate as Dido; all these characters, therefore, are true, and nothing but just imitations of nature. On the contrary, a character is false when an author so feigns it, that one can see nothing like it in the order of nature wherein he designs it shall stand; these characters should be wholly excluded from a poem, because, transgressing the bounds of probability and reason, they meet with no belief from the readers; they are fictions of the poet's brain, not imitations of nature; and yet all poetry consists of an imitation of nature.

Character is also used for certain visible qualities, which claim respect or reverence to those vested therewith.—The majesty of kings gives them a character which procures respect from the people. A bishop should sustain his character by learning and solid piety, rather than by worldly lustre, &c. The law of nations secures the character of an ambassador from all insults.

Character, among naturalists, is synonymous with the definition of the genera of animals, plants, &c.

CHARACTERISTIC, in general, is that which characterises a thing or person, i. e. constitutes its character, whereby it is distinguished. See Character.

Characteristic, Charade.

Characteristic, is peculiarly used in grammar, for the principal letter of a word; which is preserved in most of its tenses and moods, its derivatives and compounds.

Characteristic of a Logarithm, is its index or exponent. See Logarithm.

Characteristic Triangle of a Curve, in the higher geometry, is a rectilinear right-angled triangle, whose hypothenuse makes a part of the curve, not sensibly different from a right line. It is so called, because curve lines are used to be distinguished hereby. See Curve.

CHARADE, the name of a new species of composition or literary amusement. It owes its name to the idler who invented it. Its subject must be a word of two syllables, each forming a distinct word; and these two syllables are to be concealed in an enigmatical description, first separately, and then together. The exercise of charades, if not greatly instructive, is at least innocent and amusing. At all events, as it has made its way into every fashionable circle, and has employed even Garrick, it will scarcely be deemed unworthy of attention. The silliness indeed of most that have appeared in the papers under this title, are not only destitute of all pleasantry in the stating, but are formed in general of words utterly unfit for the purpose. They have therefore been treated with the contempt they deserved. In trifles of this nature, inaccuracy is without excuse. The following examples therefore are at least free from this blemish.

I.

My *first*, however here abused,
Designs the sex alone;
In Cambria, such is custom's pow'r,
'Tis Jenkin, John, or Joan.
My *second* oft is loudly call'd,
When men prepare to fist it:
Its name delights the female ear;
Its force, may none resist it:
It binds the weak, it binds the strong,
The wealthy and the poor;
Still 'tis to joy a passport deem'd,
For sullied fame a cure.
It may ensure an age of bliss,
Yet mis'ries oft attend it;
To fingers, ears, and noses too,
Its various lords commend it.
My *whole* may chance to make one drink,
Though vended in a fish shop;
'Tis now the monarch of the seas,
And has been an archbishop. *Her-ring.*

II.

My *first*, when a Frenchman is learning English, serves him to swear by. My *second*, is either hay or corn. My *whole*, is the delight of the present age; and will be the admiration of posterity. *Gar-rick.*

III.

My *first*, is plowed for various reasons, and grain is frequently buried in it to little purpose. My *second*, is neither riches nor honours; yet the former would generally be given for it, and the latter is often tasteless without it. My *whole* applies equally to spring, summer, autumn, and winter: and both fish and flesh, praise

praise and censure, mirth and melancholy, are the better for being in it. *Sea-son.*

IV.

My *first*, with the most rooted antipathy to a Frenchman, prides himself, whenever they meet, upon sticking close to his jacket. My *second*, has many virtues, nor is it its least that it gives name to my first. My *whole*, may I never catch! *Tar-tar.*

V.

My *first*, is one of England's prime boasts; it rejoices the ear of a horse, and anguishes the toe of a man. My *second*, when brick, is good; when stone, better; when *wooden*, best of all. My *whole*, is famous alike for rottenness and tin. *Corn-wall.*

VI.

My *first* is called bad or good,
May pleasure or offend ye;
My *second*, in a thirsty mood,
May very much befriend ye.
My *whole*, though styled a "cruel word,"
May yet appear a kind one;
It often may with joy be heard,
With tears may often blind one. *Fare-well.*

VII.

My *first* is equally friendly to the thief and the lover, the toper and the student. My *second* is light's opposite; yet they are frequently seen hand in hand; and their union, if judicious, gives much pleasure. My *whole*, is tempting to the touch, grateful to the sight, fatal to the taste. *Night-shade.*

CHARADRIUS, the PLOVER and DOTTEREL. See ORNITHOLOGY *Index*.

CHARAG, the tribute which Christians and Jews pay to the Grand Signior.

It consists of ten, twelve, or fifteen francs per annum, according to the estate of the party. Men begin to pay it at nine or at sixteen years old; women are dispensed with, as also priests, rabbins, and religious.

CHARAIMS, a sect of the Jews in Egypt. They live by themselves, and have a separate synagogue; and as the other Jews are remarkable for their eyes, so are those for their large noses, which run through all the families of this sect. These are the ancient Essenes. They strictly observe the five books of Moses, according to the letter, and receive no written traditions. It is said that the other Jews would join the *Charaims;* but those not having observed the exact rules of the law with regard to divorces, these think they live in adultery.

CHARANTIA. See MOMORDICA, BOTANY *Index*.

CHARBON, in the manege, that little black spot or mark which remains after a large spot in the cavity of the corner teeth of a horse; about the seventh or eighth year, when the cavity fills up, the tooth being smooth and equal, it is said to be rased.

CHARCAS, the southern division of Peru in South America, remarkable for the silver mines of Potosi.

CHARCOAL, a sort of artificial coal, or fuel, consisting of wood half burnt; chiefly used where a clear strong fire, without smoke, is required; the humidity of the wood being here mostly dissipated, and exhaled in the fire wherein it is prepared.

The microscope discovers a surprising number of pores in charcoal; they are disposed in order, and traverse it lengthwise; so that there is no piece of charcoal, how long soever, but may be easily blown through. If a piece be broken pretty short, it may be seen through with a microscope. In a range the 18th part of an inch long, Dr Hook reckoned 150 pores; whence he concludes, that in a charcoal of an inch diameter, there are not less than 5,724,000 pores. It is to this prodigious number of pores that the blackness of charcoal is owing; for the rays of light striking on the charcoal, are received and absorbed in its pores, instead of being reflected; whence the body must of necessity appear black, blackness in a body being no more than a want of reflection. Charcoal was anciently used to distinguish the bounds of estates and inheritances; as being incorruptible, when let very deep within ground. In effect, it preserves itself so long, that there are many pieces found entire in the ancient tombs of the northern nations. M. Dodart says, there is charcoal made of corn, probably as old as the days of Cæsar; he adds, that it has kept so well, that the wheat may be still distinguished from the rye; which he looks on as proof of its incorruptibility.

The operation of charring wood is performed in the following manner: The wood intended for this purpose is cut into proper lengths, and piled up in heaps near the place where the charcoal is intended to be made; when a sufficient quantity of wood is thus prepared, they begin constructing their stacks, for which there are three methods. The first is this: They level a proper spot of ground, of about 12 or 15 feet in diameter, near the piles of wood; in the centre of this area a large billet of wood, split across at one end and pointed at the other, is fixed with its pointed extremity in the earth, and two pieces of wood inserted through the clefts of the other end, forming four right angles; against these cross pieces four other billets of wood are placed, one end on the ground, and the other leaning against the angles. This being finished, a number of large and straight billets are laid on the ground to form a floor, each being as it were the radius of the circular area; on this floor a proper quantity of brush or small wood is strewed, in order to fill up the interstices, when the floor will be complete; and in order to keep the billets in the same order and position in which they were first arranged, pegs or stumps are driven into the ground in the circumference of the circle, about a foot distant from one another; upon this floor a stage is built with billets set upon one end, but something inclining towards the central billet; and on the tops of these another floor is laid in a horizontal direction, but of shorter billets, as the whole is, when finished, to form a cone.

The second method of building the stacks for making charcoal is performed in this manner: A long pole is erected in the centre of the area above described, and several small billets ranged round the pole on their ends; the interstices between these billets and the pole are filled with dry brushwood, then a floor is laid on that stage, in a reclining position, and on that a second floor, &c. in the same manner as described above; but in the lower floor there is a billet larger and longer than the rest, extending from the central

Charcoal. central pole to some distance beyond the circumference of the circle.

The third method is this: A chimney, or aperture of a square form, is built with billets in the centre, from the bottom to the top; and round these, floors and inclined stages are erected, in the same manner as in the stacks above described, except that the base of this, instead of being circular like the others, is square; and the whole stack, when completed, forms a pyramid.

The stack of either form being thus finished, is coated over with turf, and the surface plastered with a mixture of earth and charcoal dust well tempered together.

The next operation is the setting the stack on fire. In order to this, if it be formed according to the first construction, the central billet in the upper stage is drawn out, and some pieces of very dry and combustible wood are placed in the void space, called, by workmen, the chimney, and fire set to these pieces. If the stack be built according to the second construction, the central pole is drawn out, together with the large horizontal billet above described: and the void space occupied by the latter being filled with pieces of very dry combustible wood, the fire is applied to it at the base of the stack. With regard to the third construction, the square aperture or chimney is filled with small pieces of very dry wood, and the fire applied to it at the top or apex of the pyramidal stack. When the stack is set on fire, either at the top or bottom, the greatest attention is necessary in the workman; for in the proper management of the fire the chief difficulty attending the art of making good charcoal consists. In order to this, care is taken, as soon as the flame begins to issue some height above the chimney, that the aperture be covered with a piece of turf, but not so close as to hinder the smoke from passing out: and whenever the smoke appears to issue very thick from any part of the pile, the aperture must be covered with a mixture of earth and charcoal dust. At the same time, as it is necessary that every part of the stack should be equally burnt, it will be requisite for the workman to open vents in one part and shut them in another. In this manner the fire must be kept up till the charcoal be sufficiently burnt, which will happen in about two days and a half if the wood be dry; but if green, the operation will not be finished in less than three days. When the charcoal is thought to be sufficiently burnt, which is easily known from the appearance of the smoke, and the flames no longer issuing with impetuosity through the vents, all the apertures are to be closed up very carefully with a mixture of earth and charcoal dust, which, by excluding all access of the external air, prevents the coals from being any further consumed, and the fire goes out of itself. In this condition it is suffered to remain, till the whole is sufficiently cooled; when the cover is removed, and the charcoal is taken away. If the whole process is skilfully managed, the coals will exactly retain the figure of the pieces of wood: some are said to have been so dexterous as to char an arrow without altering even the figure of the feather.

There are considerable differences in the coals of different vegetables, in regard to their habitude, to fire; the very light coals of linen, cotton, some fungi, &c. readily catch fire from a spark, and soon burn out; the more dense ones of woods and roots are set on fire more difficultly, and burn more slowly: the coals of the black berry-bearing alder, of the hazel, the willow, and the lime tree, are said to answer best for the making of gunpowder and other pyrotechnical compositions, perhaps from their being easily inflammable: for the reduction of metallic calces those of the heavier woods, as the oak and the beech, are preferable, these seeming to contain a larger proportion of the phlogistic principle, and that, perhaps, in a more fixed state; considered as common fuel, those of the heavy woods give the greatest heat, and require the most plentiful supply of air to keep them burning; those of the light woods preserve a glowing heat, without much draught of air, till the coals themselves are consumed; the bark commonly crackles and flies about in burning, which the coal of the wood itself very seldom does. Charcoal.

Mathematical instrument makers, engravers, &c. find charcoal of great use to polish their brass and copper plates after they have been rubbed clean with powdered pumice stone. Plates of horn are polishable in the same way, and a gloss may be afterwards given with tripoli.

The coals of different substances are also used as pigments; hence the home-black, ivory-black, &c. of the shops. Most of the paints of this kind, besides their incorruptibility, have the advantage of a full colour, and work freely in all the forms in which powdery pigments are applied; provided they have been carefully prepared, by thoroughly burning the subject in a close vessel, and afterwards grinding the coal into a powder of due fineness. Pieces of charcoal are used also in their entire state for tracing the outlines of drawings, &c.; in which intention they have an excellence, that their mark is easily wiped out. For these purposes, either the finer pieces of common charcoal are picked out and cut to a proper shape; or the pencils are formed of wood, and afterwards burnt into charcoal in a proper vessel well covered. The artists commonly make choice of the smaller branches of the tree freed from the bark and pith; and the willow and vine are preferred to all others. This choice is confirmed by the experiments of Dr Lewis, who has found that the wood of the trunks of trees produces charcoal of a harder nature than their small twigs or branches; and the hard woods, such as box and guaiacum, produced coals very sensibly harder than the softer woods. Willow he prefers to all others. The shells and stones of fruits yielded coals so hard that they would scarce mark on paper at all; while the coals of the kernels of fruits were quite soft and mellow. The several coals produced by the doctor's experiments were levigated into fine powder, mixed both with gum water and oil, and applied as paints both thin and thick, and diluted with different degrees of white. All of them, when laid on thick, appeared of a strong full black, nor could it be judged that one was of a finer colour than another; diluted with white, or when spread thin, they had all somewhat of a bluish cast. *Philosoph. Commerce of Arts.*

Horns, and the bones both of fishes and land animals, gave coals rather glossier and deeper coloured than vegetables: and which, in general, were very hard, so as difficultly, or not at all, to stain paper. Here also the

the hardness of the coal seemed to depend on that of the subject from whence it was prepared; for silk, woollen, leather, blood, and the fleshy parts of animals, yielded soft coals. Some of these differed from others very sensibly in colour; that of ivory is superior to all the rest, and indisputably the finest of all the charcoal blacks. The animal coals had much less of the bluish cast in them than the vegetable, many of them inclining rather to a brown. Charred pit coal, on the other hand, seemed to have this blueness in a greater degree. For the chemical properties of charcoal, see CHEMISTRY *Index*.

CHARDIN, SIR JOHN, a celebrated traveller, was born at Paris in 1643. His father, who was a jeweller, had him educated in the Protestant religion; after which he travelled into Persia and India. He traded in jewels, and died at London in 1713. The account he wrote of his travels is much esteemed.

CHARENTE, a department in the south-west of France. It is about 56 miles in length, and on an average 30 in breadth; and contained 327,000 inhabitants in 1815. It covers an extent of 2240 square miles. Angouleme is the chief town.

CHARENTE Inferior, a department in the south-west of France, lying between the department of Charente above described, and the bay of Biscay. It is 80 miles long, and from 20 to 40 in breadth; and contains 2800 square miles. The population in 1815 was 393,000. The coast of this department is marshy, and the climate rather unhealthy; but the soil is fruitful in corn and flax, and produces excellent wine. There are manufactures of woollens, cottons, pottery, paper, glass, and salt. Saintes is the chief town.

CHARES the Lydian, a celebrated statuary, was the disciple of Lysippus; and made the famous Colossus of the sun in the city of Rhodes. Flourished 288 years before Christ.

CHARGE, in *Gunnery*, the quantity of powder and ball wherewith a gun is loaded for execution.

The rules for charging large pieces in war are, That the piece be first cleaned or scoured within-side: that the proper quantity of powder be next driven in and rammed down; care, however, being taken, that the powder, in ramming, be not bruised, because that weakens its effect: that a little quantity of paper, hay, lint, or the like, be rammed over it: and that the ball or shot be intruded. If the ball be red hot, a tompion, or trencher of green wood, is to be driven in before it. The common allowance for a charge of powder of a piece of ordnance, is half the weight of the ball. In the British navy, the allowance for 32 pounders is but seven sixteenths of the weight of the bullet. But a late author is of opinion, that if the powder in all ship-cannon whatever was reduced to one-third weight of the ball, or even less, it would be of considerable advantage, not only by saving ammunition, but by keeping the guns cooler and quieter, and at the same time more effectually injuring the vessels of the enemy. With the present allowance of powder the guns are heated, and their tackle and furniture strained; and this only to render the bullets less efficacious: for a bullet which can but just pass through a piece of timber, and loses almost all its motion thereby, has a much better chance of rending and fracturing it, than if it passes through with a much greater velocity.

Robins's Proposal for increasing the strength of the Navy.

CHARGE, in *Heraldry*, is applied to the figures represented on the escutcheon, by which the bearers are distinguished from one another; and it is to be observed, that too many charges are not so honourable as fewer.

CHARGE of Lead, denotes a quantity of 36 pigs. See PIG.

To CHARGE, in the military language, is to attack the enemy either with horse or foot.

CHARGE, in *Law*, denotes the instructions given to the grand jury, with respect to the articles of their inquiry, by the judge who presides on the bench.

CHARGE, in *Law*, also signifies a thing done that bindeth him who doth it; and *Discharge* is the removal of that charge. Lands may be charged in various ways; as, by grant of rent out of it, by statutes, judgments, conditions, warranties, &c.

CHARGE of Horning, in *Scots Law*. See HORNING.

CHARGE to enter Heir, in *Scots Law*, a writing passing under the signet, obtained at the instance of a creditor, either against the heir of his debtor, for fixing upon him the debt as representing the debtor, which is called a general charge; or, against the debtor himself, or his heir, for the purpose of vesting him in the right of an heritable subject to which he has made up no title, in order the creditor may attach that subject for payment of his debt, in the same manner as if his debtor or his heir were legally vested in it by service or otherwise. This last kind is called a *special charge*.

CHARGE, or rather *Overcharge*, in *Painting*, is an exaggerated representation of any person; wherein the likeness is preserved, but at the same time ridiculed.

CHARGED, in *Heraldry*, a shield carrying some impress or figure, is said to be charged therewith; so also when one bearing, or charge, has another figure added upon it, it is properly said to be charged.

CHARGED, in electrical experiments, is when a phial, pane of glass, or other electric substance, properly coated on both sides, has a quantity of electricity communicated to it; in which case the one side is always electrified positively, and the other negatively.

CHARIOT, a half coach, having only a seat behind, with a stool before. See COACH.

The chariots of the ancients, chiefly used in war, were called by the several names of *bigæ*, *trigæ*, &c. according to the number of horses applied to draw them. Every chariot carried two men, who were probably the warrior and the charioteer; and we read of several men of note and valour employed in driving the chariot. When the warriors came to encounter in close fight, they alighted out of the chariot, and fought on foot; but when they were weary, which often happened by reason of their armour, they retired into their chariot, and thence annoyed their enemies with darts and missile weapons. These chariots were made so strong, that they lasted for several generations.

Besides this sort, we find frequent mention of the *currus falcati*, or those chariots armed with hooks or scythes, with which whole ranks of soldiers were cut off together, if they had not the art of avoiding the danger; these were not only used by the Persians, Syrians, Egyptians, &c. but we find them among the ancient

cient Britons; and notwithstanding the imperfect state of some of the most necessary arts among that nation before the invasion of the Romans, it is certain that they had war chariots in great abundance. By the Greek and Roman historians, these chariots are described by the six following names: viz. Benna, Petoritum, Currus, or Carrus, Covinus, Essedum, and Rheda. The benna seems to have been a chariot designed rather for travelling than war. It contained two persons, who were called *combennones*, from their sitting together in the same machine. The petoritum seems to have been a larger kind of chariot than the benna; and is thought to have derived its name from the British word *pedwar*, signifying *four;* this kind of carriage having four wheels. The carrus or currus was the common cart or waggon. This kind of chariot was used by the ancient Britons, in time of peace, for the purposes of agriculture and merchandise, and, in time of war, for carrying their baggage, and wives and children, who commonly followed the armies of all the Celtic nations. The covinus was a war chariot, and a very terrible instrument of destruction; being armed with sharp scythes and hooks for cutting and tearing all who were so unhappy as to come within its reach. This kind of chariot was made very slight, and had few or no men in it besides the charioteer; being designed to drive with great force and rapidity, and to do execution chiefly with its hooks and scythes. The essedum and rheda were also war chariots, probably of a larger size, and stronger made than the covinus, designed for containing a charioteer for driving it, and one or two warriors for fighting. The far greatest number of the British war chariots seem to have been of this kind. These chariots, as already observed, were to be found in great numbers among the Britons; insomuch, that Cæsar relates, that Cassibelanus, after dismissing all his other forces, retained no fewer than 4000 of these war chariots about his person. The same author relates, that, by continual experience, they had at last arrived at such perfection in the management of their chariots, that "in the most steep and difficult places they could stop their horses upon full stretch, turn them which way they pleased, run along the pole, rest on their harness, and throw themselves back into their chariots, with incredible dexterity."

Chariots, in the heathen mythology, were sometimes consecrated to the sun; and the Scripture observes, that Josiah burnt those which had been offered to the sun by the kings his predecessors. This superstitious custom was an imitation of the heathens, and principally of the Persians, who had horses and chariots consecrated in honour of the sun. Herodotus, Xenophon, and Quintus Curtius, speak of white chariots crowned, which were consecrated to the sun, among the Persians, which in their ceremonies were drawn by white horses consecrated to the same luminary.

Triumphal Chariot, was one of the principal ornaments of the Roman celebration of a victory.

The Roman triumphal chariot was generally made of ivory, round like a tower, or rather of a cylindrical figure; it was sometimes gilt at the top, and ornamented with crowns; and to represent a victory more naturally, they used to stain it with blood. It was usually drawn by four white horses; but oftentimes by lions, elephants, tygers, bears, leopards, dogs, &c.

CHARISIA, in the heathen theology, a wake, or night festival, instituted in honour of the Graces. It continued the whole night, most of which time was spent in dancing; after which, cakes made of yellow flour mixed with honey, and other sweetmeats, were distributed among the assistants.—Charisia is also sometimes used to signify the sweetmeats used on such occasions.

CHARISIUS, in the heathen theology, a surname given to Jupiter. The word is derived from χαρις, *gratia*, "grace" or "favour;" he being the god by whose influence men obtain the favour and affection of one another. On which account the Greeks used at their meals to make a libation of a cup to Jupiter Charisius.

CHARISTIA, a festival of the ancient Romans, celebrated in the month of February, wherein the relations by blood and marriage met, in order to preserve a good correspondence; and that if there happened to be any difference among them, it might be the more easily accommodated by the good humour and mirth of the entertainment. *Ovid. Fast.* i. 617.

CHARISTICARY, commendatory, or donatory, a person to whom is given the enjoyment of the revenues of a monastery, hospital, or benefice.

The Charisticaries among the Greeks, were a kind of donatories, or commendatories, who enjoyed all the revenues of hospitals and monasteries, without giving an account thereof to any person.—The original of this abuse is referred to the Iconoclastæ, particularly Constantine Copronymus, the avowed enemy of the monks, whose monasteries he gave away to strangers. In after times, the emperors and patriarchs gave many to people of quality, not by way of gift to reap any temporal advantage from them, but to repair, beautify, and patronise them. At length avarice crept in, and those in good condition were given away, especially such as were rich; and at last they were all given away, rich and poor, those of men and of women, and that to laymen and to married men.

CHARITY, among divines, one of the three grand theological virtues, consisting in the love of God and of our neighbour, or the habit and disposition of loving God with all our heart, and our neighbour as ourselves.

Charity is also used for the effect of moral virtue, which consists in supplying the necessities of others, whether with money, counsel, assistance, or the like.

As pecuniary relief is generally the most efficacious, and at the same time that from which we are most apt to excuse ourselves, this branch of the duty merits particular illustration; and a better cannot be offered than what is contained in the following extracts (if we may be permitted to make them) from the elegant *Moral System* of Archdeacon *Paley*.

Whether pity be an instinct or a habit, it is in fact a property of our nature, which God appointed; and the final cause for which it was appointed, is to afford to the miserable, in the compassion of their fellow-creatures, a remedy for those inequalities and distresses which God foresaw that many must be exposed to, under

Charity. under every general rule for the distribution of property.

The Christian Scriptures are more copious and explicit upon this duty than almost any other. The description which Christ hath left us of the proceedings of the last day, establishes the obligation of bounty beyond controversy. "When the Son of Man shall come in his glory, and all the holy angels with him, then shall he sit upon the throne of his glory, and before him shall be gathered all nations; and he shall separate them one from another. Then shall the King say unto them on his right hand, Come ye blessed of my Father, inherit the kingdom prepared for you from the foundation of the world: For I was hungered, and ye gave me meat; I was thirsty, and ye gave me drink; I was a stranger, and ye took me in; naked, and ye clothed me; I was sick, and ye visited me; I was in prison, and ye came unto me. And inasmuch as ye have done it to one of the least of these my brethren, ye have done it unto me." It is not necessary to understand this passage as a literal acconnt of what will actually pass on that day. Supposing it only a scenical description of the rules and principles by which the Supreme Arbiter of our destiny will regulate his decisions, it conveys the same lesson to us: it equally demonstrates of how great value and importance these duties in the sight of God are, and what stress will be laid upon them. The apostles also describe this virtue as propitiating the divine favour in an eminent degree. And these recommendations have produced their effect. It does not appear that, before the times of Christianity, an infirmary, hospital, or public charity of any kind, existed in the world; whereas most countries in Christendom have long abounded with these institutions. To which may be added, that a spirit of private liberality seems to flourish amidst the decay of many other virtues: not to mention the legal provision for the poor, which obtains in this country, and which was unknown and unthought of by the most polished nations of antiquity.

St Paul adds upon the subject an excellent direction; and which is practicable by all who have any thing to give. "Upon the first day of the week (or any other stated time) let every one of you lay by in store, as God hath prospered him." By which the apostle may be understood to recommend, what is the very thing wanting with most men, *the being charitable upon a plan*; that is, from a deliberate comparison of our fortunes with the reasonable expences and expectations of our families, to compute what we can spare, and to lay by so much for charitable purposes, in some mode or other. The mode will be a consideration afterwards.

The effects which Christianity produced upon some of its converts, was such as might be looked for from a divine religion coming with full force and miraculous evidence upon the consciences of mankind. It overwhelmed all worldly considerations in the expectation of a more important existence. "And the multitude of them that believed were of one heart and of one soul; neither said any of them that aught of the things which he possessed was his own; but they had all things in common.—Neither was there any among them that lacked; for as many as were possessors of lands or houses sold them, and brought the prices of the things that were sold, and laid them down at the apostles feet; and distribution was made unto every man according as he had need." Acts iv. 32.

Nevertheless, this community of goods, however it manifested the sincere zeal of the primitive Christians, is no precedent for our imitation. It was confined to the church at Jerusalem; continued not long there; was never enjoined upon any (Acts v. 4.); and, although it might suit with the particular circumstances of a small and select society, is altogether impracticable in a large and mixed community.

The conduct of the apostles upon the occasion deserves to be noticed. Their followers laid down their fortunes at their feet: but so far were they from taking advantage of this unlimited confidence to enrich themselves or establish their authority, that they soon after got rid of this business as inconsistent with the main object of their mission, and transferred the custody and management of the public fund to deacons elected to that office by the people at large (Acts vi.)

There are three kinds of charity, our author observes, which prefer a claim to attention.

1. The first, and apparently one of the best, is to give stated and considerable sums, by way of pension or annuity to individuals or families, with whose behaviour and distress we ourselves are acquainted. In speaking of considerable sums, it is meant only, that five pounds, or any other sum, given at once, or divided amongst five or fewer families, will do more good than the same sum distributed amongst a greater number in shillings or half crowns; and that, because it is more likely to be properly applied by the persons who receive it. A poor fellow who can find no better use for a shilling than to drink his benefactor's health, and purchase half an hour's recreation for himself, would hardly break into a guinea for any such purpose, or be so improvident as not to lay it by for an occasion of importance, for his rent, his clothing, fuel, or stock of winter's provision. It is a still greater recommendation of this kind of charity, that pensions and annuities, which are paid regularly, and can be expected at the time, are the only way by which we can prevent one part of a poor man's sufferings, the dread of want.

2. But as this kind of charity supposes that proper objects of such expensive benefactions fall within our private knowledge and observation, which does not happen to all, a second method of doing good, which is in every one's power who has the money to spare, is by subscription to public charities. Public charities admit of this argument in their favour, that your money goes farther towards attaining the end for which it is given, than it can do by any private and separate beneficence. A guinea, for example, contributed to an infirmary, becomes the means of providing one patient, at least, with a physician, surgeon, apothecary, with medicine, diet, lodging, and suitable attendance; which is not the tenth part of what the same assistance, if it could be procured at all, would cost to a sick person or family in any other situation.

3. The last, and, compared with the former, the lowest exertion of benevolence, is in the relief of beggars. Nevertheless, the indiscriminate rejection of all who implore our alms, in this way, is by no means approved.

Charity. proved. Some may perish by such a conduct. Men are sometimes overtaken by distress, for which, all other relief would come too late. Besides which, resolutions of this kind compel us to offer such violence to our humanity, as may go near, in a little while, to suffocate the principle itself; which is a very serious consideration. A good man, if he do not surrender himself to his feelings without reserve, will at least lend an ear to importunities which come accompanied with outward attestations of distress; and after a patient hearing of the complaint, will direct himself by the circumstances and credibility of the account that he receives.

There are other species of charity well contrived to make the money expended *go far*; such as keeping down the price of fuel or provisions in case of a monopoly or temporary scarcity, by purchasing the articles at the best market, and retailing them at prime cost, or at a small loss; or the adding a bounty to a particular species of labour, when the price is accidentally depressed.

The proprietors of large estates have it in their power to facilitate the maintenance, and thereby encourage the establishment of families (which is one of the noblest purposes to which the rich and great can convert their endeavours), by building cottages, splitting farms, erecting manufactures, cultivating wastes, embanking the sea, draining marshes, and other expedients, which the situation of each estate points out. If the profits of these undertakings do not repay the expence, let the authors of them place the difference to the account of charity. It is true of almost all such projects, that the public is a gainer by them, whatever the owner be. And where the loss can be spared, this consideration is sufficient.

It is become a question of some importance, Under what circumstances works of charity ought to be done in private, and when they may be made public without detracting from the merit of the action? if indeed they ever may, the Author of our religion having delivered a rule upon this subject, which seems to enjoin universal secrecy. "When thou dost alms, let not thy left hand know what thy right hand doth; that thy alms may be in secret; and thy Father which seeth in secret, himself shall reward thee openly." (Matt. vi. 3, 4.). From the preamble to this prohibition it is plain, that our Saviour's sole design was to forbid *ostentation*, and all publishing of good works which proceeds from that motive. "Take heed that ye do not your alms before men, *to be seen of them;* otherwise ye have no reward of your Father which is in heaven; therefore, when thou doest thine alms, do not sound a trumpet before thee, as the hypocrites do, in the synagogues and in the streets, *that they may have glory of men.* Verily I say unto thee, they have their reward," v. 2. There are motives for the doing our alms in public besides those of ostentation; with which therefore our Saviour's rule has no concern: such as to testify our approbation of some particular species of charity, and to recommend it to others; to take off the prejudice which the want, or, which is the same thing, the suppression, of our name in the list of contributors, might excite against the charity or against ourselves. And so long as these motives are free from any mixture of vanity, they are in no danger of invading our Saviour's prohibition: they rather seem to comply with another direction which he has left us: "Let your light so shine before men, that they may see your good works, and glorify your Father which is in heaven." If it be necessary to propose a precise distinction upon the subject, there can be none better than the following: When our bounty is beyond our fortune or station, that is, when it is more than could be expected from us, our charity should be private, if privacy be practicable: when it is not more than might be expected, it may be public: for we cannot hope to influence others to the imitation of extraordinary generosity, and therefore want, in the former case, the only justifiable reason for making it public.

Charity. The pretences by which men excuse themselves from giving to the poor are various; as,

1. "That they have nothing to spare;" *i. e.* nothing, for which they have not some other use; nothing, which their plan of expence, together with the savings they have resolved to lay by, will not exhaust; never reflecting whether it be in their power, or that it is their duty, to retrench their expences, and contract their plan, "that they may have to give to them that need;" or rather that this ought to have been part of their plan originally.

2. "That they have families of their own, and that charity begins at home." A father is no doubt bound to adjust his economy with a view to the reasonable demands of his family upon his fortune; and until a sufficiency for these is acquired, or in due time probably will be acquired (for in human affairs probability is enough, he is justified in declining *expensive* liberality; for to take from those who want, in order to give to those who want, adds nothing to the stock of public happiness. Thus far, therefore, and no farther, the plea in question is an excuse for parsimony, and an answer to those who solicit our bounty.

3. "That charity does not consist in giving money, but in benevolence, philanthropy, love to all mankind, goodness of heart," &c. Hear St James. "If a brother or sister be naked, and destitute of daily food, and one of you say unto them, Depart in peace, be ye warmed and filled, notwithstanding *ye give them not those things which are needful for the body*, what doth it profit?" (James ii. 15, 16.).

4. "That giving to the poor is not mentioned in St Paul's description of charity, in the 13th chapter of the first epistle to the Corinthians." This is not a description of charity, but of good nature; and it is not necessary that every duty be mentioned in every place.

5. "That they pay the poor rates." They might as well allege that they pay their debts; for the poor have the same right to that portion of a man's property which the laws assign them, that the man himself has to the remainder.

6. "That they employ many poor persons;"—for their own sake, not the poor's—otherwise it is a good plea.

7. "That the poor do not suffer so much as we imagine; that education and habit have reconciled them to the evils of their condition, and make them easy under it." Habit can never reconcile human nature to the extremities of cold, hunger, and thirst, any more than it can reconcile the hand to the touch of

of a red-hot iron: besides, the question is not, how unhappy any one is, but how much more happy we can make him.

8. "That these people, give them what you will, will never thank you, or think of you for it." In the first place, this is not true: in the second place, it was not for the sake of their thanks that you relieved them.

9. "That we are so liable to be imposed upon." If a due inquiry be made, our motive and merit is the same; besides that the distress is generally real, whatever has been the cause of it.

10. "That they should apply to their parishes." That is not always practicable: to which we may add, that there are many requisites to a comfortable subsistence, which parish-relief does not always supply; and that there are some who would suffer almost as much from receiving parish-relief as by the want of it; and lastly, that there are many modes of charity, to which this answer does not relate at all.

11. "That giving money encourages idleness and vagrancy." This is true only of injudicious and indiscriminate generosity.

12. "That we have too many objects of charity at home to bestow any thing upon strangers; or that there are other charities which are more useful, or stand in greater need." The value of this excuse depends entirely upon the *fact*, whether we actually relieve those neighbouring objects, and contribute to those other charities.

Besides all these excuses, pride, or prudery, or delicacy, or the love of ease, keep one half of the world out of the way of observing what the other half suffer.

Charity Schools, are schools erected and maintained in various parishes by the voluntary contributions of the inhabitants, for teaching poor children to read, write, and other necessary parts of educations. See School.

Brothers of Charity, a sort of religious hospitallers, founded about the year 1297, since denominated *Billetins*. They took the third order of St Francis, and the scapulary, making the three usual vows, but without begging.

Brothers of Charity, also denotes an order of hospitallers, still subsisting in Romish countries, whose business is to attend the sick poor, and minister to them both spiritual and temporal succour.

They are all laymen, except a few priests, for administering the sacraments to the sick in their hospitals. The brothers of charity usually cultivate botany, pharmacy, surgery, and chemistry, which they practise with success.

They were first founded at Granada, by St John de Dieu; and a second establishment was made at Madrid in the year 1553; the order was confirmed by Gregory XIII. in 1572: Gregory XIV. forbade them to take holy orders; but by leave of Paul V. in 1609, a few of the brothers might be admitted to orders. In 1619 they were exempted from the jurisdiction of the bishop. Those of Spain are separated from the rest; and they, as well as the brothers of France, Germany, Poland, and Italy, have their distinct generals, who reside at Rome. They were first introduced into France by Mary of Medicis in 1601, and have since built a fine hospital in the fauxbourg of St Germain.

Charity of Hippolitus, a religious congregation founded about the end of the 16th century, by one Bernardin Alvarez, a Mexican, in honour of St Hippolitus the martyr, patron of the city of Mexico; and approved by Pope Gregory XIII.

Charity of our Lady, in church history, a religious order in France, which, though charity was the principal motive of their union, grew in length of time so disorderly and irregular, that their order dwindled, and at last became extinct.

There is still at Paris a religious order of women, called *nuns hospitallers of the charity of our lady*. The religious of this hospital are by vow obliged to administer to the necessities of the poor and sick, but those only women.

CHARLATAN, or Charletan, signifies an empiric or quack, who retails his medicines on a public stage, and draws people about him with his buffooneries, feats of activity, &c. The word, according to Calepine, comes from the Italian *ceretano*; of *Cæretum*, a town near Spoletto in Italy, where these impostors are said to have first risen. Menage derives it from *ciarlatano*, and that from *circulatorius* or *circulator*, a quack.

CHARLEMAGNE, or Charles I. king of France by succession, and emperor of the West by conquest in 800 (which laid the foundation of the dynasty of the western Franks, who ruled the empire 472 years till the time of Rodolphus Auspurgensis, the founder of the house of Austria). Charlemagne was as illustrious in the cabinet as in the field; and, though he could not write his name, was the patron of men of letters, the restorer of learning, and a wise legislator; he wanted only the virtue of humanity to render him the most accomplished of men; but when we read of his beheading 4500 Saxons, solely for their loyalty to their prince, in opposing his conquests, we cannot think he merits the extravagant encomiums betowed on him by some historians. He died in 814, in the 74th year of his age, and 47th of his reign.

France had nine sovereigns of this name, of whom Charles V. merited the title of *the wise* (crowned in 1364, died in 1380): and Charles VIII. signalized himself in the field by rapid victories in Italy; (crowned in 1483, died in 1498). The rest do not deserve particular mention in this place. See (*History of*) France.

CHARLEMONT, a town of France, in the department of Ardennes, containing 4100 inhabitants in 1815. It is about eighteen miles south of Namur. E. Long. 4. 40. N. Lat. 50. 10.

Charlemont is also the name of a town of Ireland, situated on the river Blackwater, in the county of Armagh, and province of Ulster, about six miles south-east of Dungannon. W. Long. 6. 50. N. Lat. 50. 16.

CHARLEROY, a strong town in the province of Namur in the kingdom of the Netherlands, situated on the river Sambre, about 19 miles west of Namur. Population 4500. E. Long. 46. 20. N. Lat. 50. 30.

CHARLES Martel, a renowned conqueror in the early annals of France. He deposed and restored

Childeric

Childeric king of France; and had the entire government of the kingdom, first with the title of *mayor of the palace*, and afterwards as *duke of France*; but he would not accept the crown. He died regretted, in 741.

Charles le Gros, emperor of the west in 881, king of Italy and Suabia, memorable for his reverse of fortune; being dethroned at a diet held near Mentz, by the French, the Italians, and the Germans, in 887: after which he was obliged to subsist on the bounty of the archbishop of Mentz. He died in 888.

Charles V. (emperor and king of Spain) was son of Philip, archduke of Austria, and of Jane queen of Castile. He was born at Ghent, February 24. 1500, and succeeded to the crown of Spain in 1517. Two years afterwards he was chosen emperor at Francfort after the death of Maximilian his grandfather. He was a great warrior and politician: and his ambition was not satisfied with the many kingdoms and provinces he possessed; for he is supposed, with reason, to have aspired at universal empire. He is said to have fought 60 battles, in most of which he was victorious. He took the king of France (Francis I.) prisoner, and sold him his liberty on very hard terms; yet afterwards, when the people of Ghent revolted, he asked leave to pass through his dominions: and though the generous king thus had him in his power, and had an opportunity of revenging his ill treatment, yet he received and attended him with all pomp and magnificence. He sacked Rome, and took the pope prisoner; and the cruelties which his army exercised there are said to have exceeded those of the northern barbarians. Yet the pious emperor went into mourning on account of this conquest: forbade the ringing of bells; commanded processions to be made, and prayers to be offered up for the deliverance of the pope his prisoner; yet did not inflict the least punishment on those who treated the holy father and the holy see with such inhumanity. He is accused by some Romish writers of favouring the Lutheran principles, which he might easily have extirpated. But the truth is, he found his account in the divisions which that sect occasioned; and he for ever made his advantage of them, sometimes against the pope, sometimes against France, and at other times against the empire itself. He was a great traveller, and made 50 different journeys into Germany, Spain, Italy, Flanders, France, England, and Africa. Though he had been successful in many unjust enterprises, yet his last attempt on Metz, which he besieged with an army of 100,000 men, was very just, and very unsuccessful.

Vexed at the reverse of fortune which seemed to attend his latter days, and oppressed by sickness, which unfitted him any longer for holding the reins of government with steadiness, or to guide them with address, he resigned his dominions to his brother Ferdinand and his son Philip; and retreated to the monastery of St Justus near Placentia in Estremadura.

When Charles entered this retreat, he formed such a plan of life for himself as would have suited a private gentleman of moderate fortune. His table was neat, but plain; his domestics few; his intercourse with them familiar; all the cumbersome and ceremonious forms of attendance on his person were entirely abolished, as destructive of that social ease and tranquillity which he courted in order to soothe the remainder of his days. As the mildness of the climate, together with his deliverance from the burdens and cares of government, procured him at first a considerable remission from the acute pains of the gout, with which he had been long tormented, he enjoyed perhaps more complete satisfaction in this humble solitude than all his grandeur had ever yielded him. The ambitious thoughts and projects which had so long engrossed and disquieted him, were quite effaced from his mind. Far from taking any part in the political transactions of the princes of Europe, he restrained his curiosity even from an inquiry concerning them; and he seemed to view the busy scene which he had abandoned, with all the contempt and indifference arising from his thorough experience of its vanity, as well as from the pleasing reflection of having disentangled himself from its cares.

Other amusements, and other subjects, now occupied him. Sometimes he cultivated the plants in his garden with his own hand; sometimes he rode out to the neighbouring wood on a little horse, the only one that he kept, attended by a single servant on foot. When his infirmities confined him to his apartment, which often happened, and deprived him of these more active recreations, he either admitted a few gentlemen who resided near the monastery to visit him, and entertained them familiarly at his table; or he employed himself in studying mechanical principles, and in forming curious works of mechanism, of which he had always been remarkably fond, and to which his genius was peculiarly turned. With this view he had engaged Turriano, one of the most ingenious artists of that age, to accompany him in his retreat. He laboured together with him in framing models of the most useful machines, as well as in making experiments with regard to their respective powers; and it was not seldom that the ideas of the monarch assisted or perfected the inventions of the artist. He relieved his mind at intervals with slighter and more fantastic works of mechanism, in fashioning puppets, which, by the structure of internal springs, mimicked the gestures and actions of men, to the no small astonishment of the ignorant monks, who, beholding movements which they could not comprehend, sometimes distrusted their own senses, and sometimes suspected Charles and Turriano of being in compact with invisible powers. He was particularly curious with regard to the construction of clocks and watches; and having found, after repeated trials, that he could not bring any two of them to go exactly alike, he reflected, it is said, with a mixture of surprise as well as regret, on his own folly, in having bestowed so much time and labour in the more vain attempt of bringing mankind to a precise uniformity of sentiment concerning the intricate and mysterious doctrines of religion.

But in what manner soever Charles disposed of the rest of his time, he constantly reserved a considerable portion of it for religious exercises. He regularly attended divine service in the chapel of the monastery, every morning and evening; he took great pleasure in reading books of devotion, particularly the works of St Augustine and St Bernard; and conversed much with his confessor, and the prior of the monastery, on

Charles.

on pious subjects. Thus did Charles pass the first year of his retreat in a manner not unbecoming a man perfectly disengaged from the affairs of this present life, and standing on the confines of a future world, either in innocent amusements which soothed his pains, and relieved a mind worn out with excessive application to business; or in devout occupations, which he deemed necessary in preparing for another state.

But, about six months before his death, the gout, after a longer intermission than usual, returned with a proportional increase of violence. His shattered constitution had not strength enough remaining to withstand such a shock. It enfeebled his mind as much as his body; and from this period we hardly discern any traces of that sound and masculine understanding which distinguished Charles among his cotemporaries. An illiberal and timid superstition depressed his spirit. He had no relish for amusements of any kind. He endeavoured to conform, in his manner of living, to all the rigour of monastic austerity. He desired no other society than that of monks, and was almost continually employed in chaunting with them the hymns of the missal. As an expiation for his sins, he gave himself the discipline in secret, with such severity that the whip of cords which he employed as the instrument of his punishment, was found, after his decease, tinged with his blood. Nor was he satisfied with these acts of mortification, which, however severe, were not unexampled. The timorous and distrustful solicitude which always accompanies superstition, still continued to disquiet him, and depreciating all that he had done, prompted him to aim at something extraordinary, at some new and singular act of piety that would display his zeal, and merit the favour of heaven. The act on which he fixed was as wild and uncommon as any that superstition ever suggested to a disordered fancy. He resolved to celebrate his own obsequies before his death. He ordered his tomb to be erected in the chapel of the monastery. His domestics marched thither in funeral procession, with black tapers in their hands. He himself followed in his shroud. He was laid in his coffin with much solemnity. The service for the dead was chaunted; and Charles joined in the prayers which were offered up for the rest of his soul, mingling his tears with those which his attendants shed, as if they had been celebrating a real funeral. The ceremony closed with sprinkling holy water on the coffin in the usual form, and, all the assistants retiring, the doors of the chapel were shut. Then Charles rose out of the coffin, and withdrew to his apartment, full of those awful sentiments which such a singular solemnity was calculated to inspire. But either the fatiguing length of the ceremony, or the impression which this image of death left on his mind, affected him so much, that next day he was seized with a fever. His feeble frame could not long resist its violence; and he expired on the 21st of September, after a life of 58 years 6 months and 21 days.

CHARLES I. } Kings of Britain. See BRITAIN,
CHARLES II. } No. 49.——254.

CHARLES XII. King of Sweden, was born in 1682. By his father's will, the administration was lodged in the hands of the queen dowager Eleonora, with five senators, till the young prince was 18; but he was declared major at 15, by the states convened at Stockholm. The beginning of his administration raised no favourable ideas of him, as he was thought both by Swedes and foreigners to be a person of mean capacity. But the difficulties that gathered round him, soon afforded him an opportunity to display his real character. Three powerful princes, Frederick king of Denmark, Augustus king of Poland and elector of Saxony, and Peter the Great, czar of Muscovy, presuming on his youth, conspired his ruin almost at the same instant. Their measures alarming the council, they were for diverting the storm by negotiations; but Charles, with a grave resolution that astonished them, said, "I am resolved never to enter upon an unjust war, nor to put an end to a just one but by the destruction of my enemies. My resolution is fixed: I will attack the first who shall declare against me; and when I have conquered him, I may hope to strike a terror into the rest." The old counsellors received his orders with admiration; and were still more surprised when they saw him on a sudden renounce all the enjoyments of a court, reduce his table to the utmost frugality, dress like a common soldier, and, full of the ideas of Alexander and Cæsar, propose these two conquerors for his models in every thing but their vices. The king of Denmark began by ravaging the territories of the duke of Holstein. Upon this Charles carried the war into the heart of Denmark, and made such a progress that the king of Denmark thought it best to accept of peace, which was concluded in 1700. He next resolved to advance against the king of Poland, who had blocked up Riga. He had no sooner given orders for his troops to go into winter quarters, than he received advice that Narva, where Count Horne was governor, was besieged by an army of 100,000 Muscovites. This made him alter his measures, and move towards the czar; and at Narva he gained a surprising victory, which cost him not above 2000 men killed and wounded. The Muscovites were forced to retire from the provinces they had invaded. He pursued his conquests, till he penetrated as far as where the diet of Poland was sitting; when he made them declare the throne of Poland vacant, and elect Stanislaus their king: then making himself master of Saxony, he obliged Augustus himself to renounce the crown of Poland, and acknowledge Stanislaus by a letter of congratulation on his accession. All Europe was surprised with the expeditious finishing of this great negotiation, but more at the disinterestedness of the king of Sweden, who satisfied himself with the bare reputation of this victory, without demanding an inch of ground for enlarging his dominions. After thus reducing the king of Denmark to peace, placing a new king on the throne of Poland, having humbled the emperor of Germany, and protected the Lutheran religion, Charles prepared to penetrate into Muscovy, in order to dethrone the czar. He quickly obliged the Muscovites to abandon Poland, pursued them into their own country, and won several battles over them. The czar, disposed to peace, ventured to make some proposals; Charles only answered, "I will treat with the czar at Moscow." When this haughty answer was brought to Peter, he said, "My brother Charles still affects to act the Alexander, but I flatter myself

Charles. self he will not in me find a Darius." The event justified him: for the Muscovites, already beaten into discipline, and under a prince of such talents as Peter, entirely destroyed the Swedish army at the memorable battle of Pultowa, July 8. 1709; on which decisive day, Charles lost the fruits of nine years labour, and of almost 100 battles! The king, with a small troop, pursued by the Muscovites, passed the Boristhenes to Oczakow in the Turkish territories: and from thence, through desert countries, arrived at Bender; where the sultan, when informed of his arrival, sent orders for accommodating him in the best manner, and appointed him a guard. Near Bender Charles built a house, and intrenched himself; and had with him 1800 men, who were all clothed and fed, with their horses, at the expence of the grand signior. Here he formed a design of turning the Ottoman arms upon his enemies; and is said to have had a promise from the vizier of being sent into Muscovy with 200,000 men. While he remained here, he insensibly acquired a taste for books; he read the tragedies of Corneille and Racine, with the works of Despreaux, whose satires he relished, but did not much admire his other works. When he read that passage in which the author represents Alexander as a fool and a madman, he tore out the leaf. He would sometimes play at chess: but when he recovered of his wounds, he renewed his fatigues in exercising his men: he tired three horses a-day; and those who courted his favour were all day in their boots. To dispose the Ottoman Porte to this war, he detached about 800 Poles and Cossacks of his retinue, with orders to pass the Niester, that runs by Bender, and to observe what passed on the frontiers of Poland. The Muscovite troops, dispersed in those quarters, fell immediately upon this little company, and pursued them even to the territories of the grand signior. This was what the king expected. His ministers at the Porte excited the Turks to vengeance; but the czar's money removed all difficulties, and Charles found himself in a manner prisoner among the Tartars. He imagined the sultan was ignorant of the intrigues of his grand vizier. Poniatowsky undertook to make his complaints to the grand signior. The sultan, in answer, some days after, sent Charles five Arabian horses, one of which was covered with a saddle and housing of great richness; with an obliging letter, but conceived in such general terms, as gave reason to suspect that the minister had done nothing without the sultan's consent: Charles therefore refused them. Poniatowsky had the courage to form a design of deposing the grand vizier, who accordingly was deprived of his dignity and wealth, and banished. The seal of the empire was given to Numan Cuproughly; who persuaded his master, that the law forbade him to invade the czar, who had done him no injury; but to succour the king of Sweden as an unfortunate prince in his dominions. He sent his majesty 800 purses, every one of which amounted to 500 crowns, and advised him to return peaceably to his own dominions. Charles rejected this advice, threatening to hang up the bashaws, and shave the beards of any janizaries who brought him such messages, and sent word that he should depend upon the grand signior's promise, and hoped to re-enter Poland as a conqueror with an army of Turks. After various intrigues at the Porte, an order was sent to attack this *head of iron*, as he was called, and to take him either alive or dead. He stood a siege in his house, with 40 domestics, against the Turkish army; killed no less than 20 janizaries with his own hand; and performed prodigies of valour on a very unnecessary and unwarrantable occasion. But the house being set on fire, and himself wounded, he was at last taken prisoner, and sent to Adrianople, where the grand signior gave him audience, and promised to make good all the damages he had sustained. At last, after a stay of above five years, he left Turkey; and, having disguised himself, traversed Wallachia, Transylvania, Hungary, and Germany, attended only by one person; and in sixteen days riding, during which time he never went to bed, came to Stralsund at midnight, November 21. 1714. His boots were cut from his swollen legs, and he was put to bed; where, when he had slept some hours, the first thing he did was to review his troops, and examine the state of the fortifications. He sent out orders that very day to renew the war with more vigour than ever. But affairs were now much changed: Augustus had recovered the throne of Poland; Sweden had lost many of its provinces, and was without money, trade, credit, or troops. The kings of Denmark and Prussia seized the island of Rugen; and besieged him in Stralsund, which surrendered; but Charles escaped to Carlscroon. When his country was threatened with invasion by so many princes, he, to the surprise of all Europe, marched into Norway with 20,000 men. A very few Danes might have stopped the Swedish army; but such a quick invasion they could not foresee. Europe was yet more at a loss to find the czar so quiet, and not making a descent upon Sweden, as he had before agreed with his allies. This inaction was the consequence of one of the greatest designs, and at the same time the most difficult of any, that were ever formed by the imagination of man. In short, a scheme was set on foot for a reconciliation with the czar; for replacing Stanislaus on the throne of Poland; and setting James II.'s son upon that of England, besides restoring the duke of Holstein to his dominions. Charles was pleased with these grand ideas, though without building much upon them, and gave his minister leave to act at large. In the mean time, Charles was going to make a second attempt upon Norway in 1718; and he flattered himself with being master of that kingdom in six months; but while he was examining the works at Frederickshall, a place of great strength and importance, which is reckoned to be the key of that kingdom, he was killed by a shot from the enemy, as has been generally believed, though it has been also reported, that he fell by the treachery of one of his own officers, who had been bribed for that purpose.

This prince experienced the extremes of prosperity and of adversity, without being softened by the one or disturbed for a moment at the other; but was a man rather extraordinary than great, and fitter to be admired than imitated. He was honoured by the Turks for his rigid abstinence from wine, and his regularity in attending public devotion.

As to his person, he was tall and of a noble mien, had a fine open forehead, large blue eyes, flaxen hair, fair

fair complexion, a handsome nose, but little beard, and a laugh not agreeable. His manners were harsh and austere, not to say savage: and as to religion, he was indifferent towards all, though exteriorly a Lutheran, and a strong believer in predestination. A few anecdotes will illustrate his character. No dangers, however great, made the least impression upon him. When a horse or two were killed under him at the battle of Narva, in 1700, he leaped nimbly upon fresh ones, saying, "These people find me exercise." One day, when he was dictating letters to a secretary, a bomb fell through the roof into the next room of the house where they were sitting. The secretary, terrified lest the house should come down upon them, let his pen drop out of his hand: "What is the matter?" says the king calmly. The secretary could only reply, "Ah, Sir, the bomb." "The bomb! (says the king) what has the bomb to do with what I am dictating to you! Go on."

He preserved more humanity than is usually found among conquerors. Once, in the middle of an action, finding a young Swedish officer wounded and unable to march, he obliged the officer to take his horse, and continued to command his infantry on foot. The Princess Lubomirski, who was very much in the interest and good graces of Augustus, falling by accident into the hands of one of his officers, he ordered her to be set at liberty: saying, "That he did not make war with women." One day, near Leipsic, a peasant threw himself at his feet, with a complaint against a grenadier, that he had robbed him of certain eatables, provided for himself and his family. "Is it true (said Charles sternly), that you have robbed this man?" The soldier replied, "Sir, I have not done near so much harm to this man as your majesty has done to his master; for you have taken from Augustus a kingdom, whereas I have only taken from this poor scoundrel a dinner." Charles made the peasant amends, and pardoned the soldier for his firmness: "However, my friend (says he to him), you will do well to recollect, that if I took a kingdom from Augustus, I did not take it for myself."

Though Charles lived hardly himself, a soldier did not fear to remonstrate to him against some bread, which was very black and mouldy, and which yet was the only provision the troops had. Charles called for a piece of it, and calmly ate it up; saying, "that it was indeed not good, but that it might be eaten."—From the danger he was in in Poland, when he beat the Saxon troops in 1702, a comedy was exhibited at Marienburg, where the combat was represented to the disadvantage of the Swedes. "Oh, (says Charles, hearing of it) I am far from envying them this pleasure. Let them beat me in the theatres as long as they will, provided I do but beat them in the field." He wrote some observations on war, and on his own campaigns from 1700 to 1709: but the MS. was lost at the unfortunate battle of Pultowa.

CHARLES'S CAPE, a promontory of Virginia, in North America, forming the northern headland of the strait that enters the bay of Chesapeak.

CHARLES's Fort, a fortress in the county of Cork, and province of Munster in Ireland, situated at the mouth of Kinsale harbour. W. Long. 8. 20. N. Lat. 51. 21.

CHARLESTON, the metropolis of South Carolina, is the most considerable town in the state; situated in the district of the same name, and on the tongue of land formed by the confluent streams of Ashley and Cooper, which are short rivers, but large and navigable. These waters unite immediately below the city, and form a spacious and convenient harbour; which communicates with the ocean just below Sullivan's island, which it leaves on the north, seven miles south-east of Charleston. In these rivers the tide rises, in common, about $6\frac{1}{2}$ feet; but uniformly rises 10 or 12 inches more during a night tide. The fact is certain; the cause unknown. The continual agitation which the tides occasion in the waters which almost surround Charleston, the refreshing sea-breezes which are regularly felt, and the smoke arising from so many chimneys, render this city more healthy than any part of the low country in the southern states. On this account it is the resort of great numbers of gentlemen, invalids from the West India islands, and of the rich planters from the country, who come here to spend the sickly months, as they are called, in quest of health and of the social enjoyments which the city affords. And in no part of America are the social blessings enjoyed more rationally and liberally than here. Unaffected hospitality, affability, ease of manners and address, and a disposition to make their guests welcome, easy, and pleased with themselves, are characteristics of the respectable people of Charleston. In speaking of the capital, it ought to be observed, for the honour of the people of Carolina in general, that when in common with the other colonies, in the contest with Britain, they resolved against the use of certain luxuries, and even necessaries of life; those articles, which improve the mind, enlarge the understanding, and correct the taste, were excepted; the importation of books was permitted as formerly.

The land on which the town is built is flat and low, and the water brackish and unwholesome. The streets are pretty regularly cut, and open beautiful prospects, and have subterranean drains to carry off filth and keep the city clean and healthy; but are too narrow for so large a place and so warm a climate. Their general breadth is from 35 to 66 feet. The houses which have been lately built, are brick, with tiled roofs. The buildings in general are elegant, and most of them are neat, airy, and well furnished. The public buildings are, an exchange, a state-house, an armoury, a poor-house, and an orphan's house. Here are several respectable academies. Part of the old barracks has been handsomely fitted up, and converted into a college, and there are a number of students; but it can only be called as yet a respectable academy. Here are two banks, a branch of the national bank, and the South Carolina bank, established in 1792. The houses for public worship are two Episcopal churches, two for Independents, three for Scotch Presbyterians, one for Baptists, one for German Lutherans, three for Methodists, one for French Protestants, a meeting-house for Quakers, a Roman Catholic chapel, and a Jewish synagogue.

Little attention is paid to the public markets; a great proportion of the more wealthy inhabitants having plantations from which they receive supplies of almost every article of living. The country abounds with

Charleston ‖ Queen Charlotte's Island.

with poultry and wild ducks. Their beef, mutton, and veal, are not generally of the best kind; and few fish are found in the market.

In 1787, it was computed that there were 1600 houses in this city, and 15,000 inhabitants, including 5400 slaves; and what evinces the healthiness of the place, upwards of 200 of the white inhabitants were above 60 years of age. In 1817, the population was 22,944, of which 11,229 were white inhabitants, and 11,715 slaves. The city has often suffered from fires. It has also often been visited by the yellow fever. This disease carried off 150 persons in each of the years 1792 and 1794, and in 1817 1249 persons fell victims to it.

Charleston was incorporated in 1783, and divided into three wards, which choose as many wardens, from among whom the citizens elect an intendant of the city. The intendant and wardens form the city-council, who have power to make and enforce by-laws for the regulation of the city. There are a considerable number of charitable institutions in the town. There is besides a literary and philosophical society, and an agricultural society. Three daily and two weekly newspapers are published in the town. Nearly the whole trade of the state centres in this town, which had 35,857 tons of shipping belonging to it in 1815.

Charles's Wain, in *Astronomy*, seven stars in the constellation called *Ursa Major*, or the Great Bear.

CHARLETON, an island at the bottom of Hudson's bay, in North America, subject to Great Britain. W. Long. 80. 0. N. Lat. 53. 30.

Charleton, *Walter*, a learned English physician, born in 1619, was physician in ordinary to Charles I. and Charles II. one of the first members of the royal society, and president of the college of physicians. He wrote on various subjects; but at last his narrow circumstances obliged him to retire to the island of Jersey, where he died in 1707.

CHARLOCK, the English name of the Raphanus. It is a very troublesome weed among corn, being more frequent than almost any other. There are two principal kinds of it: the one with a yellow flower, the other with a white. Some fields are particularly subject to be overrun with it. especially those which have been manured with cow-dung alone, that being a manure very favourable to the growth of it. The farmers in some places are so sensible of this, that they always mix horse-dung with their cow-dung, when they use it for arable land. When barley, as is often the case, is infested with this weed to such a degree as to endanger the crop, it is a very good method to mow down the charlock in May, when it is in flower, cutting it so low as just to take off the tops of the leaves of barley with it: by this means the barley will get up above the weed; and people have got four quarters of grain from an acre of such land as would have scarce yielded any thing without this expedient. Where any land is particularly subject to this weed, the best method is to sow it with grass seed, and make a pasture of it; for then the plant will not be troublesome, it never growing where there is a coat of grass upon the ground.

Queen CHARLOTTE's *Island*, an island in the South sea, first discovered by Captain Wallis in the Dolphin, in 1767, who took possession of it in the name of King George III. Here is good water, and

2

Queen Charlotte's Island ‖ Charpentier.

plenty of cocoa nuts, palm nuts, and scurvy grass. The inhabitants are of a middle stature and dark complexion, with long hair hanging over their shoulders; the men are well made, and the women handsome; their clothing is a kind of coarse cloth, or matting, which they fasten about their middle.

Queen Charlotte's Islands, a cluster of South sea islands, discovered in 1767 by Captain Carteret. He counted seven, and there were supposed to be many more. The inhabitants of these islands are described as extremely nimble and vigorous, and almost as well qualified to live in the water as upon land: they are very warlike; and, on a quarrel with some of Captain Carteret's people, they attacked them with great resolution; mortally wounded the master and three of the sailors; were not at all intimidated by the fire arms; and at last, notwithstanding the aversion of Captain Carteret to shed blood, he was obliged to secure the watering places by firing grape shot into the woods, which destroyed many of the inhabitants. These islands lie in S. Lat. 11. E. Long. 164. They are supposed to be the Santa Cruz of Mandana, who died there in 1595.

CHARM, a term derived from the Latin *carmen*, "a verse;" and used to denote a magic power, or spell, by which, with the assistance of the devil, sorcerers and witches were supposed to do wonderful things, far surpassing the power of nature.

CHARNEL, or Charnel-house, a kind of portico, or gallery, usually in or near a churchyard, over which were anciently laid the bones of the dead, after the flesh was wholly consumed. Charnel-houses are now usually adjoining to the church.

CHARON, in fabulous history, the son of Erebus and Nox, whose office was to ferry the souls of the deceased over the waters of Acheron, for which each soul was to pay a piece of money. For this reason the Pagans had a custom of putting a piece of money into the mouth of the dead, in order that they might have something to pay Charon for their passage.

CHARONDAS, a celebrated legislator of the Thurians, and a native of Catanea, in Sicily, flourished 446 before Christ. He forbade any person's appearing armed in the public assemblies of the nation; but one day going thither in haste, without thinking of his sword, he was no sooner made to observe his mistake than he ran it through his body.

CHAROST, a town of France, in Berry, with the title of a duchy. It is seated on the river Arnon. E. Long. 2. 15. N. Lat. 46. 56.

CHAROUX, a town of France, in the Bourbonnois, seated on an eminence, near the river Sioulle. It has two parishes, which are in different dioceses. E. Long. 3. 15. N. Lat. 46. 10.

CHARPENTIER, Francis, dean of the French academy, was born in 1620. His early capacity inclined his friends to educate him at the bar: but he was much more delighted with the study of languages and antiquity than of the law; and preferred repose to tumult. M. Colbert made use of him in establishing his new academy of medals and inscriptions; and no person of that learned society contributed more than himself toward that noble series of medals which were struck on the considerable events that distinguished the reign of Louis XIV. He published several works,

works, which were all well received; and died in 1702.

CHARR. See SALMO, ICHTHYOLOGY *Index*.

CHARRON, PETER, the author of a book entitled *Of Wisdom*, which gained him great reputation, was born at Paris in the year 1541. After being advocate in the parliament of Paris for five or six years, he applied himself to divinity; and became so great a preacher, that the bishops of several dioceses offered him the highest dignities in their gift. He died at Paris, suddenly in the street, November 16. 1603.

CHART, or SEA CHART, an hydrographical map, or a projection of some part of the earth's superficies *in plano*, for the use of navigators.

Charts differ very considerably from geographical or land maps, which are of no use in navigation. Nor are sea charts all of the same kind, some being what we call plane charts, others Mercator charts, and others globular charts.

Plane CHART, is a representation of some part of the superficies of the terraqueous globe, in which the meridians are supposed parallel to each other, the parallels of latitude at equal distances, and consequently the degrees of latitude and longitude everywhere equal to each other. See *PLANE Chart*.

Mercator's CHART, is that where the meridians are straight lines, parallel to each other, and equidistant; the parallels are also straight lines, and parallel to each other; but the distance between them increases from the equinoctial towards either pole, in the ratio of the secant of the latitude to the radius. See NAVIGATION.

Globular CHART, a meridional projection, wherein the distance of the eye from the plane of the meridian, upon which the projection is made, is supposed to be equal to the sine of the angle 45°. This projection comes the nearest of all to the nature of the globe, because the meridians therein are placed at equal distances; the parallels also are nearly equidistant, and consequently the several parts of the earth have their proper proportion of magnitude, distance, and situation, nearly the same as on the globe itself. See *GLOBULAR Projection*.

Hydrographic CHARTS, sheets of large paper, whereon several parts of the land and sea are described, with their respective coasts, harbours, sounds, flats, rocks, shelves, sands, &c. together with the longitude and latitude of each place, and the points of the compass. See *MERCATOR's Chart*.

Selenographic CHARTS, particular descriptions of the spots, appearances, and maculæ of the moon. See ASTRONOMY *Index*.

Topographic CHARTS, draughts of some small parts of the earth only, or of some particular place, without regard to its relative situation, as London, York, &c.

CHARTA, or CARTA, primarily signifies a sort of paper made of the plant *papyrus* or *biblus*. See PAPER and CHARTER.

CHARTA Emporetica, in *Pharmacy*, &c. a kind of paper made very soft and porous, used to filter withal. See FILTRATION, &c.

CHARTA is also used in our ancient customs for a charter, or deed in writing. See CHARTER.

Magna Charta.

Magna CHARTA, the great charter of the liberties of Britain, and the basis of our laws and privileges.

This charter may be said to derive its origin from King Edward the Confessor, who granted several privileges to the church and state by charter; these liberties and privileges were also granted and confirmed by King Henry I. by a celebrated great charter now lost; but which was confirmed or re-enacted by King Henry II. and King John. Henry III. the successor of this last prince, after having caused 12 men make inquiry into the liberties of England in the reign of Henry I. granted a new charter; which was the same as the present magna charta. This he several times confirmed, and as often broke; till, in the 37th year of his reign, he went to Westminster Hall, and there, in presence of the nobility and bishops, who held lighted candles in their hands, magna charta was read, the king all the time holding his hand to his breast, and at last solemnly swearing faithfully and inviolably to observe all the things therein contained, &c. Then the bishops extinguishing the candles, and throwing them on the ground, they all cried out, "Thus let him be extinguished, and stink in hell, who violates this charter." It is observed that, notwithstanding the solemnity of this confirmation, King Henry, the very next year, again invaded the rights of his people, till the barons entered into a war against him; when, after various success, he confirmed this charter, and the charter of the forest, in the 52d year of his reign.

This charter confirmed many liberties of the church, and redressed many grievances incident to feodal tenures, of no small moment at the time; though now, unless considered attentively and with this retrospect, they seem but of trifling concern. But, besides these feodal provisions, care was also taken therein to protect the subject against other oppressions, then frequently arising from unreasonable amercement, from illegal distresses or other process for debts or services due to the crown, and from the tyrannical abuse of the prerogative of purveyance and pre-emption. It fixed the forfeiture of lands for felony in the same manner as it still remains: prohibited for the future the grants of exclusive fisheries; and the erection of new bridges so as to oppress the neighbourhood. With respect to private rights, it established the testamentary power of the subject over part of his personal estate, the rest being distributed among his wife and children; it laid down the law of dower, as it hath continued ever since; and prohibited the appeals of women, unless after the death of their husbands. In matters of public police and national concern, it enjoined an uniformity of weights and measures; gave new encouragements to commerce, by the protection of merchant strangers; and forbade the alienation of lands in mortmain. With regard to the administration of justice, besides prohibiting all denials or delays of it, it fixed the court of common pleas at Westminster, that the suitors might no longer be harassed with following the king's person in all his progresses; and at the same time brought the trial of issues home to the very doors of the freeholders, by directing assizes to be taken in the proper counties, and establishing annual circuits; it also corrected some abuses then incident to the trials by wager of law and of battle; directed the regular award-

ing

ing of inquests for life or member; prohibited the king's inferior ministers from holding pleas of the crown, or trying any criminal charge, whereby many forfeitures might otherwise have unjustly accrued to the exchequer; and regulated the time and place of holding the inferior tribunals of justice, the county-court, sheriff's torn and court-leet. It confirmed and established the liberties of the city of London, and all other cities, boroughs, towns, and ports of the kingdom. And, lastly, (which alone could have merited the title that it bears, of the *great charter*), it protected every individual of the nation in the free enjoyment of his life, his liberty, and his property, unless declared to be forfeited by the judgment of his peers, or the law of the land.

This excellent charter, so equitable and beneficial to the subject, is the most ancient written law in the kingdom. By the 25th Edward I. it is ordained, that it shall be taken as the common law; and by the 43d Edward III. all statutes made against it are declared to be void.

CHARTER, in *Law*, a written instrument, or evidence of things acted between one person and another. The word charter comes from the Latin *charta*. anciently used for a public and authentic act, a donation contract, or the like, from the Greek χαρτης "thick paper" or "pasteboard," whereon public acts were wont to be written. Britton divides charters into those of the king, and those of private persons. 1. Charters of the king, are those whereby the king passeth any grant to any person or body politic, as a *charter of exemption*, of privilege, &c.; *charter of pardon*, whereby a man is forgiven a felony, or other offence committed against the king's crown and dignity; *charter of the forest*, wherein the laws of the forest are comprised, such as the charter of Canutus, &c. 2. Charters of private persons, are deeds and instruments for the conveyance of lands, &c. And the purchaser of lands shall have all the charters, deeds, and evidences, as incident to the same, and for the maintenance of his title.

Charter-Governments in America. See Colony.

Charter-Land, such land as a person holds by charter; that is, by evidence in writing; otherwise called *freehold*.

CHARTERPARTY, in *Commerce*, denotes the instrument of freightage, or articles of agreement for the hire of a vessel. See Freight, &c.

The charterparty is to be in writing; and to be signed both by the proprietor or master of the ship, and the merchant who freights it. It is to contain the name and burden of the vessel; the names of the master and the freighter; the price or rate of freight; and the time of loading and unloading; and the other conditions agreed on. It is properly a deed, or policy, whereby the master or proprietor of the vessel engages to furnish immediately a tight sound vessel, well equipped, caulked, and stopped, provided with anchors, sails, cordage, and all other furniture to make the voyage required, as equipage, hands, victuals, and other munitions; in consideration of a certain sum to be paid by the merchant for the freight. Lastly, The ship with all its furniture, and the cargo, are respectively subjected to the conditions of the *charterparty*. The *charterparty* differs from a *bill of lading*, in that the first is for the entire freight, or lading, and that both for going and returning; whereas the latter is only for a part of the freight, or at most only for the voyage one way.

Boyer says, the word is derived from hence, that *per medium charta incidebatur, et sic fiebat charta partita*: because, in the time when notaries were less common, there was only one instrument made for both parties; this they cut in two, and gave each his portion; joining them together at their return, to know if each had done his part. This he observes to have been practised in his time; agreeable to the method of the Romans, who, in their stipulations, used to break a staff, each party retaining a moiety thereof as a mark.

CHARTOPHYLAX, the name of an officer of the church of Constantinople, who attends at the door of the rails when the sacrament is administered, and gives notice to the priests to come to the holy table. He represents the patriarch upon the bench, tries all ecclesiastical causes, keeps all the marriage registers, assists at the consecration of bishops, and presents the bishop elect at the solemnity, and likewise all other subordinate clergy. This office resembles in some shape that of the *bibliothecarius* at Rome.

CHARTRES, a large city of France, in the department of Eure and Loire, containing 13,000 inhabitants. E. Long. 1. 20. N. Lat. 48. 26. It is a bishop's see.

CHARTREUSE, or Chartreuse-grand, a celebrated monastery, the capital of all the convents of the Carthusian monks, situated on a steep rock in the middle of a large forest of fir trees, about seven miles north-east of Grenoble, in the province of Dauphiny in France. E. Long. 5. 5. N. Lat. 45. 20. See Carthusians.

From this mother convent, all the others of the same order took their name; among which was the Chartreuse of London, corruptly called the *charterhouse*, now converted into an hospital, and endowed with a revenue of 600l. per annum.

Here were maintained 80 decayed gentlemen, not under 50 years of ago; also 40 boys are educated and fitted either for the university or trades. Those sent to the university have an exhibition of 20l. a-year for eight years: and have an immediate title to nine church-livings in the gift of the governors of the hospital, who are sixteen in number, all persons of the first distinction, and take their turns in the nomination of pensioners and scholars.

CHARTULARY, Chartularius, a title given to an ancient officer in the Latin church, who had the care of charters and papers relating to public affairs. The chartulary presided in ecclesiastical judgments, in lieu of the pope. In the Greek church the chartulary was called *chartophylax*; but his office was there much more considerable; and some even distinguished the chartulary from the chartophylax in the Greek church. See Chartophylax.

CHARYBDIS, in *Ancient Geography*, a whirlpool in the straits of Messina, according to the poets; near Sicily, and opposite to Scylla, a rock on the coast of Italy. Thucydides makes it to be only a strong flux and reflux in the strait, or a violent reciprocation of the tide, especially if the wind sets south. But on diving into the Charybdis, there are found vast gulfs and

Charybdis, Chase.

and whirlpools below, which produce all the commotion on the surface of the water.

Charybdis is used by Horace to denote a rapacious prostitute.

CHASE, or CHACE, in *Law*, is used for a driving of cattle to or from any place; as to a distress, or sortlet, &c.

CHASE, or *Chace*, is also a place of retreat for deer and wild beasts; of a middle kind between a forest and a park, being usually less than a forest, and not possessed of so many privileges; but wanting *v. g.* courts of attachment, swainmote, and justice seat *. Yet it is of a large extent, and stocked both with a greater diversity of wild beasts or game, and more keepers, than a park. Crompton observes, that a forest cannot be in the hands of a subject; but it forthwith loses its name, and becomes a *chase;* in regard all those courts lose their nature when they come into the hands of a subject; and that none but a king can make a lord chief justice in eyre of the forest. See *JUSTICE in Eyre*.

* See *Forest.*

The following history of the English chase is given by Mr Pennant. "At first the beasts of chase had this whole island for their range; they knew no other limits than the ocean, nor confessed any particular master. When the Saxons had established themselves in the heptarchy, they were reserved by each sovereign for his own particular diversion. Hunting and war, in those uncivilized ages, were the only employ of the great; their active, but uncultivated minds, being susceptible of no pleasures but those of a violent kind, such as gave exercise to their bodies, and prevented the pain of thinking.

British Zool. i. 42.

"But as the Saxon kings only appropriated those lands to the use of forests which were unoccupied, so no individuals received any injury; but when the Conquest had settled the Norman line on the throne, this passion for the chase was carried to an excess, which involved every civil right in a general ruin: it superseded the consideration of religion even in a superstitious age: the village communities, nay even the most sacred edifices, were turned into one vast waste, to make room for animals, the objects of a lawless tyrant's pleasure. The New forest in Hampshire is too trite an instance to be dwelt on; sanguinary laws were enacted to preserve the game; and in the reigns of William Rufus, and Henry I. it was less criminal to destroy one of the human species than a beast of chase. Thus it continued while the Norman line filled the throne; but when the Saxon line was restored under Henry II. the rigour of the forest laws was immediately softened.

"When our barons began to form a power, they claimed a vast, but more limited, tract for a diversion that the English were always fond of. They were very jealous of any encroachments on their respective bounds, which were often the cause of deadly feuds; such a one gave cause to the fatal battle of *Chevy-chase;* a fact which, though recorded only in a ballad, may, from what we know of the manners of the times, be founded on truth; not that it was attended with all the circumstances which the author of that natural but heroic composition has given it: for on that day neither a *Percy* nor a *Douglas* fell: here the poet seems to have claimed his privilege, and mixed with this fray some of the events of the battle of *Otterbourne*.

"When property became happily more divided by the relaxation of the feodal tenures, those extensive hunting grounds became more limited; and as tillage and husbandry increased, the beasts of chase were obliged to give way to others more useful to the community. The vast tracts of land, before dedicated to hunting, were then contracted; and, in proportion as the useful arts gained ground, either lost their original destination, or gave rise to the invention of *parks*. Liberty and the arts seem coeval; for when once the latter got footing, the former protected the labours of the industrious from being ruined by the licentious sportsman, or being devoured by the objects of his diversion: for this reason, the subjects of a despotic government still experience the inconveniences of vast wastes and forests, the terrors of the neighbouring husbandmen; while in our well regulated monarchy very few chases remain. The English still indulge themselves in the pleasures of hunting; but confine the deer kind to parks, of which England boasts of more than any other kingdom in Europe. The laws allow every man his pleasure; bnt confine them in such bounds as to prevent them from being injurious to the meanest of the community. Before the Reformation, the prelates seem to have guarded sufficiently against this want of amusement; the see of Norwich, in particular, being possessed, about that time, of thirteen parks."

CHASE, in the sea language, is to pursue a ship; which is also called *giving chace*.

Stern-CHASE, is when the chaser follows the chased astern directly upon the same point of the compass.

To lie with a ship's fore-foot in a CHASE, is to sail and meet with her by the nearest distance; and so to cross her in her way, or to come across her fore-foot.

A ship is said to have a *good chase*, when she is so built forward on, or a-stern, that she can carry many guns to shoot forwards or backwards; according to which she is said to have a *good forward* or *good stern chase*.

CHASE Guns, are such whose ports are either in the head (and then they are used in chasing of others); or in the stern, which are only useful when they are pursued or chased by any other ship.

CHASE of a Gun, is the whole bore or length of a piece taken withinside.

Wild-goose CHASE, a term used to express a sort of racing on horseback used formerly, which resembled the flying of wild geese; those birds generally going in a train one after another, not in confused flocks as other birds do. In this sort of race the two horses, after running twelve score yards, had liberty, which horse soever could take the leading, to ride what ground the jockey pleased, the hindmost horse being bound to follow him within a certain distance agreed on by the articles, or else to be whipped in by the tryers and judges who rode by; and whichever horse could distance the other won the race. This sort of racing was not long in common use; for it was found inhuman, and destructive to good horses, when two such were matched together. For in this case neither was able to distance the other till they were both ready to sink under their riders; and often two very good

Chase Chastity.

good horses were both spoiled, and the wagers forced to be drawn at last. The mischief of this sort of racing soon brought in the method now in use, of running only for a certain quantity of ground, and determining the plate or wager by the coming in first at the post.

Chasing of Gold, Silver, &c. See Enchasing.

CHASTE tree. See Vitex, Botany *Index*.

CHASTITY. Purity of the body, or freedom from obscenity.—The Roman law justifies homicide in defence of the chastity either of one's self or relations; and so also, according to Selden, stood the law in the Jewish republic. Our law likewise justifies a woman for killing a man who attempts to ravish her. So the husband or father may justify killing a man who attempts a rape upon his wife or daughter; but not if he takes them in adultery by consent; for the one is forcible and felonious, but not the other.

Chastity is a virtue universally celebrated. There is indeed no charm in the female sex that can supply its place. Without it beauty is unlovely, and rank is contemptible; good breeding degenerates into wantonness, and wit into impudence. Out of the numerous instances of eminent chastity recorded by authors, the two following are selected on account of the lesson afforded by the different modes of conduct which they exhibit.

Lucretia was a lady of great beauty and noble extraction; she married Collatinus, a relation of Tarquinius Superbus king of Rome. During the siege of Ardea, which lasted much longer than was expected, the young princes passed their time in entertainments and diversions. One day as they were at supper*, at Sextus Tarquin's, the king's eldest son, with Collatinus, Lucretia's husband, the conversation turned on the merit of their wives; every one gave his own the preference. "What signify so many words?" says Collatinus; "you may in a few hours, if you please, be convinced by your own eyes how much my Lucretia excels the rest. We are young; let us mount our horses, and go and surprise them. Nothing can better decide our dispute than the state we shall find them in at a time when most certainly they will not expect us." They were a little warmed with wine: "Come on, let us go," they all cried together. They quickly galloped to Rome, which was about twenty miles from Ardea, where they find the princesses, wives of the young Tarquins, surrounded with company, and every circumstance of the highest mirth and pleasure. From thence they rode to Collatia, where they saw Lucretia in a very different situation. With her maids about her, she was at work in the inner part of her house, talking of the dangers to which her husband was exposed. The victory was adjudged to her unanimously. She received her guests with all possible politeness and civility. Lucretia's virtue, which should have commanded respect, was the very thing which kindled in the breast of Sextus Tarquin a strong and detestable passion. Within a few days he returned to Collatia; and, upon the plausible excuse he made for his visit, he was received with all the politeness due to a near relation, and the eldest son of a king. Watching the fittest opportunity, he declared the passion she had excited at his last visit, and employed the most tender entreaties, and all the artifices possible to touch a woman's heart; but all to no purpose. He then endeavoured to extort her compliance by the most terrible threatenings. It was in vain. She still persisted in her resolution; nor could she be moved even by the fear of death. But when the monster told her that he would first dispatch her, and then having murdered a slave, would lay him by her side, after which he would spread a report, that having caught them in the act of adultery, he had punished them as they deserved; this seemed to shake her resolution. She hesitated, not knowing which of these dreadful alternatives to take, whether, by consenting to dishonour the bed of her husband, whom she tenderly loved; or, by refusing, to die under the odious character of having prostituted her person to the lust of a slave. He saw the struggle of her soul; and seizing the unlucky moment, obtained an inglorious conquest. Thus, Lucretia's virtue, which had been proof against the fear of death, could not hold out against the fear of infamy. The young prince having gratified his passion, returned home as in triumph. On the morrow, Lucretia, overwhelmed with grief and despair, sent early in the morning to desire her father and her husband to come to her, and bring with them each a trusty friend, assuring them there was no time to lose. They came with all speed, the one accompanied with Valerius (so famous after under the name of Publicola), and the other with Brutus. The moment she saw them come, she could not command her tears; and when her husband asked her if all was well? "By no means," said she, "it cannot be well with a woman after she has lost her honour. Yes, Collatinus, thy bed has been defiled by a stranger: but my body only is polluted; my mind is innocent, as my death shall witness. Promise me only not to suffer the adulterer to go unpunished: it is Sextus Tarquinius, who last night, a treacherous guest, or rather cruel foe, offered me violence, and reaped a joy fatal to me; but, if you are men, it will be still more fatal to him." All promised to revenge her; and at the same time, tried to comfort her with representing, "That the mind only sins, not the body; and where the consent is wanting, there can be no guilt." "What Sextus deserves," replies Lucretia, "I leave you to judge; but for me, though I declare myself innocent of the crime, I exempt not myself from punishment. No immodest woman shall plead Lucretia's example to outlive her dishonour." Thus saying, she plunged into her breast a dagger she had concealed under her robe, and expired at their feet. Lucretia's tragical death has been praised and extolled by Pagan writers, as the highest and most noble act of heroism. The Gospel thinks not so: it is murder, even according to Lucretia's own principles, since she punished with death an innocent person, at least acknowledged as such by herself. She was ignorant that our life is not in our own power, but in his disposal from whom we receive it. St Austin, who carefully examines, in his book *De Civitate Dei*, what we are to think of Lucretia's death, considers it not as a courageous action flowing from a true love of chastity, but as an infirmity of a woman too sensible of worldly fame and glory; and who, from a dread of appearing in the eyes of men an accomplice of the violence she abhorred, and of a crime to which she was entirely a stranger, commits a real crime upon herself voluntarily and designedly. But what cannot be

* v. l. i. c. —60. ys. l. iv. 261. —7. l. iii. 9

be sufficiently admired in this Roman lady, is her aphorrence of adultery, which she seems to hold so detestable as not to bear the thoughts of it. In this sense, she is a noble example for all her sex.

Chiomara, the wife of Ortiagon, a Gaulish prince, was equally admirable for her beauty and chastity.

During the war between the Romans and the Gauls, A. R. 563, the latter were totally defeated on Mount Olympus. Chiomara, among many other ladies, was taken prisoner, and committed to the care of a centurion, no less passionate for money than women. He at first endeavoured to gain her consent to his infamous desires; but not being able to prevail upon her, and subvert her constancy, he thought he might employ force with a woman whom misfortune had reduced to slavery. Afterwards, to make her amends for that treatment, he offered to restore her liberty; but not without ransom. He agreed with her for a certain sum, and to conceal this design from the other Romans, he permitted her to send any of the prisoners she should choose to her relations, and assigned a place near the river where the lady should be exchanged for gold. By accident there was one of her own slaves among the prisoners. Upon him she fixed; and the centurion soon after carried him beyond the advanced posts, under cover of a dark night. The next evening two of the relations of the princess came to the place appointed, whither the centurion also carried his captive. When they had delivered him the Attic talent they had brought, which was the sum they had agreed on, the lady, in her own language, ordered those who came to receive her to draw their swords and kill the centurion, who was then amusing himself with weighing the gold. Then, charmed with having revenged the injury done her chastity, she took the head of the officer, which she had cut off with her own hands, and hiding it under her robe, went to her husband Ortiagon, who had returned home after the defeat of his troops. As soon as she came into his presence, she threw the centurion's head at his feet. He was strangely surprised at such a sight; and asked her whose head it was, and what had induced her to do an act so uncommon to her sex? With her face covered with a sudden blush, and at the same time expressing her fierce indignation, she declared the outrage which had been done her, and the revenge she had taken for it. During the rest of her life, she stedfastly retained the same attachment for the purity of manners which constitutes the principal glory of the sex, and nobly sustained the honour of so glorious, bold, and heroic an action.—This lady was much more prudent than Lucretia, in revenging her injured honour by the death of her ravisher rather than by her own. Plutarch relates this fact, in his treatise upon the virtue and great actions of women; and it is from him we have the name of this, which is well worthy of being transmitted to posterity.

The above virtue in men is termed *continence*. See CONTINENCE.

CHATEAU-BRIANT, a town of France in the department of Lower Loire, with an old castle. W. Long. 1. 20. N. Lat. 47. 40.

CHATEAU-Chinon, a town of France in the department of Nievre, with a considerable manufactory of cloth. E. Long. 3. 48. N. Lat. 47. 2.

CHATEAU-Dauphin, a very strong castle of Piedmont in Italy, and in the marquisate of Saluces, belonging to the king of Sardinia. It was taken by the combined army of France and Spain in 1744, and was restored by the treaty of Aix-la-Chapelle.

CHATEAU-du-Loire, a town of France in the department of Indre and Loire, famous for sustaining a siege of seven years against the count of Maus. It is seated on the river Loire, in E. Long. 0. 25. N. Lat. 47. 40.

CHATEAU-Dun, an ancient town of France, in the department of Eure and Loire, with a castle and rich monastery; seated on an eminence near the river Loire, in E. Long. 1. 26. N. Lat. 48. 4.

CHATEAU-Neuf, the name of several towns of France, viz. one in Perche; another in Angumois, on the river Charente, near Angoulesme; a third in Berry, seated on the river Cher; and several other small places.

CHATEAU-Portien, a town of France in the department of Ardennes, with a castle built on a rock, near the river Aisne. Population 1030. E. Long. 4. 23. N. Lat. 49. 35.

CHATEAU-Renaud, a town of France, in the Gatenois, where clothes are made for the army, and where there is a trade in saffron. E. Long. 4. 25. N. Lat. 48. 0. This is also the name of a town of Touraine, in France, with the title of marquisate. E. Long. 2. 41. N. Lat. 47. 22.

CHATEAU-Roux, a town of France, in the department of Indre. It has a cloth manufacture, and is seated in a very large pleasant plain on the river Indre, in E. Long. 1. 47. N. Lat. 46. 49.

CHATEAU-Thiery, a town of France, in the department of Aisne, with a handsome castle on an eminence, seated on the river Maine. It contains 4080 inhabitants. E. Long. 3. 23. N. Lat. 49. 12.

CHATEAU-Vilain, a town of France, in the department of Upper Marne, with a castle; seated on the river Anjou. E. Long. 2. 59. N. Lat. 48. 0.

CHATEL, or CHATE, a town of Loraine, in the Vosges, seated on the river Moselle, eight miles from Mirecourt.

CHATEL-Allon, a maritime town of France, in the department of Lower Charente, five miles from Rochelle; formerly very considerable, but now greatly decayed.

CHATEL-Chalon, a town of France, in the department of Jura, remarkable for its abbey of Benedictine nuns. E. Long. 5. 25. N. Lat. 46. 50.

CHATELET, a town of the Netherlands, in Namur, seated on the Sambre, in the bishopric of Liege. E. Long. 4. 28. N. Lat. 50. 25.

CHATELET, the name of certain courts of justice established in several cities in France. The grand chatelet at Paris is the place where the presidial or ordinary court of justice of the provost of Paris is kept; consisting of a presidial, a civil chamber, a criminal chamber, and chamber of policy. The little chatelet is an old fort, now serving as a prison.

CHATELLERAULT, a town of France, in the department of Vienne, with the title of a duchy; seated in a fertile and pleasant country, on the river Vienne, over which there is a handsome stone bridge. E. Long. 0. 40. N. Lat. 46. 34.

CHATHAM, a town of Kent, adjoining to Rochester, and seated on the river Medway. It is the principal

Chatham. Chatterton.

principal station of the royal navy; and the yards and magazines are furnished with all kinds of naval stores, as well as materials for building and rigging the largest men of war. The entrance into the river Medway is defended by Sheerness and other forts; notwithstanding which, the Dutch fleet burnt several ships of war here in the reign of Charles II. after the peace of Breda had been agreed upon. In the year 1757, by direction of the duke of Cumberland, several additional fortifications were begun at Chatham; so that now the ships are in no danger of an insult either by land or water. It has a church, a chapel of ease, and a new chapel for the docks, built in 1811. The dock-yard, including the ordnance wharfs, is a mile in length. Handsome barracks, capable of accommodating 1200 men, were built in 1804. The town contained 12,652 inhabitants in 1811. The principal employment of the labouring hands is ship-building. This town gave title of earl to that great statesman William Pitt, in the reigns of George II. and III. E. Long. 0. 40. N. Lat. 51. 20.

CHATIGAN, a town of Asia, in the kingdom of Bengal, on the most easterly branch of the river Ganges. It is but a poor place, though it was the first the Portuguese settled at in these parts, and who still keep a sort of possession. It has but a few cotton manufactures; but affords the best timber for building of any place about it. The inhabitants are so suspicious of each other, that they always go armed with a sword, pistol, and blunderbuss, not excepting the priests. It is subject to the British government. E. Long. 91. 10. N. Lat. 23. 0.

CHATILLON SUR SEINE, a town of France, in the department of Cote D'or, divided into two by the river Seine. This town was the scene of the fruitless negociations between the allies and Bonaparte in 1814. E. Long. 4. 33. N. Lat. 47. 45.

CHATRE, a town of France, in the department of Indre, seated on the river Indre, 37 miles from Bourges. It carries on a considerable trade in cattle. E. Long. 1. 55. N. Lat. 46. 35.

CHATTELS, a Norman term, under which were anciently comprehended all moveable goods; those immoveable being termed *fief* or *fee*.

CHATTELS, in the modern sense of the word, are all sorts of goods, moveable or immoveable, except such as are in the nature of freehold.

CHATTERER. See AMPELIS, ORNITHOLOGY *Index*.

CHATTERTON, THOMAS, a late unfortunate poet, whose fate and performances have excited in no small degree the public attention, as well as given rise to much literary controversy. He was born at Bristol, Nov. 20. 1752; and educated at a charity school on St Augustine's Back, where nothing more was taught than reading, writing, and accounts. At 14 years of age, he was articled clerk to an attorney at Bristol, with whom he continued about three years; yet, though his education was thus confined, he discovered an early turn towards poetry and English antiquities, and particularly towards heraldry. How soon he began to be an author is not known. In the Town and Country Magazine for March 1769, are two letters, probably from him, as they are dated from Bristol, and subscribed with his usual signature, D. B. that is, *Dunhelmus Bristoliensis*. The former contains short extracts from two MSS. "written 300 years ago by one Rowley a monk," concerning dress in the age of Henry II.; the latter, "Ethelgar, a Saxon poem," in bombast prose. In the same magazine for May 1769 are three communications from Bristol, with the same signature D. B. one of them entitled, "Observations upon Saxon Heraldry, with drawings of Saxon Achievements;" and in the subsequent months of 1769 and 1770, there are several other pieces in the same magazine, which are undoubtedly of his composition.

In April 1770, he left Bristol, disgusted with his profession, and irreconcileable to the line of life in which he was placed; and coming to London in hopes of advancing his fortune by his pen, he sunk at once from the sublimity of his views to an absolute dependence on the patronage of booksellers. Things, however, seem soon to have brightened up a little with him; for, May 14. he writes to his mother, in high spirits, upon the change of his situation, with the following sarcastic reflections upon his former patrons at Bristol. "As to Mr ——, Mr ——, Mr ——, &c. &c. they rate literary lumber so low, that I believe an author, in their estimation, must be poor indeed: but here matters are otherwise. Had Rowley been a Londoner instead of a Bristowyan, I could have lived by copying his works." In a letter to his sister, May 30. he informs her that he is to be employed in writing a voluminous History of London, to appear in numbers the beginning of next winter. Meanwhile, he had written something in praise of Beckford, then lord mayor, which had procured him the honour of being presented to his lordship; and, in the letter just mentioned, he gives the following account of his reception, with certain observations upon political writing: "The lord mayor received me as politely as a citizen could; but the devil of the matter is, there is no money to be got on this side of the question.—However, he is a poor author who cannot write on both sides.—Essays on the patriotic side will fetch no more than what the copy is sold for. As the patriots themselves are searching for places, they have no gratuity to spare.—On the other hand, unpopular essays will not even be accepted, and you must pay to have them printed; but then you seldom lose by it, as courtiers are so sensible of their deficiency in merit, that they generously reward all who know how to daub them with the appearance of it."

He continued to write incessantly in various periodical publications. July 11. he tells his sister that he had pieces last month in several magazines; in The Gospel Magazine, The Town and Country, The Court and City, The London, The Political Register, &c. But all these exertions of his genius brought in so little profit, that he was soon reduced to the extremest indigence; so that at last, oppressed with poverty and disease, in a fit of despair, he put an end to his existence, August 1770, with a dose of poison. This unfortunate person, though certainly a most extraordinary genius, seems yet to have been a most ungracious composition. He was violent and impetuous to a strange degree. From the first of the above cited letters he seems to have had a portion of ill humour and spleen more than enough for a lad of 17; and the editor of his

his Miscellanies records, "that he possessed all the vices and irregularities of youth, and that his profligacy was at least as conspicuous as his abilities."

In 1777 were published in one volume 8vo, "Poems, supposed to have been written at Bristol, by Thomas Rowley and others, in the 15th century: the greatest part now first published from the most authentic copies, with an engraved specimen of one of the MSS. To which are added, a Preface, an Introductory Account of the several pieces, and a Glossary." And in 1778 were published, in one volume 8vo, "Miscellanies in Prose and Verse, by Thomas Chatterton, the supposed author of the Poems published under the names of Rowley," &c.

Of Rowley's poems we have the following account in the preface, given in the words of Mr George Catcot of Bristol, to whom, it is said, the public is indebted for them: "The first discovery of certain MSS. having been deposited in Redclift church above three centuries ago, was made in the year 1768, at the time of opening the new bridge at Bristol; and was owing to a publication in Farley's Weekly Journal, Oct. 1. containing an account of the ceremonies observed at the opening of the old bridge, taken, as it was said, from a very ancient MS. This excited the curiosity of some persons to inquire after the original. The printer, Mr Farley, could give no account of it, or of the person who brought the copy; but after much inquiry, it was discovered that this person was a youth between 15 and 16 years of age, whose name was Thomas Chatterton, and whose family had been sextons of Redclift church for near 150 years. His father, who was now dead, had also been master of the free school in Pile-street. The young man was at first very unwilling to discover from whence he had the original: but, after many promises made to him, was at last prevailed on to acknowledge that he had received this, together with many other MSS. from his father, who had found them in a large chest in an upper room over the chapel on the north side of Redclift church." It is added, that soon after this Mr Catcot commenced an acquaintance with Chatterton, and partly as presents, partly as purchases, procured from him copies of many of his MSS. in prose and verse; as other copies were disposed of in like manner to others. It is concluded, however, that whatever may have been Chatterton's part in this very extraordinary transaction, whether he was the author, or only (as he constantly asserted) the copier of all these productions, he appears to have kept the secret entirely to himself, and not to have put it in any one's power to bear certain testimony either of his fraud or of his veracity.

This affair, however, has since become the foundation of a mighty controversy among the critics, which hath yet scarcely subsided. The poems in question, published in 1777, were republished in 1778, with an "Appendix, containing some observations upon their language; tending to prove that they were written, not by an ancient author, but entirely by Chatterton." Mr Warton, in the third volume of his History of English Poetry, hath espoused the same side of the question. Mr Walpole also obliged the world with a Letter on Chatterton, from his press at Strawberry-hill. On the other hand have appeared, "Observations" upon these poems, "in which their authenticity is ascertained," by Jacob Bryant, Esq.; 1781, 2 vols. 8vo; and another edition of the "Poems, with a Comment, in which their antiquity is considered and defended, by Jeremiah Milles, D. D. Dean of Exeter, 1782," 4to. In answer to these two works, we have had three pamphlets: 1. "Cursory Observations on the Poems, and Remarks on the Commentaries of Mr Bryant and Dr Milles; with a salutary proposal addressed to the friends of these gentlemen." 2. "An Archæological Epistle to Dean Milles, editor of a superb edition of Rowley's Poems," &c. 3. "An Inquiry into the authenticity of the Poems attributed to Thomas Rowley, in which the Arguments of the Dean of Exeter and Mr Bryant are examined, by Thomas Warton;" and other pieces in the public prints and magazines: All preparatory to the complete settlement of the business in "A Vindication of the Appendix to the Poems called Rowley's, in reply to the Answers of the Dean of Exeter, Jacob Bryant, Esq. and a third Anonymous Writer; with some further Observations upon these Poems, and an Examination of the Evidence which has been produced in support of their Authenticity. By Thomas Tyrwhitt, 1782," 8vo.

CHAUCER, Sir Geofrey, an eminent English poet in the 14th century, born at London in 1328. After he left the university, he travelled into Holland, France, and other countries. Upon his return he entered himself in the Inner Temple, where he studied the municipal laws of England. His first station at court was page to Edward III. and he had a pension granted him by that prince till he could otherwise provide for him. Soon after we find him gentleman of the king's privy chamber; next year, shield-bearer to the king. Esteemed and honoured, he spent his younger days in a constant attendance at court, or for the most part living near it, in a square stone house near the park-gate at Woodstock, still called *Chaucer's House.*

Soon after, having got the duke of Lancaster for his patron, Chaucer began every day to rise in greatness. In 1373, he was sent with other persons to the republic of Genoa to hire ships for the king's navy (our want of shipping in those times being usually supplied by such means); and the king was so well satisfied with his negotiation, that, on his return, he obtained a grant of a pitcher of wine daily in the port of London, to be delivered by the butler of England; and soon after was made comptroller of the customs for wool, wool fells, and hides; an office which he discharged with great diligence and integrity. At this period, Chaucer's income was about 1000l. a-year; a sum which in those days might well enable him to live, as he says he did, with dignity in office, and hospitality among his friends. It was in this meridian blaze of prosperity, in perfect health of body and peace of mind, that he wrote his most humorous poems. His satires against the priests were probably written to oblige his patron the duke of Lancaster, who favoured the cause of Wickliff, and endeavoured to expose the clergy to the indignation of the people. In the last year of Edward III. our poet was employed in a commission to treat with the French; and in the beginning of King Richard's reign, he was in some degree of favour at court.

The duke of Lancaster at last finding his views checked, began to abandon Wickliff's party; upon which

which Chaucer likewise, how much soever he had espoused that divine's opinions, thought it prudent to conceal them more than he had done. With the duke's interest that of Chaucer entirely sunk; and the former passing over sea, his friends felt all the malice of the opposite party. These misfortunes occasioned his writing that excellent treatise, *The Testament of Love*, in imitation of Boethius on the Consolation of Philosophy. Being much reduced, he retired to Woodstock, to comfort himself with study, which produced his admirable treatise of the *Astrolabe*.

The duke of Lancaster at last surmounting his troubles, married Lady Catharine Swynford, sister to Chaucer's wife; so that Thomas Chaucer, our poet's son, became allied to most of the nobility, and to several of the kings of England. Now the sun began to shine upon Chaucer with an evening ray: for by the influence of the duke's marriage, he again grew to a considerable share of wealth. But being now 70, he retired to Dunnington castle near Newbury. He had not enjoyed this retirement long before Henry IV. son of the duke of Lancaster, assumed the crown, and in the first year of his reign gave our poet marks of his favour. But however pleasing the change of affairs might be to him at first, he afterwards found no small inconveniences from it. The measures and grants of the late king were annulled: and Chaucer, in order to procure fresh grants of his pensions, left his retirement, and applied to court: where, though he gained a confirmation of some grants, yet the fatigue of attendance, and his great age, prevented him from enjoying them. He fell sick at London: and ended his days in the 72d year of his age, leaving the world as though he despised it, as appears from his song of *Flie from the Prese*. The year before his death he had the happiness, if at his time of life it might so be called, to see the son of his brother-in-law (Henry IV.) seated on the throne. He was interred in Westminster Abbey; and in 1556, Mr Nicholas Bingham, a gentleman of Oxford, at his own charge, erected a handsome monument for him there. Caxton first printed the Canterbury Tales; but his works were first collected and published in one volume folio, by William Thynne, London, 1542. They were afterwards reprinted in 1561, 1598, 1602. Oxford, 1721.

Chaucer was not only the first, but one of the best poets which these kingdoms ever produced. He was equally great in every species of poetry which he attempted; and his poems in general possess every kind of excellence, even to modern readers, except melody and accuracy of measure; defects which are to be attributed to the imperfect state of our language, and the infancy of the art in this kingdom at the time when he wrote. "As he is the father of English poetry (says Mr Dryden), so I hold him in the same degree of veneration as the Grecians did Homer, or the Romans Virgil. He is a perpetual fountain of good sense, learned in all sciences, and therefore speaks properly on all subjects. As he knew what to say, so he knows also when to leave off; a continence which is practised by few writers, and scarcely by any of the ancients, except Virgil and Horace." This character Chaucer certainly deserved. He had read a great deal; and was a man of the world, and of sound judgment. He was the first English poet who wrote *poetically*, as Dr Johnson observes in the preface to his Dictionary, and (he might have added) who wrote like a gentleman. He had also the merit of improving our language considerably, by the introduction and naturalization of words from the Provençal, at that time the most polished dialect in Europe.

CHALCIS, in *Ancient Geography*, the country of the Chouci, a people of Germany: divided into the *Minores*, now *East Friesland*, and the county of *Oldenburgh;* and into the *Majores*, now the duchy of *Bremen* and a part of *Lunenburgh*.

CHAUD MEDLEY, in *Law*, is of much the same import with *CHANCE Medley*. The former in its etymology signifies an affray in the heat of blood or passion: the latter, a casual affray. The latter is in common speech too often erroneously applied to any manner of homicide by misadventure; whereas it appears by the stat. 24 Hen. VIII. c. 5. and ancient books (Standf. P. C. 16.), that it is properly applied to such killing as happens in self-defence upon sudden encounter.

CHAUL, a town of the East Indies, on the coast of Malabar, in the province of Baglana, and kingdom of Visapour. Its river affords a good harbour for small vessels. The town is fortified, and so is the island on the south side of the harbour. It had formerly a good trade, but is now miserably poor. It was taken by the Portuguese in 1507, to whom it still belongs. It is 15 miles south of Bombay, and five miles from the sea. E. Long. 72. 45. N. Lat. 18. 30.

CHAULIEU, WILLIAM AMFREYEDE, Abbé d'Amale, one of the most polite and ingenious of the French poets, was born in 1639, and died at the age of 84. The most complete edition of his poems is that printed in two vols. 8vo, in 1733.

CHAUMONT, a town of France, in the department of Upper Marne, of which it is the capital. It is seated on a mountain near the river Marne. E. Long. 5. 15. N. Lat. 48. 6.

CHAUNE, a town of France, in the department of Somme, with the title of a duchy. E. Long. 2. 55. N. Lat. 49. 45.

CHAUNTRY. See CHANTRY.

CHAUNY, a town of France, in the department of Aisne, seated on the river Oise, in Chantry. E. Long. 3. 17. N. Lat. 49. 37.

CHAUVIN, STEPHEN, a celebrated minister of the reformed religion, born at Nismes, left France at the revocation of the edict of Nantz, and retired to Rotterdam, where he began a new *Journal des Sçavans;* and afterwards removing to Berlin, continued it there three years. At this last place, he was made professor of philosophy, and discharged that office with much honour and reputation. His principal work is a philosophical dictionary, in Latin, which he published at Rotterdam in 1692; and gave a new edition of it, much augmented, at Lewarden, in 1703, in folio. He died in 1725, aged 85.

CHAVEZ, a strong town of Tra-los-Montes in Portugal, seated at the foot of a mountain on the river Tamega. It has two suburbs, and as many forts; one of which looks like a citadel. Between the town and suburb of Magdalena, is an old Roman stone bridge about 92 geometrical paces long. W. Long. 7. 1. N. Lat. 41. 45.

Chazelles, Chazinzarians.

CHAZELLES, Jean Matthew, a celebrated French mathematician and engineer, was born at Lyons in 1657. M. du Hamel, with whom he got acquainted, finding his genius incline towards astronomy, presented him to M. Cassini, who employed him in his observatory. In 1684, the duke of Mortemar made use of Chazelles to teach him mathematics; and, the year after, procured him the preferment of hydrography professor for the galleys of Marseilles, where he set up a school for young pilots designing to serve aboard the galleys. In 1686, the galleys made four little campaigns, or rather four courses, purely for exercise. Chazelles went on board every time with them, kept his school upon the sea, and showed the practice of what he taught. In the years 1687 and 1688, he made two other sea campaigns, in which he drew a great many plans of ports, roads, towns, and forts, which were lodged with the ministers of state. At the beginning of the war which ended with the peace of Ryswick, some marine officers, and Chazelles among the rest, fancied the galleys might be so contrived as to live upon the ocean; that they might serve to tow the men of war when the wind failed or proved contrary, and also help to secure the coast of France upon the ocean. Chazelles was sent to the west coasts in July 1689, to examine the practicability of this scheme; and in 1690, fifteen galleys new built set sail from Rochefort, and cruised as far as Torbay, in England, and proved serviceable at the descent upon Tinmouth. After this, he digested into order the observations he had made on the coasts of the ocean; and drew distinct maps, with a portulan to them, viz. a large description of every haven, of the depth, the tides, the dangers and advantages discovered, &c. These maps were inserted in the *Neptune Françoise*, published in 1692, in which year Chazelles was engineer at the descent at Oneille. In 1693, Monsieur de Pontchartrain, then secretary of state for the marine, and afterwards chancellor of France, resolved to get the *Neptune Françoise* carried on to a second volume, which was also to take in the Mediterranean. Chazelles desired that he might have a year's voyage on this sea, for making astronomical observations; and the request being granted, he passed through Greece, Egypt, and other parts of Turkey, with his quadrant and telescope in his hand. When he was in Egypt, he measured the pyramids: and finding the sides of the largest precisely facing the four cardinal points, naturally concluded this position to have been intended, and also that the poles of the earth and meridians had not since deviated. Chazelles likewise made a report of his voyage in the Levant, and gave the academy all the satisfaction they wanted concerning the position of Alexandria: upon which he was made a member of the academy in 1695. He died in 1710.

CHAZINZARIANS, a sect of heretics who rose in Armenia in the seventh century. The word is formed of the Armenian *chazus*, "cross." They are also called *staurolatræ*, which in Greek signifies the same as *Chazinzarians* in Armenian, viz. *adorers of the cross;* they being charged with paying adoration to the cross alone. In other respects they were Nestorians; and admitted two persons in Jesus Christ: Nicephorus ascribes other singularities to them; particularly their holding an annual feast in memory of the dog of their false prophet Sergius, which they called *artzibartzes*.

Chazinzarians, Cheadle.

CHEADLE, a town of England in the county of Stafford, situated on the side of a hill. It is surrounded by coal pits; and in the neighbourhood are carried on extensive manufactories in brass, copper, and tin. A weekly market is held here, and there are four annual fairs. Population 3191 in 1811. Distant 15 miles N. E. of Stafford, and 146 N. N. W. of London. W. Long. 2. N. Lat. 53.

Cheadle Bulkeley, a township of England in the county of Chester, situated on the river Bollin. Population 2509.

Cheadle Moseley, a township of England in the county of Chester, situated on the river Bollin, adjoining Cheadle Bulkeley. Population 1209. Distant three miles S. W. from Stockport.

CHEATS, are deceitful practices, in defrauding, or endeavouring to defraud, another person of his right, by means of some artful device, contrary to the plain rules of common honesty: as by playing with false dice, or by causing an illiterate person to execute a deed to his prejudice, by reading it over to him in words different from those in which it was written, &c.—If any person deceitfully get into his hands or possession any money or other things of any other person's, by colour of any false token, &c. being convicted, he shall have such punishment by imprisonment, setting upon the pillory, or by any corporeal pain except pains of death, as shall be adjudged by the persons before whom he shall be convicted.—As there are frauds which may be relieved civilly, and not punished criminally; so there are other frauds which in a special case may not be helped civilly, and yet shall be punished criminally. Thus, if a minor goes about the town, and, pretending to be of age, defrauds many persons by taking credit for a considerable quantity of goods, and then insisting on his nonage, the persons injured cannot recover the value of their goods, but they may inflict and punish him for a common cheat. Persons convicted of obtaining money or goods by false pretences, or of sending threatening letters in order to extort money or goods, may be punished with fine or imprisonment, or by pillory, whipping, or transportation.

CHEBRECHIN, a town of Poland, in the province of Red Russia and palatinate of Belskow. It is seated on the declivity of a hill; and the river Wierpi waters its walls, and afterwards falls into the river Bog. The Jews there are very rich. E. Long. 23. 51. N. Lat. 50. 35.

CHECAYA, in Turkish affairs, the second officer of the janizaries, who commands them under the aga, and is otherwise called *protogero*.

There is also a checaya of the treasury, stables, kitchen, &c. the word signifying as much as lieutenant, or the second in any office.

CHECK, or *Check-Roll*, a roll or book, wherein are contained the names of such persons as are attendants and in the pay of the king, or other great personages, as their household servants.

Clerk of the Check in the king's household, has the check and controlment of the yeomen of the guard, and all the ushers belonging to the royal family, allowing their absence or defects in attendance, or diminishing

nishing their wages for the same, &c. He also, by himself or deputy, takes the view of those who are to watch in the court, and has the setting of the watch, &c.

Clerk of the CHECK *in the royal dock yards*, an officer who keeps a muster or register of all the men employed aboard his majesty's ships and vessels, and also of all the artificers and others in the service of the navy at the port where he is settled.

CHECK, in falconry, a term used of a hawk, when she forsakes her proper game, to fly at pies, crows, rooks, or the like, that cross her in her flight.

CHECKY, in *Heraldry*, is when the shield, or a bordure, &c. is chequered, or divided into chequers or squares, in the manner of a chessboard.

This is one of the most noble and most ancient figures used in armoury; and a certain author saith, that it ought to be given to none but great warriors, in token of their bravery; for the chessboard represents a field of battle; and the pawns placed on both sides represent the soldiers of the two armies, which move, attack, advance, or retire, according to the will of the gamesters, who are the generals.

This figure is always composed of metal and colour. But some authors would have it reckoned among the several sorts of furs.

CHEEK, in *Anatomy*, that part of the face situated below the eyes on each side.

CHEEKS, a general name among mechanics, for almost all those pieces of their machines and instruments, that are double and perfectly alike. Thus, the cheeks of a printing press are its two principal pieces: they are placed perpendicular, and parallel to each other; serving to sustain the three sommers, viz. the head, shelves, and winter, which bear the spindle and other parts of the machine. See PRINTING *Press*.

The cheeks of a turner's lathe, are two long pieces of wood, between which are placed the puppets, which are either pointed or otherwise, serving to support the work and the mandrils of the workman. These two pieces are placed parallel to the horizon, separated from one another by the thickness of the tail of the puppets, and joined with tenons to two other pieces of wood placed perpendicularly, called the *legs of the lathe*.

Cheeks of the glazier's vice, are two pieces of iron joined parallel at top and bottom; in which are the axles, or spindles, little wheel, cushions, &c. whereof the machine is composed.

The cheeks of a mortar, or the *brackets*, in *Artillery*, are made of strong planks of wood, bound with thick plates of iron, and are fixed to the bed by four bolts; they rise on each side of the mortar, and serve to keep her at what elevation is given her, by the help of strong bolts of iron which go through both cheeks both under and behind the mortar, betwixt which are driven quoins of wood; these bolts are called the *bracket bolts*; and the bolts which are put one in each end of the bed, are the traverse bolts, because with handspikes the mortar is by these traversed to the right or left.

CHEEKS, in *Ship-building*, are two pieces of timber, fitted on each side of the mast at the top, serving to strengthen the masts there. The uppermost bail or piece of timber in the beak of a ship is called the *cheek*. The knees which fasten the beak head to the ship are called *cheeks*; and the sides of any block, or the sides of a ship's carriage of a gun, are also called *cheeks*.

Cheeks, Cheese.

CHEESE, a sort of food prepared of curdled milk purged from the serum or whey, and afterwards dried for use.

Cheese differs in quality according as it is made from new or skimmed milk, from the curd which separates spontaneously upon standing, or that which is more speedily produced by the addition of runnet. Cream also affords a kind of cheese, but quite fat and butyraceous, and which does not keep long. Analyzed chemically, cheese appears to partake much more of an animal nature than butter. It is insoluble in every liquid except spirit of nitre, and caustic alkaline ley. Shaved thin, and properly treated with hot water, it forms a very strong cement if mixed with quicklime *. When prepared with hot water, it is recommended in the Swedish Memoirs to be used by anglers as a bait; it may be made into any form, is not softened by the cold water, and the fishes are fond of it.—As a food, physicians condemn the too free use of cheese. When new, it is extremely difficult of digestion: when old, it becomes acrid and hot; and, from Dr Percival's experiments, is evidently of a septic nature. It is a common opinion that old cheese digests every thing, yet is left undigested itself; but this is without any solid foundation. Cheese made from the milk of sheep digests sooner than that from the milk of cows, but is less nourishing; that from the milk of goats digests sooner than either, but is also the least nourishing. In general, it is a kind of food fit only for the laborious, or those whose organs of digestion are strong.

* See *Cement*.

Every country has places noted for this commodity: thus Cheshire and Gloucester cheese are famous in England; and the Parmesan cheese is in no less repute abroad, especially in France. This sort of cheese is entirely made of sweet cow-milk: but at Rochefort in Languedoc, they make it of ewes milk; and in other places it is usual to add goat or ewes milk in a certain proportion to that of the cow. There is likewise a kind of medicated cheese made by intimately mixing the expressed juice of certain herbs, as sage, baum, mint, &c. with the curd, before it is fashioned into a cheese.—The Laplanders make a sort of cheese of the milk of their rein deer; which is not only of great service to them as food, but on many other occasions. It is a very common thing in these climates to have a limb numbed and frozen with the cold: their remedy for this is the heating an iron red hot, and thrusting it through the middle of one of these cheeses; they catch what drops out, and with this anoint the limb, which soon recovers. They are subject also to coughs and diseases of the lungs, and these they cure by the same sort of medicine: they boil a large quantity of the cheese in the fresh deer's milk, and drink the decoction in large draughts warm several times a-day. They make a less strong decoction of the same kind also, which they use as their common drink, for three or four days together, at several times of the year. For an account of the different processes for making cheese, see CHEESE, AGRICULTURE *Index*.

CHEESE *Rennet*. See GALIUM and RUNNET.

CHEGOE, or NIGUA, the Indian name of an insect common in Mexico, and also found in other hot countries, where it is called *pique*, is an exceeding small animal, not very unlike a flea, and is bred in the dust. It fixes upon the feet, and breaking insensibly the cuticle, it nestles betwixt that and the true skin, which also, unless it is immediately taken out, it breaks, and pierces at last to the flesh, multiplying with a rapidity almost incredible. It is seldom discovered until it pierces the true skin, when it causes an intolerable itching. These insects, with their astonishing multiplication, would soon depopulate those countries, were it less easy to avoid them, or were the inhabitants less dexterous in getting them out before they begin to spread. On the other hand, nature, in order to lessen the evil, has not only denied them wings, but even that conformation of the legs and those strong muscles which are given to the flea for leaping. The poor, however, who are in some measure doomed to live in the dust, and to an habitual neglect of their persons, suffer these insects sometimes to multiply so far as to make large holes in their flesh, and even to ocasion dangerous wounds.

CHEIRANTHUS, STOCK-GILLIFLOWER, or *Wall-flower*. See BOTANY *Index*.

CHEKAO, in *Natural History*, the name of an earth found in many parts of the East Indies, and sometimes used by the Chinese in their porcelain manufactures. It is a hard and stony earth; and the manner of using it is this: they first calcine it in an open furnace, and then beat it to a fine powder. This powder they mix with large quantities of water: then stirring the whole together, they let the coarser part subside; and pouring off the rest, yet thick as cream, they leave it to settle, and use the matter which is found at the bottom in form of a soft paste, and will retain that humidity a long time. This supplies the place of the earth called *hoache*, in the making of that elegant sort of china-ware which is all white, and has flowers which seem formed by a mere vapour within its surface. The manner of their using it is this: they first make the vessel of the common matter of the manufacture; when this is almost dry, they paint upon it the flowers, or whatever other figures they please, with a pencil dipt in this preparation of the chekao; when this is thoroughly dry, they cover the whole vessel with the varnish in the common way, and bake it as usual. The consequence is, that the whole is white: but the body of the vessel, the figures, and the varnish, being three different substances, each has its own particular white; and the flowers being painted in the finest white of all, are distinctly seen through the varnish upon the vessel, and seem as if traced by a vapour only. The hoache does this as well as the chekao; and has besides this the quality of serving for making the porcelain ware either alone, or in the place of kaolin: the chekao has not this property, nor any other substance besides this hoache, which appears to be the same with our steatites or soap-rock.

CHEKE, SIR JOHN, a celebrated statesman, grammarian, and divine, of an ancient family in the isle of Wight, was born at Cambridge in the year 1514, and educated at St John's college in that university; where, after taking his degrees in arts, he was first chosen Greek lecturer, and in 1540 professor of that language, with a stipend of 40l. a-year. In this station he was principally instrumental in reforming the pronunciation of the Greek language, which, having been much neglected, was imperfectly understood. About the year 1543 he was incorporated master of arts at Oxford, where, we are told, he had studied for some time. In the following year he was sent to the court of King Henry VIII. and appointed tutor for the Latin language, jointly with Sir Anthony Cooke, to Prince Edward, about which time he was made canon of the college newly founded at Oxford; wherefore he must have now been in orders. On the accession of his royal pupil to the crown, Mr Cheke was first rewarded with a pension of 100 merks, and afterwards obtained several considerable grants from the crown. In 1550 he was made chief gentleman of the privy-chamber, and was knighted the following year; in 1552, chamberlain of the exchequer for life; in 1553, clerk of the council; and soon after secretary of state and privy-counsellor. But these honours were of short duration. Having concurred in the measures of the duke of Northumberland for settling the crown on the unfortunate Jane Grey, and acted as her secretary during the nine days of her reign, on the accesion of Queen Mary, Sir John Cheke was sent to the Tower, and stript of the greatest part of his possessions. In September 1554 he obtained his liberty, and a license from her majesty to travel abroad. He went first to Basil, thence to Italy, and afterwards returned to Strasburg, where he was reduced to the necessity of reading Greek lectures for subsistence. In 1556 he set out in an evil hour to meet his wife at Brussels: but, before he reached that city, he was seized by order of King Philip II. hoodwinked, and thrown into a waggon; and thus ignominiously conducted to a ship, which brought him to the Tower of London. He soon found that religion was the cause of his imprisonment; for he was immediately visited by two Romish priests, who piously endeavoured to convert him, but without success. However, he was at last visited by Fleckenham; who told him from the queen, that he must either comply or burn. This powerful argument had the desired effect; and Sir John Cheke accordingly complied in form, and his lands, upon certain conditions, were restored; but his remorse soon put an end to his life. He died in September 1557, at the house of his friend Mr Peter Osborne in Wood-street, London, and was buried in St Alban's church. He left three sons, the eldest of whom, Henry, was knighted by Queen Elizabeth. He wrote, 1. A Latin translation of two of St Chrysostom's homilies. Lond. 1543, 4to. 2. The Hurt of Sedition. Lond. 1549, 1576, 1641. 3. Latin translation of the English Communion Service. Printed among Bucer's opuscula. 4. *De pronunciatione Græcæ*. Basil, 1555, 8vo. 5. Several letters published in his life by Strype; and a great number of other books.

CHE-KYANG, or TCHE-KIANG, a maritime province of China, and one of the most considerable in the empire; is bounded on the south by Fo-kien: on the north and west by Kiang-nan and Kiang-si; and on the east by the sea. The air is pure and healthful, and the soil fertile, being watered by a number of rivers and canals, as well as springs and lakes. The chief produce is silk; a vast quantity of which is cultivated

tivated here, and for which the whole country is covered with mulberry trees. These are purposely checked in their growth by the natives, experience having taught them, that the leaves of the smallest trees produce the best silk. The stuffs made in this province, which are embroidered with gold and silver, are reckoned the best in the empire; and notwithstanding a vast exportation to the Japan and Philippine islands, as well as to every part of China, and to Europe, such an abundance is left in the province, that a complete suit of silk may be bought here as cheap as one of the coarsest woollen in France.

This province is also remarkable for a particular species of mushrooms, which are exported to every part of the empire. They are pickled, and then dried; when they will keep good for a whole year. When used they must be soaked in water, which renders them as fresh as at first. Here also the tallow tree is met with; and the province affords excellent hams, and those small gold fishes with which the ponds are usually stocked.

Che-kyang contains 11 cities of the first class, 72 of the third, and 18 fortresses, which, in Europe, would be accounted large cities. The principal of these are, 1. Hang-tcheou-fou, the metropolis, accounted by the Chinese to be the paradise of the earth. It is four leagues in circumference, exclusive of the suburbs; and the number of its inhabitants is computed at more than a million, and 10,000 workmen are supposed to be employed within its walls in manufacturing of silk. Its principal beauty is a small lake, close to the walls on the western side, the water of which is pure and limpid, and the banks almost everywhere covered with flowers. Its banks are likewise adorned with halls and open galleries supported by pillars, and paved with large flag stones for the convenience of those who are fond of walking; and the lake itself is intersected with causeways cased with cut stone, openings covered with bridges being left in them for the passage of boats. In the middle are two islands with a temple and several pleasure houses, and the emperor has a small palace in the neighbourhood. The city is garrisoned by 3000 Chinese and as many Tartars, and has under its jurisdiction seven cities of the third class. 2. Hou-tcheou-fou is also situated on a lake, and manufactures an incredible quantity of silk, insomuch, that the tribute of a city under its jurisdiction, amounts to more than 500,000 ounces of silver. 3. Ning-po-fou, by Europeans called Liampo, is an excellent port, opposite to Japan. Eighteen or twenty leagues from it is an island called Tcheou-can, where the English first landed on their arrival at China. 4. Ning-po is remarkable for the silk manufactured there, which is much esteemed in foreign countries, especially Japan, where it is exchanged for gold, silver, and copper. 5. Chao-hing-fou, situated in an extensive and fertile plain, is remarkable for a tomb about half a league distant, which is said to be that of *Yu*. The people of this province are said to be the most versed in chicanery of any in China. 6. Tchu-tcheou-fou, remarkable for having in its neighbourhood pines of an extraordinary size, capable of containing 40 men in their trunks. The inhabitants are ingenious, polite, and courteous to strangers, but very superstitious.

CHELIDONIAS, according to Pliny, an anniversary wind, blowing at the appearance of the swallows; otherwise the Favonius, or Zephyrus.

CHELIDONIUM, CELANDINE, and HORNED or PRICKLY POPPY. See BOTANY *Index*.

CHELIDONIUS LAPIS, in *Natural History*, a stone said by the ancients to be found in the stomachs of young swallows, and greatly esteemed for its virtues in the falling sickness.

CHELM, a town of Poland, capital of a palatinate of the same name. It is situated in the province of Red Russia. E. Long. 23. 30. N. Lat. 51. 25.

CHELMSFORD, the county town of Essex, situated on the river Chelmer, in E. Long. 0. 30. N. Lat. 51. 40. It sends two members to parliament.

CHELONE. See BOTANY *Index*.

CHELSEA, a fine village situated on the northern bank of the river Thames, a mile westward of Westminster, remarkable for a magnificent hospital of invalids and old decrepid soldiers; and a pleasure house, called Ranelagh, to which a great deal of fine company resort in summer; and a noble botanic garden belonging to the company of apothecaries. The royal hospital of invalids was begun by Charles II. carried on by James II. and finished by King William. Its consists of a vast range of buildings, that form three large squares, in which there is an uncommon air of neatness and elegance observed. It is under the direction of commissioners, who consist generally of the officers of state and of war. There is a governor with 500l. salary, a lieutenant-governor with 400l. and a major with 250l. besides inferior officers, serjeants, corporals, and drums, with above 400 men, who all do garrison duty: and there are above 10,000 out-pensioners, who receive an annuity of 7l. 12s. 6d. each; all which expence is defrayed by a poundage deducted from the army, deficiencies being made good by parliament. The botanic garden is very extensive, enriched with a vast variety of domestic and exotic plants, the original stock of which was given to the apothecaries of London by Sir Hans Sloane.—At Ranelagh garden and amphitheatre, the entertainment is a fine band of music, with an organ and some of the best voices; and the regale is tea and coffee.

CHELTENHAM, or CHILTENHAM, a market town of Gloucestershire, seven miles north-east of Gloucester. W. Long. 2. 10. N. Lat. 51. 50. It is chiefly remarkable for its mineral waters, of the same kind with those of Scarborough. See SCARBOROUGH.

CHEMISE, in *Fortification*, the wall with which a bastion, or any other bulwark of earth, is lined for its greater support and strength: or it is the solidity of wall from the talus to the stone row.

Fire CHEMISE, a piece of linen cloth, steeped in a composition of oil of petrol, camphor, and other combustible matters, used at sea to set fire to an enemy's vessel.

CHEMISTRY.

INTRODUCTION.

1 Definition. CHEMISTRY is defined, by Dr Black, to be "the study of the effects produced by heat and by mixture, in all bodies, or mixtures of bodies, natural or artificial, with a view to the improvement of the arts, and the knowledge of nature;" or, according to the definition proposed by the learned editor of his lectures, "chemistry is the study of the effects of heat and mixture, with the view of discovering their general and subordinate laws, and of improving the useful arts."

Fourcroy has defined "chemistry to be that science which teaches the knowledge of the intimate and reciprocal action of all the bodies in nature on one another." To this definition it has been objected that it requires much explanation, that the terms reciprocal and intimate action not being readily understood, would need new definitions to explain them, and that it embraces more than what strictly belongs to the science of chemistry.

Perhaps no definition of chemistry has yet been given which is of sufficient logical precision to be entirely free from objection. The object of chemistry, however, as distinguished from other departments of science, admits of no ambiguity. It is the province of natural history to arrange and distribute natural bodies into classes and orders, and to give an accurate character of each, by means of which the objects which it includes may be readily recognized and distinguished. Mechanical science is employed about those agencies of bodies which have no reference to their composition, and the force and measure of which are subject to calculation. But it is the object of chemistry to discover the component parts of bodies, to examine the properties and uses of the combinations formed, either naturally or artificially, from these simple elements, and to observe and trace the laws by which the formation of these combinations is regulated.

Sect. I. *Division of Natural Knowledge.*

2 Variety of objects immense. When we consider the boundless variety of objects which present themselves to the eye, it must appear, at first sight, impossible to acquire even a general knowledge of their qualities and properties. The longest life, with the most vigorous mind and the most indefatigable industry, would be greatly inadequate to the task of examining every individual object. It is a law of the human mind, by which it spontaneously facilitates its own intellectual acquirements, to arrange the objects of its investigation into certain classes, the individuals of which are found to possess certain general properties. These are again subdivided into other classes with additional discriminative marks; and these last are still farther subdivided, till we arrive at the individual; and, if the arrangement be correct, this must possess all the characteristic marks of reference to the general and subordinate divisions of that class of objects to which it belongs. This proves conducive to the communication as well as to the acquirement of knowledge. Thus it is the province of natural history to arrange the objects which come under our observation, and to describe them with such precision and accuracy that they may be easily distinguished from each other. It may be considered as a descriptive view of the material world. 3 Natural history.

But the operations of nature are subjected to important movements. Change succeeds change, new combinations are formed, and new productions make their appearance. The primary planets revolve round the sun as their centre; the secondary planets, or moons, attracted by the primary, perform similar revolutions; the air of the atmosphere presses on the surface of the earth with a certain force; a stone, when unsupported, falls to the earth in a course directed towards its centre; water deprived of a certain portain of heat becomes solid, and assumes the form of ice; when combined with a greater portion of heat than what is necessary to retain it in the fluid state, it assumes the form of vapour, ascends into the atmosphere, is there by certain processes robbed of its heat, and re appears in the form of rain; or, when a large portion is abstracted, takes that of snow or hail, and falls to the earth. When a seed is put into the ground; if heat, air, and moisture be applied, it germinates and springs up; and if, with the addition of light, the operation of the same agents be continued, it becomes a new plant, puts forth leaves and flowers, and produces seeds similar to that from which it sprung. 4 Natural philosophy.

Now, to determine what are these changes, to observe the laws by which they are effected, and to ascertain the measure and quantity of the effect produced, belong to that department of knowledge which is included under the general term *natural philosophy* or *physics*. But of these changes or motions, some are obvious and palpable; others entirely elude our senses. We see a stone descend to the earth; and experience informs us, that it falls with a force in a certain proportion to its weight and the height from which it fell. The peculiar change or motion which takes place when water assumes the solid form, when a fluid undergoes the process of fermentation, or when a combustible body is burned, is altogether imperceptible. These motions are too minute to be recognized. The effect is produced before we can discover the change. 5 Physics.

Thus natural philosophy divides itself into two great branches. The objects of the *first* are the sensible changes or motions which are observed in the material world; and the consideration of these objects is, properly speaking, natural philosophy or physics. The *second* great branch, which is employed in discovering the laws, and appreciating the effects, of the insensible motions of bodies, constitutes the science of chemistry. 6 Chemistry.

Sect. II. *Of the Objects and Importance of Chemistry.*

The importance and extensive utility of this science must appear obvious to those who have at all considered ed the subject. But for the sake of others who are yet unacquainted with it, we shall take a general view of the objects which it embraces, and the advantages to be derived from the study of chemistry, whether in explaining many of the striking operations of nature, or in improving the arts of life.

7 [...]l in [...]ining [...]al [...]one-

The most wonderful effects, after frequent repetition, become familiar, and cease to produce any emotion in the mind. It is on this account that many of the most striking appearances of nature pass unheeded as trifling occurrences, and are unnoticed by common observers. Had we been always accustomed to the rigour of winter, and never known the genial warmth of spring, or the ripening heat of summer, the striking changes effected by the return of these seasons could not have failed to fill us with admiration. The beneficial effects of these changes are felt in the inanimate as well as in the animated creation. The same power which gives origin to a gay profusion of numberless vegetable species, restores to a new existence myriads of animals, whose vital functions had been suspended. The air, the earth, the waters, now swarm with life.

The principal agent in the production of these changes is heat; an agent, the most powerful and irresistible in its operations, unlimited in its effects, and extensive in its importance and utility. This agent, therefore, acting so powerfully in chemical operations, becomes an essential object of chemical science. Closely connected with heat is light, which is also a powerful agent in many of the processes of nature, and becomes a subject of chemical investigation, not less curious and interesting. Such, indeed, is the universal importance of light and heat in all the processes of nature, that no change takes place, no new combination is formed, or new product makes its appearance, in which the one or the other, or both, are not either evolved or absorbed.

In acquiring a knowledge of the constitution of the atmosphere, in investigating the changes to which it is subject, the variations of temperature, the laws of winds, dew, rain, hail, and snow, chemistry is our principal, our only satisfactory guide. These remarkable changes are chemical operations on a magnificent scale, and can only be explained by chemical laws.

8 [...]nan in [...]study

In surveying the infinite variety of objects from which man must derive the means of his comfort, his happiness, and his luxuries, and even of his existence, chemistry affords him the most important aid. Whether his researches be carried into the mineral, the vegetable, or the animal kingdoms, the cultivation of chemical science becomes essentially requisite for the successful progress of his investigations.

9 [...]erals.

Of the importance of chemistry to the mineralogist, the limited and unsettled state of mineralogy previous to the improvements of modern chemistry, is a convincing proof. The knowledge of chemistry is indispensable in detecting and discriminating the various substances of which the globe which we inhabit is composed, in separating and purifying these substances, and in adapting them to the numerous purposes of life.

10 [...]tables.

Of the knowledge which we possess of the vegetable kingdom, chemistry furnishes a very large share. It is from this science that we derive the means of tracing the progress of vegetation, of illustrating the peculiar functions of plants, and discovering the compounds which are formed from a few simple principles, the nature and properties of these compounds, and their relative proportions, which exhibit an immense variety of new productions, many of them of the utmost importance to man, on account of their nutritious qualities, or indirectly useful to him by affording nourishment to those animals which he employs as food. Hence the advantage of applying chemical knowledge to agriculture, in determining the nature of the soil fit for the reception of plants, their proper food, and the mode of supplying it in the preparation of manures. With these objects in view, chemistry holds out incalculable advantages in the improvement of many departments of agriculture and rural economy, many of which, from the rapid and successful progress of the science, there is room to hope, may be soon obtained.

11 Animals.

Nor is the application of chemical science to the economy of animals less limited in its importance and utility. It not only contributes to the means of decomposing animal matters, and of exhibiting and examining separately the constitutent parts of animal substances; but also serves to explain in some measure many of the essential functions of the living animal body: such are digestion, respiration, secretion, which, so far as matter is concerned, and the changes which it undergoes, are to be considered as true chemical processes, and can only be investigated by chemical principles. But it is here necessary to observe, that the functions of the living vegetable or animal cannot be wholly accounted for from the nature of chemical action, without taking into consideration the operations of the vital principle, which counteract and regulate the operation of other chemical laws, aid and promote the beneficial effects of those that are useful to its health and growth, resist those that are hurtful, and give rise to chemical as well as vital phenomena peculiar to itself.

12 Medicine.

The utility of chemistry in medicine is too obvious to require much illustration. It is now universally considered as one of the essential branches of medical education. So far as the principles of chemistry can be applied in investigating the nature of the functions of the animal body in a state of health, or can be employed in accounting for the irregular action of these powers, whether excessive or deficient, which indicates a deranged state of the functions, and constitutes disease, its relation to medicine must be allowed to be close and intimate. But the medical art comprehends more than a bare knowledge of the structure and functions of the animal body. It also includes an accurate knowledge of the substances employed as remedies, of their nature and properties as simple substances, and their new qualities and effects under new combinations. This knowledge can only be acquired by the study of chemistry, which is indebted to the excitements afforded by medicine for some part of its progress as an art, in the discoveries which were accidentally made by the rude experiments of medical practitioners in the early ages, to ascertain the sensible qualities and salutary effects of the remedies which they employed. Chemistry, by its rapid progress in modern times, has amply repaid these advantages, and in the hands of the intelligent and accurate observer, has, in some points, greatly contributed to give more rational and simple views of medical science.

13 The arts.

In considering the application of chemistry to the improvement

Introduction. improvement of the arts of civilized life, a wide field of contemplation opens to our view. So extensive indeed are its influence and importance, that in most of the arts, many of the processes, in some all that are employed, depend on chemical principles. The bare mention of some of these arts will suggest ample illustration of its extensive utility. In the art of extracting metals from their ores, in purifying and combining them with each other, and in forming instruments and utensils, whether for useful or ornamental purposes, almost all the processes are purely chemical. The essential improvements which modern chemistry has introduced in the manufacture of glass and porcelain, shew its importance and utility in these arts. Nor has it contributed less by the application of its principles to the arts of tanning, soapmaking, dyeing, and bleaching. All the processes in baking, brewing, and distilling, most of the culinary arts, and many others in domestic economy, are chemical operations. In short, wherever, in any of the processes of nature or of art, the addition or the abstraction of heat takes place; wherever substances in combination are to be decomposed or separated; wherever the union of simple substances and the formation of new compounds are wanted, the effects produced can only be explained by chemical principles.

From this general view of the extensive application of chemical science, those who have not considered the objects which it embraces will be enabled to judge of the importance of this study.

14 As a science. But however much we may be interested in observing and admiring the effects produced by chemical action, if we extend our views to the consideration of chemistry purely as a science, and the subject of philosophical investigation, it will command a greater share of our attention and study. Perhaps there is no study better calculated to encourage that generous love of truth which confers dignity and superiority on those who successfully pursue it. In this view, indeed, no science holds out more interesting subjects of research, in the singular and surprising changes which everywhere present themselves. And it is surely no small recommendation to the study of chemistry, that its speculations are not barren, and that while we store the mind with interesting truths, we add something to the stock of human knowledge, which is perhaps immediately applicable to some of the most important purposes of life. The practical value of the facts and discoveries in any science might be fairly estimated by the proportion in which they enlarge our resources by their useful application, and interest and gratify the mind as subjects of curious speculation. From these joint considerations the whole range of chemical facts derives the highest value, and becomes entitled to a distinguished place among the sciences.

Chemistry has a still higher claim to our attention, as it affords some of the most striking proofs of the wisdom and beneficence of the Creator of the universe. A machine constructed by human art is admired in proportion to the simplicity of its contrivance, the extent of its usefulness, and the niceness of its adaptations. But the works of man sink into nothing when brought into comparison with the works of nature. In our examination of the former, every step of our progress is obscured with comparative clumsiness and defect: in contemplating the latter, we behold perfection rise on perfection, and more exquisite wonders meet our view. It is the merit of chemistry that by its aid we are enabled to take a minuter survey of the great system of the universe. And so far as our limited powers can comprehend it, the whole is nicely balanced and adjusted, and all its changes tend to the most beneficial purposes. Circumstances which, on a superficial view, were seeming imperfections and defects, a closer inspection points out to be real excellencies. In all the changes which are constantly going forward, the more closely we observe and examine them, the more we shall admire the simple means by which they are accomplished, and the intelligent design and perfect wisdom displayed in the beneficial ends to which they are directed.

Introduction. 15 In contemplati[on of] the wor[ks] of natur[e].

SECT. III. *History of Chemistry.*

The word Chemistry, which is supposed to have been of Egyptian origin, seems to have been first used in a very extensive sense (A). It appears to have included all the knowledge which the ancients possessed of natural objects. It was afterwards more limited in its signification, and solely confined to the art of working metals. The great importance which the ancients attached to this art was probably the cause of this limitation. Such indeed was its importance, that those who were supposed to have discovered or improved it, were regarded by mankind as their greatest benefactors. They were deemed worthy of being enrolled among the gods, and temples and statues were consecrated to their honour.

It is not necessary to trace minutely the history of chemistry to the remote periods of antiquity, or labour to prove its origin to be coeval with the earliest ages of the world. Man indeed could not exist long without some knowledge of chemical processes; and as he improved in civilization and accurate observation, this knowledge must have been improved and extended. Tubal-Cain, who is mentioned in the sacred Scriptures as a worker in metals, and is supposed to have given rise to the fabulous story of Vulcan, in ancient mythology and poetry, is considered by some as the first chemist whose name has been transmitted to the present times. But, although the working of metals, and other chemical arts, were known in the earliest ages of the 16 Chemistr[y] existed a[s] an art.

(A) According to some it is derived from the word *kema*, which was supposed to be a book of secrets given to the women by the demons. Others derive it from *Cham* the son of Noah, from whom Egypt took the name of *Chemie*, or *Chamie*. Sometimes the origin of the word is ascribed to *Chemmis*, a king of the Egyptians; and sometimes to the Greek word χυμος, which signifies *liquid*, because the art was at first applied in the preparation of liquids; and sometimes to the Greek verb χυω "pour out," because chemistry is the art of fusing metals.

Introduction. the world; and among the Egyptians, Greeks, and Romans, many of the arts dependent on chemistry had reached some degree of perfection; this knowledge can only be considered as consisting of a number of scattered, unconnected facts, which have no claim to be dignified with the name of science. A carpenter may erect a piece of machinery, arranged and constructed exactly similar to a pattern which he has seen, without the knowledge of a single principle of its construction; while the man of science, who can neither handle the axe nor the chissel, observes and estimates the power and operation of all its parts, and determines the general effect of the whole.

Nor will it afford us much instruction to pursue the supposed history of chemistry, even to a comparatively later period. Moses, who is said to have been skilled in all the wisdom of the Egyptians, has been ranked among the number of the earliest chemists, and as a proof of his knowledge of chemistry, the means he employed of dissolving the golden calf made by the Israelites, to render it potable, are adduced. It is said that Democritus was, of all the Greeks who travelled into Egypt to

17 Among the Egyptians, acquire knowledge, the only one admitted into their mysteries. According to Diodorus Siculus, the art of chemistry had made considerable progress among the Egyptians. The knowledge of their priests is supposed to have consisted chiefly of chemical processes. They were acquainted, it is said, with the preparation of many medicines, perfumes, plasters, and soaps: they used burnt ashes as caustic substances; they fabricated bricks, glass, porcelain; they painted on glass, and practised the art of gilding with silver and gold. They extracted natron or soda from the mud of the Nile. They prepared alum, sea salt, and sal ammoniac; worked in gold and copper, and possessed many other processes in metallurgy. The extraction of oils, and the preparation of wine and vinegar, were well known to them; and they were also acquainted with the art of dyeing silk by the intermedium of mordants.

18 Greeks, Fewer traces of chemistry are found among the Greeks, although they derived the knowledge of many of the arts from Egypt. The ancient philosophers of Greece, as Pythagoras, Thales, and Plato, were more devoted to the cultivation of mathematical and astronomical knowledge, than the physical sciences. Some chemical arts, however, were not unknown to this people. The alloy of metals formed at Corinth has been much celebrated. Cinnabar was employed in some parts of Greece. Tychius knew the art of tanning leather; Plato has described the process of filtration; Hippocrates was acquainted with that of calcination; Galen speaks of distillation *per descensum*, and the word *embic* as the name of a piece of apparatus, is mentioned by Dioscorides a long time before the Arabic article *al* was prefixed to it. According to Athenæus, there was a manufactory of glass established at Lesbos. Democritus of Abdera prepared and examined the juices of plants: Aristotle and Theophrastus treated of stones and of metals.

19 Phœnicians. The Phœnicians are said to have been acquainted with the making of glass; and among this people the celebrated Tyrian purple was found. They were also skilled in the working of metals and other mineral substances. The Persians are said to be the first who distinguished the metals by the names of the planets, a practice which they retained for many centuries. Introduction.

Among the Chinese, if we may believe their historians, many chemical arts were known from the earliest ages: they were acquainted with nitre, borax, alum, gunpowder, verdigris, mercurial ointments, sulphur, and colouring matters; nor were the arts of dyeing linen and silk, paper-making, manufacturing of pottery and porcelain, unknown to them. They were skilled in the art of alloying metals, and in the working of ivory and of horn. From the early knowledge which the Chinese possessed of these arts, they have been supposed by some to have been a colony from Egypt. 20 Chinese,

The wars in which the Romans were almost constantly engaged, and the spirit which prompted them to military affairs, gave them neither time nor taste to cultivate and improve the arts of peace. Chemistry, therefore, appears to have been little known among that people. Petronius indeed speaks of malleable glass, which was presented to Cæsar; and a similar fact is mentioned by Pliny with regard to Tiberius. But it appears, that this art was long known before the time of the Romans. 21 Romans.

To us it may seem singular, that chemistry, now of such universal importance to mankind, should be indebted, in some measure, for its origin as an art, and for part of its progress, to one of the least generous of the human passions. It was cultivated in its early dawn, by men who were instigated by avarice to prosecute and study it. About the 10th century, or perhaps earlier, a set of men arose, and continued to flourish till the 16th, who assumed, by way of distinction, the name of *alchemists*, that is *the chemists*, because they considered themselves, on account of the knowledge they possessed, as more highly favoured than the rest of mankind. It was natural enough for men who observed the remarkable changes produced by chemical action, to be powerfully struck with these effects; and overlooking the variations and differences in the result of their operations, which were the consequences of partial or inaccurate observation, to flatter themselves, that their power over the substances on which they operated was as extensive as their wishes. Hence originated all the extravagances and follies, similar indeed to those of speculators and projectors of every age, with which the history and works of the alchemistical writers are filled. Many of the alchemists were the dupes of their own ignorance and credulity; but many more, there is little doubt, took advantage of the ignorance and barbarity which prevailed in the dark ages, during which period they chiefly flourished, to impose on the credulity of mankind. 22 The alchemists.

It was one of the first principles among the alchemists, that all metals consist of the same ingredients, and, that hence the substances which enter into the composition of gold, are found in all metals, but mixed with many impurities, from which they might, by certain processes, be freed. The constant object of all their researches, was the discovery of a substance possessed of the wonderful property of converting the baser metals into gold, which, on account of its scarcity and durability, is more valued than the other more common metals. This celebrated substance was denominated

Introduction. minated the *philosophers stone;* and those who were supposed to be so singularly fortunate as to accomplish this great discovery, or those to whom it was imparted

23 Philosophers stone. by others, were regarded as the peculiar favourites of heaven. They were ranked in the highest order of alchemists, and assumed the name of *adepts*.

These adepts never seemed to think of enriching themselves by their great discoveries. They were too generous to monopolize the wealth of the world. They accordingly offered their services to others, and liberally proposed to communicate the fruit of their labours for a moderate reward. The ambitious man to procure riches, that he might increase his power, and the avaricious man to add to his wealth, eagerly sought after, and encouraged them in the prosecution of their extravagant schemes. They were kept in the pay of princes and other great men, to fill and repair their exhausted treasuries. These flattering hopes, it may well be supposed, were never realized. The rich prospect fled before them, and the golden prize, which they often supposed was just within their reach, eluded their eager grasp. The magnitude of the plan, however, fired the imagination, and produced a sort of conviction in the mind, of the possibility, and even certainty, of obtaining the object of all their wishes and labours. With unabating ardour, and unexampled assiduity, they pursued their researches, persuading themselves and their employers, that they were on the point of being soon in possession of unlimited wealth.

Beholding man by anticipation possessed of immense riches, the alchemists saw that something more was requisite to secure him in the uninterrupted enjoyment of them. Experience fatally taught them, that his feeble frame was liable to the pains and languor of disease; that gold and silver could neither prevent the paroxysm of a fever, nor confer on the possessor the blessings of constant health. Another most desirable object was consequently held up to view, and deluded

24 Universal medicine. their distempered minds into the false hope of attaining it. This was the famous *panacea*, or universal medicine, which was to cure all diseases; and even to prevent their occurrence. Thus fortunate in the enjoyment of vast riches; thus blessed with unbroken health, the desires of man were yet unsatisfied. Another seeming evil still remained, which was naturally to be dreaded as the destroyer of this fancied scene of apparently perfect felicity. The melancholy reflection, that it was limited by the short span of human life, roused the alchemists again into exertion, and produced new efforts of ingenuity in their labours, to secure to man exemption from the common lot of mortality. In imagination they had discovered the means of prolonging life at pleasure to an indefinite length, of rescuing man from the grave, and of making him immortal upon earth.

Such were the extraordinary pursuits of the alchemists. The exact period of the origin of this study is unknown; nor can it now be ascertained what progress it had made, or indeed whether it was at all cultivated among those whom we strictly call the ancients. Julius Firmicus Maternus is the first historian who mentions this study as well known in his day; and the period when he flourished was about the beginning of the 4th century. A subsequent author, Æneas Blasius, who lived in the following century, also makes mention of it: and Suidas defines the term by informing us, that it is the art of making gold and silver. Dioclesian, he says, prohibited all chemical operations, during his persecution of the Christians, that his subjects might not be instigated to acts of rebellion against him by the formation of gold. In some places where gold is washed down in minute particles, by brooks and rivulets, from the mountains, it is customary to suspend the skins of animals in the water, by which means the particles containing the gold are detained; a circumstance from which the fabulous story of the golden fleece probably derived its origin. Suidas, however, who flourished in the 10th century, is not entitled to any high degree of credit, especially as the ancient authors are wholly silent on the subject of alchemy.

It is from the physicians of Arabia that we obtain the most satisfactory evidence concerning alchemy. Avicenna, who lived in the 10th century, is said, by one of his own disciples, to have written on this subject. He likewise takes notice of rose water, and some other chemical preparations; and in the 12th century we find it recommended to physicians to cultivate an acquaintance with the chemists. Another Arabian writer says, that the method of preparing rose-water, &c. was at that time well understood. These proofs of the existence of alchemy among the Arabians, and particularly from the particle *Al* prefixed to it, have induced some to conclude, that the doctrine of the transmutation of metals first originated with the Arabians, and was introduced into Europe by the crusades, as well as by the rapid conquests of the Arabians, in Europe, Asia, and Africa. At that period Europe was in a state of the utmost barbarity, owing to the incursions of the northern nations; but some of the sciences, among which alchemy was comprehended, were happily revived by the Arabians: and about the middle of the 17th century, the extravagance of such as were the professors of alchemy arrived at its greatest height.

It appears that the alchemists began to be established in the west of Europe, as early as the ninth century; and between the eleventh and fifteenth, this study was in its most flourishing state. Among the principal alchemists who flourished during this period, and who were distinguished for their discoveries and writings, were Albertus Magnus, Roger Bacon, Arnoldus de Villanova, and Raymond Lully. They all lived in the 13th century. Albertus Magnus was a Dominican monk of Cologne, and was regarded by his cotemporaries, as a magician. He was born in the year 1205, and died in 1280. He left numerous works, one of the most curious of which is a treatise entitled *De Alchemia*, which exhibits a distinct view of the state of chemistry at the time he lived. Roger Bacon, another monk, was born in the county of Somerset in England in 1214, and died in 1294. He was celebrated for many ingenious inventions and discoveries in chemistry and mechanics. Among these are mentioned the *camera obscura*, the *telescope*, and gunpowder. His works discover astonishing sagacity and acuteness, and, considering the age in which he lived, are composed with no small degree of elegance and conciseness. Some of them, however, bearing the character of the times, are mystical and obscure. Arnoldus

25 Principal alchemists. (margin note beside "It appears that the alchemists began to be established")

Introduction.

noldus de Villanova was a native of Languedoc in France, and was born about the year 1240. He has mentioned the mineral acids, and joined to his chemical studies extensive knowledge in medicine. His writings are characterised by all the obscurity of the alchemistical authors. Raymond Lully, whose reputation raised him to the rank of *adept*, was born at Barcelona in 1235. He wrote on strong waters and metals. His last will and testament is one of the most celebrated of his writings; and these are not less obscure than those of his cotemporaries.

About the end of the 14th century, Basil Valentine, a German Benedictine monk, was the first who formally applied chemistry to medicine. He was the original discoverer of many of the virtues of antimonial medicines; and in his celebrated treatise on antimony, entitled *Currus triumphalis Antimonii*, are found many preparations which have since been announced to the world as new discoveries. About the same time lived Isaacus Hollandus, whose works have been greatly commended by Boerhaave.

26 Paracelsus.

In the beginning of the 16th century arose Paracelsus, one of the most extraordinary men who ever lived. He was born in 1493, near Zurich in Switzerland. Of a bold and enterprising spirit, he despised the common rules of conduct by which men are usually guided. By his singularities he raised his reputation to a great height; he became an enthusiast in chemistry, and in the application of substances prepared by chemical processes to the cure of diseases. He was the first public teacher of chemistry in Europe, having been appointed to deliver lectures on that subject in the city of Basil: but his restless spirit did not permit him to remain long in this situation. In two years he was involved in a quarrel with the magistrates, from whom he had received his appointment, and left the city. Despising the common principles of medical practice, and succeeding wonderfully in some cures by the free use of opium and mercury, he thought he had discovered the universal medicine, and promised immortality to himself and to his patients. But while he thus made such flattering promises, his own fate furnished a sad proof of the futility of his doctrine. After an almost uninterrupted course of debauchery, having wandered a great part of his life from place to place, he died at an inn in Saltzburg, in the 48th year of his age.

27 The first public teacher of chemistry.

A great number of medical practitioners, in the course of the 16th century, adopted and propagated the principles of Paracelsus. Among the most distinguished of these was Van Helmont, a man of considerable genius, who was born in the year 1577. Many of the followers of Paracelsus were greatly devoted to the study of chemistry; and this, with the absurd and unprincipled conduct of their master, tended not a little to bring the views and speculations of the alchemists into disrepute. Chemistry, now freed from the trammels of alchemy, consisted only of a number of detached, unconnected facts. To have these facts brought together in one point of view, and arranged into classes, so that the knowledge of them might be applied to useful purposes, and the objects pointed out to which future researches might be advantageously directed, was now the great desideratum. This task was accomplished by Beccher, who distinguished himself by the extent of his views, in a work entitled *Physica subterranea*, which was published at Frankfort in the year 1669. This was the first dawn of true chemical science, and in the history of which the publication of Beccher's work formed an important æra.

28 Alchemy declines.

29 Chemistry assumes the form of a science.

30 Discoveries of the alchemists.

In taking a retrospective view of the progress of chemistry, previous to the publication of Beccher's work, we find that a great number of important facts had been discovered and collected. To the class of acids, the sulphuric, the nitric, and the muriatic, were added; the alkalies were better known, and the volatile alkali was obtained from sal ammoniac by Basil Valentine, by decomposing it by means of soda or potass; the sulphate of potass, prepared in three or four different ways, received as many different names; the nitrate of potass was called *nitre*, a name which had been formerly applied to soda; Sylvins discovered the muriate of potass which he denominated *digestive salt;* and Glauber, the sulphate of soda, to which he gave the name *wonderful salt*, though better known by the name of Glauber's salt, by which it is still distinguished. Some of the earthy salts began to be known about this period, and among others the muriate of lime, which received the name of *fixed sal ammoniac*.

The earths themselves were also better known; lime water was prepared, and some of the alkaline sulphurets were pointed out and examined.

The properties of some of the metallic salts were studied and examined; the nitrate of silver was known under the name and form of *crystals of Diana*, and of *lapis infernalis;* the muriate of silver, under that of *luna cornea*. The two muriates of mercury were described, and employed for various purposes. The red precipitate, called *arcanum corallinum*, *saccharum-saturni*, or sugar of lead, the butter of antimony, and the powder of algaroth, were either discovered, or their properties more attentively investigated and ascertained.

During this period also, the distinction was made between the brittle and the ductile metals. Bismuth, zinc, antimony, and even arsenic were obtained in a metallic state. A number of oxides, some metallic dyes, fulminating gold, turpith mineral, the saline precipitates of mercury, or the mercurial oxides of different colours, minium and litharge, colcothar, the saffron of Mars, and diaphoretic antimony, were discovered, and the mode of preparing them sufficiently described.

During this period, the preparation of oils by distillation commenced, and the distinction was made between the volatile and empyreumatic. Ethers were discovered, and the spirit of wine was well known by the name alcohol, which it still bears.

31 Their history useful.

The extravagant history of the alchemists is instructive, as affording a useful lesson to moderate our expectations in the pursuit of knowledge, and to restrain them within the bounds which the Almighty has prescribed to the range of our investigations. This history is instructive also, as presenting a singular and extraordinary feature in the history of mankind. To our present purpose it is immediately useful, as showing us the commencement of chemical researches. Chemistry, it is true, in the hands of the alchemists, like every other department of knowledge during the dark ages, was involved in mystery, and the knowledge it communicated in a barbarous jargon, to be understood only by the initiated, and scarcely to be decyphered

Introduction.

and comprehended at the present day, with the assistance of the extensive knowledge of chemical facts which we now possess. But with all the extravagance displayed in the objects they pursued, the means employed were ultimately useful to the progress of chemistry. By their incessant labours, discovery was added to discovery, facts were multiplied on facts, though unaccompanied by any regular train of research or reasoning.

32 Their discoveries comparatively few.

It may appear surprising that these important discoveries were not more numerous. The alchemists had laboured incessantly in chemical pursuits for nearly a thousand years, and with all the zeal and ardour of enthusiasts; the labour of whole lives was exhausted, and immense fortunes were dissipated, in endeavouring to obtain the grand object of all their researches. But the spirit which prevailed among the alchemists was directly hostile to the free communica-

33 The reason.

tion and accumulation of knowledge. The prominent feature of their character was secrecy. This indeed was closely connected with the nature of the object, to attain which all their pursuits and inquiries were directed: and so strongly was this impressed upon their minds, that they believed, or pretended to believe, that the dreadful wrath of Heaven would fall on him who should presume to disclose to any, but to the initiated, the secrets of the art. That spirit which arose from motives of avarice and self-conceit, became at last one of the leading principles of their conduct. With an object so important in view, as the discovery of the means of putting themselves in possession of unlimited wealth, it is little to be wondered at, if they should carefully conceal from the world, and even from one another, the steps in the progress which led to the accomplishment of this end. Thus, all their processes were carried on in private, all their discoveries were kept secret. In their pretended communication of knowledge with each other, they employed conventional signs and figures, and assumed a mysterious mode of writing, that they might be understood only by *adepts*, and might be totally unintelligible to the rest of mankind.

Thus it was scarcely to be expected that they should reveal to the world, either by speech or writing, discoveries which most of them probably believed were to be of such vast benefit to themselves. In this view, we should rather be surprised that any of their processes were ever made known. But here vanity, and even avarice, probably had considerable influence in calling forth what they pretended was an account of their attainments and discoveries. Some of the alchemists, perhaps by means of trick and imposture, had acquired a high reputation for knowledge, and had imposed a belief on many, that they were actually in possession of the philosopher's stone. They were therefore sought after, and often received great rewards for their labour, in proving the effects, or trying the success of this wonderful agent. To be thus employed was perhaps the object of many in the publication of their works. But, at the same time, they cautiously avoided revealing their knowledge, by employing mysterious and metaphorical language. Thus we may account for the impenetrable obscurity, as well as many of the absurdities which characterized their writings.

Introduction.

Considering the cautious concealment with which they carried on all their processes, it is not improbable that many important discoveries were never announced by the first observers; for the very appearance of any thing new or unexpected, would flatter their hopes that they had advanced another step toward the attainment of their objects, and that the next would put them in full possession of it. Thus, such a discovery would be held inviolably secret, and might in this way be lost for ever.

The work of Beccher, which gave the first scientific form to chemical knowledge, appeared about the middle of the seventeenth century, when the light of science began to spread over Europe, and chemistry received its share. The facts which had been accumulated by the labours of the alchemists, and to which Beccher had given a systematic form, were still farther methodised and extended by his pupil Stahl. Indeed, so much was done by the latter, in simplifying and improving the theory of his master, that it was afterwards denominated from his name the *Stahlian* or *phlogistic theory*. This theory was then received and adopted by all chemists, and continued to flourish for more than half a century.

34 Stahl improves the theory of Beccher.

After the middle of the seventeenth century, the establishment of philosophical societies in Europe greatly contributed to the diffusion of knowledge. It was about this time that the academy of sciences was established in France, and some of its members rose high in reputation by their experiments and discoveries in chemistry. The Royal Society of London was founded about the same period; but its members, following the example of Newton, were more occupied in mechanical philosophy, and paid less attention to chemical science. The latter, however, was not entirely overlooked. Newton himself threw out some important hints in this department, and took some general views of chemical phenomena; Boyle, along with his researches in mechanical philosophy, prosecuted the study of chemistry; and the experiments of Hooke and Mayow, on the nature of combustion and respirable air, discover a high degree of sagacity and skill in their investigations.

35 Chemistry studied in

36 Britain.

Towards the middle of the eighteenth century, the study of chemistry became fashionable in France. Before this time Homberg, Geoffroy, and Lemery, had distinguished themselves by their chemical discoveries. Geoffroy is still deservedly celebrated for his invention of the tables of chemical affinities, an ingenious method of exhibiting, at one view, the principal results of experiments in this science. These tables were afterwards improved by several chemists, especially by Rouelle, Wenzel, and Bergman.

37 In France

38 Black's discovery.

But the discoveries of Dr Black formed one of the most important æras in the history of this science, and gave a new and unexpected turn to the views of chemists. It was the object of Dr Black's researches to discover the cause of the remarkable change which a piece of limestone undergoes when it is calcined or burnt, and to point out the reason of the great difference of the properties of this substance in its different states; and his investigations were crowned with success. In the year 1755, he ascertained that these changes were owing to the combination or separation of a peculiar kind of air, different in its properties from the

Introduction.

the air of the atmosphere. Lime, when combined with this air, is in the mild state, or the state of limestone: when this air is driven off, which is done by the process of calcination or burning, the limestone has changed its properties; it is reduced to the caustic state, and has lost considerably of its weight; and this loss of weight, Dr Black proved, was exactly equal to the weight of the air driven off. To this air Dr Black gave the name of *fixed air;* because, when united to the lime and other substances, with which it enters into combination, it is in a fixed state. This discovery, one of the most important in chemistry, opened a new field for investigation: for it had not been once suspected, that aerial substances formed combinations with solid bodies.

From this time, the progress of chemistry became rapid and brilliant. Facts and discoveries were daily multiplied, and a spirit of enthusiasm for the study burst

9 O... im... nt dis... ies.

forth, and was widely diffused. In the year 1774, Dr Priestley, who had contributed largely to the stock of chemical knowledge, discovered pure or vital air, and its property of being exclusively fit for the purposes of respiration and combustion. In the year 1781, Mr Cavendish, another ingenious English chemist, proved that water is not a simple element, but composed of pure or vital air, and inflammable air; called now in chemical language, oxygen and hydrogen.

But, previous to this time, two chemists had appeared in Sweden, had distinguished themselves by their zeal, ingenuity, and indefatigable industry, and had obtained the highest reputation for their invaluable discoveries in chemical science. These were the celebrated Bergman and Scheele, whose names will not be forgotten, as long as modesty, candour, and truth, are honoured among mankind.

In the mean time, the French chemists were not idle. The celebrated Lavoisier, in conjunction with some of his philosophical friends, confirmed, by the most decisive experiments, the truth of Mr Cavendish's discovery of the composition of water, which was now received and adopted by almost every chemist. The same unfortunate philosopher, Lavoisier, whose bright career was cut short by the horrors of the French revolution, had, previous to the time alluded to, enriched chemical science with many valuable and important facts. He had greatly contributed to the overthrow of the phlogistic theory, by a series of accurate experiments and observations on the calcination of metals. It had now become a question, whether metals, during the process of calcination, gave out any substance; that is, whether they contained any phlogiston; and Lavoisier incontestably proved, that metals cannot be calcined, excepting in contact with pure air, and that the calx thus obtained was, in all cases, exactly equal to the weight of the metal, added to the quantity of air which had disappeared.

Chemistry had now, by its rapid and unexampled progress, so far extended itself, and had accumulated so large a body of facts, that the barbarous and arbitrary language which the alchemists employed to veil their mysteries, and part of which had been adopted and imitated in language equally obscure and arbitrary by the earlier chemists, rendered it extremely difficult to be acquired or understood. This disadvantage was loudly and justly complained of, but the difficulties in the way of remedying it seemed almost insurmountable. The French chemists, however, undertook the arduous task, and completely succeeded in their labours. To these illustrious philosophers we are indebted for the present language of chemistry, which is so constructed, that every word, and every combination, has an appropriate meaning, and clearly expresses the nature and composition of the substance which it represents. It is to this improvement in its language, that we are to ascribe the facility and precision with which the knowledge of chemistry can now be communicated, and which has materially contributed to its general diffusion and cultivation.

40 New nomenclature.

The career of chemical science has accordingly been of late years even more rapid than was then anticipated. It has been signalized by the brilliant discoveries of the composition of the alkalies and earths, the doctrine of definite combining quantities, or the atomic theory, by multitudes of elegant improved manipulations, new compound substances, new simple elements, and new practical applications of chemical knowledge. In this place we shall refrain from any formal eulogy on living chemists. The results of their labours will be recorded in the body of this article, with a minuteness proportioned to its general extent, and will form, we hope, an instructive improvement in the present, compared with the former editions of this work. On some subjects we shall refer to the corresponding article contained in the SUPPLEMENT, which is now in course of publication, exhibiting a separate view of the most recent improvements. It has been necessary, however, to alter this article materially, as our latest discoveries not only serve to enlarge our former views, but to correct them.

SECT. IV. *Of the First Principles of Bodies, and of the Methods of studying and arranging them.*

41 Elements of bodies among the ancients.

1. According to the ancient philosophers, all matter consisted of four principles or elements. These were fire, air, water, and earth. This opinion, under different modifications, seems to have universally prevailed. But the discoveries of modern chemistry have proved, that three of these elements, at least, are compound substances. Fire is a compound of light and heat; air, of oxygenous and azotic gas; and water, of oxygen and hydrogen.

42 The alchemists.

The alchemists, not satisfied with this division of the principles of bodies, adopted another, which was more appropriate to the nature of their labours and experiments, and was better calculated to explain the appearances with which they were acquainted. The elements of all bodies, according to their theory, were *salt*, *sulphur*, and *mercury:* and these were long known among the alchemists by the appellation of the *tria prima.* These were admitted by all the alchemistical writers down to the time of Paracelsus, who adopted them, and added two more to the number. These five elements or principles were thus characterized. Every thing came under the name of *salt* which was soluble or sapid; all inflammable substances were called *sulphur;* and every volatile substance, which flies off without burning, was called *mercury* or *spirit.* Every thing liquid and insipid was called *phlegm* or *water:* every thing that was dry, insipid, fixed, and insoluble, was called *earth*, or *caput*

caput mortuum. The two last, which were added by Paracelsus, are synonymous with the water and earth of the ancients. According to the original theory of the alchemists, all bodies may be decomposed by fire, and resolved into their three constituent principles. The mercury, or spirit, escapes during combustion in the form of smoke; the sulphur is inflamed; and the salt, or fixed principle, remains behind.

43 Beccher's elements.

Beccher, whom we have already mentioned as the founder of chemical science, perceiving the vague and unsettled notions of the alchemists, with regard to the principles of bodies, generalized and simplified still more, the chemical facts which were then known. According to his theory, all bodies consisted of earth and water. Under the former he included every thing that was dry, and under the latter, every thing humid. He admitted three earthy principles, namely, the fusible earth, the inflammable earth, and the mercurial earth. The first was the principle of dryness, of infusibility and hardness. The fusible earth, combined with water, composed an acid, which was called the *universal acid*, because all other acids owed their properties to it. The inflammable earth was considered as the principle of combustibility; and the mercurial earth as the principle of volatility. The fusible and the mercurial earths, with water, composed common salt; and the inflammable earth, with the universal acid, formed sulphur. The metals were composed of these three earths in equal proportions. When the mercurial earth was in small proportion, the compound was *stone;* when the fusible was in greater proportion, the compound formed the *precious stones;* and the resulting compounds are the colorific earths, when the inflammable earth is in the largest, and the fusible in the smallest proportion.

44 Stahl's.

This theory of Beccher was considerably modified by his pupil Stahl. The inflammable earth of Beccher seems to have been changed by him into the principle of inflammability or fixed fire, which he called *phlogiston.* He admitted the universal acid, but rejected the mercurial earth. The number of elements in the theory thus modified by Stahl amounted to five. These were, *air*, *water*, *phlogiston*, *earth*, and the *universal acid.*

This mode of considering the elements of bodies, of their first principles, and of admitting such arbitrary and erroneous distinctions, is justly banished from chemical science. All substances are supposed to be simple, which have not been decomposed, without regard to primitive elements or principles, such as are hitherto not ascertained by experiment.

2. To acquire the knowledge of those properties of bodies, investigation of which is properly included under the chemical science, two methods are employed: The one is the method of analysis or decomposition; the other is that of synthesis, or composition. By the one, the different simple substances of which compound bodies consist, are separated, and their properties individually examined; by the other, the simple substances are combined together, and the properties of the new compound are investigated.

45 Analysis.

Different modes of analysis have been admitted and described by chemical writers. Some bodies, when exposed to the action of heat and air, undergo a total separation of their component parts. This is called *spontaneous* analysis. Thus, some minerals, and all vegetable and animal matters, when deprived of life in favourable circumstances, slowly separate into their component parts; and in the same way the principles of which some liquids are composed, re-act on each other, and spontaneously separate, thus giving an opportunity of investigating the nature of these substances.

Analysis by fire operates by the accumulation of caloric in bodies; and by the power which it has of separating their particles to favour their examination. But this instrument of analysis is to be considered only as one of the means which should concur with many others, to throw light on the real composition of bodies. For it will afterwards appear, that the different quantities of caloric accumulated in bodies, have the greatest effects in giving different results, and changing the order of decomposition.

Another mode of analysis is by means of re-agents. This is conducted by placing the compound body which is to be examined, in contact with various substances, which have the power of separating its constituent parts. This is always done by forming a combination with one of the constituents, to the exclusion of others. It is here that the genius and science of the chemist appear most conspicuous; for every substance in nature, and all the products of art, become valuable instruments in his hands, to ascertain the nature, and to examine the properties, of the substances which come under his examination. The different means of analysis which chemists have employed, to arrive at the knowledge of compound bodies, have been deemed of such importance and utility, that chemistry has been called *the science of analysis.*

46 Synthesis.

Synthesis, or composition, is the union of two or more simple substances. This union, from whence a new compound results, has become an important step in prosecuting knowledge of the properties of bodies, and in forming a number of products useful in the arts, and necessary to our wants; and thus it is considered by chemists as in some measure the inverse of the method of analysis, as the perfection of their art, and one of the great instruments of their operations. The method of synthesis or composition, considered as a chemical process to acquire the knowledge of the intimate and reciprocal action of bodies, is in reality more frequently employed than that of analysis; and the name of the science, if we were to regard these two methods, should rather be called the *science of synthesis* than the science of analysis. In all cases of complicated analysis, the operations are synthetic. Compounds of an inferior order are formed, but more numerous than the first compounds which were subjected to analysis or examination.

But besides, there are many bodies which have never yet been decomposed. It is only by composition or synthesis, that is, by combining them with others, and by examining the nature of the compounds which are formed by this combination, that the chemical properties of these can be investigated.

However various the operations of chemistry may be; however numerous and different from each other the results obtained; they may all be referred to analysis or synthesis, and be regarded either as combinations or decompositions.

3. It must be universally allowed, that it is of vast importance,

Introduction.

importance, in acquiring or communicating knowledge, to have a clear view of the objects of our studies; and this becomes the more necessary, in proportion as the facts in any science are accumulated, and the objects which it comprehends become more numerous. In many of the arrangements of chemical knowledge which have been proposed to the world, the objects of this science have been classed together according to certain resemblances in one or two points, while they are totally distinct in all others. But an arrangement which is founded on the properties and characters of substances which have not been fully ascertained and generally admitted, must tend to obstruct, rather than facilitate the acquisition of science. If, for instance, the objects of chemical knowledge are to be arranged according to their combustibility or incombustibility, the nature of the process of combustion ought to be fully understood, and the effects of combustion on the substances to be classed in this way, clearly established. If all this has not been previously attended to, the principles of the arrangement must be false, and must unavoidably lead to error. As a proof of the truth of our remarks, the same substance has been considered by one chemist as a combustible body, and arranged by another in the class of combustibles; and even by the same chemist it is described as combustible at one time, and incombustible at another, according to the theoretic nomenclature which then prevails.

Without pursuing any method of arrangement founded on particular theories or systems, we shall endeavour, in the following treatise, to lay before our readers a full view of the present state of chemical science; and in arranging the great body of facts of which it consists, we shall observe the two following rules. 1. To introduce the substances to be examined according to the simplicity of their composition; and, 2. According to their importance as chemical agents. The plan which we propose to pursue, in treating of these different classes of bodies, is, 1. To consider their properties as simple substances, and, 2. The combinations which they form with those which have been described. By previously following out this plan, we hope to have less anticipation and repetition than would otherwise be occasioned.

In conformity with the principles now stated, the following table exhibits a view of the order which we shall observe in this treatise. In the present state of chemical science, and in its application to explain the phenomena of nature, or to improve the arts of life, the whole may be conveniently arranged into twenty chapters.

I. Affinity.
II. Light.
III. Heat.
IV. Oxygen Gas.
V. Azotic Gas and its combinations.
VI. Hydrogen, &c.
VII. Carbone, &c.
VIII. Phosphorus, &c.

5. Dyeing.
6. Bleaching.

48 explained.

In the preceding arrangement, the first chapter treats of affinity, or the laws of chemical action. In the two following chapters, the properties of light and heat are detailed. These are considered as material substances; but their properties can only be known in combination with other bodies, as they have never been found in a separate state. They likewise so far elude the sense of touch as to be imponderable and unresisting. Oxygen, azote, and hydrogen, which are considered as the basis of oxygenous, azotic, and hydrogenous gases, are treated of in the 4th, 5th, and 6th chapters; but these substances are not generally cognizable by the sense of sight, as light and heat elude the grasp of touch. They are known in a state of combination, the aeriform or gaseous state, when they are combined with caloric, or the matter of heat. The three following substances, carbone, phosphorus, and sulphur, which are the subjects of the 7th, 8th, and 9th chapters, are considered as simple, because they have never been decomposed. They can be exhibited in the solid state. Two of them being very abundantly diffused in nature, and entering into an immense number of combinations with other bodies; and the third, namely, phosphorus, possessing very singular properties; it becomes of great importance that they should be early known.

The acids are treated of in the 10th chapter. They fall to be arranged in this place, because the constituent parts of some of the most important are derived from the substances which have been already treated of. The properties of the class of acid bodies ought also to be early known, because they are the most powerful instruments of analysis in the hands of the chemist. In many of them he can scarcely proceed a single step without their aid.

The bodies treated of in the 11th chapter, namely, alcohol, ether, and oils, under the head of inflammable substances, are now introduced, because the nature and properties of the substances which enter into their composition have been previously examined; because one of them is the result of a chemical action between the acids and alcohol; and because some of them are extensively employed as chemical agents. In the 12th, 13th, and 14th chapters, the properties and combinations of the alkalies, earths, and metals, are detailed. These three classes of bodies were formerly considered as alike, simple, undecompounded substances. That character, however, belongs only to the metals. Some of them have formed the subjects of the most important and interesting chemical researches. They are first to be treated of in their nature as simple or compound substances; and next, as they enter into combination with the different classes of bodies which are already known, particularly with that of the acids, forming the numerous classes of alkaline, earthy, and metallic salts, most of which are not only of vast importance, as objects of chemical research, but also of extensive utility in the arts of life.

In the six following chapters, our chemical knowledge is to be applied in explaining the appearances of nature, so far as they are supposed to depend on chemical action. The 15th chapter treats of the chemical changes and combinations which take place in the atmosphere. The waters, as they are found on the earth; the different ingredients with which they are impregnated; the nature and quantity of these ingredients, and the methods of discovering and ascertaining them, form the subject of the 16th chapter. The 17th chapter is employed in giving a view of the component parts of mineral productions, and in describing the methods of analyzing or separating the parts which enter into their composition. The functions of vegetables and animals, or those changes which take place in them in the living state, which seem to be dependent on chemical action; the changes which they undergo by spontaneous analysis, or separation into their constituent parts, and the nature and properties of these elements, will be the subject of discussion in the 18th and 19th chapters. The 20th chapter, in which chemical science is applied to the improvement of arts and manufactures, is not one of the least important and interesting; and a full view of this part of the subject would exhaust the whole of the useful detail of chemical knowledge. But, in the following treatise, it is not proposed to enter at full length into the different branches of the arts and manufactures, but only to give a slight view of their general principles, so far as they depend on chemistry, referring for the particular discussion of each to the different heads under which they will be found arranged in the course of the work.

Chap. I. Of AFFINITY.

Before we enter into the detail of those changes which take place by the action of bodies upon each other, producing compounds which are possessed of totally different properties, and thus exhibiting the characters of chemical action, it is necessary to take a view of the circumstances in which these changes are effected, or, in other words, the laws of combination or chemical affinity.

49 History.

The term *affinity*, which is the expression of a force by which substances of different natures combine with each other, seems to have been pretty early employed by chemical writers. Barchusen seems to be among the first who employed it. "Arctam enim atque reciprocam inter se habent affinitatem." It was afterwards brought into more general use, and its application more precisely defined by Boerhaave*. His words are remarkable. "Particulæ solventes et solutæ, se affinitate suæ naturæ colligunt in corpora homogenea." And to explain his meaning still more clearly, he adds, "non igitur hic etiam actiones mechanicæ, non propulsiones violentæ, non inimicitiæ cogitandæ, sed amicitia." To avoid the metaphorical expression *affinity*, Bergman proposed the term *attraction;* and to distinguish chemical attraction, which exists only between particular substances, from that attraction which exists between all the bodies in nature, he prefixed the word *elective.* The word affinity, however, is now employed by all chemists.

* Elem. Chem. part. 2

The different tendencies of bodies to combine with

Affinity. each other, or the relative degree of affinity which exists between them, could not long be overlooked by those whose attention was occupied in observing chemical changes. And to explain this difference of actiod, a maxim of the schoolmen was adopted; *simile venit ad simile*. The same doctrine was held by Becher, that substances which were capable of chemical combination, possessed a similarity of particles. Other attempts were made to explain chemical action, by considering solvents as consisting of points, finer or coarser, which were mechanically disposed to enter into the pores of certain substances which they were capable of holding in solution. But Stahl, as appears from his works, rejected the notion of mechanical force, and ascribed the power of solvents to contact, or to the attraction of cohesion. "Combinationes quascunque non aliter fieri, quam per arctam appositionem." And afterwards, he speaks still more precisely when he says, "non per modum cunei, neque per modum incursus, in unam partidulam separandam, sed potius per modum apprehensionis, seu arctæ applicationis;" and then he adds, "est inde rationi quam maximæ consentaneum, quod effectus tales potius arctiore unione solventis cum solvente contingant, quam nuda et simplici formali instrumentali divisione †."

Having made this important step in the consideration of chemical action, the experiments and observations of the sagacious chemist led him to conclude that a combination between two substances, once formed, could not be destroyed, without effecting a more intimate union of one of the constituent parts with some other substance.

The next step in the method of observing and studying chemical affinity was made by Geoffroy the Elder. He collected the scattered facts, to determine the force or measure of their degrees of union, and to establish rules of analysis and composition. His first table of affinity was presented to the Royal Academy of Sciences at Paris in the year 1718. This consisted only of 17 columns, which were but imperfectly filled up, and exhibited rules, most of which have been changed; but with all its errors, it ought to be considered as one of the earliest true guides in medical knowledge.

The first material improvement in Geoffroy's table was made by Gellert, professor at Freyberg. In his *Chemia Metallurgica*, published in 1750, there is a new table of affinity, which extends to 28 columns. At the bottom of each column is given a list of substances with which the body at the head of the column has no action. Rudiger, in the year 1756, inserted a table of affinity in his system of chemistry, in which he reduced the number of columns to 15. In this table he placed the fixed alkalies and lime parallel with each other, and before ammonia, the column of acids. He pointed out also with a good deal of accuracy, in a small separate table, those substances which refuse to combine without the agency of intermediate substances.

The next important addition to the knowledge of affinities, was made by M. Limbourg. In his table the number of columns was extended to 33. This table was the fullest and most accurate of any that had yet appeared. He had justly observed that zinc, of all metallic substances, should be placed at the head in the column exhibiting the affinities of the acids, and that even in the dry way it precipitated them all. He asserted that lime and the caustic alkalies acted by affinity on animal matters: and besides, he stated some cases in which a change took place in the order of affinities, by a change of temperature, or by the volatility of one of the substances.

This subject, the importance of which was sufficiently obvious, was now assiduously investigated by many chemists. The number of tables was multiplied, and the system of affinity more fully established. But the greatest improvement which it had hitherto received, was made by the celebrated Bergman, in his dissertation on elective attractions, published in the Transactions of the Royal Society of Upsal, in the year 1775. His tables, editions of which appeared in 1779 and 1783, have been justly regarded as commanding specimens of the sagacity and industry of the author. The affinities of 59 substances are ascertained with great accuracy: and the distinction between those that take place in the moist and dry way, is particularly stated, as well as the distinction between simple and compound affinities, which has led to the explanation of a great number of apparent anomalies. Since the time of Bergman, this subject has been prosecuted by many of the most distinguished philosophical chemists. Among these we may mention the industrious and indefatigable Kirwan of our country; and among the French philosophers, Morveau and Berthollet, more especially the latter, distinguished for his skill and sagacity, who, in his researches concerning the laws of affinity, and his Treatise on Chemical Statics, has opened a new field of inquiry, corrected many former errors, and pointed out some new laws in this interesting and important subject. 56 By Bergman.

All bodies with which we are acquainted are influenced by a certain force, by which they are attracted towards each other. A stone, when unsupported, falls to the ground; the planets are attracted by the sun; two polished plates of metal, of glass, or of marble, when brought into close contact, adhere with a certain force; a piece of wood or stone requires a considerable degree of force to separate its particles; and lime and sulphuric acid enter into such close combination, that an equal degree of force is required to overcome that combination, or to separate the particles from each other. Whatever may be the nature of these attractions, or the cause of these different combinations, or whether they are all to be ascribed to the same universal law pervading matter, as some have supposed, they have been described by philosophers under different names. The attraction, which exists between all bodies in the solar system, was designated by Newton by the general term *attraction;* he demonstrated that this uniform and universal law was precisely the same as the law of gravitation, or the descent of heavy bodies towards the earth; that this attraction was an essential property of all matter; that the minutest particles, in proportion to their bulk, were equally influenced with the largest masses; that the same power which retained the planets in their orbits, gave form to the drops of rain. 57 All bodies attract.

That attraction which is exerted between two polished surfaces brought into contact, has been called *adhesion*. When particles of the same nature are attracted or held together, the expression of the force by which this is effected, has received the name of *cohesion*, 58 Different names of affinity.

Affinity.

sion, *homogeneous affinity*, or the *attraction of aggregation;* but when dissimilar particles, or the particles of two substances of different qualities, combine together, the force or attraction which is here exerted has been called *heterogeneous affinity*, *the attraction of composition*, or, strictly speaking, *chemical affinity*. In the three following sections, we propose to give an account of the opinions and doctrines which have been held by philosophers with regard to the nature and force of these attractions. Of the two first we shall only take a short view; but shall enter more fully into the detail of the latter, namely, chemical affinity, which more strictly belongs to our present subject.

Sect. I. *Of Adhesion*.

By adhesion, is to be understood, that force which retains different substances in contact with each other. Thus, water adheres to the finger, which is said to be wet, and mercury brought into contact with gold, adheres with great force. Adhesion takes place, either between two solids, as marble or glass; or between solids and fluids, as when water rises in capillary tubes; or between two fluids, as water and oil. Dr Desaguliers found by experiment, that two plates of glass, of one-tenth of an inch in diameter, adhered with a force equal to 17 ounces. The adhesion of two fluids has been proved by the experiment of Lagrange and Cigna, as that of oil and water, between which it was formerly supposed there existed a natural repulsion; and the experiments on capillary attraction, and particularly the ascent of water between two panes of glass, which was ascertained by Dr Brook Taylor, have established the attraction between solids and fluids.

59 In what circumstances it happens.

60 Accounted for.

This adhesive force, or the cause of this attraction, has been differently accounted for by philosophers. In a dissertation on the weight of the atmosphere, published in 1682 by James Bernoulli, he ascribes the resistance which two polished pieces of marble opposed to their separation to the pressure of the air; and in proof of this, he states as a fact, that the two plates could be easily separated *in vacuo*. But it has been supposed that he had either never attempted to verify this fact, or that the experiment had been accompanied by some fallacy. Dr Taylor concluded from his experiments, that the intensity of the adhesive power of surfaces might be measured by the weight which was required to separate them. About the same time Mr Hawksbee proved by experiment, that the adhesion of surfaces and capillary attraction were not to be ascribed to the pressure of the atmosphere, as Bernoulli had supposed: but Lagrange and Cigna, after having proved the adhesion between oil and water, thought that it was owing to a different cause from that of attraction. They supposed that it was occasioned by the pressure of the air, and that the opinion of Dr Taylor was not well founded. Such were the opinions held by philosophers on this subject, when Morveau, in the year 1773, instituted a series of experiments on adhesion, which he exhibited at Dijon. By these experiments he proved, that this attraction was not owing to the pressure of the air, but entirely to the mutual attraction of the two substances. To prove this, a polished plate of glass was suspended from the arm of a balance, and placed in contact with a surface of mercury. The weight necessary to separate the two surfaces was equal to nine gros and some grains. The whole apparatus was placed under the receiver of an air-pump, which was exhausted of the air as much as possible. Exactly the same force was still required to separate the surfaces. The same disk of glass brought into contact with pure water, adhered to it with a force equal to 258 grains; but from the surface of a solution of potash, it required only a force of 210 grains. This inequality of effects with equal diameters, and in the inverse order of the respective densities, seemed not only to be decisive in favour of Dr Taylor's method, but appeared to point out the possibility of applying it to the calculation of chemical affinities. For the force of adhesion being necessarily proportional to the points of contact, and the sum of the points of contact not varying in the adhesion of a fluid and a solid with equal surfaces, but by the figure of their constituent parts, the difference of the results points out to us precisely a cause analogous to that which produces affinity, the force of which it becomes easy, in these circumstances, to measure and compare.

61 Morveau's experiments.

To ascertain the accuracy of this method, plates of the different metals, of an inch in diameter, and of equal thickness, perfectly round, and well polished, were procured. They were furnished, each with a small ring in the centre, to keep them suspended parallel to the horizon. Each of the plates was suspended in turn to the arm of an assay balance, and accurately counterpoised by weights in the opposite scale. Thus balanced, the plate was applied to the surface of mercury in a cup, by sliding it over the mercury in the same manner as is practised for silvering mirrors, to exclude the whole of the air. Weights were then put into the opposite scale, till the adhesion between the plate and the mercury was broken. In each experiment fresh mercury was employed. The following table exhibits the results of these experiments.

	Grains.
Gold adheres to mercury with a force equal to	446
Silver - - - -	429
Tin - - - - -	418
Lead - - - -	397
Bismuth - - - -	372
Zinc - - - -	204
Copper - - - -	142
Antimony - - - - -	126
Iron - - - - -	115
Cobalt - - - -	8

In considering the remarkable differences, we clearly see that the pressure of the atmosphere has little or no influence, since its effects must have been precisely similar in the different cases, nor do they depend on the difference of polish on the surface; for a plate of iron, simply smooth and filed, adheres more strongly than a plate of the same diameter which has received the highest polish. Nor are these differences owing to the difference of density; for in this case silver would follow lead; cobalt would adhere with a greater force than zinc, and iron with a greater than that of tin. On the contrary, the order of their densities is reversed. What then is the order in which the adhesion of these different substances takes place? It is precisely, says Morveau, the order of affinity, or the greater or less solubility

lity of the metals in mercury. Gold, of all the metals, attracts mercury most strongly; but mercury dissolves neither iron nor cobalt, and therefore they are placed at the bottom of the list. This correspondence, he farther observes, cannot certainly be the effect of chance, but clearly depends on the general property of matter called attraction. This property, which is always the same, and always subject to the same laws, produces according to him very different effects, corresponding to the different distances between the particles occasioned by the variety of elementary forms; and thus it may be possible to estimate the force of chemical affinity by the force of adhesion. In the present case, for instance, the real affinities which tend to combine mercury with gold, silver, zinc, and copper, may be expressed by the above numbers 446, 429, 204, and 142.

62 ard's.

Achard of Berlin, convinced by Morveau's experiments, of the accuracy of Dr Taylor's method, saw its importance in chemistry; and having examined the principle, made a great number of applications of it, which he published in 1780. The result of these observations, if accurately obtained, can alone guide us in estimating the points of contact by adhesion, and by calculating the points of contact, to ascertain the figure of the particles which touch, and the resulting affinities.

63 uisites.

Three conditions are essential to the accuracy and uniformity of each experiment. 1. That the solid body whose adhesion with a fluid is to be estimated be so suspended as to be in a horizontal position, and that the force employed to detach it, should always act in a line which forms a right angle with the surface of the fluid. 2. That there be no air interposed between the surface of the solid and the fluid; and, 3. That the weights employed as a counterpoise may be added, especially towards the end, in very small quantity, not more than a quarter of a grain each; and to avoid any sudden jerk, they should be placed gently in the scale.

The first point which he wished to ascertain was, whether the difference of atmospherical pressure, the temperature remaining the same, caused any difference in the adhesion of surfaces. For he found that the adhesive force between a plate of glass and distilled water was the same at all pressures, but the uniformity of the results varied when he operated at different degrees of temperature, while the elevation of the barometer continued the same; and he found that this variation did not arise from the different temperatures of the surrounding air, but from that of the water. When the fluids are colder, the adhesion is the stronger; and the reason is obvious: containing more matter under the same volume, they must present a greater number of points of contact in the same space; and since the force of the adhesion is in proportion to the number of the points of contact, it ought to increase when the fluids are condensed by cold, and to diminish when they are rarefied by heat. Achard did not stop with observing these variations of the force of adhesion between glass and water heated to different temperatures; he subjected them to calculation, to verify his observations, and render their application easy to all degrees. We subjoin his table exhibiting the force of adhesion by observation, and also by calculation. He proceeded on the following data.

Let x be the temperature of the water, y the corresponding adhesion, b its coefficient, and a the constant force. We have then the equation $x=a-by$. To find the value of a and b, he employed two observations; the one in which water at 104° of Sulzer's thermometer, adhered to the glass disk with a force equal to 80 grains, and the other in which water at 56° adhered with a force equal to 89 grains. Proceeding from these two terms $104^{\circ}=a-80b$

$$56=a-89b,$$

we have $a=530$

$$b=\frac{-48}{9}$$

And thus the relation of the temperature of water to its adhesion to glass may be thus expressed: $x=530-\frac{48}{9}y$; and from thence are deduced the corresponding values of x and y for all the adhesions of glass to water at any temperature. Such are the data from which, and the corresponding experiments, Achard formed the table which exhibits the adhesive force of a glass disk of $1\frac{1}{2}$ inch in diameter, to water at different temperatures; and shewing the difference of the results.

64 Adhesion of glass to water.

TABLE I.

Degrees of Sulzer's Therm.	Degrees of Fahren. Therm.	Adhesion by Experiment.	Adhesion found by Calculation.	Difference.

The temperature being supposed to continue the same, if this principle be well founded, the force of adhesion of any given body with water, ought not only to increase or diminish according to the extent of surface, but these differences ought to be as the difference of the surfaces.

If then p be the force with which a disk of glass whose diameter is a, adheres to water, and y the force of adhesion of another disk, whose diameter is b, we shall have the proportion $a^2 : b^2 :: p : y$ and $y=\frac{b^2 p}{a^2}$.

To verify the order of this progression, either with water or other fluids, Achard employed disks of glass from $1\frac{1}{2}$ to 7 inches in diameter, having first ascertained their force of adhesion with these fluids, by the number

number of grains which were necessary to overcome it. He afterwards calculated the same by the above equation. The following Table exhibits the results of experiment and of calculation, which if the procedure be free from error, correspond as nearly as could be expected.

TABLE II.

The force of adhesion between glass disks of different diameters, and different kinds of fluids, determined by experiment and calculation.

Achard also instituted a series of experiments with different solid substances, formed into disks of equal diameters, and applied to the surface of different fluids. The following table shows the results of those experiments; but from these results it appears, that the force of adhesion does not depend on the specific gravity, either of the solid or the fluid; nor does it correspond with the order of chemical affinities. But besides, some of the results cannot be admitted as perfectly legitimate, on account of the chemical action which would necessarily take place when some of the substances were brought into contact; as some of the metals would be acted on by the acids, and others by the solutions of metallic salts.

From all these observations, then, we may conclude, that the force of adhesion between different bodies is altogether independent of the pressure of the air; that it varies according to the number of points of contact of the touching surfaces; and that it is probably owing to the same cause as the force of affinity. It appears also, that the force of adhesion between solids and fluids is in the inverse ratio of the temperature indicated by the thermometer, and the direct ratio of the squares of their surfaces; that different solids adhere with different degrees of force to the same fluid; but still it must be allowed, that experiments and observations are yet wanting, to derive any advantage from the results of adhesive force which have been obtained, in the cultivation of chemical affinities.

SECT. II. *Of the Attraction of* AGGREGATION.

67 ...sion. That force which is inherent in the particles of matter, by which they are held together, and form masses, is called *cohesion;* and when particles of the same kind are united together, it is denominated the *attraction of aggregation*, or *homogeneous affinity*. It is probably the same in kind with that which we have already considered, but differing in degree. Thus, it requires a much greater force to separate the particles of a mass of marble, than two polished surfaces of the same substance brought into contact.

68 Difference of force. As the force of cohesion often opposes itself to chemical action, and must in the researches of the chemist be destroyed or overpowered, it becomes a matter of considerable importance to be able to estimate it. This force differs greatly in different bodies. A very great force is necessary to overcome the power of cohesion among the particles of an iron or gold wire, while a small degree of force can separate the particles of a piece of wood or stone. To ascertain this force, experiments have been made by different philosophers, and particularly by Muschenbroeck, on that of the cohesion of solid bodies. A rod of the substance whose

Affinity.

cohesive force was to be estimated, was suspended perpendicularly, and weights attached to the lower extremity. The weight necessary to destroy the cohesive force of the particles of matter in the rod, or to tear it asunder, was considered as the measure of that force. The following are the results of his experiments made on different substances. The substances employed were rods of an inch square, and the numbers in the table indicate pounds avoirdupois.

69 Opinions on the nature of cohesion.

Various opinions have been entertained of the nature of this cohesive force. According to Newton, as we have already observed, it is properly essential to all matter, and the cause of the variety observed in the texture of different bodies. "The particles," says he, "of all hard homogeneous bodies which touch one another, cohere with a great force; to account for which some philosophers have recourse to a kind of hooked atoms, which, in effect, is nothing else but to beg the thing in question. Others imagine that the particles of bodies are connected by rest; that is, in effect, by nothing at all; and others by conspiring motions, that is, by a relative rest among themselves. For myself, it rather appears to me, that the particles of bodies cohere by an attractive force, whereby they tend mutually towards each other: which force, in the very point of contact, is very great; at little distances is less, and at a little farther distance is quite insensible."

70 Newton's.

71 Desaguliers.

"If compound bodies," Dr Desaguliers observes, "be so hard as by experience we find some of them to be, and yet have a great many hidden pores within them, and consist of parts only laid together; no doubt those simple particles which have no pores within them, and which were never divided into parts, must be vastly harder. For such hard particles gathered into a mass cannot possibly touch in more than a few points; and therefore, much less force is required to sever them, than to break a solid particle whose parts touch throughout all their surfaces, without any intermediate pores or interstices. But how such hard particles only laid together, and touching only in a few points, should come to cohere so firmly, as in fact we find they do, is inconceivable; unless there be some cause by which they are attracted and pressed together. Now, the smallest particles of matter may cohere by the strongest attractions, and constitute larger, whose attractive force is feebler: and again, many of these larger particles cohering, may constitute others still larger, whose attractive force is still weaker; and so on for several successions, till the progressions end in the largest particles, on which the operations in chemistry, and the colours of natural bodies, do depend; and which, by cohering, compose bodies of a sensible magnitude."

72 Boscovich.

A theory, which possesses great ingenuity and plausibility, has been proposed by Boscovich, to account for cohesive attraction; and some suppose, that it is on immaterial means or powers that this attraction, according to this theory, depends. Dr Hutton * seems to think, that Dr Priestley applies it in this view, in the following passage, in which he attempts to solve some difficulties with regard to the Newtonian doctrine of light. "The easiest method," says Dr Priestley, speaking of this subject, "of solving all difficulties, is to adopt the hypothesis of Mr Boscovich, who supposes that matter is not impenetrable, as has, perhaps, been universally taken for granted; but that it consists of physical points only, endued with powers of attraction and repulsion, in the same manner as solid matter is generally supposed to be: provided, therefore, that any body move with a sufficient degree of velocity, or have a sufficient momentum to overcome any powers of repulsion that it may meet with, it will find no difficulty in making its way through any body whatever:

* Math. Dict. 25

ever: for nothing else will penetrate one another but powers such as we know do in fact exist in the same place, and counterbalance or overrule one another. The most obvious difficulty, and indeed almost the only one, that attends this hypothesis, as it supposes the mutual penetrability of matter, arises from the idea of the nature of matter, and the difficulty we meet with in attempting to force two bodies into the same place. But it is demonstrable, that the first obstruction arises from no actual contact of matter, but from mere powers of repulsion. This difficulty we can overcome, and having got within one sphere of repulsion, we fancy that we are now impeded by the solid matter itself. But the very same is the opinion of the generality of mankind, with respect to the first obstruction. Why, therefore, may not the next be only another sphere of repulsion, which may only require a greater force than we can apply to overcome it, without disordering the arrangement of the constituent particles, but which may be overcome by a body moving with the amazing velocity of light †."

† ...t. of ...n, vol. i. 392.

3 ...ained.

According to the theory of Boscovich, the first elements or atoms of matter are indivisible, unextended, but simple, homogeneous, and finite in number. They are dispersed in one immense space, in such a manner, that any two or more may be distant from each other any assignable interval. This interval may be indefinitely augmented or diminished, but cannot entirely vanish. Actual contact of the atoms is therefore impossible, seeing that the repulsive power which prevents the entire vanishing of the interval must be sufficient to destroy the greatest velocities by which the atoms tend to unite. The repulsive power must encircle every atom, must be equal at equal distances from the atoms, and, moreover, must increase as the distance from the atoms diminishes. On the contrary, if the distance from the atoms increases, the repulsive power will diminish, and at last will become equal to nothing or vanish; then, and not till then, an attractive power commences, increases, diminishes, vanishes. But the theory does not stop here; for it supposes, that a repulsive power succeeds to the second or attractive, increases, diminishes, vanishes; and that there are several alternations of this kind, till at the last an attractive power prevails; and though diminishing sensibly, as the squares of the distances increase, extends to the most distant regions of our system. All the varieties of cohesion, Boscovich has shown, may be satisfactorily accounted for from the diversity of size, figure, and density of the cohering particles.

4 M...er in th... st...

Bodies exist in three different states, which are quite distinct from each other; in the solid state, the liquid, and in the state of elastic fluid. Solidity, he supposes, is the consequence of the irregular figure of the particles, and their great deviation from the spherical form, by which free motion among them is prevented. And thus, in solid bodies, the motion of one particle is followed by that of the whole mass; or if the motion of the whole mass requires a greater force to effect it than what is necessary to destroy the cohesion of the particles, the latter takes place. The diversity in solids arises from the various degrees of force in the limits of cohesion.

5 S...

6 F...

The particles of fluid bodies, according to Boscovich, are spherical, and their forces are more directed to their centres than to their surfaces; by which motion is freely allowed when any force is applied. Fluids, he supposes, are of three kinds; one in which the particles have no mutual power, as sand and fine powders; one in which they have repulsive power; such are the elastic fluids, as air: and the third in which they have an attractive power, as water, mercury, &c. And these three kinds are produced by the primary differences in the particles which compose them.

77 Of three kinds.

78 Viscid substances.

There is a class of bodies which are intermediate between the solids and fluids; the nature of which may be explained on the same principles. These are the viscid substances, the particles of which attract each other more strongly than the fluids, but not so strongly as the solids. In these bodies the particles deviate so far from the spherical form, as to produce a certain resistance among each other, and to impede their relative motion.

79 Solution.

According to this theory, chemical phenomena may be traced to the same principle, namely the law of the forces and the differences in the particles which thence arise. Solution, for instance, is thus explained. The particles of some solid bodies have less attraction for each other than for the particles of some fluids, and consequently when these are applied to each other, the particles of the solid separate, and combine with those of the fluid; and thus a mixture of the two is formed. But the separation of the particles of the solid can only take place so long as the particles of the fluid are in the sphere of their attraction; and when either of them get beyond it, or when the attraction of the mixture thus formed becomes equal to the attraction of the particles of the solid for each other, no farther solution takes place, and the fluid is said to be saturated. But if, into this mixture, another solid, whose particles have a greater attraction for the fluid, be introduced, the fluid will leave the former solid and combine with the particles of the latter. The particles of the former will fall to the bottom, i. e. *precipitation* will take place.

80 Evaporation.

Substances which are dissolved, may not only be obtained again by precipitation, but also by slowly abstracting part of the fluid in which they are dissolved. This is called *evaporation*, and the solid bodies which are thus slowly formed, generally assume some regular shape, and are denominated *crystals*. As the fluid is removed, the particles come gradually into the sphere of the attractive power of each other, and thus attain to some limit of cohesion, when the fluid which kept them asunder is removed. But when a solid is obtained by precipitation, the fluid is suddenly removed from betwixt the particles, which are consequently left beyond the sphere of attraction of each other, and do not therefore assume any regular form. And thus it will follow, that the more slowly the process of evaporation goes on, the more regular will be the crystals which are formed; and this corresponds with experiment and observation *.

* See *Boscovich's theory*,

81 Crystallization.

Thus, solid bodies are found, either in irergular masses, or assuming regular forms by crystallization; and the same substances which are capable of assuming regular figures, uniformly affect the same form; subject, however, to certain variations from particular circumstances. No bodies can assume the form of crystals, Affinity. crystals, excepting such as can be reduced to the fluid state. This, as is well known, is the usual method of crystallizing salts. The substances to be crystallized are dissolved in water, which is then slowly evaporated; and as the bulk of the fluid is diminished, the particles gradually come nearer to each other, combine together, and form crystals. These crystals, which are at first small, receiving the addition of other particles, become larger, and fall to the bottom by their gravity.

Some saline bodies, which are very soluble in hot water, are dissolved but in small proportion in cold water. Hot water, which is saturated with any of these salts, is no longer capable of holding them in solution when it cools. The particles then gradually approach each other, and arrange themselves according to certain determinate forms, or in other words, they crystallize. Many of the saline bodies which crystallize in this manner, when they assume the solid form, combine with a considerable portion of water, which is called the *water of crystallization*. There is another class of saline bodies which assume regular forms according to a different law. Being equally soluble in hot and in cold water, they cannot be crystallized by cooling the fluid in which they are dissolved, but by diminishing its quantity; and this is effected by continuing the application of heat; that is, by the process of evaporation. Salts which are crystallized in these circumstances, contain but a small quantity of water of crystallization. This is the case with common salt, which is crystallized by boiling the fluid which holds it in solution.

Many substances assume regular forms which are not soluble in any liquid. Such, for instance, is the case with metallic substances, and with glass, as well as some other bodies. To crystallize substances of this nature, they must be subjected to fusion, and thus by combining with caloric, they are reduced to the liquid state, and the particles being separated from each other, are left at liberty to arrange themselves into regular crystalline forms, and by slow and gradual cooling, the crystals are obtained more perfect.

82 Accounted for by

But what is the cause that the particles of bodies in these circumstances arrange themselves in this manner? or what is the cause of the same bodies in the same circumstances assuming regular figures? Some of the ancient philosophers considered the elements of bodies as consisting of certain regular geometrical figures; but it does not appear that they employed this theory to explain crystallization. The regular figure of crystals was ascribed by the schoolmen to their substantial forms; while others supposed that it was owing merely to the aggregation of the particles, without explaining the reason of this aggregation, or of the regular figures which it formed.

83 Newton,

According to Newton, and the theory of Boscovich which we have quoted, the particles of bodies which are held in solution by a fluid, are arranged in regular order, and at regular distances. When the force of cohesion between the particles and the fluid is diminished, that between the particles themselves is increased; they therefore separate from the fluid, and combine together in groups, which are composed of the particles nearest to each other. If it be supposed, that the particles which compose the same body have the same figure, the aggregation of any determinate number of such particles will produce similar figures. According to the ingenious theory of the Abbé Hauy, the integrant particles always combine in the same body in the same way; they attach themselves together by the same faces or the same edges; but these faces and edges are different in different crystals. And although the same substances are observed to crystallize in a great variety of different forms, yet they all contain what Hauy calls the *primitive* form, or have it within them as a nucleus; and this nucleus or primitive figure may be extracted by careful mechanical division. If then the figure of crystals is owing to the figure of the integrant particles, and to the peculiar mode of their arrangement in combination, these particles, when they are left at full liberty, as is the case when they are dissolved in a fluid, will combine in the same way, and thus the crystals of the same body will always exhibit similar forms. 84 by Hauy 85 who ascribes it

86 the primitive forms

In prosecuting this subject, Hauy found that all the primitive forms of crystals which he had observed, might be reduced to six; namely,

1. The parallelopiped.
2. The tetrahedron.
3. The octahedron.
4. The regular six-sided prism.
5. The dodecahedron, terminated by equal rhombs.
6. The dodecahedron, with triangular faces, composed of two pyramids, united base to base.

But the nucleus or primitive form of a crystal, he observes, is not the last term of its mechanical division. It may be subdivided parallel to its different faces, and sometimes also in different directions. If the nucleus or primitive form be a parallelopiped, which cannot be subdivided, but in a direction parallel to its faces, as takes place in carbonate of lime, it is obvious that the integrant particle or molecule is similar to the nucleus itself. And he has found by experiment, that the figure of the integrant particles of all crystals may be reduced to the three following. These are, 87 Figure of the integrant particles.

1. The tetrahedron, or the simplest of all pyramids.
2. The triangular prism, or the simplest of all the prisms.
3. The parallelopepid, or the simplest of the solids which have their faces parallel two and two.

From these primitive forms, the difference of size, proportion, and density of the different particles of bodies, he supposes, may account for all the differences of attraction which take place in simple aggregation and composition of bodies. The integrant particles sometimes unite by their faces, and sometimes by their edges, in forming the primitive crystals; and this accounts for the different figures of the primitive crystals, which are composed of integrant particles of the same form. But bodies when they are crystallized do not always exhibit the same primitive form. The deviations from this, and the varieties of forms which are produced, are called by Hauy *secondary forms*. In some salts, for instance, the primitive form is the octahedron; but in deviating from this form, they assume, when crystallized, that of the cube or the dodecahedron. 88 Secondary forms

These secondary forms seem to depend sometimes on variations in the ingredients which compose the integrant particles of particular bodies, the solvent in which

which the crystals are formed, or the different decrements of the laminæ of the crystals. But for a full view of this ingenious theory, see CRYSTALLIZATION.

SECT. III. *Of the Attraction of* COMPOSITION.

Bodies which are composed of particles of the same nature cohere with a certain force, as in the particles of water or of mercury, and those of wood or of metal; and this force, we have seen, acts with very different degrees of intensity. In the two former, the water and the mercury, it is comparatively weak, but in the two latter it is very powerful.

89 ...ained. But the particles of dissimilar bodies also enter into combination; and thus combined, form homogeneous substances, the parts of which cohere with great force; and wherever these combinations take place, the force of cohesion formerly subsisting between the particles of each of the bodies must be destroyed or overcome, before the new combination can take place. Thus a piece of marble is dissolved in muriatic acid; but before this can take place, the force of cohesion which existed between the particles of the marble must be overcome; or, in other words, the force of attraction between the particles of muriatic acid and the particles of the marble must be greater than that between the particles of marble themselves. This attraction then which exists between the particles of substances of a different nature, has been called the *attraction of composition*, *heterogeneous affinity*, or more properly *chemical affinity*.

90 ...affini- ...mited. An attraction or affinity, thus efficient, does not exist between the particles of all bodies. Thus there is no affinity between a piece of marble and water, as is the case between marble and muriatic acid, or it is not sufficient to overcome the attractions opposed to it; and it has been thought that there is no affinity between oil and water, because the particles of the one do not enter into combination with those of the other.

91 ...rtance Chemistry may be said to be the history of affinities, as it consists in the detail of the numerous compositions and decompositions which take place among natural bodies. Without attending to the phenomena which arise from affinity, the chemist could carry on no process, either of synthesis or analysis; for it is by means of their affinities that the chemical nature of bodies can be discovered.

In taking a general view of the phenomena which depend upon chemical attraction, the changes or events which are the results of this action, have been divided into certain classes, and from their being constant and uniform, they have been characterized by the name of *laws of chemical affinity*. These may be considered as chemical axioms, which are the principles or foundation of the science, and therefore it is necessary that they should be well understood, before we enter into the detail of the facts which it embraces.

92 ...s. Fourcroy has arranged the facts which depend on chemical affinity under ten different heads, which he has denominated *the laws of affinity*. In illustrating this interesting part of chemical science, we shall observe the same arrangement.

FIRST LAW.

Chemical affinity takes place only between bodies of a different nature, or between dissimilar particles. 93 Affinity between dissimilar particles.

This law, when considered as a law of chemical affinity, may be regarded as negative; for when the particles of bodies of the same nature combine together, it is by the force of cohesion, and therefore comes under that species of affinity called the attraction of aggregation. No chemical action has taken place, no new compound is formed; which are the characteristics of chemical affinity.

But as an instance of the effect of chemical affinity between two bodies of a different nature, we may refer to the experiments above alluded to, of the combination which takes place between a piece of marble and muriatic acid; for by mutual action between these two bodies the marble has disappeared, and the acid has totally changed its properties. The compound, which is the result of this combination, proves that the heterogeneous bodies have entered into intimate mutual union.

Chemical affinity may act between two bodies, and a combination take place, when these bodies are totally uncombined with all others. In this case the combination is produced by the force of affinity between the two bodies; but when one or both of these bodies is in a state of combination with others, the bodies which are said to have the greater affinity for each other, do not entirely combine together, and leave the bodies with which they were first in combination. Suppose A and B are two bodies which have an affinity for each other, and are in a state of combination; and suppose C is a third body which has a stronger affinity for the body B than the affinity which exists between A and B. Now, the body C having a greater affinity for the body B than what exists between the compound body AB when it is brought into circumstances where the force of that affinity can be exerted, the compound body AB will be decomposed, that is, the body C will combine with the body B, and will leave the body A. It was formerly supposed by chemical philosophers, that this decomposition was complete; that is, as in the case stated above, the affinity between C and B being greater than the affinity between A and B, the body C, when in sufficient quantity, abstracted every particle of the body B from its combination with the body A. But the experiments and observations of the sagacious Berthollet have placed this matter in a new light. This will be best illustrated by detailing some of the experiments by which this ingenious philosopher has clearly ascertained many curious facts with regard to chemical affinity (D).

The sulphuric acid has a very strong affinity for the earth

(D) The reader, it is hoped, will find no difficulty in understanding the general reasonings on this subject; but if he should, he will be able to comprehend it fully by reverting to them, after the substances whose affinities are given as examples, are treated of in detail in their proper places.

Affinity.

94 Examples.

earth called barytes, forming with it a compound which is insoluble either in hot or cold water. Sulphuric acid also has an affinity for potash, but it is much weaker than that which exists between the acid and barytes; yet the potash, although possessed of the weaker affinity, abstracts part of the sulphuric acid from the barytes, and combines with it. This is proved by Berthollet in the following experiments.

1. He took equal quantities of pure potash, and sulphate of barytes (E), and boiled them together in a small quantity of water. According to the views which former chemists entertained of chemical affinity, no decomposition should take place, because the affinity between the sulphuric acid and the barytes was stronger than that between the acid and the potash. But from the result of this experiment it appears, that the sulphate of barytes was partially decomposed by the potash, and that the sulphuric acid was divided between the two bases; that is, between the barytes and the potash.

2. The oxalic acid has a greater affinity for lime than for potash; but if oxalate of lime, that is oxalic acid combined with lime, be boiled along with potash in a small quantity of water, in the proportion of one part of the oxalate of lime to two of the potash, a partial decomposition of the oxalate of lime will take place, part of the oxalic acid is abstracted from the lime, and combines with the potash*.

* Researches, Transl.

95 Affinity increased by the mass.

3. One part of phosphate of lime was boiled together in a small quantity of water with two parts of potash. The phosphoric acid has a greater affinity for lime than for potash; but from this experiment it appeared that the phosphate of lime was partially decomposed, and part of the phosphoric acid having combined with the potash, formed a new compound, phosphate of potash.

From these experiments Berthollet observes, that the bases which are supposed to form the strongest combinations with the acids may be separated from them by others whose affinities are supposed to be weaker, and that the acid divides itself between the two bases. Where a small quantity only of the decomposing substance is employed, the effect is not perceptible: but if a large quantity be employed, as in one of the above exeriments, if the sulphate of barytes had been treated with successive portions of potash, it would have been ultimately and almost entirely decomposed; for the weaker affinity of any body is made up by increasing the quantity of that body.

Bergman has remarked, that if six times as much of the decomposing substance be employed as is sufficient to satnrate the base, a decomposition will be effected, which may be considered as total, because the opposing substance retains so small a part of that with which it was combined, that it may escape the observer's notice, and be considered as an evanescent quantity. But the above experiments shew, that a similar decomposition could be produced, if the reverse of the experiment which Bergman recommends had been attempted.

When one substance acts on another in combination with a third, the subject of combination divides itself between the two others, not only in proportion to the energy of their respective affinities, but also in proportion to their quantities. The two substances which act on the combination may be considered as opposing forces acting on the subject of combination, and sharing it between them in proportion to the intensity of their action; and this intensity may be estimated by the quantity of the substance and the energy of its affinity. The effect, therefore, must increase or diminish as the quantity increases or diminishes. Thus it appears that elective affinity in general does not act as a determinate force by which one body can completely separate another from a combination; but that in all compositions and decompositions produced by affinity, there is a partition of the subject of the combination between the two bodies, the energy of whose affinities is opposed, and the proportions of this partition depend not solely on the difference of energy in the affinities, bnt also on the difference of the quantities of the bodies; for it has been observed that an excess of the quantity of the body whose affinity is the weaker, compensates for the weakness of affinity.

Second Law.

96 Affinity between ultimate particles.

Chemical affinity takes place only between the ultimate particles of bodies.

The attraction of aggregation or cohesion which is exerted between the integrant particles of bodies, is opposed to the action of chemical affinity. For, as in the case just mentioned, of the combination that takes place between a piece of marble and muriatic acid, the force of cohesion between the particles of the marble must be overcome before chemical action begins, and a new compound can be formed. The new compound consists of the constituent particles of the two bodies, which are now intimately united by the force of affinity existing between them.

Third Law.

97 Between several bodies.

Chemical affinity takes place between several bodies.

It is not merely compounds consisting of the particles of two bodies, that are formed by chemical affinity, for we shall find that there are numerous instances of three or four substances entering into chemical combination. Alum, a well known substance, is a compound of three substances which have entered into chemical union. These are, sulphuric acid, alumina or pure clay, and potash. The same thing happens also in all those componnds which were formerly called triple, now double salts, which consist, like alum, of three different substances, i. e. a double base to the acid; but the most remarkable instances of the effects of chemical affinity on several bodies are observed in the alloys of some of the metals. The temperature at which the metals are fused is generally pretty high, but the alloys of some of them may be brought to a state of fusion at a low temperature. This is the case with the alloy of bismuth, lead, and tin, which may be melted at the temperature of boiling water, which is far below the fusing

98 Alloy metals.

(E) This is the compound of sulphuric acid and barytes, according to the new chemical nomenclature, the principles of which will be afterwards explained.

Affinity. fusing point of any of the uncombined metals, and shews by this change of their properties, that a chemical union has been effected.

FOURTH LAW.

99 That chemical affinity may take place between two bodies, it is necessary that one of them be in the liquid or fluid state.

This law is not strictly universal. In some instances solid bodies presented to one another combine to form a fluid. This is the case with ice and snow.

The solution of a solid body in a fluid, may be considered as the destruction of the cohesion of its particles, and their equal diffusion in that fluid. It is the combination of the particles of the solid with those of the fluid; and the compound still possesses the characteristic physical properties of the fluid. Thus, in the first place, the force of cohesion between the particles of a solid body is destroyed, by its solution in a fluid; which force must always be overcome before a new compound can be formed by the action of chemical affinity. But, 2dly, The particles of a body dissolved in a fluid are in their ultimate, or at least a very minute, state of division; by which means the points of contact between the particles of the body held in solution, and those of any other with which it may combine, are greatly multiplied, and thus the operation of chemical action between these particles is greatly extended. Many familiar processes are examples of the effects of solution, as sugar dissolved in water; common salt in the same fluid; or the experiment mentioned above, of marble in muriatic acid. In the process of making glass we have another example of the same nature. The two substances which enter into the composition of glass are in the solid state. These are siliceous earth or sand, and an alkali. But to effect the combination of the two solids, one of them is brought to the fluid state by the application of heat. The alkali first melts, and in the state of fusion the sand or siliceous earth combines with it, and forms an uniform compound, which is glass.

100 But Berthollet has shewn, that the solubility of bodies has a very great influence in modifying the action of chemical affinity. For, he observes, when a body is in some degree soluble, its action is composed of that of the part dissolved and of that of the part which has retained its solidity. It follows that its action does not increase in proportion to the quantity employed. Lime, for instance, acts by the part dissolved, and by that which remains solid; but it is probably the dissolved part which contributes principally to the effect produced. If the quantity of lime employed in an experiment be doubled, without increasing the quantity of the liquid, the quantity of lime dissolved will rather be diminished than increased, because a part of the liquid is absorbed by the lime which has been added.

When an insoluble combination can become soluble by being deprived of a part of its composition, the inconvenience of insolubility is easily removed. Thus it is when the phosphate of lime is acted on by an acid. The part of it which is within the sphere of action is instantly converted into super-phosphate, and the other part successively, until both the opposed substances be reduced to a liquid state.

"When an eliminated substance becomes insoluble, the precipitate which is formed retains a portion of the substance with which it was combined, in proportion to the individual forces which acted in the moment of the precipitation. The operation is no farther influenced by this portion, so that the quantity of the precipitating body adequate to the precipitation is all that is necessary until the end of the operation. But the case is different when the eliminated substance assumes the liquid state, for then the resistance increases according to the progress of the decomposition; and hence it follows, if a substance nearly insoluble be opposed to a combination, and its action be consequently only partial, whilst the substance eliminated remains liquid, that the decomposition must be quickly stopped, whatever may be the force of the affinities. Because it has been already shewn, that the decomposing action depends not merely on the affinities, but also on the relative quantities in action. When the sulphate of potash was decomposed by means of lime, the operation was necessarily stopped as soon as the sulphuric acid was entirely divided between the potash and lime, in proportion to their respective affinities, and to the quantity of each which had acted on the sulphuric acid; that is, in proportion to their respective masses *."

101 But fluids in the elastic state, or the state of gas, are subjected to forces which are the reverse of the force of cohesion; and thus modify in a different manner the effects of the particular affinity of each substance. Elasticity acts, either by the removal of some substances from the action of others, or by diminishing the proportion of them that comes within the sphere of action. But if all the substances in action be in the elastic state, this effect will not follow, because then they all exist in a similar condition. When a substance, on separating from a state of intimate combination, assumes the state of gas, it becomes elastic, and then it can oppose no further resistance to the decomposing action. And thus it appears that substances of this nature do not act by their mass. A complete decomposition can then be effected by the decomposing substance, and no greater quantity of it is required than what would have been necessary to form the compound by direct combination. Thus, carbonic acid, which is an elastic fluid, may be disengaged from its combination by another substance whose affinity for the base may be less, because that other substance can act by its mass, and can therefore overcome the affinity of the carbonic acid by its successive action. But if the whole of the carbonic acid is to be expelled, the decomposing substance must be used in greater quantity than what is strictly necessary to produce saturation.

102 The action which takes place when concentrated sulphuric acid is poured on dry common salt, that is, both substances being as much as possible deprived of water, affords a good illustration of the effect of the elasticity of one of the substances. Common salt is composed of muriatic acid and soda. The affinity of the sulphuric acid for soda is greater than that of muriatic acid. When, therefore, the sulphuric acid is poured on the common salt, it combines with the soda, and the affinity of the muriatic acid is diminished. It consequently assumes the gaseous state, and acts no longer by its mass. But if a solution of common salt in

* Berthollet's Researches.

Margin notes: 99 The body must be liquid. — 100 Effect of solubility. — 101 Elastic fluids. — 102 Example.

Affinity.

in water be employed, or a diluted acid, then the muriatic acid may be retained in the water, and in this case it can act by its mass.

When, therefore, a substance is in the state of gas, its elasticity is to be considered as a force opposed to the affinity of liquid substances. When the elasticity of gaseous substances is diminished, as happens by compression, they then combine in greater quantity with liquids. When water is brought into contact with carbonic acid, which is in the state of gas, it does not become saturated with that acid, because the elasticity of the gaseous acid opposes the dissolving power of the water: and before its dissolving force is exhausted, the two forces are balanced. But when the opposing elastic force is diminished, as by compression, the dissolving power of the water continues its action, and thus it is more fully saturated with the acid.

Fifth Law.

103 Change of temperature.

When bodies combine together, they undergo a change of temperature.

All bodies contain a certain quantity of caloric, or the matter of heat; but when any change takes place in the nature or constitution of any body, its power of retaining that portion of caloric is also changed. During these changes heat is either given out or absorbed; and this increase or diminution of temperature becomes obvious to our senses, or may be measured by the thermometer.

The effects of this variation of temperature will be greater or less, in promoting or retarding the action of chemical affinity, according to the change which takes place on the substances which are decomposed, or according to the state of the compound which is formed. When there is a great elevation of temperature, in consequence of the heat produced by the combination of substances, it is necessary to attend to the difference of volatility of which the substances are susceptible by that elevation of temperature. If the substances are not all in the liquid state, or if one of them only be soluble, the effect of heat is to favour their mutual action; because the force of cohesion, which acts even between the particles of bodies in the liquid state, is thus diminished. If the expansion by heat of the one of two substances be greater than that of the other, the more expanded substance acquires a greater degree of elasticity, and this, as has been already observed, must be considered as a force opposing the affinity which existed between the two bodies.

104 Examples.

In chemical combinations, according to this law, the temperature changes. The increase or diminution of temperature, according to the nature of the combination which is effected, will be best illustrated by an example or two.

1. When lime is slaked, that is, when water is thrown upon burnt lime, a great elevation of temperature takes place. The water enters into combination with the lime; it passes from the fluid to the solid state; and during this change, a great quantity of caloric, or the matter of heat, is given out, which is the cause of the increase of temperature (F).

2. As an example of two fluids when mixed together producing a similar effect, take four parts of concentrated sulphuric acid, and pour it on one part of water; the temperature of the combined fluids will be elevated to the boiling point of water.

In the solution of solid bodies in a fluid, there is a great change of temperature: but in this case it is diminished. This is particularly the case when salts are dissolved in water.

1. Take muriate of ammonia, or sal ammoniac, and dissolve it in water, and while the solution is going on, if a thermometer be plunged into it, a considerable fall of the mercury will be found to take place in consequence of the absorption of caloric, or the diminution of temperature.

2. If a quantity of water, at the temperature of 50° or 60° of Fahrenheit, be poured on an equal quantity of ice, the temperature of the water will be diminished to the freezing point, or 32°.

3. A very low temperature is produced by a mixture of ice and common salt; and a still lower by a mixture of snow and powdered muriate of lime. We shall become better acquainted with the effects of these substances in explaining the method of producing artificial cold.

Sixth Law.

10[5] Compo[unds] have n[ew] propert[ies].

The compounds formed by chemical affinity possess new properties, and different from those of their constituent parts.

We are too little acquainted with the nature of chemical affinity, to be able to determine, *à priori*, what is to be the result of a combination between two substances. No information can be obtained what the nature of the union will be, from knowing the properties of the substance which are to be combined. It is only by experiment that the nature and properties of the new compound can be ascertained.

Unwilling to suppose, or unable to conceive, that the properties of the two substances which enter into combination, had totally disappeared in the new compound, the earlier chemists imagined that the properties of the latter were of a middle nature, consisting of the mixed properties of the composing substances. Hence the compounds of the acids and the alkalies were denominated *middle salts*, *sales medii*, from possessing the combined properties of their component substances.

But the truth of this doctrine, with regard to the nature of compound substances, has been fully disproved by the more accurate observations of modern chemists; for it is found by experiment, that the compound formed often exhibits not a single property of any of the substances of which it is composed. From two mild and insipid substances, a compound is formed which is highly acrid and corrosive; and the result of the combination of two powerfully corrosive substances, is frequently a mild and insipid compounnd.

It

(F) The explanation of this phenomenon will be given when we come to treat of heat.

finity.

It is one of the usual characteristics of chemical affinity, that there be a change in the properties of the substances which enter into combination. This change takes place in the sensible qualities of many of the compounds; and some of these, as an illustration of this law, may be mentioned.

(1.) Changes of colour. The colour of lead is a bluish white, but when combined with oxygen it assumes a bright yellow or red colour, in proportion to the quantity of oxygen. Cobalt, which is of a gray colour, becomes, when combined with oxygen, of a fine blue; and copper, which is red, exhibits, combined in the same way, a green colour.

(2.) Changes in smell. The smell of muriatic acid is highly pungent; ammonia, or the volatile alkali, is not less so; but when these two are combined, forming muriate of ammonia, or sal ammoniac, the new compound is perfectly inodorous. This last is a remarkable instance of two highly volatile and odorous substances becoming fixed in the compound, and destitute of smell, and thus exhibiting a total change of properties.

(3.) Changes in taste. 1. The taste of sulphur is nearly insipid; and oxygen, which is one of the component parts of the atmosphere, is not only innocent, but necessary for the existence of animals: but when these two enter into union, the compound formed, which is sulphuric acid, is one of the most corrosive substances. —2. Sulphuric acid, which is sour and corrosive, forms a combination with soda, which is also of a corrosive nature; the result, which is Glauber salt, or sulphate of soda, is a compound of a bitter nauseous taste, but possessing none of the corrosive properties of its component parts.

Seventh Law.

106
...e of
...ity

The force of chemical affinity is estimated by the force which is necessary to separate the substances which enter into combination.

In treating of cohesion, or the attraction of aggregation, it was stated, that the method employed by philosophers to estimate that force, was to measure the opposite force, or that which was necessary to overcome the cohesive force. Thus, the weight attached to the lower extremity of a metallic wire perpendicularly suspended, which was just sufficient to tear it asunder, is considered as the measure of its power of cohesion. But it will appear, from what follows, that this law must be adopted with considerable modification.

107
...ated
...e time
...lution;

In estimating the force of chemical affinity, various methods have been proposed by different philosophical chemists. It was thought by Wenzel, that the time which one body required to dissolve another, might be considered as the measure of the force of affinity between these two bodies; but it must appear from what has been already said, that the time of solution must depend greatly on the cohesive force of the body to be dissolved, and the nature of the compound which is formed; and, these being various, no certain measure can be obtained from this method.

According to some, the measure of the force of chemical affinity may be estimated by the difficulty of separating the substances which have entered into combination; or by taking the compound ratio of this, and the facility with which they are combined. But as no method has been invented to ascertain either the one or the other, which are the necessary previous steps in the method proposed, it is impossible, in this way, to estimate the force of chemical affinities.

Affinity.
108
by the difficulty of separation;

Observing the effects of the union and the abstraction of caloric, in the operations of chemical affinity, Lavoisier and La Place, in a memoir published in 1783, proposed this as the method of estimating the force of affinity. But it seems scarcely possible to measure the force of chemical affinity between two substances by the degree of temperature which is reqnired to overcome the force of cohesion; as this degree of temperature has no measurable proportion with the force of chemical affinity, it can afford no data for estimating this force. And this quantity being variable and unknown, a fixed term is wanting to form a scale of comparison.

109
by the affinity for caloric.

We have already mentioned, in treating of adhesion, the experiments of Dr Taylor on the adhesion of surfaces, and the experiments and conclusions of Morveau and Achard on the same subject. From these Morveau has proposed to deduce a method of estimating the force of chemical affinities. But for an account of this, we refer the reader to the first section.

110
Kirwan's method.

A different method has been proposed by Mr Kirwan, in his experiments and observations on the attractive powers of mineral acids *. He observes, that the principal end which he had "in view was, to ascertain and measure the degrees of affinity or attraction that subsist between the mineral acids and the varions bases with which they may be combined; a subject of the greatest importance, as it is upon this foundation that chemistry, considered as a science, must finally rest; and though much has been already done, and many general observations laid down on this head, yet so many exceptions have occurred, even to such of these observations as seem to have been most firmly established, that not only a variety of tables of affinity have been formed, but many very eminent chemists have been induced to doubt whether any general law whatsoever could be traced†."

* *Phil. Trans.* vol. lxxiii.

† *Ibid.* p. 34.

"The discovery of the quantity of real acid in each of the mineral acid liquors, and the proportion of real acid taken up by a given quantity of each basis at the point of saturation, led me unexpectedly to what seems to me the true method of investigating the quantity of attraction which each acid bears to the several bases to which it is capable of uniting. For it was impossible not to perceive,

1st, That the quantity of real acid necessary to saturate a given weight of each base, is inversely as the affinity of each base to such acid.

2dly, That the quantity of each base requisite to saturate a given quantity of each acid, is directly as the affinity of each acid to such base.

Thus, 100 grs. of each of the acids require for their saturation a greater quantity of fixed alkali than of calcareous earth, more of this earth than of volatile alkali, more of this alkali than of magnesia, and more of magnesia than of earth of alum: as may be seen in the following table.

Quantity of base taken up by 100 grs. of each of the three acids.

	Potash.	Soda.	Lime.	Ammonia.	Magnesia.	Alum.
	grs.	grs.	grs.	grs.	grs.	grs.
Sulphuric acid	215	165	110	90	80	75
Nitric acid	215	165	96	87	75	65
Muriatic acid	215	158	89	79	71	55

"As these numbers," Mr Kirwan observes, "agree with what common experience teaches us concerning the affinity of these acids with their respective bases, they may be considered as adequate expressions of the quantity of that affinity. Thus, the affinity of the sulphuric acid to potash, that is, the force with which they unite to each other, is to the affinity with which the same acid unites to lime, as 215 grs. to 110; and to that which the nitric acid bears to lime, as 215 to 96."

111 Objections. But to this method of Mr Kirwan, objections have been made by Morveau and Berthollet. It is stated that the essential principle, of the force of affinity being in the direct ratio to the quantity of base, is not fully established. According to the experiments of Morveau, a quantity of sulphuric acid containing 100 grs. of real acid, required for saturation 201 grs. of crystallized carbonate of potash: a quantity of nitric acid which contained 100 grs. of real acid, required 302 grs. for saturation; and a quantity of muriatic acid containing 100 grs. of real acid, required no less than 905 grs. of the same salt for saturation. From these experiments it appears, that Mr Kirwan's calculations are erroneous, or that the principle on which he has proceeded is false; for equal quantities of real acids require for saturation different quantities of potash; and besides, the quantity of base required is in the inverse ratio to the force of affinity, which is the reverse of Mr Kirwan's principle.

Mr Kirwan, however, has acknowledged the force of these objections, and has deduced the proportion of real acid in the nitric and sulphuric acids, from less exceptionable principles. His table, therefore, which expresses in numbers the strength of affinities, was considered as more correct than any previously published; but his general principle, that the quantity of base required to saturate a given quantity of real acid, is the expression of the force of affinity between the acid and the base, is a mere assumption of a peculiar language. Affinity is mutual between the combining bodies. It is incongruous to make the expression of it as applied to an acid the reverse of what it is in an alkali.

Mr Kirwan has corrected the quantity of base taken up by 100 parts of sulphuric, nitric, muriatic, and carbonic acids, as will be seen in the following table*.

* Anal. Min. Waters.

100 pts.	Potash.	Soda.	Ammonia.	Barytes.	Strontites.	Lime.	Magnesia.
Sulphuric	121.48	78.32	26.05	200.	138.	70.	57.92
Nitric	117.7	73.43	40.35	178.12	116.86	55.7	47.64
Muriatic	177.6	136.2	58.48	314.46	216.21	118.3	89.8
Carbonic	95.1	149.6		354.5	231.+	122.	50.

But in addition to the objection now stated to his theory, the force of affinity, according to the experiments and observations of Berthollet, varies in proportion to the mass of any body, and therefore no method, however accurate in other respects, will afford a certain rule for estimating the force of chemical affinity.

EIGHTH LAW.

112 Different affinities among bodies. *Bodies have different degrees of affinity for each other.*

On the different force of affinity which exists between different bodies, depend many of the most important operations in chemistry; and it is by multiplying the facts which fall under this law, that chemical science can be improved and extended.

113 Two kinds. Affinity has been divided into two kinds, *simple* affinity, and *compound* affinity; producing simple elective attractions, and double elective attractions.

114 Between two bodies. *Simple affinity.*—The first of these includes all those combinations which directly take place between two bodies, as when muriatic acid and lime are combined together. We have also a case of simple affinity, or single elective attraction, when to a solution which contains two substances, a third is added which produces the separation of one of the dissolved bodies. This takes place when potash is added to the solution of lime in muriatic acid. The potash has a stronger affinity for the muriatic acid than the lime; it therefore separates the acid from the lime, combines with it, and remains in the solution. The lime, thus separated from its combination, appears in the solid form, falls to the bottom, and is called a precipitate.

115 Precipitates. In practical chemistry precipitates are distinguished into several kinds. It is said to be a real or true precipitate, when the body which is disengaged from the combination falls to the bottom, as in the case above, where the lime fell to the bottom, after being separated from the muriatic acid. A false precipitate is when the new compound which is formed falls down, as when sulphuric acid is added to any solution of lime; for the compound being insoluble, it appears in the form of a precipitate. A precipitate is said to be pure, when the body which has been decomposed can be formed again

again from the separated constituent parts; and impure, when this cannot be effected; which is probably occasioned from the decomposition not being complete. It sometimes happens, when a body which consists of two substances is decomposed by means of third, that the disengaged substance assumes the elastic form. This is the case when muriate of ammonia is decomposed by quicklime. The muriatic acid, which is in combination with the ammonia, unites with the lime, for which it has the greater attraction; and the ammonia, set free, is instantly volatilized.

16 *Compound affinity.*—But there are substances which cannot be decomposed when a third substance is presented. The affinity of two substances A and B in combination, may be so much stronger than the affinity of a third C for either A or B, that no decomposition will take place when the body C is presented to the compound of A and B. Suppose the two substances A and B are held united with a force equal to 12, and the force of affinity between the body C and B is equal only to 8, it is obvious that no change can be effected, because the force of affinity between C and B cannot overcome the cohesive force that exists between A and B. But if a fourth body D is presented to the compound A and B, and acts with a force on the body A equal to 6, while the body C acts on B with a force equal to 8, it is evident that the combined action of these two forces will overcome the force of affinity between A and B, which was supposed to be equal to 12, because the measure of a force equal to 14 is greater than one equal to 12; and in this way the decomposition of the body A and B is effected by the united action of two other bodies, which would not have succeeded had any one been presented to it singly. From this double action, a decomposition of this kind is called a *double elective attraction*, a name given by Bergman, or a case of compound or complex affinity, as it has been proposed to be denominated by later chemists.

Bergman invented a method of exhibiting these attractions, in such diagrams as the following.

Nitrate of Potash.

Sulphate of potash.	Potash.	Nitric acid.	Nitrate of silver.
	Sulphuric acid.	Oxide of silver.	

Sulphate of silver.

In this example the substances to be decomposed are placed on the right and left sides of the diagram. These are the sulphate of potash, composed of sulphuric acid and potash on the left side; and the nitrate of silver, which consists of nitric acid and the oxide of silver. When these compounds are combined together, a decomposition is effected by the mutual affinities between the constituent parts of the compounds. Thus the sulphuric acid in combination with the potash, forms a new compound with the oxide of silver, and the nitric acid in combination with the silver, forms a new compound with the potash; because the sum of the force of affinities between the nitric acid and the potash, and the suphuric acid and the oxide of silver, is greater than the sum of the affinities between the sulphuric acid and the potash, and the nitric acid and the oxide of silver; and thus an exchange of principles takes place, and the new compounds are represented at the top and bottom of the diagram, namely the nitrate of potash and the sulphate of silver.

Mr Elliot in the year 1782 proposed, as an improvement on Bergman's method, to represent the force of these attractions by numbers. The same case, in Mr Elliot's method, is represented in the following diagram.

Nitrate of potash.

	Potash.	8	Nitric acid.	
Sulphate of potash.	9		2	Nitrate of silver.
	Sulphuric acid.	4	Oxide of silver.	

Sulphate of silver.

As it thus represented, the sulphuric acid and the potash are supposed to act with a force equal to 9; and the nitric acid and the oxide of silver attract with a force equal to 2. The affinity of the potash for the nitric acid is equal to 8; and the affinity between the sulphuric acid and the oxide of silver is equal to 4. But $9+2=11$, and $8+4=12$; consequently the sum of the affinities between the nitric acid and the potash, and the sulphuric acid and the oxide of silver, exceeds the sum of the affinities between the nitric acid and the oxide of silver, and the sulphuric acid and the potash, and thus a decomposition is effected.

But "in all decomposition," says Mr Kirwan, "we must consider, 1st, The powers which resist any decomposition, and tend to keep the bodies in their present state; and, 2dly, The powers which tend to effect a decomposition and a new union. The first I shall call quiescent affinities, and the second, divellent. 117 Two forces to be considered.

"A decomposition will always take place when the sum of the divellent affinities is greater than that of the quiescent; and, on the contrary, no decomposition will happen when the sum of the quiescent affinities is superior to, or equal to that of the divellent; all we have to do, therefore, is to compare the sums of each of these powers. Thus, if the solutions of sulphate of potash and nitrate of lime be mixed together, a double decomposition will take place." This may be illustrated by the following diagram.

Nitrate of potash.

	Potash.	215 +	Nitric acid.	
Sulphate of potash.	215 + Quiescent	Divellent affinities =	affinities 96 = 311.	Nitrate of lime.
	Sulphuric acid.	110 / 325	Lime.	

Sulphate of lime.

The

Affinity.

The affinities between the nitric acid and lime, and between the sulphuric acid and the potash, which taken together amount to 311, are the quiescent affinities. The affinities of the sulphuric acid and the lime, and of the nitric acid and the potash, are the divellent affinities which are opposed to the first. But the amount of the latter is equal to 325, that is, the combined affinities of the substances which tend to form a new combination, and thus they overcome the force of the resistance of the quiescent affinities, as 325 exceeds 311.

Another example will serve to make this decomposition by double or compound affinity still more familiar.

Muriate of potash.

	Muriatic acid.	32	Potash.	
Muriate of barytes.	36	+	9=45	Carbonate of potash.
	Barytes.	$\frac{14}{46}$	Carbonic acid.	

Carbonate of barytes.

118 This force not constant.

In this case a solution of muriate of barytes is mixed with a solution of the carbonate of potash. The affinity of the muriatic acid for the barytes, and that of the potash for the carbonic acid, are the quiescent affinities, which are opposed to any decomposing force. But, on the contrary, the affinity of the muriatic acid for the potash, and that of the barytes for the carbonic acid, are the divellent affinities. The quiescent affinities are only equal to 45, while the sum of the divellent affinities is equal to 46; the latter must therefore prevail. The former combinations are broken, and instead of muriate of barytes, and carbonate of potash, we obtain muriate of potash and carbonate of barytes, which latter is insoluble, and is therefore precipitated.

But Berthollet has shewn that the force of affinity between the same substances is not constant and uniform, but is greatly influenced by the quantity and the state of saturation. As, for instance, when two bases act in opposition on an acid, the acid divides its action in proportion to their respective masses. If there be two acids instead of one, and no separation take place, either by precipitation or crystallization, both acids will act equally on both bases, in proportion to their masses. If each of the acids be previously combined with a base, and the solutions of their salts be mixed, the sum of the reciprocal forces will be the same as before. No muriate of potash or sulphate of lime will be formed; but there will be a combination of potash, of lime, of sulphuric and muriatic acid, which will have the same degree of saturation as before the mixture. And hence it happens, that when two salts are mixed together, the mutual decomposition of which would produce combinations of very different proportions, the separation of the component parts, which should result from such decomposition, is not perceptible. No change of bases therefore takes place.

The force of cohesion causes the separation which takes place by precipitation or crystallization. Berthollet observes, that a similar effect is produced by the same cause, in the action of complex affinities. If a solution of sulphate of potash be mixed with muriate of lime, dissolved in a small quantity of water, the lime brought into contact with the sulphuric acid will be more powerfully influenced by the force of cohesion than the potash. This is therefore to be considered as an additional force to those which pre-existed, and determines the combination of the sulphuric acid with the lime, and the precipitation of the new compound.

In all decompositions effected by compound affinity, the prevailing affinity has been ascribed to those substances which have the property of precipitating, or of forming a salt which can be separated by crystallization. Thus the knowledge of the solubility of salts which may be formed in a liquid, will point out those substances which are least soluble, and therefore most apt to precipitate. To these substances chemists formerly ascribed the strongest affinity.

Lime, magnesia, strontites, and barytes, form insoluble salts with carbonic acid. When therefore any of the soluble salts of these earths are mixed with alkaline carbonates, an exchange is produced, from which result the formation and precipitation of an earthy carbonate. The compound of sulphuric acid and barytes forms an insoluble salt. When, therefore, a solution of a sulphate is mixed with that of a salt of barytes, a precipitation of sulphate of barytes, which is insoluble, will be effected. The sulphate of lime has also but little solubility, and consequently is much disposed to precipitate. Lime therefore decomposes all the soluble sulphates. But the sulphate of lime being much more soluble than the sulphate of barytes, the salts of barytes, which are more soluble than the sulphate of lime, decompose it. 11[9] Most in[so]luble com[pounds] precipitate.

There are other circumstances which tend to change the action of compound affinities. The solubility of salts, which has so much influence in this action, is varied by temperature. In estimating the result of compound affinities, therefore, the degree of temperature must be considered and taken into the account. To give an instance of this effect, nitrate of potash mixed with muriate of soda, crystallizes at a low temperature. During the evaporation the muriate of soda is separated. No change of bases will take place, because the nitrate of soda is somewhat more soluble when cold than nitrate of potash; and muriate of potash is more soluble when hot than muriate of soda. 12[0] Temperature to [be] considered.

The action of complex affinities may also be changed by the formation of a triple salt which precipitates; but if the solubility of the combination be known, the decomposition which is effected, and the resulting compounds, may also be foreseen.*

According to the theory of Berthollet, all substances in the liquid state exert a reciprocal action. In a solution of sulphate of potash and muriate of soda, these two salts are not distinct, nor do they become so, until some extraneous cause produces their separation. Sulphuric and muriatic acids, potash and soda, are contained in the liquid. To ascertain what combinations are produced by the force of crystallization, he made the following experiments. 12[1] Reciprocal action.

"*Experiment* 1.—A mixture was made of equal parts of nitrate of lime and sulphate of potash: after the separation 12[2] Force of crystallization.

* *Berthollet's Researches*, art. 1[…]

Affinity.

paration of the sulphate of lime formed in the commencement, (and of which no farther mention is to be made in the following experiments), the liquid was evaporated, and nitrate of potash and sulphate of lime were alone obtained by successive operations. Yet, after the last evaporation, some crystals of sulphate of potash were obtained: there was but a small residue of uncrystallizable liquid, in which carbonate of soda and nitrate of barytes produced precipitations; whence it appears that it consisted of a small quantity of sulphuric acid and lime, and very probably of a larger portion of nitrate of potash.

"The quantity of sulphate of lime which precipitated during this evaporation, was much greater than what could be dissolved in an equal quantity of water; whence it appears that its solubility was augmented by the action of the other substances.

"*Experiment* 2.—Two parts of sulphate of potash, and one of nitrate of lime, yielded, by the first evaporation, sulphate of potash and sulphate of lime; and by the following, nitrate of potash with the two sulphates, the proportions of which continued to diminish until the salts ceased to crystallize: only a few drops of uncrystallized liquid remained, in which no precipitate was formed on adding to it some carbonate of soda, but this effect was produced by the nitrate of barytes; whence it appears probable, that the liquid consisted of sulphate of potash, and a small proportion of nitrate of potash.

"*Experiment* 3.—Two parts of nitrate of lime, and one of sulphate of potash, yielded by the first evaporation a small quantity of sulphate of lime, and on cooling, some nitrate of potash; by the succeeding evaporations nothing but nitrate of potash was obtained. After the last, however, some crystals of sulphate of lime were perceivable on the surface of the liquid. Though the residue, which was abundant, was repeatedly put to evaporate and cool, no crystallization was effected. This uncrystallizable residue, treated with alcohol, yielded an abundant precipitate, in the solution of which in water no precipitate could be produced by nitrate of barytes; whence it appears that it contained no sulphuric acid, and that it was composed of pure nitrate of potash. What had been dissolved in the alcohol was nitrate of lime, with a small proportion of nitrate of potash: the uncrystallizable residue consisted, therefore, of nitrate of potash and nitrate of lime.

"It appears that the sulphate of lime was rendered much less soluble in this than in the preceding experiments; and that the action of nitrate of lime prevented a considerable quantity of the nitrate of potash from crystallizing.

"Sulphate of lime was necessarily formed in these three experiments, because its component parts were in contact; and the insolubility of the compound formed by them, occasioned its precipitation to a certain extent.

"In the first and second experiments, the sulphate of lime was rendered much more soluble than it naturally is, by the action of the substances in solution; but in the third experiment, its solubility was not perceptibly increased, for this reason, probably, that the nitrate of lime and nitrate of potash, which existed in the uncrystallizable liquid, had mutually saturated each other so much as to diminish their action on the sulphate of lime*.

From these considerations, he deduces the theory of uncrystallizable residues: which the succeeding observations tend to confirm.

"Saline substances exert a mutual action, which augments their solubility; as has been proved by the experiments published by my learned colleague Vauquelin. This reciprocal action varies in different salts; it was once supposed that the solubility of the nitrate of potash was not augmented by the action of earthy salts; and yet it is augmented more by them than by any others.

"There must be doubtless, in this respect, some difference arising from the nature of the salts, in the effect which they produce; but this difference is, in general, very trifling, compared to that resulting from the force of crystallization.

"*Experiment* 4.—A mixture of equal parts of nitrate and sulphate of potash, yielded by evaporation, and successively, according to their solubility, sulphate of potash and nitrate of potash, without leaving any uncrystallizable residue; but having made a similar experiment with a mixture of nitrate and sulphate of soda, each of which has but a feeble tendency to crystallize, and nearly an equal degree of solubility, there was separated by crystallization but a small portion of the sulphate of soda, the other parts of the mixture continuing in the liquid state, incapable of being crystallized by any means. Muriate of soda and sulphate of alumina, submitted to the same treatment, were perceived to become more soluble; but they were totally separated in the end by alternate evaporation and cooling.

"It appears, then, that substances which are endued with an active tendency to crystallize, though rendered more soluble than they naturally are, separate however in the order of their insolubility, without leaving any, or but very little, uncrystallizable residue.

"But when a mixture consists of salts which have but a weak tendency to crystallize, their mutual action counteracts that tendency, so that a large portion of uncrystallizable liquid remains: this effect is still more complete when the mixture contains a substance naturally uncrystallizable, as in the third experiment, in which there was an excess of nitrate of lime, the action of which excess on the nitrate of potash rendered a great part of it uncrystallizable" †.

From this it appears, Berthollet observes, that the formation of salts obtained by crystallization, depends on the proportions of the substances which act on each other: and combinations may be formed which vary according to the proportions of the substances employed, or the stage of the operation; that is, according to the proportions which continue in action, when the combinations which might take place are not endued with a force of cohesion sufficient to withdraw them from the sphere of action.

Ninth Law.

Affinity is the inverse ratio of saturation.

123 Affinity diminishes towards the point of saturation.

In most of the combinations which take place between bodies, there exists a certain determinate proportion of the quantity of the substances which form the compound. On this indeed depend the constancy and

* *Berthollet's Researches*, art. 13.

† *Ibid.*

Affinity. and permanency, both of natural and artificial compounds. It is to this uniformity and permanency that their characteristic properties are owing; for when the proportions in compound bodies vary, although the constituent parts be of the same nature, the properties of the compound are materially changed. Thus, in a case already mentioned, the different proportions of oxygen with lead, different compounds are produced; with a smaller proportion of oxygen, the resulting compound is yellow, but with a greater it is red.

124 Saturation. As there are certain limits to the proportions in which bodies combine together, beyond which they cannot pass, these are called the points of *saturation;* and when two bodies, in uniting together, have reached this point, they are said to be saturated, or the one body is said to be saturated with the other: in other words, the change has taken place, and a new compound is formed. When, for instance, common salt is dissolved in water, the water combines only with a certain proportion; and whatever quantity of salt is added beyond this proportion, it falls to the bottom undissolved. The reason of this is, that the particles of the salt are held together by their affinity for each other; that is, by the force of cohesion. Now, before any combination can be effected between the particles of the salt and the water, this force must be overcome. The force of affinity, therefore, between the water and the particles of salt, is greater than that between the particles of salt themselves, and thus they are separated and dissolve in the water: but this force of affinity between the water and the salt is limited; and when it has arrived at its utmost limit, the action between the two bodies ceases. The two forces which were opposed to each other, that is, the force of affinity between the water and the salt on the one hand, and the force of cohesion between the particles of the salt on the other, are balanced. The water in this case is said to be saturated with salt.

In a sense somewhat similar, the word *neutralization* has been employed. When to an acid there is added the solution of an alkali to a certain point, they combine together, and form a compound, in which the properties both of the acid and of the alkali totally disappear. They are then said to have neutralized each other; and hence the name of *neutral salts*, which has been given to these compounds.

in different proportions. Some bodies, it would appear, enter into combination with others, only in one determinate proportion, and some in two proportions, and these proportions are denominated their *maximum* and *minimum* of saturation; that is, the smallest and greatest proportions in which they combine with each other. There is another set of bodies which combine in any proportion between the highest and the lowest points, while a fourth set combine only in certain determinate proportions between these points.

Now, from these observations, let us endeavour to illustrate the meaning of this law, by attending to what takes place in the different combinations of bodies with each other. A smaller quantity of salt dissolved in a given quantity of water, is held in combination by a greater force of affinity, than a greater quantity; because this force is to be estimated by the affinity which exists between the salt and the water, and its mass. The nearer, therefore, it comes to the maximum or highest point of saturation, the weaker is the affinity between the water and the salt, and in approximating to this point, this force is gradually diminished.

When two bodies combine together in two different proportions, or what are called the maximum and minimum points of saturation, the force of affinity is greatest between the two bodies at the lowest point. Suppose that two bodies, A and B, can enter into combination with each other, in two different proportions. Suppose the quantity of A is =20 grs. and the first portion of B which combines with it is = 10 grs.; it is evident from this combination, that part of the force of the affinity of A is exhausted, but still it combines with another portion of B; suppose this is =5 grs. and then it has reached its highest point of saturation, or the maximum. But as the last portion of B, which combined with A, is retained in the compound by the force of affinity in A, which remained after its combination with the first portion of B, it is obvious that this force must be greatly diminished, and therefore the last portion of B will be most easily separated from its combination with A. This accordingly is found to to hold in all cases.

Tenth Law.

Between two compound bodies which are not acted on by compound affinities, decomposition may take place, if the affinity of a compound consisting of two of the principles for a third be greater than that which unites this third to one of the two first, or to the fourth principle, although, at the moment of action, the union between the two first does not exist.

12[?] Disposing affinity. This is called *disposing* or *predisposing* affinity, because no change takes place without the influence or action of a third body on some of the compounds; for it is this action which operates the formation of the compound, and the decomposition of another compound, without the formation of the first. To have a clear conception of this disposing affinity, let us suppose that there are two compounds, AB and CD; the affinity of whose constituent parts, that is, the affinity between A and C, and the affinity between B and D, is not greater than the affinity which exists between AB and CD. In this case, it is obvious that no decomposition can be effected by compound affinity, because the sum of the quiescent affinities exceeds the sum of the divellent; but if the force which tends to combine B and C together, added to that which tends to unite the compound BC to D, be greater than the force of cohesion between the compounds AB and CD, the result of this action will be a decomposition, the formation of a new compound BCD, and the separation of the first component part A.

Water is composed of two substances, which have received the names of oxygen and hydrogen. Sulphur has no direct action on water. This shows that the affinity between sulphur and any of the constituent parts of the water, is not so great as the affinity of the oxygen and hydrogen for each other; but if sulphur be united with an alkali, the water is decomposed by this combination, although there is supposed to be no affinity between the alkali and the oxygen. But the attraction of the alkali for the sulphuric acid gives rise to the formation of that acid, and causes the sulphur to combine

Light. bine with the oxygen of the water. It is now, however, since the luminous researches of Berthollet, allowed to be an absurdity, to maintain that the affinity of any body for a compound not yet existing, should be adequate to cause the formation of that compound (in this case the acid): and it is allowed, that the substance causes such a formation, by the affinity which it has for its two constituent parts (*e. g.* the oxygen and the sulphur), although such affinity may be prevented from showing itself on other occasions, by its weakness and the opposing influence of extraneous circumstances. The alkali has a real affinity for the oxygen of the water, which is exerted in the present instance, though too weak to be efficient for producing a separate binary combination of these two bodies.

126 ...w of ...d combining ...ghts, ...he atomic theory.

Eleventh Law.

Another very important law must now be added to the preceding, and it is one which has been of comparatively recent establishment.

That every combining substance has a certain relative weight, in which, or in simple multiples of which, it unites chemically with an equally fixed weight of every other.

Let us suppose, for the sake of illustration, that we have 24 simple bodies, named from the 24 letters of the alphabet: one of them has a combining weight double that of another, or two-thirds, or in proportions more minutely fractional. Suppose A to be as 10, B as 12, C as 8; then 10 grains of A combine always with exactly 12 of B, to form a definite compound. So far the doctrine had been always maintained. But, further, if there is another compound of the same bodies in another proportion, this will always be twice, three times, or some other multiple of the lowest proportion: 10 grains of A combine with 24, 36, &c. of B; with C, it combines in proportions as 10 to 8, to 16, to 24, or some multiple. Or, on the other hand, 12 grains of B or 8 of C will combine with 10, 20, 30, or some other multiple of the combining weight of A. What is of greater importance still, it is found, that if B and C also form definite compounds, they in their turn combine in proportions as 12 to 8, or the one of these numbers to a multiple of the other. This is the case in most instances. Where it is not, it is still in simple arithmetical proportions of them, as twice the combining weight of the one, with three times that of the other.

This law does not apply to that kind of chemical union which consists in the solution of a solid body in a liquid menstruum. In this case the gradations are indefinite, and the proportions necessary to saturation vary with the temperature. But it applies to the formation of all compounds in which a change takes place in the state of aggregation of the constituent parts, and in which their previous chemical agencies are prevented from appearing, and others entirely new are elicited. For example:

1. Wherever two gases unite to form a solid or a liquid, the proportions of these combining weights are observed.

2. Also, wherever a gas combines with a solid to form a new gas, which shews none of the agencies which marked the simpler gas, but others which are entirely peculiar to it. Of Light.

3. Also, wherever a gas, in combination with a solid substance, forms a definite liquid peculiar in its chemical relations, or forms a solid equally peculiar, and which resists entirely those powers by which the simple solid was readily affected.

4. Finally, Two gases may unite, and the compound formed may be a third gas, possessing a peculiar character, and exhibiting a much more extensive activity than either of the constituents in a simple state.

In these, and other analogous cases, the compound may, by various manipulations, be purified from the admixture of any portion of either of the constituents still remaining uncombined; and when this is done, the proportional weights of the combining substances are invariably observed.

This doctrine, as the expression of a general fact, was suggested by certain remarkable uniformities which occurred as the results of chemical analysis extensively compared. The minutiæ of it were investigated by subsequent experiments, by which it has been established to a great extent. In some particulars it labours under difficulties, and discordant reports, arising from the difficulty of chemical analysis. Several anomalies which appeared when the doctrine was new, have been cleared up by subsequent discoveries. If a few others remain, these only shew us that the details are not yet perfected, and that room is left for varied experiments.

For the particulars we refer to the article Atomic Theory in the Supplement of this work. That designation has been given to the doctrine, in consequence of the explanation of the facts assigned by Mr Dalton; that every simple body consists of chemical atoms, which possess in each one constant weight. These substances, in combining chemically, unite generally atom to atom, or as 1 of the one to 2, 3, 4, &c. of the other. Sometimes as 2 to 3.

This doctrine gives necessarily a new aspect to the whole of Chemistry. The combining weights are found out by accurate experiments. And these, when compared as made on the same substances in the varieties of their combination with others, agree admirably with one another. Even those which were obtained previously, approximate in a wonderful degree to those which are in conformity to the atomic theory. The other doctrines of chemistry, and the other chemical properties of different kinds of matter, may be understood without it, and advantages will be derived from the study of it as free from this doctrine, which to a beginner sometimes appears a little intricate. We therefore shall still proceed in this article, independently of that theory, except in so far as some of the facts on which it rests force themselves on our notice as in other respects of leading importance.

We now proceed, in the following chapters, to examine the properties of those bodies, the knowledge of which belongs to chemical science; the changes which take place by the action of affinity, and the new compounds which are the result of these changes; and, at the same time, to point out some of their applications, and uses.

†

Light.

Chap. II. Of LIGHT.

Light and heat, which are to be treated of in this and the succeeding chapters, are highly interesting, not only as curious subjects of speculation, but as acting a very important part in the changes which are constantly going on among natural bodies. Indeed no change happens, in which the one or the other is not either absorbed or extricated, and sometimes both are concerned.

Light, of which we are now to treat, is the principal agent in many chemical processes: and this consideration, as well as the astonishing velocity of its motions, and the properties which it has of penetrating and traversing substances with which it comes in contact, render it an object worthy of great attention.

Light is too familiar to every one to require any definition, and too simple to admit of any. It is by the light of the sun, or that which proceeds from burning bodies, that we are informed of the presence of objects; the rays of light proceeding from these bodies, and entering the eye, produce the sensation of vision. We have no certain knowledge concerning the nature of light.

127 Opinions of the nature of light.

Various conjectural theories, however, have been proposed, with regard to it. Two of these we shall only mention. According to Des Cartes, Huygens, and some other philosophers, all space is filled up with a very subtile fluid, and this fluid is agitated or put in motion by the sun, or burning bodies. This motion consists of vibrations or undulations, which, extending themselves and reaching the eye, render the bodies which have produced these motions visible.

128 An undulating fluid.

The other theory is that of Newton and his followers.

129 Material.

According to this theory, light is supposed to be a material emanation from luminous bodies; that is, a subtile fluid, consisting of peculiar particles of matter, which are constantly separating from such bodies, and, by entering the eye, excite the sensation of light, or the perception of the objects from which it proceeds, or those from which it is reflected. This theory, which has been deduced from numerous facts and observations, was established by Newton by mathematical demonstration. If then it be admitted, that light is a subtile fluid, consisting of minute particles, several consequences follow, which require explanation, with regard to the size, the velocity, and the momentum of these particles. In what follows, we shall consider light with regard to its physical properties; its chemical properties, or the effects it produces on bodies with which it enters into combination; and, lastly, the sources from which it is obtained.

Sect I. *Of the Physical Properties of Light.*

130 Velocity

1. One of the most astonishing properties of light is its velocity. It has been observed by astronomers, that the eclipses of the satellites of the planet Jupiter appear to take place sooner, when that planet is nearest to the earth, and later when Jupiter is on the opposite side of his orbit from the earth.

131 discovered.

Roemer, a Danish astronomer, in attempting to account for this apparent anomaly, proved that it was owing to the difference of time which the particles of light required, to pass through the semidiameter of Jupiter's orbit: and from this he demonstrated, that the particles of light move through one half of the diameter of the earth's orbit in about eight minutes. This discovery of Roemer has been fully confirmed by the theory proposed by Dr Bradley, to account for the aberration of the light of the fixed stars. From these data it has been computed, that light moves at the rate of 200,000 miles in a second;—a velocity of which the human mind can form no distinct conception. In comparing it with that of a cannon ball, it may be observed, that light passes through a space in about eight minutes, which a cannon ball with its ordinary velocity could not traverse in less than thirty-two years!

132 Confirmed

133 Particles very minute.

2. From the remarkable velocity of light, may be inferred the extreme minuteness of its particles. The force with which moving bodies strike, is in proportion to their masses, multiplied by their velocities. If, therefore, the one or the other, or both, be increased, the striking force is proportionally augmented; and consequently, if the particles of light were not extremely small, their excessive velocity would generate a momentum highly destructive to the existing arrangements of other matter. Were they even equal in weight to the two millionth part of a grain of sand, this impulse would not be less than that of sand shot from the mouth of a cannon.

The minuteness of the rays of light may be also demonstrated from the great facility with which they pass through transparent solid bodies. In moving through such bodies, light seems not to suffer the slightest diminution of its velocity. If there is nothing to obstruct the rays of light which proceed from a candle, it will fill the whole space within two miles around, almost instantaneously, before it has lost any sensible part of its substance.

134 Reflection.

3. When a ray of light falls on a polished substance in a perpendicular direction, it is thrown back in the same direction; but when a ray of light falls on the same body obliquely, it returns from the surface on the opposite side of a perpendicular line drawn from the point on which the ray falls, and at an equal distance from that perpendicular. The angle which the ray of light forms with the perpendicular as it falls, is equal to the angle which it forms with the same line, when it is thrown back. The first angle is called the *angle of incidence*, and the second the *angle of reflection*. Hence the optical law, that the angle of incidence is equal to the angle of reflexion. When the rays of light fall obliquely on polished surfaces, they are reflected before they actually touch these surfaces, which is supposed to be owing to a repulsion between the particles of light and the particles of the polished body. But when rays of light fall obliquely on a transparent substance, as a plate of glass, they pass through to the other side, and then return to the same surface, and are reflected.

135 Inflection.

4. When a ray of light is admitted into a dark room, through a small hole, it forms a luminous spot on any object opposite to that from which the light proceeds; and if the blades of two knives are placed on opposite sides of the hole, having their planes parallel to the plane of the window shutter or pasteboard through which the ray passes, when the edges of the knives

knives are brought near each other, the rays of light are drawn from their former direction towards the edges of the knives, and the luminous spot appears enlarged. This is called the *inflection* of light. A similar effect is produced by nearly shutting the eyes, and looking at a candle. The rays of light appear to proceed from it in various directions: for the light, in passing through the eye-lashes, is inflected, and is divided into separate beams, diverging from the luminous object.

136 Refraction. 5. A ray of light passing from one medium to another, in a line perpendicular to the surface by which they are separated, moves on in the same direction; as, for instance, when light passes from air to water, or from water into air. But if a ray of light passes in an oblique direction from one medium to another, it is bent from its former course, and then moves on in a new direction: this is called the *refraction* of light. A straight rod, which is introduced obliquely into a vessel of water, appears bent at the place where it touches the surface of the water. This is owing to the refraction of the rays of light passing from the rarer medium of the air to the denser medium of the water.

When the light passes into a medium of greater density, as for instance from air into water, it is refracted or bent towards the perpendicular; but when it passes from a denser into a rarer medium, as from water into air, it is refracted from the perpendicular. The measure of the quantity of this refraction is nearly in proportion to the density of the medium: with this exception, however, that if the medium be a combustible substance, the refractive power is then found to be greater. It was from the observation of this law of the refraction of light, that the conjecture which was thrown out by Newton, of the combustible nature of water and the diamond, which has been verified by the discoveries of modern chemistry, occurred to the mind of that sagacious philopher.

137 Spectrum. 6. When a ray of light is admitted through a small hole, and received on a white surface, it forms a luminous spot. If a dense transparent body be interposed, the light will be refracted, in proportion to the density of the medium; but if a triangular glass prism be interposed, the light is not merely refracted, but it is divided. The ray of light no longer forms a luminous spot, but has assumed an oblong shape, terminating in semicircular arches, and exhibiting different colours, generally reckoned seven in number. This image is called the spectrum, and, from being produced by the prism, the *prismatic spectrum*. These different coloured rays appearing in different places of the spectrum,
138 Seven colours. shew that their refractive power is different. Those which are nearest the middle are the least refracted, and those which are the most distant, the greatest. The order of the seven rays of the spectrum is the following: RED, ORANGE, YELLOW, GREEN, BLUE, INDIGO, VIOLET. The red, which is at one end of the spectrum, is the least, and the violet, which is at the other end, is the most refracted.

Sir Isaac Newton found that, if the whole spectrum was divided into 360 parts, the proportional space occupied by each of the colours would be the following.

Red,	45 parts.
Orange,	27
Yellow,	48 parts
Green,	60
Blue,	60
Indigo,	40
Violet,	80

These different coloured rays are not subject to farther division. No change is effected upon any of them by being farther refracted or reflected; and, as they differ in refrangibility, so also do they differ in the power of inflection and reflection. The violet rays are found to be the most reflexible and inflexible, and the red the least. 139 Not farther divisible.

7. Light, it is well known, seems to suffer no interruption in passing through some bodies; such are glass or water: but it is interrupted in its passage through other bodies, as a piece of wood or stone. The first set of bodies are called *transparent*, and the other *opaque*. The density of water or of glass is greater than that of a piece of wood. It cannot therefore be owing to the density of the later, or the closeness of the particles which compose it, that the transmission of light is prevented. In the explanation which has been given by Newton, it is supposed that the particles which compose transparent bodies are of equal density, and are uniformly arranged; but in opaque bodies he supposes the particles to be of unequal density, or not uniformly arranged. From the uniform arrangement and equal density which, according to this explanation, are supposed to exist in transparent bodies, the light passing through them moves in a straight line, because it is equally attracted by the particles of the body. But in the latter (the opaque bodies) the attraction between light and the particles of the body is unequal; its direction is constantly changing, till at last it is entirely interrupted. 140 Transparency. 141 Opacity.

8. Dr Herschel, who has made some interesting discoveries concerning light and heat, found that the illuminating power of the different rays was different. From the observations which he made on this subject, he says, that "with respect to the illuminating power assigned to each colour, we may conclude, that the red-making rays are very far from having it in any eminent degree. The orange possesses more of it than the red, and the yellow rays illuminate objects still more perfectly. The maximum of illumination lies in the brightest yellow or palest green. The green itself is nearly equally bright with the yellow; but from the full deep green the illuminating power decreases very sensibly; that of the blue is nearly upon a par with that of the red: the indigo has much less than the blue; and the violet is very deficient *." 142 Illuminating power.

* Philos. Trans. vol. xc. p. 26.

SECT. II. *Of the* CHEMICAL PROPERTIES *of* LIGHT.

1. From the properties of light now detailed, it appears that it is subject to the universal law of attraction, as well as other bodies; but it is also found to enter into chemical combination with many substances. These substances, it has been discovered by experiment, after being for some time exposed to the light, and carried into a dark place, appear luminous. It is found, however that this property is lost when they are kept in the dark, and they do not recover it till after they have been again exposed to the 143 Light enters bodies.

Light.

the light. Some substances possess this property in a greater degree than others. One which was discovered by Mr Canton, who made a number of experiments on this phosphorescent light, as it has been called, is prepared by the following process. He took some oyster-shells and calcined them, after which they were reduced to powder, and the purest part of them was put through a fine sieve. Three parts of this powder were mixed together with one part of the flower of sulphur; the mixture was put into a crucible, and firmly pressed to the bottom, which was then exposed for an hour to a red heat. It was then removed from the fire, and when it cooled, the purest parts of the mixture were scraped off, and put up in a well-closed phial. This is called Canton's pyrophorus. When this is exposed to the light for a short time, it becomes so luminous that objects may be distinctly perceived in the dark, by the light which it emits. It loses the property, however, by being kept in the dark, but recovers it again when it is exposed to the light. And, after being kept in the dark for some time, the light from the pyrophorus becomes feeble, or is nearly extinct, but it may be revived or increased by plunging the phial into hot water. But, if the whole of the light has been separated previous to the application of heat, no farther application can cause it to emit light, till it has been exposed to a luminous body. Thus it appears that light enters into combination with other bodies, and that it afterwards leaves them without having undergone any perceptible change.

144 Canton's pyrophorus.

145 From which light is again emitted.

2. If a quantity of purple-coloured fluate of lime (Derbyshire spar) be reduced to coarse powder, and exposed to heat in a dark place, it emits a great quantity of coloured light; but when this light which has been in combination with the spar is once expelled, it does not recover its property of shining in the dark, as in the case of Canton's pyrophorus.

146 Supposed to be slow combustion.

It has been supposed by some, that the light emitted by these substances is the consequence of slow combustion; but many of the substances which have this property are not combustible, and none of the changes which take place during that process have been observed. In some cases it would appear that the light which is given out is different from that to which they were exposed, and which they must have absorbed. In some of the pyrophori, the blue rays were observed to have a greater effect, and the light which was emitted was of a red colour,

147 Emitted by animal matters, &c.

3. Light is well known to be given out by a number of animal and vegetable matters, when the process of putrefaction commences. In this case it seems to have constituted one of their component parts. This particularly happens to fish of different kinds, as the herring and the mackerel; and is supposed to be the cause of the phosphorescent light of the sea, which appears when the water is broken and agitated. These phenomena were observed by Mr Boyle and Dr Beale, both in the flesh of quadrupeds and fishes, and earlier by Fabricius ab Aquapendente and Bartholin in the flesh of quadrupeds. Experiments were made on the same subject by Mr Canton, whom we have already mentioned, and more lately by Dr Hulme. The latter concludes from his experiments, that this light is a constituent principle of marine fishes; that it is incorporated with their whole substance, making a part of it, in the same manner as any other constituent principle; that when this spontaneous light is extinguished by some substances, it may be again revived; that the quantity of light emitted is not in proportion to the degree of putrefaction, but the reverse.

148 A constituent principle.

For the sake of those who may wish to repeat these experiments, we shall detail the following made on the herring and mackerel, in the words of the author.

The Flesh of Herring.

149 Dr Hulme's experiments.

(1.) "A fresh herring was divided longitudinally by a knife, into two parts. Then about four drams of it, being cut across, were put into a solution, composed of two drams of Epsom salt, and two ounces of cold spring water drawn up by the pump. The liquid was contained in a wide-mouthed three-ounce phial, which was placed in the laboratory. Upon carefully examining the liquid on the second evening after the process was begun, I could plainly perceive a lucid ring (for the phial was round) floating at the top of the liquid, the part below it being dark; but, on shaking the phial, the whole at once became beautifully luminous, and continued in that state. On the third evening, the light had again risen to the top; but the lucid ring appeared less vivid, and, on shaking the phial as before, the liquid was not so luminous as on the preceding night.

(2.) The same experiment was repeated. On the second night, the liquid, being agitated, was very luminous; on the third, not so lucid; and on the fourth the light was extinguished.

(3.) With sea salt half a dram and two ounces of water. On the second night, the liquid, when agitated, was dark; on the third, lucid; on the fourth, very luminous; on the fifth, it began to lose light; on the sixth, it continued to decrease; and on the seventh, it was quite gone. Neither the liquid nor the herring had contracted any putrid smell.

(4.) With sea water two ounces. On the second night, dark; on the third, fourth, and fifth, luminous; on the sixth, nearly extinct; and on the seventh, totally. The piece of herring, when taken out and examined, was remarkably sweet.

Roe of Herring.

(5.) About four drams, with Epsom salt two drams, and water two ounces. On the second night, the liquid was pretty luminous; on the third and fourth, still luminous; and on the fifth, its light was extinct.

(6.) With Glauber's salt or vitriolated natron, two drams to two ounces of water. On the second night, when the phial was shaken, as usual in all these experiments, the liquid was pretty luminous; on the third, less so; and on the fourth the light was scarcely visible.

(7.) With sea water two ounces. On the second night dark; on the third, the liquid was moderately luminous; on the fourth and fifth, it had extracted much light; and on the seventh it was still shining. After this process, both the roe and the sea water remained perfectly sweet.

The Flesh of Mackerel.

(8.) With Epsom salt two drams, and water two ounces. On the second night, the liquid was finely illuminated;

luminated; on the third, a similar appearance; on the fourth, a diminution of light; on the fifth, it continued lucid in a small degree; and on the sixth the light was extinguished.

Roe of Mackerel.

(9.) With Epsom salt two drams, and water two ounces. On the second night, the liquid, when agitated, was exceedingly bright; on the third, the same; and on the fourth and fifth, still lucid†.

Dr Hulme found that some substances have the power of extinguishing this light. It was quickly extinguished when mixed with water alone, with water impregnated with lime, carbonic acid gas, or sulphurated hydrogen gas; by fermented liquors and ardent spirits; by the acids, both concentrated and diluted; by the alkalies when dissolved in water; by many of the neutral salts, as the solutions of common salt, Epsom salt, and sal ammoniac. It was also extinguished by infusions of chamomile flowers, of long pepper, and of camphor, made with boiling hot water, but not used till quite cool.

When the substances emitting this light were placed in a freezing medium, the light was in a short time quite extinguished; but when exposed to a moderate degree of temperature, it was revived. A moderate degree of heat increased this light, but it was extinguished by a high temperature, and no luminous appearance could again be discovered.

4. When all the rays of light are reflected from any body, that body is said to be white; when all the rays are absorbed, the body which absorbs them is said to be black: but experience informs us, that different bodies absorb and reflect different rays. Thus, if a body absorb all the rays excepting the yellow, that body is said to be of a yellow colour; or if a body reflect the red rays, while the others are absorbed, it is said to be red. The colour of the body is characterized by the colour of the ray which is reflected.

5. One of the most singular effects which is observed in the combination of light with bodies, is its power of reducing the oxides of the metals. Some of these, as for instance, the red oxide of lead, when exposed to the light of the sun, lose part of their weight. The oxide of gold may be reduced in the same way, the white salts of silver become black, and the oxide is reduced; and when that process is going on, oxygen gas is emitted, which, it would appear, has been separated by the action of light. Some of the rays are found to have a greater effect than others. Scheele, who made a set of experiments to ascertain the difference of effect of the different coloured rays in blackening the muriate of silver, discovered that the violet ray was the most powerful in reducing the oxide of silver.

Light.

152 Peculiar rays.

It was formerly the general opinion, that the colorific rays of light were the cause of the reduction of the oxides of the metals; but the experiments and observations of Messrs Bockman and Ritter in Germany, and of Dr Wollaston in England, prove that the muriate of silver is more strongly and rapidly darkened by rays of the sun which have been more refracted than the violet rays: for it appeared that the muriate was affected in a space lying beyond the violet light. These rays, therefore, have not the property of giving light, nor do they produce any sensible degree of heat: in fact, it appears that there are three different sets of rays; namely, rays which illuminate, rays which warm without giving any light (which will be mentioned in the next chapter), and rays which produce a chemical action on bodies, but which give neither light or heat. From the consideration of these curious and interesting experiments, it has been very naturally supposed, that the chemical actions dependent on solar light are owing to the invisible rays which are refracted beyond the violet rays; and that the colorific rays have no share in these actions: for it has been observed, that the effect of the different colours increases with their refrangibility; the whole therefore is owing to the invisible rays, which increase in quantity as they approach to the violet ray, and are in greatest quantity at a certain distance beyond it.

153 Light absorbed by plants.

6. The absorption of light by plants produces another remarkable effect. It has been long known, that the green colour of the leaves of plants is produced by the light of the sun. Experiments were first made to ascertain this fact by M. Dufay and some others of the French academicians. The subject has been farther prosecuted and extended by Senebier of Geneva. When seeds are sown in a dark place, they vegetate, and the plant grows with considerable luxuriance; but it never has any green colour as long as the light is excluded; the leaves continue white; and this happens although air be freely admitted. When the plant in this state is exposed to the light, the green colour begins to appear, and the plant assumes its ordinary habit. While the plant remains white, it also contains but a small quantity of combustible matter, and has but little taste. When it reassumes the green colour after its exposure to the light, it acquires its natural taste, and the ordinary quantity of combustible matter. It is upon this principle that the art of blanching celery and other garden plants depends; by heaping up the earth about the stems, we exclude the light, and thus they are deprived of any pungent taste, and become white and tender." (K).

SECT.

(K) This is remarkably illustrated by the following observations of Professor Robison. "Having occasion, in autumn 1774, to go down and inspect a drain in a coalwork, where an embankment had been made to keep off a lateral run of water, and, crawling along, I laid my hand on a very luxuriant plant, having a copious, deep-indented, white foliage, quite unknown to me. I inquired of the colliers what it was. None of them could tell me. It being curious, I made a sod be carried up to the daylight, to learn from the workmen what sort of a plant it was. But nobody had ever seen any like it. A few days after, looking at the sod, as it lay at the mouth of the pit, I observed that the plant had languished and died, for want of water, as I imagined. But looking at it more attentively, I observed that a new vegetation was beginning, with little sproutings from the same stem, and that this new growth was of a green colour. This instantly brought to my recollection the curious

Light.

Sect. III. *Of the Sources of Light.*

154 The sun. 1. The principal source of light is the sun. It has been a question of more curiosity than utility, what is the cause of the sun constantly emitting light, and what are the means of repairing the waste? By calculations it is supposed, that there ought to issue from one square foot of the sun's surface in one second, $\frac{1}{400000}$th part of a grain of matter, to supply the consumption of light; that is, at the rate of little more than two grains a-day, or about 4,752,000 grains, or 670lb. in 6000 years, which would have shortened the sun's diameter about 19 feet, if it was formed of matter of the density of water only *.

* *Priestley's Optics*, p. 389.

But at the time this calculation was made, the discoveries of Herschel, of the constitution of the sun, were not known. The body of the sun, according to the observations of this philosopher, is not luminous, but opaque; the light which was supposed to come from his surface, proceeds from a luminous atmosphere which surrounds that body; and there are probably some means by which the waste that is constantly going on is repaired. The light which comes from the stars is of the same nature with that of the sun.

155 Combustion. 2. Another source of light is the burning of bodies. In all cases of burning, light is emitted. This light, therefore, must have been in combination with some of the substances which are employed in these processes.

156 Heat. 3. But when bodies, without undergoing the process of combustion, are heated to a certain temperature, they emit light: and it would appear, from experiments which have been made upon the subject, that all bodies which are not decomposed before they arrive at the proper temperature, begin to give out light, exactly at the same degree of heat. Iron heated to 635°, according to Sir Isaac Newton's experiments, becomes visible in the dark; at 752° it shines brightly; and becomes luminous in the twilight at 884°. The temperature is above 1000° when it shines in broad day light. A red heat, according to the experiments of others, commences at the temperature of 800°, and when a body reaches the proper degree of heat, it appears luminous, independent of the air. Mr T. Wedgwood, who made a number of experiments on this subject, found that a piece of iron wire became red hot when immersed in melted glass. Air, therefore, is not necessary to the shining of ignited bodies.

It was also ascertained by Mr Wedgwood, that a piece of red-hot metal continues to shine for some time after it has been removed from the fire, which proves that constant accessions of light or heat are not necessary for the shining of ignited bodies. But if the red-hot metal be strongly blown upon, it instantly ceases to shine, the temperature being now diminished †.

† *Philos. Trans.* vol. lxx. p. 279.

157 Gases not luminous. From the experiments of Mr Wedgwood, it appears that the gases do not become luminous, even at a higher temperature. He took an earthen-ware pipe of a zig-zag form, and placed it in a crucible filled up with sand. The ends of the pipe were left uncovered. To one end was attached a pair of bellows, and to the other a globular vessel with a lateral bent pipe, to let out air, but exclude the external light, and having a neck in which was inserted a circular plate of glass. The crucible, with the sand and the part of the pipe contained in it, was heated to redness. The eye was fixed in the neck of the vessel, which was then observed to be perfectly dark within. A stream of air was then directed through the tube from the bellows, but this air which passed through the red-hot tube was not luminous. A small strip of gold was then fixed into the orifice of the tube opposite to the eye, and after two or three blasts, it became faintly red; which shows, that though the air was not luminous, it was equal in temperature to what is called red heat. Dr Darwin made an experiment of the same kind, and with a similar result. The heated air was altogether invisible; but when a bit of gold was introduced, it acquired a bright glow in a few seconds *.

* *Philos. Trans.* vol. lxx. p. 271.

158 Attrition and percussion. 4. Light is also emitted by attrition and percussion. In the experiments which were made by Mr Wedgwood, on the attrition of bodies, he found that different coloured rays were emitted; sometimes it was a pure white light, as from the diamond; sometimes of a faint red, as from blackish gun flint; and sometimes of a deep red, as from unglazed white biscuit earthen ware. But this effect, produced by attrition, may perhaps be considered as the same with that of percussion. It

---

curious observations of M. Dufay; and I caused the sod to be set in the ground and carefully watered. I was the more incited to this, because I thought that my fingers had contracted a sensible aromatic smell by handling the plant at this time. After about a week, this root set out several stems and leaves of common tansy. The workmen now recollected that the sods had been taken from an old cottage garden hard by, where a great deal of tansy was still growing among the grass. I now sent down for more of the same stuff, and several sods were brought up, having the same luxuriant white foliage. This, when bruised between the fingers, gave no aromatic smell whatever. All these plants withered and died down, though carefully watered, and, in each, there sprouted from the same stocks fresh stems, and a copious foliage, and produced, among others, common tansy, fully impregnated with the ordinary juices of that plant, and of a full green colour. I have repeated the same experiment with great care on lovage (*levisticum vulgare*), mint, and caraways. All these plants throve very well below, in the dark, but with a blanched foliage, which did not spread upwards, but lay flat on the ground; in all of them there was no resemblance of shape to the ordinary foliage of the plant; all of them died down when brought into daylight; and the stocks then produced the proper plants in their usual dress, and having all their distinguishing smells.

From such experiments, I thought myself entitled to say that the sun's rays not only produced the green fæcula of plants, but also the distinguishing juices, and particularly the essential oils. The improvements which have been made in chemical science since that time, have, I think, fully confirmed my conjecture." *Black's Lect.* i. 533.

It is a familiar circumstance, that sparks of light are emitted, when two hard bodies, as, for instance, two quartz stones, are smartly struck against each other; it appears that light is emitted, or sparks given out, when these bodies are treated by percussion or attrition, even under water; and they seem equally luminous in atmospheric air, oxygen gas, carbonic acid, or hydrogen gases. The emission of this light is accompanied with a peculiar smell, which varies in different bodies. The smell appears to be strongest where the friction is greatest; it has no dependence on the light produced by attrition, because it is often very strong when no light is emitted. Rock crystal, quartz, and other hard bodies, also emit this smell under water *.

When flint and steel are struck smartly together, a spark is produced which will communicate fire to combustible substances. This spark has been found to be a particle of the iron which is driven off, and which catches fire as it passes through the air. It is to be considered as a case of combustion, and quite different from what happens when two stones are rubbed or struck against each other.

The matter driven off, when stones of quartz are struck against each other, consists of small, black, friable bodies, which leave a black stain when rubbed on paper, and, when examined with a magnifying glass, have the appearance of being fused. The light is produced, in these cases, by the substances struck together having been red hot. Some have supposed that they are a combination with oxygen; while others, who have probably examined them more accurately, assert that they are pieces of the quartz surrounded with a quantity of black powder; and having been raised to a very high temperature, set fire, in their passage through the air, to the combustible bodies that are floating in it.

Chap. III. Of CALORIC.

59 THE word *heat* in common language has two different meanings. When we say that we feel heat, we mean the sensation of heat excited in the body; but when we say that the fire or a stone is hot, it means that the power of exciting the sensation of heat in us, exists in the stone or fire. The one is the cause, and the other the effect. Thus the word *heat* is generally employed to express both the sensation and the cause of that sensation. To prevent any ambiguity in the use of terms, the word *caloric* has been adopted in the new chemical nomenclature, to signify that state or condition of matter by which it excites in us the sensation of heat; and in this sense it is now to be employed.

The nature and effect of caloric are highly interesting, as curious subjects of speculation; and the knowledge of them is of the utmost importance in the study of chemical phenomena, because no change takes place, no decomposition is effected, and no new compound is formed, without the agency of caloric.

Sect. I. *Of the Nature and Properties of Caloric.*

60 Two opinions have been maintained by philosophers concerning the nature of caloric. According to one, it is supposed to be a peculiar subtile fluid, of a highly elastic and penetrating nature, which is universally diffused. According to the other opinion, it depends on a peculiar tremor or vibration existing among the particles of heated bodies. Caloric.

Among the first who seem to have adopted the latter opinion, was the celebrated Bacon. In his treatise, *De forma calidi*, which he proposed as a model of scientific investigation, he enumerates all the facts which were then known concerning heat; and after a cautious consideration of these facts, concludes, that heat is motion. The facts on which he founded this opinion were derived from some of the most familiar methods by which heat is produced in bodies. A blacksmith can make a rod of iron red hot by striking it smartly with a hammer; the heavy parts of machinery, by friction upon each other, and the axles of the wheels of carriages, by being heavily loaded, sometimes take fire. A fire may be kindled by the friction of two pieces of dry wood; and the branches of trees strongly rubbed against each other by the violence of a storm, have set fire to thick forests. From the observation and consideration of these facts, this eminent philosopher was led to conclude, that heat is the effect of mechanical impulse. Since the time of Bacon, this theory has had many followers, and even at the present day it is maintained by some philosophers. 161 Bacon's, 162 That heat is motion.

But the theory which supposes caloric to be a distinct material substance, is now more generally adopted. It was first supposed, by those who favoured this theory, that this peculiar matter was chiefly characterized by the great elasticity, or repulsive power, of the particles among each other; but, besides this property, Dr Cleghorn supposed that it possessed another, namely, that its particles are at the same time attracted by other kinds of matter, with different degrees of force. But whatever opinion may be formed of the nature of caloric, after we have investigated its properties and effects, we shall probably find, that the phenomena which it exhibits will be easier understood, and more satisfactorily accounted for, on the supposition that it is a distinct substance. 163 A distinct substance. 164 Is attracted.

1. The rays of light and caloric accompany each other as they proceed from the sun, or from burning bodies. It is therefore supposed that they move with the same degree of velocity. If this be the case, the velocity of the rays of caloric must be 200,000 miles in a second. An experiment made by Mr Pictet proves their great velocity. Two concave mirrors, the one of tin, and the other of gilt plaster, 18 inches in diameter, were placed at the distance of 69 feet from each other. A thermometer was placed in the focus of the latter, and a heated bullet of iron in the former. When the bullet was placed in the focus, a thick screen, which was a few inches from the face of the metallic mirror, was removed. The thermometer instantly rose, so that the time which caloric requires to move through the space of 69 feet, cannot be estimated. And indeed, if caloric, as is most probable, moves with the velocity of light, the time that it passes the distance of 69 feet, or even 69,000 feet, is by far too minute to be measured by our instruments; so that no conclusion whatever with regard to the measurement of its velocity, can be drawn from such an experiment. 165 Velocity.

2. From the extreme velocity of caloric, and from its being equal to that of light, it is concluded that its particles are equally minute. From the accumulation of 166 Minute particles.

Caloric. of caloric in bodies, and particularly from one striking effect which this accumulation produces, namely, expansion, it was natural to suppose that bodies having received this addition, acquired an increase of weight. Experiments have therefore been made to ascertain this effect. Boerhaave weighed a mass of iron of 5lb. weight, while red hot, and afterwards repeated the same experiment with other metals, but found no variation, either in the hot or cold bodies, but what he could account for from the errors of the balance.

167 Experiments to ascertain the weight of caloric.

Muschenbroek supposed that heat is ponderous, or produced by a ponderous substance; and Buffon thought he had proved, by his own experiments, that a body is heavier when it is hot than when it is cold; but when similar experiments were repeated, particularly by Dr Roebuck and Mr Whitehurst, with very nice and delicate balances, the bodies which were weighed appeared heavier cold than when they were hot. This seems to be owing to the rarefaction of the air surrounding that scale in which the heated body is placed; the buoyancy of which favours an ascending motion in the scale. From more recent experiments, and particularly one made by Dr Fordyce, it appeared that bodies become heavier, but in a very small degree only, not by the increase, but by the diminution of temperature. When the whole quantity of 1700 grs. of water was frozen, it was found to be, when carefully weighed, $\frac{3}{10}$ths of a grain heavier than it had been when fluid. At this time the thermometer applied to the vessel which contained the frozen water, stood at 10°; but when it was allowed to remain till the thermometer rose to 32°, it weighed only $\frac{2}{10}$ths of a grain more than when fluid, and at the same temperature.

168 unsuccessful

That the addition of caloric to bodies produces no sensible change on their weight, seems to be placed beyond a doubt by the accurate experiments of Lavoisier, which were made with a view of ascertaining whether the weight of bodies is altered by heating or cooling them; but he found no difference.

In the year 1787, Count Rumford repeated the experiment of Dr Fordyce with the greatest care; and varying it in every possible way to avoid error, the results led him to conclude, that there is no sensible difference in the weight of bodies, either by the addition or abstraction of caloric.

169 Repulsion.

3. Caloric agrees with light in another of its peculiar properties; this is, its *repulsive* power, or the tendency of its particles to separate from each other. The particles of caloric, therefore, can never be supposed to cohere.

170 Reflection.

4. It is found that the rays of caloric have, like light, the property of being reflected by polished surfaces. Scheele discovered, that the angle of reflection of the rays of caloric is equal to the angle of incidence. This has been more fully established by Dr Herschel. Some very interesting experiments were made by Professor Pictet of Geneva, which proved the same thing. These experiments were conducted in the following manner. Two concave mirrors of tin, of nine inches focus, were placed at the distance of twelve feet two inches from each other. In the focus of the one was placed the bulb of a thermometer, and in that of the other a ball of iron two inches in diameter, which was heated, but not so as to be visible in the dark. In the space of six minutes the thermometer rose 22°. A similar effect was produced by substituting a lighted candle in place of the ball of iron. Conceiving that both the light and heat acted in the last experiment, he interposed between the two mirrors a plate of glass, with the view of separating the rays of light from those of caloric. The rays of caloric were thus interrupted, but the rays of light were not perceptibly diminished. In nine minutes the thermometer sunk 14°; and in seven minutes after the glass was removed, it rose about 12°. He therefore justly concluded, that the caloric reflected by the mirror, was the cause of the rise of the thermometer. He made another experiment, substituting boiling water in a glass vessel in place of the iron ball; and when the apparatus was adjusted, and a screen of silk which had been placed between the two mirrors removed, the thermometer rose 3°; namely, from 47° to 50°.

The experiments were varied by removing the tin mirrors to the distance of 90 inches from each other. The glass vessel, with boiling water, was placed in one focus, and a sensible thermometer in the other. In the middle space between the mirrors, was a common glass mirror, suspended so that either side could be turned towards the glass vessel. When the polished side of this mirror was turned towards the glass vessel, the thermometer rose only $\frac{5}{10}$ths of a degree; but when the other side, which was darkened, was turned towards the glass vessel, the thermometer rose 3°.5. And in another experiment, performed in the same way, the thermometer rose 3° when the polished side of the mirror was turned to the glass vessel, and 9° when the other side was turned. These experiments shew clearly, that the rays of caloric are reflected from polished surfaces, as well as the rays of light.

171 Refract

5. Transparent bodies have the power of refracting the rays of caloric, as well as those of light. They differ also in their refrangibility. So far as experiment goes, the most of the rays of caloric are less refrangible than the red rays of light. The experiments of Dr Herschel shew, that the rays of caloric, from hot or burning bodies, as hot iron, hot water, fires and candles, are refrangible, as well as the rays of caloric which are emitted by the sun. Whether all transparent bodies have the power of transmitting these rays, or what is the difference in the refractive power of these bodies, is not yet known.

172 Three of rays,

6. The light which proceeds from the sun seems to be composed of three distinct substances. Scheele discovered, that a glass mirror held before the fire, reflected the rays of light, but not the rays of caloric: but when a metallic mirror was placed in the same situation, both heat and light were reflected. The mirror of glass became hot in a short time, but no change of temperature took place on the metallic mirror. This experiment shews that the glass mirror absorbed the rays of caloric, and reflected those of light; while the metallic mirror, suffering no change of temperature, reflected both.

173 colour and he ing.

And if a plate of glass be held before a burning body, the rays of light are not sensibly interrupted, but the rays of caloric are intercepted; for no sensible heat is observed on the opposite side of the glass; but when the glass has reached a proper degree of of temperature, the rays of caloric are transmitted with the same facility as those of light. And thus the rays of light and caloric may be separated.

But the curious experiments of Dr Herschel have clearly proved, that certain invisible rays which are emitted by the sun, are possessed of the greatest heating power. In these experiments, the different coloured rays were thrown on the bulb of a very delicate thermometer, and their heating power was observed. The heating power of the violet, green, and red rays, was found to be to each other as the following numbers:

Violet	16.
Green	22.4
Red	55.

The heating power of the most refrangible rays was least, and this power increases as the refrangibility diminishes. The red ray, therefore, has the greatest heating power, and the violet, which is the most refrangible, the least. The illuminating power, it has been already observed, is greatest in the middle of the spectrum, and diminishes towards both extremities; but the heating power, which is least at the violet end, increases from that to the red extremity: and when the thermometer was placed beyond the limit of the red ray, it rose still higher than in the red ray, which has the greatest heating power in the spectrum. The heating power of these invisible rays was greatest at the distance of $\frac{1}{2}$ inch beyond the red ray, but it was sensible at the distance of $1\frac{1}{2}$ inch.

Dr Herschel's experiments have been varied, and still farther confirmed; by a set of experiments by Sir H. Englefield, the results of which were the following:

Therm. in the blue ray rose	in 3′	from 55° to 56°
in the green	in 3′	from 54° to 58°
in the yellow	in 3′	from 56° to 62°
in the full red	in $2\frac{1}{2}$′	from 56° to 72°
in confines of the red	in $2\frac{1}{2}$′	from 58° to $73\frac{1}{2}$°
quite out of visible light	in $2\frac{1}{2}$′	from 61° to 79°

The thermometer used in these experiments had its bulb blackened with Indian ink.

In the following experiments, three thermometers were employed; one had a naked ball, another was whitened, and the third was blackened. They were exposed to the sun's rays till they became stationary, when the thermometer with the

Naked ball stood at	$58\frac{1}{2}$°
Whitened ball	$58\frac{1}{2}$°
Blackened ball	63°

In the full red ray	the blackened thermom. rose	in 3′ from 58° to 61°
	whitened - - -	in 3′ from 55° to 58°
In quite dark -	blackened thermom. -	in 3′ from 59° to 64°
	whitened - - -	in 3′ from 58° to $58\frac{1}{2}$°
In confines of the red -	black thermom. - -	in 3′ from 59° to 71°
	white - - -	in 3′ from $57\frac{1}{2}$° to $60\frac{1}{2}$°

In other experiments, which were made afterwards, the results were,

In the full red ray	the black therm. rose	in 3′ from 66° to 82°
	white - - -	in 3′ from 66° to $69\frac{1}{2}$°
In quite dark, $\frac{1}{2}$ inch out of the red, the black thermom. rose -	- - - -	in 3′ from 70° to 84°

In this last experiment, when the thermometer was carried into the faint red light, it sunk quickly; and rose again as quickly, when carried into the dark focus; but when carried into the dark on the other side of the red light, it sunk very rapidly, and did not appear to receive any heat at all †.

Thus it appears that the rays of caloric, and the rays of light are different. These experiments clearly show, that there are rays which produce heat, but give no light, and rays which give light but produce no heat. It was formerly mentioned, that there is another set of rays which give neither light nor heat, but produce a remarkable effect in reducing the metallic oxides and salts. The light which is emitted from the sun then consists of three distinct sets of rays, which have been fully recognized by their different degrees of refrangibility and their different effects. The heating rays are in the smallest degree refrangible; the rays which have the greatest effect on the metallic oxides are the most refrangible, and the coloured rays are in an intermediate degree. The invisible rays beyond the red extremity of the spectrum, which are least refracted, have the greatest heating power; the invisible rays beyond the violet end, which are most refracted, have the greatest power in reducing the metallic salts or oxides, and the rays in the middle of the spectrum have the greatest illuminating power.

Sect. II. *Of the Effects of Caloric.*

175 The effects of so powerful an agent as heat must be very considerable: and these effects are found to be different in different bodies, or as it is more or less accumulated in these bodies. One general effect is, that the accumulation of heat enlarges, and its abstraction proportionally diminishes, the bulk of all bodies. When this accumulation is continued in some bodies, they change their condition from the state of solid to that of liquid; and, when the accumulation is still greater, liquid bodies are reduced to the form of vapour. These effects, certainly curious and interesting of themselves, are of the utmost importance in the phenomena of nature and in the processes of art; and the knowledge of the laws which have been deduced from these remarkable changes, enables us to explain many natural appearances, and to improve many of the arts of life.

Effects of caloric different in different bodies.

1. Of Expansion.

176 1. One of the most general effects of heat, it has been observed, is the expansion of bodies; that is, when caloric is accumulated in any body, it is enlarged in

Caloric expands all bodies.

† *Phil. Trans. R. Inst.*

Caloric. in bulk; and, when that quantity of caloric is abstracted, there is a corresponding contraction. Experience teaches us, that this effect of caloric is invariable by uniform in all the simpler kinds of matter. In some bodies, however, there are seeming exceptions to this general rule. In these bodies, when the temperature rises a little above, or falls a little below a certain point, they are subject to irregular variations of their bulk; but these irregularities are limited to a few bodies, and to certain states of temperature of these bodies; for when they are exposed to equal variations of heat, above or below the temperature at which these irregularities are observed, the general law of expansion uniformly holds. The expansion of all bodies by heat, therefore, and their corresponding contraction by the abstraction of caloric or by cold, may be considered as one of the most general facts in chemical science.

177 Exceptions.

178 Expansion proved.

2. We have many familiar instances of the expansion of bodies by means of caloric, and the law can be proved by very simple experiments. We shall mention an example of this effect on bodies in the solid, the liquid, and the gaseous state.

179 In a solid body.

(1.) If a rod of metal, as of iron, of an inch in diameter, six or eight inches long, and the same thickness through its whole length, be exactly fitted to pass through a hole in a plate of the same metal, and to be admitted lengthwise within the projecting edges of a ruler while it is cold, the same rod, when it is made red hot, will be found to have enlarged in bulk so much, that it will not fall between the projecting parts of the ruler, nor will it pass through the hole; but when it is cooled, or reduced to its former temperature, it again contracts, and returns precisely to its former dimensions.

180 In a liquid.

(2.) As an example of a liquid, whose bulk is enlarged by the accumulation of caloric, fill the body of a glass vessel which has a long slender neck with spirit of wine. On the application of heat, the liquid in the body of the vessel is expanded, and rises in the neck; and when the heat is abstracted, and the liquid returns to its former temperature, it is again contracted, and returns to its original bulk. This experiment is most conveniently performed by immersing the body of the vessel in hot water.

181 In an el[astic] fluid.

(3.) The expansion of a body in the gaseous state by the accumulation of caloric, is shewn by the following experiment. Let a quantity of air be confined in a bladder, but not so much as to distend it fully. If the bladder is exposed to heat, the confined air expands, and the bladder is now fully distended; but when it is again cooled, the air resumes its former bulk, and the bladder its original flaccid state.

182 Uniform [in] the sam[e] bodies.

3. Thus it appears, that all bodies expand by heat, and contract by cold, and the quantity of this expansion is uniformly the same in the same bodies, when exposed to the same temperature. But this quantity is found to differ greatly in different kinds of matter, by the same increase or diminution of their heat. In solid bodies it is least, in liquids it is greater, but in elastic fluids greatest of all; and in different kinds of solids, liquids, and elastic fluids, this difference is very considerable. The ratio at which this expansion takes place in different bodies, can only be ascertained by experiment; and as the knowledge of this is a matter of great consequence in many of the arts, experiments have been made with this view by different philosophers. (L).

183 But ve[ry] differen[t in] solids, li[quids, and] elastic fluids.

The expansion of gaseous bodies, we have said, is greatest, that of liquids less, and that of solids least of all, by being exposed to the same degree of heat, which will appear from the following proportions.

100 cubic inches of	Atmospheric air,	from 32° to 112° increased to	137.5 cubic inches.
	Water,		104.5
	Iron,		100.1

184 Effects of expansion on brittle substances.

4. This expansive effect of heat enables us to account for the cracking or breaking of vessels which are made of brittle substances, by its sudden application or abstraction. This is particularly the case with substances which have little flexibility, as cast iron, glass, or earthen ware; and accidents of this kind most frequently happen in vessels made of these materials. If, for instance, heat be suddenly applied to a glass vessel of considerable thickness, its external surface, to which it is first applied, expands more than the internal parts; the consequence must therefore be, that they are separated or drawn asunder, and the vessel is split or broken.

185 In fitting iron hoops to carriage wheels.

5. One of the best illustrations of this expansion by heat and contraction by cold on solid bodies, is in the application of iron hoops to carriage wheels. The hoop which has been intended for the wheel is made of rather smaller dimensions than exactly to fit it. It is then made red hot, and while it is thus expanded, it is applied to the wheel. It is suddenly cooled by throwing cold water upon it, when it contracts, and returning to its former dimensions, is strongly fastened on the wheel.

186 Differe[nt] metals [un]equally [af]fected.

The unequal contraction at the same degree of temperature, which is observed among solids, liquids, and aeriform substances, when respectively compared, also takes place among solids themselves. Thus, different metallic substances, at the same temperature, are found to expand and contract very unequally.

6. Advantage has been taken of this unequal contraction of metallic substances, to remedy those defects and imperfections of delicate instruments, which are occasioned by the contractions and expansions of the substances employed in their construction, when exposed to different temperatures. These inconveniences were most felt in instruments which were employed for the measurement of time, where great accuracy was required. The spring of a watch and the pendulum of a clock being subject to the same law of contraction and expansion by heat and cold, in these changes, necessarily

(L) See experiments on this subject by Mr Elliot, Phil. Trans. vol. xxxix. and by Mr Smeaton, ibid. vol. xlviii.

cessarily caused variations, in proportion to the extent of the effect. But as different metals were observed to expand unequally by the same temperature, this was applied to the construction of those parts of the instrument on which the accuracy of its indications depends. The equable measurement of time, for instance, by a clock, depends on the length of the pendulum always

187 of this n- ting endu-

continuing the same. If it is subject to variations in length by expansion or contraction, there will also be variations in the rate of its motions; when the pendulum is lengthened by heat, the clock goes slower; and when it is shortened by cold, it goes faster. It becomes therefore an object of great importance, that these instruments should go at an equable rate in all temperatures; but this can only be effected by having the pendulum so constructed, that it shall neither lengthen by heat, nor contract by cold. This object is obtained by constructing a pendulum in the following manner.

"Supposing we have two metals, one of which expands three times as much as the other by the same increment of temperature. From the point of expansion A (fig. 1. Plate CXLII.) a rod of thick wire, AB, of the less expansible metal, must hang down a certain length. At the lower end it must have a stud, or cross piece, BC, strongly fastened, and projecting a little to one side. On the projecting part, C, of this cross piece, must be erected a pillar, CD, of the more expansive metal. To the top of this pillar, another cross and projecting piece, DE, must be strongly fastened; and, from this last, must again hang down another rod or wire, EF, of the first metal, having the ball of the pendulum at its extremity. And now, if the height of the pillar CD be one-third of the length of the two rods taken together, the pendulum can neither be lengthened by heat nor shortened by cold. For by the expansion of the pillar, the pendulum is shortened, or the ball is raised nearer to the point of suspension, because the upper end D of the pillar is more raised by its expansion, than the lower end C is depressed by the expansion of AB; and, on the other hand, by its contraction, the pendulum is lengthened, or the ball is lowered: but, while this happens, the two rods, by their expansion or contraction, produce a contrary effect; and the quantity of expansion or contraction is the same in the rods that it is in the pillar, the greater length in the rods compensating for the greater expansibility of the pillar. The consequence therefore must be, that the length of the pendulum, that is, the distance between the point of suspension and the ball, cannot be varied by heat or cold. Accordingly, the clocks made for the use of astronomers, have pendulums constructed upon this principle.

188 bulk ater n fro- is in- sed;

7. There are, however, some remarkable instances which are seeming exceptions to this general law of expansion. This is the case with those bodies which pass from the liquid to the solid state; as for instance, water, when it assumes the solid form. Close vessels which are filled with water, are burst when it freezes. In an experiment made by Mr Boyle, a brass tube three inches in diameter, which was closed with a moveable stopper, was filled with water; when the water was frozen, it raised a weight equal to 74lb. with which the stopper was loaded. In an experiment made by the Florentine academicians, a hollow brass globe, the diameter of whose cavity was an inch, was burst by freezing the water with which it was filled. Muschenbroeck has computed the force necessary to produce this effect, by estimating it equal to a pressure of 27,720lbs. weight. But the most remarkable experiments to prove the expansive force of ice, were made by Major Williams in Canada, in the years 1784 and 1785. The iron plugs with which iron bombshells filled with water were closed up by driving them in strongly with a hammer, were thrown out to a great distance by the force of the congelation of the water; and when the plugs were so firmly secured as to resist this force, the shell itself was burst*.

189 and acts with prodigious force.

8. To the same expansive force in the congelation of water, the bursting of water pipes, the splitting of trees and of rocks, is to be ascribed, which not unfrequently happens, when the water which has been collected in their cavities or fissures is frozen. The stones of the pavement are also raised and loosened by the expansion of the water, by frost, in the earth in which they are imbedded.

190 Other effects.

9. Attempts have been made to discover the cause of this astonishing effect. According to some, it is owing to the extrication of the air which water holds in combination in a dense, nonelastic state. When the water is freezing, part of the air assumes the elastic form, and separates from it; but when the surface of the water is covered with ice, no more air can make its escape. It is then confined, and forms those numerous cavities which are observed in ice. In consequence of these cavities, a mass of ice must be of greater bulk than the water previous to congelation, and cannot therefore be contained in the same space. But another cause, which is perhaps the most probable, has been assigned for this increase of bulk, and consequent expansive force. Water, when it passes from the liquid to the solid state, has a strong tendency among its parts to arrange themselves in a determinate manner. They assume the form of prismatic crystals, which cross each other at angles of 60° and 120°. In this way the increase of bulk, and the expansive force of water, when it is consolidated, are accounted for.

191 Accounted for from the new arrangement of the particles.

10. Another, and a much more singular exception to this law, occurs in water while still fluid, between the degrees of 32° and 40° (Fahr.). Within this short range of temperature it contracts by heat and expands by cold. At 40°, or nearly so, this fluid is at its maximum density. It expands while it is lowered to 32°, as it does when it is raised to 48°.

192 More remarkable exception in fluid water under 40°.

Exper. If we fill a tall cylindrical vessel with water at 40°, and apply a temperature of 32° round the outside, by means of ice, at the middle of its height, the water thus cooled does not sink as it would if the water had been at 60°. It is found to rise. A thermometer immersed near the top, shews, by falling, that colder water now surrounds it; while another thermometer at the bottom remains stationary at 40°.

This probably arises from the particles of water now changing their arrangement, in such a way as is preparatory to their crystalline or frozen state, in which the volume is so powerfully expanded.

This singular law of water, serves the important purpose of preventing the downward progress of freezing in the water of deep lakes. While it cools, and before it is so low as 40°, the colder water at the surface, by its

* *Edin. Trans.* vol. ii. p. 23.

Caloric.

its superior density, sinks, and the cooling process is thus uniformly diffused; but this motion stops when it is at 40°. The water cooled still lower is now expanded, and therefore remains on the surface; and even when the surface is frozen, and a stratum of ice-cold water lies under the ice, the lower strata remain at 40°, and are only cooled lower by a very slow transmission of the temperature, independent of the motion of the particles or by motions of an occasional or accidental kind. Hence lakes retain at the bottom a temperature adapted to the life of fishes during the hardest winters.

Some metallic substances, particularly cast iron, are observed to enlarge in bulk, when they pass from the fluid to the solid state, in the same way as water. To this increase of bulk in cast iron when it cools, are owing the sharpness and distinctnass of the lines in the ornamental figures on grates and furnaces which are
193 In cast iron. made of this metal. The metal is introduced into the mould while in a state of fusion, and increasing in bulk as it cools, the minute cavities of the mould are more accurately filled. This increase of bulk, as in the case of water when it becomes solid, is also ascribed to a determinate arrangement of the parts of the metal, or to crystallization.

II. On the expansive property of bodies depends the construction of the thermometer, which is employed for the measurement of the relative temperatures of bodies.
194 The thermometer invented. The invention of this instrument is generally ascribed to Santorio, an Italian physician, who lived about the beginning of the 17th century, although it is said by some, that thermometers were made by Drebel, a Dutch physician, and that they were common in Holland, and even in England, before Santorio was known in these conntries.

195 First construction. In the thermometer of Santorio, the expansive power of air was employed to measure the temperature. His thermometer is constructed in the following manner. A tube of glass of 18 inches or two feet in length, open at one end, is blown into a ball at the other. When the ball is heated, the air within is expanded, and if the open end of the tube be now immersed in a vessel filled with any coloured fluid; as the internal air cools, and is diminished in bulk, the liquid will rise in the tube by the pressure of the external air on the surface of the liquid in the vessel. A scale of equal degrees was then applied to the whole length of the tube, and the thermometer was constructed. To ascertain the heat of any body, as for instance the hand, it was applied to the ball, and if this temperature was greater than the medium in which the apparatus was placed, the internal air was rarefied, and consequently depressed the surface of the coloured liquid in the tube. The number of degrees of this depression was observed and compared in different ex-
196 Imperfect. periments. As, for instance, the difference of temperature of the human body at different periods, to ascertain which, it is said, it was employed by the inventor. But the inaccuracy of this instrument will be obvious, when we consider that it depended, not only on the temperature, but also on the pressure of the atmosphere.

This defect in the air thermometer was avoided in the one invented by Mr Boyle, and by the Florentine 197 Improved. academicians, nearly at the same time. The first fluid that was used was spirit of wine, which contracting and expanding more than water at the same temperature, and not being liable to be frozen by cold, was found to be much more convenient. Quicksilver was some time afterwards employed in the same way. The ball of the glass, and part of the tube, was filled with the fluid, when the open extremity of the tube was closed. When heat was applied to the ball, the fluid within expanded, and contracted by cold, without being influenced by the pressure of the atmosphere, as in Santorio's thermometer. But still this thermometer was very imperfect, for want of determinate points in the scale, by which different instruments might be compared together. This desideratum was first supplied by Sir Isaac Newton, and after various improvements, it was brought to its present state of perfection.

The method of constructing Fahrenheit's thermome- 198 Fahrenheit's thermometer. ter, which is now in general use in this country, is the following: A small ball is blown on the end of a glass tube, of uniform width throughout. The ball and part of the tube are then to be filled with quicksilver, which has been previously boiled to expel the air. The open end of the tube is then to be hermetically sealed (M). The next object is to construct the scale. It is found by experiment, that melting snow or freezing water is always at the same temperature. If, therefore, a thermometer be immersed in the one or the other, the quicksilver will always stand at the same point. It has been observed, too, that water, while under the same pressure of the atmosphere, boils at the same temperature. A thermometer, therefore, immersed in boiling water, will uniformly stand at the same point. Here then are two fixed points from which a scale may be constructed, by dividing the intermediate spacc into equal parts, and carrying the same divisions as far above and below the two fixed points as may be wanted. Thus, thermometers constructed in this way may be compared; for if they are accurately made, and placed in the same temperature, they will always point to the same degree on the scale.

The fluid that is now generally employed is quicksilver; and it is found to answer best, because its expansions are most equable. The freezing point of Fahrenheit's thermometer, is marked 32°, as this artist thought that he had produced the greatest degree of cold by a mixture of snow and salt; and the point at which the thermometer then stood in this temperature, was marked zero. The intermediate space between the boiling and freezing points being divided into 180°, the boiling point in this thermometer is 212°. This is the thermometer that is commonly used in Britain.

There are three other thermometrical scales employed in different countries of Europe, which differ from each other in the number of degrees between the freezing and boiling points.

Reaumur's

(M) This is done by heating the end of the tube with the flame of a lamp, and by closing it while the glass is softened.

oric.

99 Re mur's. Reaumur's thermometer was generally used in France before the revolution, and is still employed in different countries on the continent. The freezing point in this thermometer is marked zero, and the boiling point 80°. To convert the degrees of Reaumur's thermometer to those of Fahrenheit, the following is the formula. Reaum. $\frac{9}{4}+32=$Fahr. that is, multiply the degrees of Reaumur by 9, divide by 4, and add 32. This gives the corresponding degrees on Fahrenheit's scale.

00 Ce ls. The thermometer of Celsius has the space between the freezing and boiling points divided into 100°. The boiling point is 100°, and the freezing point zero. This thermometer is used in Sweden, and in France, where it is distinguished by the term *centigrade*. To convert the degrees of this thermometer into those of Fahrenheit; Cel. $\frac{9}{5}+32=$Fahr.

01 De le's. In Delisle's thermometer, which is used in Russia, the space between the boiling and freezing points is divided into 150°; but the degrees are reckoned downwards. The boiling point is marked zero, and the freezing point 150°. To reduce the degrees of this thermometer under the boiling point to those of Fahrenheit, Del. $\frac{6}{5}-212=$Fahr. and above the boiling point, Del. $\frac{6}{5}+212=$Fahr.

Caloric.

Such are the principles and mode of construction of the thermometer; an instrument which has been of the utmost importance in enabling us to discover many of the properties and effects of caloric, as by it only we can ascertain with accuracy the relative temperatures (N).

12. It has been an object of considerable interest and importance to ascertain the quantity and rate of expansion in bodies. Among solid bodies the quantity of expansion is very small, so that a nice apparatus is necessary to ascertain it. But it appears that the ratio of this expansion is equable, or nearly so. The results of experiments made by Mr Smeaton and some other philosophers upon this subject, are exhibited in the following table. 202 Quantity of expansion.

03 Di fferent m s.

190	100,069
212	100,083

05 Of iquids. 13. The expansion of liquid bodies is greater than that of solids, but it is not equable with equal additions of temperature. It has been observed, that those liquids which are most readily brought to the state of vapour, or whose boiling point is lowest, expand most. With the same given temperature, the expansion of water is greater than that of mercury, and the expansion of alcohol is greater than that of water. The boiling point of water is lower than that of mercury, and the boiling point of alcohol is lower than that of water; from which it would appear, that the expansion of liquids is nearly in the inverse ratio of their boiling temperatures, and this expansion seems to increase with the temperature; that is, the nearer a liquid is to that point of temperature at which it boils, the greater is the degree of expansion by the addition of caloric; and the farther it is from the boiling temperature, the smaller is the increase of bulk by the addition of caloric. The following table exhibits the ratio of expansion of several liquids, as they have been ascertained by different philosophers.

Table

(N) For measuring high degrees of temperature, the pyrometer of Wedgwood is employed, which will be described under the earth *alumina*.

206
All gases expand equably.

14. It has been proved by experiment that all gaseous bodies undergo the same expansion, with the same addition of heat. This has been ascertained by the ingenious experiments of Mr Dalton and M. Gay Lussac. The increase of bulk of some elastic fluids from 32° to 212°, as determined by the latter, will be seen in the following table :

Atmospheric air 100 parts, increased	37.50	
Hydrogen gas	37.52	difference +0.2
Oxygen gas	37.40	——— —0.02
Azotic gas	37.49	——— —0.01*

* *Ann. de Chim.* vol. xliii. p. 167.

In other experiments he found, that the expansion of the vapour of water and of ether corresponded with the expansion of other gases; and he remarks, that this property of the equable dilatation of the vapour of ether and water, and the gases, with the same degrees of temperature, depends not on the peculiar nature of the vapour and gases, but solely on their elastic state.

Mr Dalton's experiments shew that the expansion of air is very nearly equable. It appears, however, that the rate of expansion diminished as the temperature increased. The expansion from 55° to 132½°, which includes 77½°, was 167 parts; but the expansion from 132½° to 212°, the next 77½°, was only 158 parts, which was nine parts less than the first. The same philosopher observes, that the results of several experiments which he made upon hydrogen gas, oxygen gas, carbonic acid gas, and nitrous gas, correspond with those on atmospherical air, not only in the total expansion, but in the gradual diminution of it in ascending. Small differences were observed, but they never exceeded six or eight parts in the whole amount 325; and differences to this amount, he adds, will take place in common air, when not freed from aqueous vapour, which, he says, was the situation of his factitious gases.

2. Of Fluidity.

1. When still greater additions are made to most bodies, they are followed not merely by a change of bulk, but by a total change of their state and properties. 207 Change of state.

All matter exists, either in the state of solid, of liquid, or of vapour. Most bodies, by the addition or the abstraction of caloric, are convertible from one of these states into another. Ice is water in the solid state. When a mass of ice has received a certain quantity of caloric, it assumes the liquid state; and, when this liquid has received another portion of caloric, it is changed into the state of vapour. On the other hand, if the vapour is deprived of a certain portion of caloric, it returns to the state of liquid or that of water; and when this water is deprived of another portion of caloric, it becomes solid, or is converted into ice.

This seems to be a general law of bodies, to which there are but few exceptions. Some may be converted into all the three states, as water; others, as spirit of wine, are known only in the fluid or the gaseous state, and there are some solid bodies which are not convertible into the state of liquid; but these exceptions are so few, that it has been supposed the same effect would follow, were these bodies exposed to the requisite degree of temperature.

2. The temperatures at which these changes are effected are invariably the same in the same body. Thus, a mass of ice is converted into the state of liquid or of water, when it is exposed to a temperature above 32°; and water, when it is raised to the temperature of 212° under the usual pressure of the atmosphere, assumes the state of vapour or of steam. But although this temperature is constant in the same bodies, 2 Bodies come at the degree of temperature.

dies, it varies greatly in different bodies. Thus, spirit of wine and ether are converted into vapour at a very low temperature, while mercury and the fixed oils, to undergo this change, require a temperature far above that which is necessary for water.

09 In me instanta ous

3. Some bodies are instantaneously converted from the solid to the liquid state. Thus ice, when the temperature is raised, passes immediately from the solid to the fluid state. Other bodies undergo a gradual change. They first become soft, as in the instance of melting wax, and pass through different degrees of softness, till at last they become perfectly fluid.

10 In hers gr ally.

4. It may perhaps now seem surprising, that these phenomena should have so long been familiarly known, while no conception was entertained of the true explanation. The want of instruments to measure accurately the relative degrees of temperature at which these changes took place, might be one cause of the unsuccessful investigations of philosophers on this subject. But even after the invention and improvement of the thermometer, it was long before the simple cause of these wonderful effects was fully ascertained. The discovery of this law, of such universal application to the phenomena of nature, was reserved for the sagacity of Dr Black; and the era may be regarded as one of the most important in the history of chemical science.

11 G t disc y of D lack.

Dr Black was distinguished for caution and precision in all his views; and the progressive steps by which this celebrated philosopher was led to ascertain the true cause of fluidity, afford us a fine example of simple and elegant investigation.

5. After stating that the cause of fluidity which had been formerly given was unsatisfactory, and inconsistent with the phenomena, he observes that " these phenomena, when attentively considered, shew that fluidity is produced by heat, in a very different manner from that which was commonly imagined; a manner, however, which, when understood, enables us to explain many particulars relating to heat or cold, which appeared, in the former view of the subject, quite perplexing and unaccountable.

12 F lity, s osed t ow- i o a s addi- w of ca- lo

" Fluidity had been universally considered as produced by a small addition to the quantity of heat which a body contains, when it is once heated up to its melting point; and the returning of such body to a solid state, as depending on a very small diminution of the quantity of its heat, after it is cooled to the same degree; that a solid body, when it is changed to a fluid, receives no greater addition to the heat within it than what is measured by the elevation of temperature indicated after fusion by the thermometer; and that, when the melted body is again made to congeal, by a diminution of its heat, it suffers no greater loss of heat than what is indicated also by the simple application to it of the same instrument.

13 I nsist- e ith fa

" This," says the author, " was the universal opinion on this subject, so far as I know, when I began to read my lectures in the university of Glasgow, in the year 1757. But I soon found reason to object to it, as inconsistent with many remarkable facts, when attentively considered; and I endeavoured to shew, that these facts are convincing proofs that fluidity is produced by heat in a very different manner.

" I shall now describe the manner in which fluidity appeared to me to be produced by heat, and we shall then compare the former and my view of the subject with the phenomena.

" The opinion I formed from attentive observation of the facts and phenomena, is as follows: When ice, for example, or any other solid substance, is changing into a fluid by heat, I am of opinion that it receives a much greater quantity of heat than what is perceptible in it immediately after by the thermometer. A great quantity of heat enters into it, on this occasion, without making it apparently warmer, when tried by that instrument. This heat, however, must be thrown into it, in order to give it the form of a fluid; and I affirm, that this great addition of heat is the principal and most immediate cause of the fluidity induced. 214 Caloric is absorbed by solids becoming fluid.

" And, on the other hand, when we deprive such a body of its fluidity again, by a diminution of its heat, a very great quantity of heat comes out of it, while it is assuming a solid form, the loss of which heat is not to be perceived by the common manner of using the thermometer. The apparent heat of the body, as measured by that instrument, is not diminished, or not in proportion to the loss of heat which the body actually gives out on this occasion; and it appears from a number of facts, that the state of solidity cannot be induced without the abstraction of this great quantity of heat. And this confirms the opinion, that this quantity of heat, absorbed, and as it were, concealed in the composition of fluids, is the necessary and immediate cause of their fluidity. 215 Fluids becoming solid give out caloric.

" To perceive the foundation of this opinion, and the inconsistency of the former with many obvious facts, we must consider, in the first place, the appearances observable in the melting of ice, and the freezing of water.

" If we attend to the manner in which ice and snow melt, when exposed to the air of a warm room, or when a thaw succeeds to frost, we can easily perceive, that however cold they might be at the first, they are soon heated up to their melting point, or begin soon at their surface to be changed into water. And if the common opinion had been well founded, if the complete change of them into water required only the further addition of a very small quantity of heat, the mass, though of a considerable size, ought all to be melted in a very few minutes or seconds more, the heat continuing incessantly to be communicated from the air around. Were this really the case, the conquences of it would be dreadful in many cases; for, even as things are at present, the melting of great quantities of snow and ice occasions violent torrents, and great inundations in the cold countries, or in the rivers that come from them. But, were the ice and snow to melt as suddenly as they must necessarily do, were the former opinion of the action of heat in melting them well founded, the torrents and inundations would be incomparably more irresistible and dreadful. They would tear away and sweep up every thing, and that so suddenly, that mankind should have great difficulty to escape from their ravages. This sudden liquefaction does not actually happen; the masses of ice or snow melt with a very slow progress, and require a long time, especially if they be of a large size, such as are the collections of ice, and wreaths of snow, formed in some places during the winter. These, after they begin to melt, often require many weeks of warm weather, 216 Proved by the melting of ice and freezing of water. 217 Melting of ice a very slow process.

Caloric. weather, before they are totally dissolved into water. This remarkable slowness with which ice is melted, enables us to preserve it easily during the summer, in the structures called ice-houses. It begins to melt in these, as soon as it is put into them: but, as the building exposes only a small surface to the air, and has a very thick covering of thatch, and the access of the external air to the inside of it is prevented as much as possible, the heat penetrates the ice-house with a slow progress, and this, added to the slowness with which the ice itself is disposed to melt, protracts the total liquefaction of it so long, that some of it remains to the end of summer. In the same manner does snow continue on many mountains during the whole summer, in a melting state, but melting so slowly, that the whole of that season is not a sufficient time for its complete liquefaction.

"This remarkable slowness with which ice and snow melt, struck me as quite inconsistent with the common opinion of the modification of heat, in the liquefaction of bodies.

218 Foundation of the discovery.

"And this very phenomenon is partly the foundation of the opinion I have proposed; for if we examine what happens, we may perceive that a great quantity of heat enters the melting ice, to form the water into which it is changed, and that the length of time necessary for the collection of so much heat from the surrounding bodies, is the reason of the slowness with which the ice is liquefied. If any person entertain doubts of the entrance and absorption of heat in the melting ice, he needs only to touch it; he will instantly feel that it rapidly draws heat from his warm hand. He may also examine the bodies that surround it, or are in contact with it, all of which he will find deprived by it of a great part of their heat; or if he suspend it by a thread, in the air of a warm room, he may perceive with his hand, or by a thermometer, a stream of cold air descending constantly from the ice; for the air in contact is deprived of a part of its heat, and thereby condensed and made heavier than the warmer air of the rest of the room; it therefore falls downwards, and its place round the ice is immediately supplied by some of the warmer air; but this, in its turn, is soon deprived of some heat, and prepared to descend in like manner; and thus there is a constant flow of warm air from around, to the sides of the ice, and a descent of the same in a cold state, from the lower part of the mass, during which operation the ice must necessarily receive a great quantity of heat.

"It is, therefore, evident, that the melting ice receives heat very fast, but the only effect of this heat is to change it into water, which is not in the least sensibly warmer than the ice was before. A thermometer, applied to drops or small streams of water, immediately as it comes from the melting ice, will point to the same degree as when it is applied to the ice itself, or, if there is any difference, it is too small to deserve notice. A great quantity, therefore, of the heat, or of the matter of heat, which enters into the melting ice, produces no other effect but to give it fluidity, without augmenting its sensible heat; it appears to be absorbed and concealed within the water, so as not to be discoverable by the application of a thermometer.

219 Thermometer does not indicate the caloric absorbed.

"In order to understand this absorption of heat into the melting ice, and concealment of it in the water, more distinctly, I made the following experiments.

220 Proved by experiments.

"The plan of the first was to take a mass of ice, and an equal quantity of water, in separate vessels, of the same size and shape, and as nearly as possible of the same heat, to suspend them in the air of a warm room, and, by observing with a thermometer the celerity with which the water is heated, or receives heat, to learn the celerity with which it enters the ice; and the time necessary for melting the ice being also attended to, to form an estimate, from these two data, of the quantity of heat which enters the ice during its liquefaction.

221 First experiment.

"In order to prepare for this experiment, I chose two thin globular glasses, four inches diameter, and very nearly of the same weight: I poured into one of them five ounces of pure water, and then set it in a mixture of snow and salt, that the water might be frozen into a small mass of ice. As soon as frozen, it was carried into a large empty hall, in which the air was not disturbed or varied in its temperature during the progress of the experiment; and in this room the glass was supported, as it were, in mid air, by being set on a ring of strong wire, which had a tail issuing from the side of it five inches long, and the end of this tail was fixed in the most projecting part of a reading desk or pulpit: And in this situation the glass remained until the ice was completely melted.

"When the ice was thus placed, I set up the other globular glass precisely in the same situation, and at the distance of 18 inches to one side, and into this poured five ounces of water, previously cooled, as near to the coldness of melting ice as possible, viz. to 33°, and suspended in it a very delicate thermometer, the bulb of which being in the centre of the water, and the tube being so placed, that, without touching the thermometer, I could see the degree to which it pointed. I then began to observe the ascent of this thermometer, at proper intervals, in order to learn with what celerity the water received heat, stirring the water gently with the end of a feather about a minute before each observation. The heat of the air, examined at a little distance from the glasses, was 47° of Fahrenheit's scale.

"The thermometer assumed the temperature of the water in less than half a minute, after which, the rise of it was observed every five or ten minutes, during half an hour. At the end of that time, the water was grown warmer than at first, by 7 degrees; and the temperature of it had risen to the 40th degree of Fahrenheit's scale.

"The glass with the ice was, when first taken out of the freezing mixture, four or five degrees colder than melting snow, which I learned by applying the bulb of the thermometer to the bottom of it; but after some minutes, it had gained from the air those four or five degrees, and was just beginning to melt, which point of time was then noted, and the glass left undisturbed ten hours and a half. At the end of this time, I found only a very small and spongy mass of the ice remaining unmelted, in the centre of the upper surface of the wuter, but this also was totally melted in a few minutes more; and, introducing the bulb of the thermometer into the water, near the sides of

Caloric.

of the glass, I found the water there was warmed to the 40th degree of Fahrenheit. From this it appears, that when a considerable part of the ice was melted, and the quantity of water around it was increasing, the heat was not transmitted through this water to the remaining ice altogether so fast as it was received by the water; which is easily understood, if we consider that the distance between the remaining ice and the external surface of the vessel through which the heat entered, was gradually increasing, and that heat always requires time to pass through bodies or to be communicated from one part of them to another.

"It appears, therefore, from this experiment, that it was necessary that the glass with the ice receive heat from the air of the room during 21 half-hours, in order to melt the ice into water, and to heat that water to the 40th degree of Fahrenheit. During all this time, it was receiving the heat, or matter of heat, with the same celerity (very nearly) with which the water-glass received it during the single half-hour in the first part of the experiment. For, as the water received it with a celerity which was diminishing gradually during that half hour, in consequence of the diminution of difference between its degrees of heat and that of air; so the glass with the ice also received heat with a diminishing celerity, which corresponded exactly with that of the water-glass, only that the progression of this diminution was much more slow, and corresponded to the whole time which the water surrounding the ice required to become warmed to the 40th degree of Fahrenheit. The whole quantity of heat, therefore, received by the ice-glass during the 21 half-hours, was 21 times the quantity received by the water-glass during the single half-hour. It was, therefore, a quantity of heat, which, had it been added to liquid water, would have made it warmer by $\overline{40-33} \times 21$, or 7×21, or 147 degrees. No part of this heat, however, appeared in the ice-water, except 8 degrees; the remaining 139 or 140 degrees had been absorbed by the melting ice, and were concealed in the water into which it was changed.

"The communication of heat to the melting ice was easily perceived, during the whole time of its exposition, by feeling the stream of cold air which descended from the glass.

"This experiment was an analysis of the manner in which ice is melted by the heat of the air in ordinary circumstances.

"But another obvious method of melting ice occurred to me, in which it would be still more easy to perceive the absorption and concealment of heat, and this was the action of warm water.

22
Second experiment.

"When hot and cold water are mixed together, the excess of heat contained in the hot water is equally distributed in an instant through the whole mixture, and raises the temperature of it according to the greatness of the excess of temperature, and the proportion which the hot water bore to the cold. If the quantities of hot and cold water are equal, the temperature is the middle degree between that of the hot and that of the cold. No part of the heat disappears on this occasion, so far as we can perceive, but the intensity of it only is diminished, by its being diffused through a larger quantity of matter. It was, therefore, obvious, that if a quantity of heat is absorbed, and disappears in the melting of ice, this would easily be perceived when the ice is melted with warm water.

"To make this experiment, I first froze a quantity of water in the neck of a broken retort, in order to have a mass of ice of an oblong form.

"At the same time I heated a quantity of water, nearly equal in weight to the ice, in a very thin globular glass, the mouth of which was sufficiently wide to take in the piece of ice. The water was heated by a small spirit of wine lamp applied to the bottom of the glass; it was also stirred with the end of a feather, and a thermometer hung in it.

"While the water was heating, the mass of ice was taken out of the mould in which it had been formed, and was exposed to the air of a temperate room, until it was perceived to be beginning to melt over the whole of its surface.

"I then put a woollen glove on my left hand, and taking hold of the ice, I wiped it quite dry with a linen towel, laid it in the scale of a balance on a piece of flannel, and hastily counterpoised it with sand in the opposite scale, that I might examine the weight of it afterwards; and I immediately plunged it into the hot water, and extinguished the lamp at the same time. The lamp being small, the heat of the water had been increasing very slowly, and had almost ceased to increase; and being examined immediately before I put the ice into it, the temperature was found to be just 190 degrees. The ice was all melted in a few seconds, and produced a mixture, the temperature of which was 53 degrees.

"The weight of the ice, when put into the hot water, was seven ounces three drams and a half. The weight of the glass, with the whole mixture in it, was 16 ounces, seven drams, and seven grains. The weight of the glass alone was nearly one ounce.

"In considering this experiment, we may overlook quantities less than half a dram, or 30 grains, and reckon the quantities of the different articles by the number of half-drams in each.

"Thus the weight of the ice was		119 half-drams.
———	Hot water	135
———	Mixture	254
———	Glass alone	16

"The melting of the ice was affected, not only by the heat of the hot water, but also by that of the glass. And, by other experiments, I learned that 16 parts of hot glass have more power in heating cold bodies, than eight parts of equally hot water; we may therefore substitute, in place of the 16 half-drams of warm glass, eight half-drams of warm water, which, added to the above quantity of warm water, make up 143 half-drams.

"The heat of this warm water was 190 degrees, that is 158 hotter than the ice; and if this heat had abated in the mixture only in consequence of the quantity and coldness of the ice, and if nothing had happened when the ice was put in, but merely a communication of this heat, and an equal distribution of it through the mixture, the temperature of the mixture should have been 158, viz. the excess of heat in the warm water, multiplied

Caloric.

multiplied by 143, the quantity of the warm matter, and divided by 262, the quantity of the whole, which gives 86.

223 Caloric is absorbed.

"The mixture should have been 86 degrees warmer than melting ice; but it was found only 21 degrees warmer. Therefore a quantity of heat has disappeared, which, if it had remained in a sensible state, would have made the whole mixture and glass warmer by 65 degrees than they were actually found to be. But this quantity of heat would be sufficient for increasing, by 143 degrees, the heat of a quantity of water, equal in weight to the ice alone. It was, however, absorbed by the ice, without in the least increasing its sensible heat (o).

"The result of this experiment coincides sufficiently with that of the former; the difference is not greater than what may be expected in similar experiments, and might arise from the accident of the central parts of the mass of ice being colder than the surface, by one or two degrees.

"I have, in the same manner, put a lump of ice into an equal quantity of water, heated to the temperature 176, and the result was, that the fluid was no hotter than water just ready to freeze. Nay, if a little sea salt be added to the water, and it be heated only to 166 or 170, we shall produce a fluid sensibly colder than the ice was in the beginning, which has appeared a curious and puzzling thing to those unacquainted with the general fact.

"It is, therefore, proved that the phenomena which attend the melting of ice in different circumstances, are inconsistent with the common opinion which was established upon this subject, and that they support the one which I have proposed *."

* Black's Lect. vol. i. p. 125.

6. These experiments shew clearly and incontrovertibly, that the conversion of ice into water is owing to the absorption of a certain portion of caloric: and that the quantity of caloric absorbed is equal to what would have given to the temperature of a body which remained unchanged, as, for instance water, a rise of 140 degrees. These 140°, therefore, have disappeared (for no increase of temperature is indicated by the thermometer), have been absorbed by the ice, and are necessary to reduce it to the liquid state. This portion of caloric, which had thus disappeared, Dr Black called *latent heat*, because in this state of combination its presence was not indicated by the thermometer. By others this has been called *the caloric of fluidity*.

224 Called *latent heat.*

225 Experiments on other bodies prove the same thing.

7. In the progress of these investigations, experiments were made on other substances, which clearly shewed that their fluidity is owing to the same cause. These experiments were made on wax, tallow, spermaceti, sulphur, alum, nitre, and some of the metals. The late ingenious Dr Irvine, the pupil of Dr Black, and who materially assisted him in many of his experiments, ascertained the quantity of caloric which was necessary for the fluidity of the following substances; which, when compared with that of ice, will shew that the quantity of the caloric of fluidity increases with the temperature at which the body is converted into the liquid state.

Spermaceti,	148°
Bees wax,	175
Tin,	500 *

* Black's Lect. vol. i. p. 137.

226 Softness and malleability owing to the same cause.

8. Dr Black farther observes on the operation of this cause, that there is reason to think, that not only the fluidity of bodies, but even the softness of such as are rendered plastic by heat, depends on a quantity of heat combined with them, in the form of latent heat; and that the malleability and ductility of metals depend upon the same cause. For, while they are extended under the hammer, they become warm, and in some cases very hot; at the same time they become rigid, and are no longer malleable. They have lost their toughness and softness. To restore this, they must be annealed, or made hot in the fire and allowed to cool. They thus recover their malleability, of which they may be again deprived by a second hammering.

227 Temperature at which bodies become fluid constant.

9. The temperature at which solid bodies begin to be converted into the liquid state, is consant; and till they are raised to this temperature, no change takes place. Water in the solid state, or ice, always remains unchanged till it is placed in a temperature above 32°. This point, which is called the *melting* point, is constant in the same body, but is very different in different bodies. The following table exhibits the melting point of a number of solid bodies.

3. Of Vapour.

228 Water changed into vapour.

1. If, after a mass of ice is converted into water or the liquid state, the application of heat to that water be continued, it undergoes other changes, and exhibits very different phenomena. If the temperature be raised sufficiently high, the water becomes agitated with an intestine

(o) "These two experiments, and the reasoning which accompanies them, were read by me in the Philosophical Club, or Society of Professor and others in the University of Glasgow, in the year 1762."

testine motion, and if it is supplied with a sufficient quantity of caloric, the whole of the water is dissipated. This agitation of the water, it is well known, is called, in common language, *boiling*.

2. As solid bodies which are capable of being converted into the liquid state by an increase of caloric, have a certain determinate temperature, so many of those bodies which are capable of assuming the form of an elastic fluid undergo this change only when they are raised to a certain temperature. Some liquids, indeed, assume the form of vapour at all temperatures, which is the case with water, with volatile oils, spirits of wine and ether. This change is called *spontaneous evaporation*; but there are others which remain unchanged till the temperature is raised to that point at

229 …ing, …t.

which they boil. Boiling is nothing else but the rapid conversion of the liquid into vapour. The heat being

230 …ing …t con- …t;

applied to the bottom of the vessel which contains the liquid, the particles at the bottom first assume the elastic form; and as they rise through the liquid, cause it to be violently agitated. This boiling point, under the same pressure, is always the same in the same liquid; and however strong the heat that may be applied, or however long it may be continued, the temperature of the liquid, in open vessels, never rises above this point. The boiling point of water, for instance, is 212°, and it never becomes hotter: the application of a higher heat around it only hastens the progress of evaporation; and if the heat be continued, the whole is dissipated, and converted into vapour.

231 …varies …pres-

3. But this boiling point is found to vary considerably, and this variation depends on the pressure on the surface of the liquid. When the pressure is diminished, liquids boil at a lower temperature; but when this pressure is increased, they require a higher temperature to produce boiling. Water boils at a low temperature on the top of a high mountain, or in the vacuum of an air pump, where the pressure is greatly diminished; but when it is confined in close vssels, as in Papin's digester, the temperature may be raised to 300° or 400° without boiling.

232 …of la- heat …nded.

4. The general law which was discovered by Dr Black, of the conversion of solids into liquids, was also applied by him to account for the change of liquids into elastic fluids. This was proved by the following experiments.

"*Experiment* 1.—I procured, (says Dr Black), some cylindrical tin-plate vessels, about four or five inches diameter, and flat-bottomed. Putting a small quantity of water into them, of the temperature 50°, I set them upon a red-hot kitchen table, that is, a cast-iron plate, having a furnace of burning fuel below it, taking care, that the fire should be pretty regular. After four minutes, the water began sensibly to boil, and in 20 minutes more, it was all boiled off. This experiment was made 4th October 1762.

"*Experiment* 2.—Two flat-bottomed vessels, like the former, were set on the iron plate, with eight ounces of water in each, of the temperature 50°. They both began to boil at the end of three minutes and a half, and in eighteen minutes more, all the water was boiled off.

"*Experiment* 3.—The same vessels were again supplied with 12 ounces of water in each, also of the temperature 50°. Both began to boil at the end of six minutes and a quarter, and the water was all boiled off from the one in 28 minutes, and from the other in something more than 29.

"I reasoned from these experiments in the following manner: The vessels in the first experiment received 162 degrees of heat in four minutes, or $40\frac{1}{2}$ degrees each minute. If we, therefore, suppose that the heat enters equally fast during the whole ebullition, we must suppose that 810 degrees of heat have been absorbed by the water, and are contained in its vapour. Since this vapour is no hotter than boiling water, the heat is contained in it in a latent state, if we consider it only as the cause of warmth. Its presence is sufficiently indicated, however, by the vaporous or expansive form which the water has now acquired.

"In experiment second, the heat absorbed, and rendered latent, seems to be about 830. 233 Quantity of caloric in vapour.

"In the third experiment, the heat absorbed seems to be somewhat less, viz. about 750. The time of rising to the boiling heat, in experiment third, has nearly the same proportion to that in experiment first, that the quantities of water have. The deficiency, therefore, in the heat absorbed, has been probably only apparent, and arising from irregularity in the fire. Upon the whole, the conformity of their results with my conjecture was sufficient to confirm me in my opinion of its justice. In the course of further experiments made both by myself and by some friends, and in which the utmost care was taken to procure a perfect uniformity in the heat applied, the absorption was found extremely regular, and amounted at an average to about 810 degrees.

"There are other cases where this absorption appears in a much more singular manner. I put into a very strong phial, about as much water as half filled it, and I corked it close. The phial was placed in a sand-pot, which was gradually heated, until the sand and phial were several degrees above the common vaporific pint of water. I was curious to know what would be the effect of suddenly removing the pressure of the air, which is well known to prevent water from boiling. The water boiled a very short while, but the ebullition gradually decreased, till it was almost insensible. Here the formation of more vapour was opposed by a very strong pressure, proceeding from the quantity of vapour already accumulated, and confined in the upper part of the phial, and from the increased elasticity of this vapour, by the increase of its heat. When matters were in this state, I drew out the cork. Now, according to the common opinion of the formation of vapour by heat, 234 Other proofs of caloric absorbed in vapour.

Caloric.

heat, it was to be expected that the whole of the water would suddenly assume the vaporous form, because it was all heated above the vaporific point. But I was beginning by this time to expect a different event, because I could not see whence the heat was to be supplied, which the water must contain when in the form of vapour. Accordingly, it happened as I expected; a portion only of the water was converted into vapour, which rushed out of the phial with a considerable explosion, carrying along with it some drops of water. But, what was most interesting to me in this experiment was, that the heat of what remained was reduced in an instant to the ordinary boiling point. Here, therefore, it was evident, that all that excess of heat which the water had contained above the boiling point, was spent in converting only a portion of it into vapour. This is plainly inconsistent with the common opinion, that nothing more is necessary for water's existing in a vaporous form under the pressure of the atmosphere, than its being raised to a certain temperature. The experiment makes it more probable, that if the influx of heat could at that instant have been prevented, it would have remained in the form of water, although raised, in a very sensible degree, above the boiling temperature.

"I was anxious to learn whether the heat which disappeared in this experiment was in an accurate proportion to the quantity of vapour produced, or the quantity of water that had disappeared. But the drops of water that were hurried along by the explosion, without being converted into vapour, made it impossible for me to ascertain this with any tolerable accuracy, although I repeated the experiment several times.

235 The caloric absorbed in proportion to the quantity of vapour.

"This experiment was afterwards made by my friend Mr Watt, in a very satisfactory manner. His studies for the improvement of his steam-engine, gave him a great interest in every thing relating to the production of steam. He put three inches of water into a small copper digester, and, screwing on the lid, he left the safety-valve open. He then set it on a clear fire of coals, and after it began to boil and produce steam, he allowed it to remain on the fire half an hour, with the valve open. Then, taking it off the fire, he found that an inch of water had boiled away. In the next place, he restored that inch of water, screwed on the lid, and set it on the fire; and as soon as it began to boil, he shut the safety-valve, and allowed it to remain on the fire half an hour as before. The temperature of the whole was many degrees above the boiling point. He took it off the fire, and set it upon ashes, and opened the valve a very small matter. The steam rushed out with great violence, making a shrieking noise for about two minutes. When this had ceased, he shut the valve, and allowed all to cool. When he opened it, he found that an inch of water was consumed.

"It is reasonable to conclude from this experiment, that nearly as much heat was expended during the blowing of the steam pipe, as had been formerly expending in boiling off the inch of water. For, before opening the valve, the temperature was many degrees above the boiling point, and all this disappeared with the vapour. The same inference may be drawn from the time that the digester continued upon the fire with the valve shut, because we may conclude that the heat was entering nearly at the same rate during the whole time. It is plain, however, that the experiment is not of such a kind as to admit of nice calculation; but it is abundantly sufficient to shew that a prodigious quantity of heat had escaped along with the particles of vapour produced from an inch of water. The water that remained could not be hotter than the boiling point, nor could the vessel be hotter, otherwise it would have heated the water, and converted it into vapour. The heat, therefore, did not escape along with the vapour, but *in* it, probably united to every particle, as one of the ingredients of its vaporous constitution. And as ice, united with a certain quantity of heat, is water; so water, united with another quantity of heat, is steam or vapour *."

* Black's Lect. vol. p. 161.

236 Confirmed by Dr Irvine.

The following experiment made by the late Dr Irvine of Glasgow, at the desire of Dr Black, and recorded by the latter, is a still farther confirmation of the general fact, that the conversion of liquids into elastic fluids is produced by their combining with caloric.

"Five measures (each containing 4lb. 5 oz. and 6 dr. avoirdupois) of water, of the temperature 52°, were poured into a small still in the laboratory. The fire had been kindled about 40 minutes before, and was come to a clear and uniform state. The still was set into the furnace, and, in an hour and 20 minutes, the first drop came from the worm; and in three hours and 45 minutes more, three measures of water were distilled, and the experiment ended. The refrigeratory contained 38 measures of water, of which the temperature, at the beginning of the experiment, was 52°. When one measure had come over, the water in the refrigeratory was at 76°. When two had come over, it was at 100°; and when three had come over, it was at 123°.

"In this experiment, the heat, which emerged from three measures of water, had raised the temperature of the water in the refrigeratory from 52° to 123°, or 71°. Now 3 is to 38 as 71 to $899\frac{1}{3}$, and the heat would have raised the three measures $899\frac{1}{3}$ degrees in its temperature, if this had been possible without converting it into vapour. The heat of the vapour from which this emerged was 212°, or 160° more than that of the water. Taking this from 899°, there remains 739°, the heat contained in the vapour in a latent state.

"But this must be sensibly less than the truth. During the experiment, the vessels were very warm—the head of the still as hot as boiling water, and the refrigeratory gradually rising from 52°, which was within a degree or two of the temperature of the air of the laboratory, to 123°. A very considerable portion of the latent heat of the steam must have been carried off by the air in contact with a considerable surface, some of which was exceedingly hot. A great deal must also have been carried off in the steam which arose very sensibly from the water in the refrigeratory, towards the end of the experiment. Mr Irvine also observed, that, during the distillation, the temperature of the water which ran from the worm was about 11° hotter than the water in the refrigeratory. The steam, therefore, at a medium, was not 160° hotter than the water which ran from the worm, but 125°, its mean temperature being

being about 87°. This consideration alone will make the latent heat of the steam not less than 774 degrees, without any allowance for waste.

"Some comparison may also be made between the heat expended in the production of the steam, and that which emerges during its condensation. The time which elapsed during the raising of the temperature of the five measures of water from 52° to 212°, that is 160°, was one hour and 20 minutes, or 80′,—and 225′ elapsed during the boiling off of three measures. Therefore, since 80 is to 225 as 160 to 450, as much heat was expended as would have raised the five measures 450° in temperature. This would have raised three measures 750° above the boiling heat already produced. This gives 750 for the latent heat of the steam, besides what was unavoidably lost by communication to the ambient air, and what was expended in heating the vessels*."

In some experiments made by Mr Watt, who also assisted Dr Black in conducting these invaluable experiments, it appears that the latent heat of steam is from 900° to 950°. This he discovered by observing the quantity of caloric which was absorbed by the water in its conversion into steam or vapour, and the quantity given out, when that vapour returned to the state of water.

The latent heat of steam, estimated by the experiments of M. Lavoisier, amounts to more than 1000°.

5. Thus is this general law established, that all liquids are converted into elastic fluids, by combining with a certain portion of caloric. This portion of caloric is not indicated by the thermometer, and is therefore said to be latent heat, as we have already mentioned; but when the elastic fluid returns to the liquid state, it again becomes sensible, and precisely the same quantity is extricated which has been absorbed.

6. It is an object of some importance to ascertain the elastic force of vapour, and the ratio of the increase of this elasticity by increase of temperature. The elasticity of vapour which is formed by a liquid boiling in the open air, is equal to the pressure of the atmosphere; and it has been ascertained by the experiments of Mr Dalton and of M. Gay-Lussac, that the elasticity of all elastic fluids is the same with that of the vapour of water, with the same increase or diminution of temperature from the boiling point. If, then, the boiling point of any liquid be known, the elasticity of its vapour may be discovered, by comparing it with the elasticity of the steam of water, the same number of degrees above or below the boiling point. In the following table, constructed by Mr Dalton from his experiments and calculations, the elasticity of the vapour of water is given for every temperature from 40° to 325°. To find the elasticity of the vapour of ether at 40° below its boiling point, which is 98°, take 40° from 98°, there remains 58, and the same number from 212° the boiling point of water, there remains 172°, opposite to which number in the table is 12.73, which is the elasticity of the steam of water at 172°, and also the elasticity of the vapour of ether at 58°.

Table of the Force of Vapour from Water in every temperature, from that of Congelation of Mercury, or 40° below Zero of Fahrenheit, to 325°†.

Calori

Sect. III. *Of the Motion of Caloric.*

1. It appears that the motion of caloric, when it is not interrupted, is equal in velocity to that of light. When therefore it is emitted by one body, it moves on with this velocity till it is received by another. This has been called the *transmission* or *radiation* of heat. This radiation or separation of heat from any body, arises from the force with which it is conncted with that body being diminished; that is when a greater quantity of caloric is accumulated in that body than it can contain. The experiments of Dr Herschel shew, that heat is radiated, refracted, and reflected in the same manner as light. The reflection of caloric has also been proved by the experiments of Mr Pictet formerly mentioned. But caloric is communicated from one body to another by direct contact of these bodies.

240 Velocit caloric equal to that of light.
241 Radiate
342 Refract
243 and refle ed.

2. It is well known that a cold body brought into contact with a warm body, becomes in a certain time hot, but this does not take place instantaneously; and the time necessary for one body to receive caloric from another, or for the different parts of the same body to acquire the same temperature, varies according to the nature and state of these bodies. This is called the *conducting* power of bodies.

244 Is comm nicated contact.

3. But as different bodies have different degrees of affinity for caloric, or contain different proportions of it, it must be separated or absorbed with greater or less facility. The motion of caloric therefore, in these different circumstances, will be considerably varied in its celerity. This may be proved by direct experiment. If one extremity of two substances of different properties, as, for instance, a rod of iron and another of wood, be put into the fire, and the hand brought into contact with the other extremity, the rod of iron will soon be heated too much for the hand to bear, while the rod of wood will not have its temperature increased. This shews, that the caloric is carried a shorter distance through the wood; or, in other words, the iron is a better conductor than the wood.

245 More ra pidly in some bo dies.

4. All solid bodies are conductors of caloric, but they possess this power in very different degrees. Those which conduct caloric with facility are called *good* conductors; those through which it passes with difficulty, or very slowly, are said to be *bad* conductors. The motion of caloric from one body to another, or through the same body, is not altogether in proportion to their densities, as might be supposed from the instance of the communication of caloric through wood and iron, just mentioned. Caloric is conducted very slowly through a more porous substance, such as a mass of cork, or a quantity of wool, feathers, or furs. It is on account of the slowness with which heat is conducted in these substances, that some of them are employed in cold weather, and in cold countries, as materials for clothing. The heat being slowly conducted through such substances, they prevent the heat of the body from being dissipated; they retard the communication between the warm body and the cold air. We find a wise provision of nature, in furnishing all animals which are inhabitants of the colder regions of the earth, with a thick covering of fur or feathers. The conducting power of fur, feathers, silk, and wool, was found in the experiments of Rumford, to diminish in proportion to the fineness of their texture.

246 Good c ductors.
247 Bad co ductors.
248 Their

Metallic

49 Metals the best conductors. Metallic substances are the best conductors of caloric; but among the metals there is considerable variety of conducting power, and this is not in proportion to their density, as appears from the experiments of Dr Ingenhousz on the following metals, which are set down in the order of their conducting power *.

Silver,
Gold,
Copper,
Tin,
Platina,
Iron,
Steel,
Lead.

50 Conducting power of woods. A set of experiments was made on the conducting power of different woods, by Professor Mayor of Erlangen, of which the following are the results, compared with the conducting power of water †.

Water,	10.0
Ebony,	21.7
Crab apple,	27.4
Ash,	38.0
Beech,	32.1
Hornbeam,	32.3
Plum tree,	32.5
Female oak,	32.6
Pear tree,	33.2
Birch,	34.1
Oak,	36.3
Pitch pine,	37.5
Alder,	38.4
Pine,	38.6
Fir,	38.9
Lime tree,	39.0

The experiments of Guyton shew, that the conducting power of charcoal is to that of fine sand nearly in the proportion of 2 to 3 ‡.

251 Fluids are conductors. 5. Fluid bodies, as well as solids, are conductors of caloric; but they are found to conduct it so slowly, that it was at one time supposed that they did not possess this power at all, that is, that the caloric was not conducted from particle to particle in fluids, as it is in solid bodies. This opinion seemed to be supported by the nature and constitution of fluids, in which the particles have free motion among each other, so that when one set of particles acquires an additional quantity of caloric, their specific gravity is necessarily diminished; and if lower, they naturally change place with those other particles of the fluid which have been less heated, and are consequently heavier. These different appearances which were observed in the heating of fluids led Count Rumford, who made many ingenious experiments on this subject, to conclude, that fluids are heated, or conduct caloric, in a different manner from solids. In a spirit of wine thermometer, which was placed in a window to cool, he observed the fluid in the tube in rapid motion. There were two currents going in different directions, the one ascending, and the other descending. The descending current occupied the sides of the tube, and the ascending current the middle. The currents were owing to the change in the specific gravity of the particles, which being heated became lighter, and rose to the top; the heavier particles at the same time descended. The particles which ascended having reached the sides or top of the tube, gave out their caloric, became specifically heavier, and again fell to the bottom. The motion of the currents was considerably increased by the application of a cold body to the sides of the tube. The count also repeated the experiment with linseed oil, and with water, in the latter of which he dissolved potash, to bring its specific gravity to that of amber, small pieces of which he introduced, to observe the currents more distinctly. These experiments were followed with the same result. When the temperature was increased or diminished, the currents were set in motion, and only ceased when the temperature became equal to that of the surrounding bodies.

In prosecuting this subject, the count made other experiments, to ascertain how far the heating or cooling of fluids is affected by a difference of fluidity. The thermometer which he employed in these experiments, had a copper bulb and a glass tube, and was filled with linseed oil. This was placed in the centre of a brass cylinder, and the space between the sides of the cylinder and the thermometer, was 0.25175. The thermometer being secured, the cylinder was filled with 2276 grs. of pure water, and held in melting snow, till the thermometer fell to 32°. It was then immersed in boiling water, and the thermometer rose from 32° to 200° in 597″. The caloric which raised the thermometer must have been communicated to it through the water in the cylinder. The experiment was then varied, by boiling 192 grs. of starch in the water in the cylinder. The thermometer now required 1109″ to rise from 32° to 200°. The same experiment was repeated by mixing 192 grs. eider down with the same quantity of water, and also with a quantity of stewed apples. The result of these experiments will be seen in the following tables §.

Caloric.

The substances which were added to the water in these experiments, had, by diminishing its fluidity, the effect of retarding the internal motions or currents by which the caloric is conducted through fluids. Thus, when starch was mixed with water, it required nearly double the time to raise the thermometer to the same degree, as with pure water. From these and from some other experiments, Count Rumford concluded, that fluid bodies are heated in a different manner from solids; that caloric is not communicated through fluids from particle to particle, but that all the particles individually come in contact with the heating body, and this is supposed to be the cause of the currents which are observed during the heating of the fluids.

6. Fluids no doubt acquire great part of their temperature in this manner; but it has been clearly proved, by the experiments of others, that they are also conductors of caloric exactly the same way as solid bodies, only in an inferior degree. This has been established in the most satisfactory manner by the experiments of Dr Thomson * and Dr Murray †, which were published in Nicholson's Journal; and also by another set of experiments by Mr Dalton, which were published in the Manchester Memoirs ‡. By these experiments it is demonstrated, that fluids conduct caloric from the surface downwards; which could not be the case, were it only communicated through them by the ascending
252 but worse than solids, currents of particles, in the way Count Rumford supposed; but they are worse conductors of caloric than solids; that is, it passes through them much more slowly.

† Ibid. octavo, vol i. p. 165.
‡ Vol. v. p. 373.

Sect. IV. *Of the Distribution of Caloric.*

253 All bodies acquire the same temperature in the same medium.

If a number of bodies be exposed to different temperatures, and then be all placed in the same temperature, or brought into contact with each other, they acquire in a certain time the same temperature. Thus, if one body be raised to the temperature of 200°, another to that of 100°, and a third to the temperature of 60°; and if these three bodies be placed in the temperature of 80°, they all indicate, in a short time, the same temperature. The bodies which were at the temperature of 200° and 100° are reduced to 80°, and the temperature of the body at 60° rises to the same. This is called the *distribution*, or the tendency to *equilibrium* of caloric. To whatever degree bodies are heated or cooled, they all acquire in time the temperature of the surrounding medium, as indicated by the thermometer. It may therefore be received as a general law, *that all bodies which communicate freely with each other, and are subject to no inequality of external action, acquire the same temperature.*

254 Radiation not the sole cause of cooling.

1. Bodies are deprived of caloric, not only by radiation from their surfaces, but it is also conducted by the surrounding bodies with which the heated body comes in contact, and this depends greatly on the nature of the cold body. The experiments of Professor Pictet and Count Rumford, however, shew, that radiation is not the only cause. By those of the former it appeared, that hot bodies suspended in the vacuum of an air pump, cooled more slowly than in the open air; and by those of the latter, the cooling was still slower in the Torricellian vacuum.

255 Good conductors cool more rapidly.

2. The time requisite for the heating or cooling of bodies depends much on their conducting power. A substance which is a good conductor of caloric cools much more rapidly than a bad conductor. Mercury and water heated to the same temperature cool in very different times: the mercury cools more than twice as fast as the water in the same circumstances. The time of the cooling of fluids has been considered as nearly in the inverse ratio of their conducting power. It depends, however, in part on other qualities, as their moveableness and their capacity for heat, a subject to be afterwards explained, and which has the principal influence in the difference between water and mercury.

256 Distribution of caloric explained by Boerhaave, &c.

3. This equal distribution of caloric was attempted to be explained by Boerhaave, Muschenbroeck, and others, by supposing that there is an equal quantity of caloric in every equal measure of space, however that space might be filled up with different bodies, and that these bodies floated, as it were, in this caloric. From this equal distribution of caloric in space, they concluded that there was an equal quantity of caloric in all bodies, because, whatever was the density or different circumstances of bodies, they always indicated the same temperature to the thermometer. A cubic foot of gold, and a cubic foot of air, according to this theory, contained the same quantity of caloric.

257 By Pictet.

Professor Pictet gave another explanation of this phenomenon. He supposed that the accumulation of caloric in a body increased the repulsive force between its particles, by the diminution of the distance between them. By the action of this repulsive force, the particles are driven off in all directions. This repulsion continues to act till it is opposed by a new force, which is the force of repulsion between the particles of caloric separated from another body; and, till these two forces acquire the same intensity, the particles of caloric continue to separate from the hotter body. When the two forces are balanced, the bodies are of the same temperature. Thus, if two bodies of different temperatures are brought into contact with each other, the repulsive force of the particles of caloric in the hotter body is the greatest, and therefore the particles tend to separate from each other; but the repulsion between the particles of the colder body being less, they come nearer each other. The caloric from the hotter body continues to separate, and to enter the colder body, till the two forces exactly balance each other, and then the temperature is the same *. But this theory, with all its simplicity and ingenuity, being unsatisfactory in accounting for the equilibrium of temperature, has been given up, even by its author.

* Essai sur le Feu, chap. i.

258 His theory unsatisfactory.

259 Prevost's theory.

4. Another theory has been proposed by M. Prevost, professor of philosophy at Geneva. "Accustomed," says he, "for a long time, to consider this subject in a different view from what had been formerly taken of it, I endeavoured to draw the attention of naturalists to this investigation, in a memoir on the equilibrium of caloric †, and in my *researches on heat* ‡. In these works, I believe it was first proposed to substitute a moveable equilibrium in place of the immoveable equilibrium, the existence of which had been generally admitted.

† Journal de Phys. Avril 1791.
‡ Geneva 1792.

"On this hypothesis, it is equally easy and satisfactory to account for the reflection of cold, as for that of heat. I consider it indeed a characteristic of its truth; for these two facts being of the same kind, the theory that

that will account for the one is applicable to the other. Before I proceed to state in a few words the principle of this theory, I may premise, that I had the satisfaction of seeing it adopted by M. Pictet and others, who are well qualified to judge of it.

"Caloric is a discrete, agitated fluid: each particle of free caloric moves with immense volocity; one particle moves in one direction, and another particle moves in another, so that a heated body gives out calorific rays in all directions; and these particles are so far separated from each other, that two or more currents may cross each other, as is the case with light, without mutual disturbance in their course. Conceiving this to be the constitution of caloric, if we suppose two contiguous spaces in which it abounds, there will be continual changes between these spaces. If in the two spaces caloric abounds equally, the exchanges will be equal; there will be an equilibrium. If one of the spaces contain more caloric than the other, the exchanges will be unequal. The coolest will receive more particles of caloric than it gives out, and after a sufficient time, the continual repetition of these changes will restore the equilibrium *.

"From these principles may be deduced all the laws of the increase and diminution of temperature. Let us suppose a body placed in a medium hotter than itself, and that this medium has a constant temperature. We may consider the caloric of the medium as composed of two parts, the one equal to that of the body, and the other equal to the difference of the two. With regard to the first, the exchanges are equal; between the body and the medium there is an equilibrium. The excess of the heat of the medium may then only be considered; and relatively to this excess the body is absolutely cold. Let us suppose that in one second the body receives $\frac{1}{10}$ of this caloric; at the end of the first second the excess will be no more than $\frac{1}{10}$: the $\frac{1}{10}$ of this new excess will pass into the body during the next second; and the excess will be reduced to $\frac{9}{10}$ of $\frac{9}{10}$; and in pursuing this, at the end of the third second, the excess will be $(\frac{9}{10})$, and so on; so that, conformably to the observed law, the times increase in arithmetical progression, and the differences decrease in geometrical progression. In the same way may be easily deduced the law of the cooling of a body placed in a medium colder than itself. And thus the true theory of heat, founded on facts totally different from those by which Richmann established this law, necessarily leads us to it †.

SECT. V. *Of the* QUANTITY *of* CALORIC *in Bodies.*

We are next to consider the *quantity* of caloric which different bodies contain. This subject has occupied the attention and speculations of many philosophers. In these speculations, two objects were kept in view, the one to ascertain the whole quantity of caloric which a body contains, and the other the quantity of caloric necessary to raise different bodies to the same temperature. This last is most easily investigated, and is usually called *specific caloric.*

1. OF SPECIFIC CALORIC.

1. If one lb. of water at the temperature of 100° be mixed with another lb. of water at the temperature of 50°, they will very soon acquire the same temperature, which will be the mean of the two temperatures. The pound of water at 100° will give out 25°, and the pound of water at 50° will receive 25°, which brings both to the temperature of 75°.

2. But if we take one pound of water at 100°, and one pound of mercury at 50°, the temperature, after mixing the water and the mercury, will not be 75°, the medium temperature in the former case. On the contrary, when the mixture is made, the temperature will be found to be 88°. The water therefore has lost only 12°, and the mercury has gained 38°. If this experiment be reversed, and one pound of water at 50° be mixed with a pound of mercury at 100°, the temperature of the mixture will be found to be only 62°; so that in this case the mercury has given out 38°, and the water has received only 12°. In this experiment, therefore, it appears clearly, that different quantities of caloric are necessary to increase or diminish the temperature of different bodies; for, the quantity of caloric which raises water 12°, raises mercury no less than 38°. This quantity of caloric which bodies require to raise them to the same temperature, is called *specific caloric.*

3. "It was formerly a common supposition," says Dr Black, "that the quantities of caloric required to increase the heat of different bodies by the same number of degrees, were directly in proportion to the quantity of matter in each; and therefore, when the bodies were of equal size, the quantities of caloric were in proportion to their density. But very soon after I began to think of this subject, in the year 1760, I perceived that this opinion was a mistake, and that the quantities of heat which different kinds of matter must receive, to reduce them to an equilibrium with one another, or to raise their temperature by an equal number of degrees, are not in proportion to the quantity of matter in each, but in proportions widely different to this, and for which no general principle or reason can yet be assigned ‡." This difference was first pointed out by Dr Black, which he states in the above observations, and he distinguished it by the term *capacity of bodies for heat.* Dr Black's method, which is given by Professor Robison, is the following. 261

"Dr Black estimated the capacities, by mixing the two bodies in equal masses, but of different temperatures; and then stated their *capacities as inversely proportional to the changes of temperature of each by the mixture.* Thus, a pound of gold, of the temperature 150°, being suddenly mixed with a pound of water, of the temperature 50°, raises it to 55° nearly: Therefore the capacity of gold is to that of an equal weight of water as 5 to 95, or as 1 to 19; for the gold loses 95°, and the water gains 5°.

"It will be most convenient to compare all bodies with water, and to express the capacity of water by unity, or to call it 1. Let the quantity of the water be W, and its temperature *w*. Let the quantity of the other body be B, and its temperature *b*. Let the temperature of the mixture be *m*. The capacity of B is $\frac{W \times \overline{m-w}}{B \times \overline{b-m}}$, or when the water has been the hotter of the two, the capacity of B is $\frac{W \times \overline{w-m}}{B \times \overline{m-b}}$. In other words,

Margin notes: Caloric. — * Phil. Trans. — † Phil. Trans. — ‡ Black's Lect. vol. i. p. 79. — Dr Black's method.

words, *multiply the weight of the water by its change of temperature. Do the same for the other substance. Divide the first product by the second. The quotient is the capacity of the other substance, that of water being accounted* 1 * (P)."

* Lect. v. i. p. 506.

4. This subject was still farther prosecuted by other philosophers, particularly by Dr Irvine of Glasgow, Dr Crawford of London, and Professor Wilcke of Stockholm.

262 Dr Crawford's.

The method which was employed by Dr Crawford was similar to that of Dr Black. Two substances, which were of different temperatures, were uniformly mixed; the change of temperature produced on each was observed, and this was considered as inversely proportional to its specific caloric.

263 Mr Wilcke's.

Mr Wilcke has ascertained the specific caloric of many metals, by a set of very ingenious experiments, which were conducted in the following manner. The metal, which was the subject of the experiment, was first accurately weighed. The quantity employed was generally a pound. It was then suspended by a thread, plunged into a vessel of tin-plate filled with boiling water, and allowed to remain till it reached a certain temperature indicated by the thermometer. A quantity of water at the temperature of 32°, exactly equal in weight to the metal, was put into another vessel of tin plate. The metal was then immersed in this vessel, and suspended in it so as to be kept clear of the sides and bottom. The temperature, at the moment when the metal and water were reduced to the same, was observed. The specific caloric of the metal was then deduced by calculation from the change of temperature. He first calculated what the temperature would have been, if a quantity of water of equal weight with the metal, and of the same temperature, had been added to the ice-cold water. The following is the process.

Let M be a quantity of water at the temperature C, m another quantity at the temperature c, and let their common temperature after mixture be x; according to a rule demonstrated long ago by Richman, $x=\frac{MC+mc}{M+m}$. In the present case the quantities of water are equal, therefore M and m are each $=1$; C, the temperature of the ice-cold water, $=32$: therefore $\frac{MC+mc}{M+m}=\frac{32+c}{2}$. Now c is the temperature of the metal. Therefore if 32 be added to the temperature of the metal, and the whole be divided by 2, the quotient will express the temperature of the mixture, if an equal weight of water with the metal, and of the same temperature with it, had been added to the ice-cold water instead of the metal.

He then calculated what the temperature of the mixture would have been, if, instead of the metal, a quantity of water of the same temperature with it, and equal to the metal in bulk, had been added to the ice-cold water. As the weights of the ice-cold water and the metal are equal, their volumes are inversely as their specific gravities. Therefore the volume of ice-cold water is to a quantity of hot water equal in volume to the metal, as the specific gravity of the metal to that of the water. Let M $=$ volume of cold water, $m=$ volume of hot water, $g=$ specific gravity of the metal, $1=$ specific gravity of water; then $m:M::1:g$; hence $m=\frac{M}{g}=$ (M being made $=1$) $\frac{1}{g}$. Substituting this value of m in the formula, $\frac{MC+mc}{M+m}=x$, in which $M=1$ and $C=32$, x will be $=\frac{32g+c}{g+1}$. Therefore, if the specific gravity of the metal be multiplied by 32, and the temperature of the metal be added, and the sum be divided by the specific gravity of the metal $+1$, the quotient will express the temperature to which the ice-cold water would be raised, by adding to it a volume of water equal to that of the metal, and of the same temperature with it.

He then calculated how much water at the temperature of the metal it would take to raise the ice-cold water the same number of degrees which the metal had raised it. Let the temperature to which the metal had raised the ice-cold water be $=N$, if in the formula $\frac{MC+mc}{M+m}=x$, x be made $=N$, $M=1$, $C=32$, m will be $=\frac{N-32}{c-N}$. Therefore, if from the temperature to which the ice-cold water was raised by the metal 32 be subtracted, and if from the temperature of the metal be subtracted the temperature to which it raised the water, and the first remainder be divided by the last, the quotient will express the quantity of water of the

(P) "These experiments require the most scrupulous attention to many circumstances which may affect the result. 1. The mixture must be made in a very extended surface, that it may quickly attain the medium temperature. 2. The stuff which is poured into the other should have the temperature of the room, that no change may happen in the pouring it out of its containing vessel. 3. The effect of the vessel in which the mixture is made must be considered. 4. Less chance of error will be incurred when the substances are of equal bulk. 5. The change of temperature of the mixture, during a few successive moments, must be observed, in order to obtain the real temperature at the beginning. 6. No substances should be mixed which produce any change of temperature by their chemical action, or which change their temperature, if mixed, when of the same temperature. 7. Each substance must be compared in a variety of temperatures, lest the ratio of the capacities should be different in different temperatures.

"When all these circumstances have been duly attended to, we obtain the measure of the *capacities* of different substances for heat." *Black's Lect.* vol. i. p. 506.

the temperature of the metal which would have raised the ice-cold water the same number of degrees that the metal did.

Now, $\frac{N-32}{c-N}$ expresses the specific caloric of the metal, that of water being $=1$. For (neglecting the small difference occasioned by the difference of temperature) the weight and volume of the ice-cold water are to the weight and volume of the hot water as 1 to $\frac{N-32}{c-N}$, and the number of particles of water in each are in the same proportion. But the metal is equal in weight to the ice-cold water, it must therefore contain as many particles of matter; therefore the quantity of matter in the metal must be to that in the hot water as 1 to $\frac{N-32}{c-N}$. But they gave out the same quantity of caloric; which, being divided equally among their particles, gives to each particle a quantity of caloric inversely as the bulks of the metal and water; that is, the specific caloric of the water is to that of the metal as 1 to $\frac{N-32}{c-N}$ (R).

It will now be proper to give a specimen or two of his experiments, and the calculations founded on them, as above described.

It is needless to add, that the last column marks the denominator of the specific caloric of the metal; the numerator being always 1, and the specific caloric of water being 1. Thus the specific caloric of gold is $\frac{1}{19.712}$. In exactly the same manner, and by taking a mean of a number of experiments at different temperatures, did Mr Wilcke ascertain the specific caloric of a number of other bodies *.

† Thomson's Chemistry, vol. i. 314.

5. With the same view, to ascertain the specific caloric of bodies, a simple and ingenious apparatus was contrived by Lavoisier and La Place. This instrument is called a *calorimeter*, or measurer of heat. Its principles and construction are the following:

264 Lavoisier's method.

"If, after having cooled (says Lavoisier) any body to the freezing point, it be exposed in an atmosphere of 88.25°, the body will gradually become heated, from the surface inwards, till at last it acquire the same temperature with the surrounding air. But, if a piece of ice be placed in the same situation, the circumstances are quite different: it does not approach in the smallest degree towards the temperature of the circumambient air, but remains constantly at 32°, or the temperature of melting ice, till the last portion of ice be completely melted.

"This phenomenon is readily explained; as, to melt ice, or reduce it to water, it requires to be combined with a certain portion of caloric, the whole caloric attracted from the surrounding bodies is arrested or fixed at the surface or external layer of ice which it is employed to dissolve, and combines with it to form water; the next quantity of caloric combines with the second layer to dissolve it into water, and so on successively till the whole ice be dissolved, or converted into water, by combination with caloric; the very last atom still remaining at its former temperature, because the caloric could never penetrate so far, while any intermediate ice remained to melt, or to combine with.

"Upon these principles, if we conceive a hollow sphere of ice at the temperature of 32° placed in an atmosphere of 54.5°, and containing a substance at any degree of temperature above freezing; it follows, That the heat of the external atmosphere cannot penetrate into the internal hollow of the sphere of ice; and, That the heat of the body which is placed in the hollow of the sphere, cannot penetrate outwards beyond it, but will be stopped at the internal surface, being continually employed to melt successive layers of ice, until the temperature of the body be reduced to 32° by having all its superabundant caloric above that temperature carried off to melt the ice. If the whole water, formed within the sphere of ice during the reduction of the temperature of the included body to 32°, be carefully collected, the weight of the water will be exactly proportioned to the quantity of caloric lost by the body, in passing from its original temperature to that of melting ice; for it is evident that a double quantity of caloric would have melted twice the quantity of ice. Hence the quantity of ice melted is a very exact measure of the proportional quantity of caloric employed to produce that effect, and consequently of the quantity lost by the only substance that could possibly have supplied it.

"I have made this supposition, of what would take place in a hollow sphere of ice, for the purpose of more readily explaining the method used in this species of experiment, which was first conceived by M. de la Place.

Caloric.

Place. It would be difficult to procure such spheres of ice, and inconvenient to make use of them when got; but, by means of the following apparatus, we have remedied that defect.

"The calorimeter is represented in Plate CXLII. fig. 2. The capacity or cavity is divided into three parts, which, for better distinction, I shall name the interior, middle, and external cavities. The interior cavity *ffff*, into which the substances submitted to experiment are put, is composed of a grating or cage of iron wire, supported by several iron bars; its opening or mouth LM, is covered by the lid HG, fig. 3. which is composed of the same materials. The middle cavity *bbbb*, fig. 2. contains the ice which surrounds the interior cavity, and which is intended to be melted by the caloric of the substances employed in the experiment. The ice is supported by the grate *mm* at the bottom of the cavity, under which is placed the sieve *nn*.

265 Apparatus described.

"In proportion as the ice contained in the middle cavity is melted by the caloric disengaged from the body placed in the interior cavity, the water runs through the grate and sieve, and falls through the conical funnel *ccd*, fig. 2. and the tube *xy*, into a receiver. This water may be retained or let out at pleasure, by means of the stop-cock *u*. The external cavity *aaaa*, fig. 2. is filled with ice, to prevent any effect upon the ice in the middle cavity from the heat of the surrounding air, and the water produced from it is carried off through the pipe ST, which shuts by means of the stop-cock *r*. The whole machine is covered by a lid made of tin, and painted with oil colour, to prevent rust.

"When this machine is employed, the middle cavity *bbbb*, fig. 2. and the lid GH, fig. 3. of the interior cavity, the external cavity *aaaa*, fig. 2. and the lid which covers the whole, are all filled with pounded ice, well rammed, so that no void spaces remain, and the ice of the middle cavity is allowed to drain. The machine is then opened, and the substance submitted to experiment being placed in the interior cavity, it is instantly closed. After waiting till the included body is completely cooled to the freezing point, and the whole melted ice has drained from the middle cavity, the water collected in the receiver is accurately weighed. The weight of the water produced during the experiment is an exact measure of the caloric disengaged during the cooling of the included body, as this substance is evidently in a similar situation with the one formerly mentioned as included in a hollow sphere of ice. The whole caloric disengaged from the included body is stopped by the ice in the middle cavity, and that ice is preserved from being affected by any other heat by means of the ice contained in the cover and in the external cavity. Experiments of this kind generally last from 15 to 20 hours, but they are sometimes accelerated by covering up the substance in the interior cavity with well drained ice, which hastens its cooling.

"It is absolutely requisite that there be no communication between the external and middle cavities of the calorimeter, otherwise the ice melted by the influence of the surrounding air, in the external cavity, would mix with the water produced from the ice of the middle cavity, which would no longer be a measure of the caloric lost by the substance submitted to experiment.

"When the temperature of the atmosphere is only a few degrees above the freezing point, its heat can hardly reach the middle cavity, being arrested by the ice of the cover, and of the external cavity; but, if the temperature of the air be under the degree of freezing, it might cool the ice contained in the middle cavity, by causing the ice in the external cavity to fall, in the first place, below 32°. It is therefore essential that this experiment be carried on in a temperature somewhat above freezing: Hence, in time of frost, the calorimeter must be kept in an apartment carefully heated. It is likewise necessary that the ice employed be not under 32°, for which purpose it must be pounded, and spread out thin for some time, in a place where the temperature is higher. *Elem. Chim.*

6. Tables of the specific caloric of bodies have been given by Dr Crawford, Mr Kirwan, Bergman, Gadolin, and Meyer. The following are the results of their investigations.

TABLE *of the Specific Caloric of various Bodies, that of Water being* = 1.0000.

Bodies.	Specific Gravity.	Specific Caloric.
I. GASES.		
Hydrogen gas - -	0.000094	21.4000
Oxygen gas - - -	0.0034	4.7490
Common air - -	0.00122	1.7900
Carbonic acid gas -	0.00183	1.0459
Steam - - -		1.5500
Azotic gas - -	0.00120	0.7036
II. LIQUIDS.		
Water - - -	1.0000	1.0000
Carbonate of ammonia -		1.851
Arterial blood - -		1.030
Cows milk - - -	1.0324	0.9999
Sulphuret of ammonia -	0.818	0.9940
Venous blood - -		0.8928
Solution of brown sugar -		0.8600
Nitric acid - -		0.844
Sulphate of magnesia 1, Water - - 8		0.844
Common salt 1, Water - 8 - -		0.832
Nitre 1, Water 8 - -		0.8167
Muriate of ammonia 1, Water - - -		0.779
Tartar 1, Water 237.3 - -		0.765
Solution of potash - -	1.346	0.759
Sulphate of iron 1, Water - 2.5 -		0.734
Sulphate of soda 1, Water - 2.9 -		0.728
Oil of olives - -	0.9153	0.710
Ammonia - -	0.997	0.7080

2. Of the Absolute Quantity of Caloric.

1. Such are the different methods which have been proposed to ascertain the relative quantities of caloric which are necessary to reduce bodies to the same temperature. Attempts have also been made to discover the temperature of absolute privation, and thus to ascertain the whole quantity of caloric which a body contains.

The first attempt made with this view was by the late Dr Irvine of Glasgow. The theorem which he invented to ascertain the real zero, or the absolute quantity of caloric which a body contains, is founded on the uniformity of the specific caloric of bodies at all temperatures. And taking it for granted that the specific caloric of bodies is always the same, whatever be the temperature, the whole quantity, or the absolute quantity, will be proportional to the specific caloric. Having discovered the ratio between the absolute calorics of bodies, and the difference between two absolute calorics, the whole quantity in any body might be found by calculation. But either the data on which the theorem proceeds are wrong, or the experiments which have been made with the view of applying it to the

266 Dr Irvin[e's] method

267 founded [on] the uni[for]mity of specific caloric.

Caloric.

the estimation of the absolute quantity of caloric have been very inaccurately conducted, the results varying so much from each other. According to Dr Irvine's own experiments and calculation, the real zero with regard to ice would be 1228° below 0°; but according to Dr Crawford's it is 1500°. Mr Kirwan makes it 1318° below 0°, from a comparison of the specific caloric of water and ice. Lavoisier and La Place fix it at 3426° below 0°, from the result of experiments on a mixture of water and quicklime. But in other experiments by the same philosophers, there is a great variation in the result. Four parts of sulphuric acid, and three parts of water, mixed together, give a result for the real zero equal to 7260° below 0°; and four parts of sulphuric acid, and five of water, give it only equal to 2598° below 0°. Professor Robison, speaking of the specific and absolute quantities of heat in bodies being supposed to be proportional, observes that "this opinion is just, only on the supposition that the measures obtained by experiments and calculation are constantly the same, whatever the temperatures may be in which the experiments are made. Dr Irvine's ingenious method of discovering the temperature of absolute privation, evidently presupposes this constancy of specific heat; or, if they are not constant, it supposes that we know the whole law of variation. Now, both of these assumptions are improbable. In none of the progressions of natural operations that we are acquainted with do we find this constancy. It is much more analogous to other phenomena, to suppose that, in the temperatures near to that of absolute privation, the quantities of heat necessary for producing equal elevation gradually diminish, and this, perhaps, without end, like the distance of the hyperbola from its assymptote. It is equally probable that the law of diminution may be different in different substances. This will cause the measures of specific heats to change their proportions continually; and therefore the specific capacities observed in temperatures, all of which are far removed from that of the entire absence of heat, give us no means of obtaining the proportions of the accumulated sum of all the heats which have been received into the substances. It follows from this, that even although it should be granted to Dr Irvine, that the heat which emerges, in mixing vitriolic acid and water, or in the freezing of water, is the difference between the absolute heats of the mixture or the ice, and the absolute heats of the substances before mixture, or of the water before freezing, still we cannot ascertain those absolute heats, or the temperature of no heat.

Accordingly it appears, that it has been only in a very few cases that Dr Irvine found a tolerable coincidence of his determination of this extreme cold, and the determination by means of mixtures differed enormously from those obtained by means of congelation; and still more from those obtained by means of the condensation of vapour *.

2. Mr Dalton has proposed another hypothesis for determining the real zero, or the absolute quantity of caloric in bodies. He observes that the remarkable fact of the quantity of expansion of elastic fluids being the same in the same circumstances, shews, that it depends solely upon heat: "whereas the expansion in solid and liquid bodies seems to depend upon an adjustment of the two opposite forces of heat and chemical affinity, the one a *constant* force in the same temperature, the other a *variable* one, according to the nature of the body; hence the unequal expansion of such bodies. It seems therefore that general laws respecting the absolute quantity and the nature of heat, are more likely to be derived from elastic fluids than from other substances.

"In order to explain the manner in which elastic fluids expand by heat, let us assume an hypothesis that the repulsive force of each particle is exactly proportional to the whole quantity of heat combined with it, or in other words to its temperature reckoned from the point of total privation: then since the diameter of each particle's sphere of influence is as the cube root of the space occupied by the mass, we shall have $\sqrt[3]{1000} : \sqrt[3]{1325}$ (10 : 11, nearly) :: the absolute quantity of heat in air of 55°: the absolute quantity in air of 212°. This gives the point of total privation of heat, or absolute cold, at 1547° below the point at which water freezes. Dr Crawford deduces the said point, by a method wholly different, to be 1532°. So near a coincidence is certainly more than fortuitous.

"The only objection I see to this hypothesis is, that it necessarily requires the augmentation of elastic fluids for a given quantity of heat to be greater in the higher temperatures than in the lower, because the cubes of a series of numbers in arithmetical progression differ more the larger the numbers or roots: but it has just been shewn that in fact an augmentation of a contrary kind is observed. This refers us to the consideration whether the mercurial thermometer is an accurate measure of the increments of heat: if it be, the hypothesis fails; but if equal increments of heat cause a greater expansion in mercury, in the higher than in the lower temperatures, and that in a small degree, the fact noticed above, instead of being an objection, will corroborate the hypothesis. Dr Crawford determines the expansions of mercury to be very nearly in proportion to the increments of heat: M. de Luc makes them to be less for a given quantity of heat in the lower than in the higher part of the scale; and in a ratio that agrees with this hypothesis. Now as every other liquid we are acquainted with is found to expand more in the higher than in the lower temperatures, analogy is in favour of the conclusions of De Luc, that mercury does the same."

Manch. Mem. v. 602.

The different methods which have been proposed by philosophers to determine the real zero, or the absolute quantity of caloric in bodies, and the want of coincidence between the results of the experiments and calculations founded on these methods, shew us, at least, that the subject is attended with great difficulty and uncertainty. Perhaps the present state of our knowledge does not furnish us with the means of removing the difficulty.

Cold.

3. Having thus considered the relative and absolute quantities of caloric in bodies, and the methods which have been proposed for ascertaining these quantities, it may be necessary to state in what sense, or with what limitations, the term *cold* is to be employed. When we leave a room at the temperature of 60°, and go into the air in a frosty day at the temperature of 32°, we say that it is cold; or when the hand is held in water at the temperature of 100° for a few minutes, and

Caloric.

and then suddenly plunged into water at the temperature of 40°, the latter is said to be cold. This, however, is merely an expression of the sensation excited in the body, which depends solely on the abstraction of its heat. This may be proved by the following experiment. If three quantities of water are taken, the first at the temperature of 32°, the second at the temperature of 50, and the third at the temperature of 100°. Immerse the right hand into the water at the temperature of 100°, and the left into the water at the temperature of 32°. Let them remain for a minute, and then suddenly plunge both hands into the water at the intermediate temperature of 50°; the right hand will feel cold, and the left hand warm; and thus different sensations are produced by the same body at the same time and at the same temperature. This depends entirely on the previous state of the hands, and on the absorption or abstraction of caloric; and this seeming paradox is easily explained by what has been said on the equal distribution of caloric. The right hand which was placed in the water at the temperature of 100° absorbed caloric, because the temperature of the water is above that of the body. This excites the sensation of heat; but when the same hand is placed in the water at the temperature of 50° it is deprived of caloric, because the surrounding medium is far below its temperature; and thus the sensation of cold is produced. But from the left hand, placed in the water at 32° caloric is abstracted, which gives the sensation of cold, and the same hand placed in the water at 50° receives caloric, and this entering the body, excites the sensation of heat.

Thus, then, the term *cold* is merely expressive of the relative temperature of two bodies. In common language the word *cold* is sufficiently intelligible, but in the present view of the doctrine of caloric, it can have no other precise meaning, than to express the absence of a quantity of heat.

The remarkable effects which were produced on fluids by the abstraction of caloric, were once ascribed rather

271 Frigorific particles.

to the addition of a new body, than to the abstraction of one formerly in combination. The hypothesis of Le Mairan and Muschenbroeck, supposed the existence of frigorific particles; and this prevailed till the effects of caloric were developed by the discoveries of modern chemistry. They were led to this hypothesis from observing the increase of bulk which takes place when water is converted from the fluid into the solid state. These frigorific particles were imagined to have some resemblance to nitre. This opinion probably arose from the circumstance of a great degree of cold, or diminution of temperature, being produced by dissolving nitre in water. The frigorific particles were supposed to be constantly floating in the air, and by mixing with liquid bodies, as water, converted them into solids, by acting the part of wedges, which prevented the free motion of the particles among each other.

272 Cold seems to be reflected.

The experiments of Professor Pictet, in which cold seemed to be reflected, still gave some support to this opinion. Two concave mirrors of tin were placed at the distance of $10\frac{1}{2}$ feet from each other; a glass vessel full of snow was placed in the focus of the one, and an air thermometer in that of the other. The thermometer sunk several degrees, but when the snow was removed, it rose again; and when a greater degree of cold was produced on the snow, by pouring an acid upon it which dissolved it rapidly, the thermometer fell several degrees lower. At first sight it appears, that cold has been given out by the snow, and this cold reflected by the mirrors occasioned the fall of the thermometer. The explanation of this fact has been reckoned difficult; but, on closer attention, all difficulty vanishes. The thermometer itself is a radiant body and; its loss of heat, by radiation, is rendered apparent when placed in a situation in which a stream of caloric is invited by the cold body, the snow; and the direction of this current made to pass through the bulb of the thermometer, as through a focus, by the adaptation of the metallic reflecting surfaces. See the article Cold in our Supplement: in which it is to be observed, however, that the doctrine of Professor Lesslie is adopted, by which the phenomena of radiation are ascribed to certain rapid vibrations or pulses taking place in the surrounding air, in straight lines, between a hot and a cold body, whether the air is in other respects stagnant or subjected to motions in any other direction. This doctrine, we may observe in the passing, receives great countenance from the fact already mentioned, of the great interruption to radiation, when a heated body is placed in an exhausted receiver, or the Torricellian vacuum.

273 Accounted for.

374 To produce great cold.

4. Great degrees of cold are produced, by mixing together substances which dissolve rapidly. The reason of this will appear by recollecting what has been said of the absorption of caloric when a solid body is converted into a fluid. Mixtures to produce artificial cold, are generally made of the neutral salts dissolved in water; of diluted acids and some of the neutral salts; and of snow or pounded ice with some of these salts. A great number of experiments were made upon this subject by Mr Walker *; also by Professor Lowitz of Petersburgh †; by Fourcroy and Vauquelin ‡; and by Guyton §. The following table exhibits the results of these experiments.

* *Phil. Trans.* 1795, p. 270. 160 p. 120.

TABLE of Freezing Mixtures continued.

	Mixtures.	Parts	Thermometer sinks.
7.	Sulphate of soda Nitrate of ammonia Diluted nitric acid	6 5 4	From 50° to 14°
8.	Phosphate of soda Diluted nitric acid	9 4	From 50° to 12°
9.	Phosphate of soda Nitrate of ammonia Diluted nitric acid	9 6 4	From 50° to 21°
10.	Sulphate of soda Muriatic acid -	8 5	From 50° to 0°
11.	Sulphate of soda Diluted sulphuric acid	4 4	From 50° to 3°
12.	Snow - - Common salt -	1 1	From 32° to 0°
13.	Snow or pounded ice Common salt -	2 1	From 0° to — 5°
14.	Snow or pounded ice Common salt - Muriate of ammonia and nitre -	1 5 5	From — 5° to — 18°
15.	Snow or pounded ice Common salt - Nitrate of ammonia	12 5 5	From — 18° to — 25°
16.	Snow and diluted nitric acid -		From 0° to — 46°
17.	Potash - - Snow - -	4 3	From 32° to — 51°
18.	Snow - - Diluted sulphuric acid Diluted nitric acid	2 1 1	From — 10° to — 56°
19.	Snow - - Diluted sulphuric acid	1 1	From 20° to — 60°
20.	Muriate of lime Snow - -	3 2	From 32° to — 50°
21.	Muriate of lime Snow - -	2 1	From 0° to — 66°
22.	Muriate of lime Snow - -	3 1	From — 40° to — 73°
23.	Diluted sulphur. acid Snow - -	10 8	From — 68° to — 91°

When any of these substances are to be employed as freezing mixtures, the salts should be used fresh crystallized, and reduced to fine powder; and it will be found most convenient to observe the proportions which are set down in the table. Suppose it is wanted to produce a degree of artificial cold equal to —50°, which is that produced from 32° by the 20th freezing mixture. The substances employed, namely, the muriate of lime and the snow, must be previously cooled down to the temperature of 32°, or any degree below it. This may be done by placing them separately in the 11th freezing mixture, the sulphate of soda and diluted sulphuric acid, which reduces the temperature from 50° to 3°; or in the 12th freezing mixture of snow and common salt, which reduces it from 32° to 0. The materials, thus cooled down, are then to be mixed together as quickly as possible, when, if the experiment succeed, the temperature will fall from 32° to —50°, as in the 20th freezing mixture. The vessels which are employed for these processes should be very thin, and made of the best conductors of caloric. Vessels of tin plate answer the purpose, and when acids are to be used, they may be lined with wax, which will secure them sufficiently against their action. They should be of no larger dimensions than just to contain the materials. 276 Vessels.

SECT. VI. *Of the Sources of Caloric.*

We are now to consider the means by which caloric may be evolved, or rendered sensible. This is a subject of great importance, both as a curious investigation, and as a useful and necessary application in chemistry and the arts of life. The different sources from which caloric is derived, or the means which are employed for its evolution, may be reckoned five in number; namely, percussion, friction, mixture, the sun, combustion: and in this order we shall now consider them.

First Source of Caloric,

Percussion.

The production of heat by striking together flint and steel, is a well-known fact. The same thing also takes place when many other hard bodies are struck against each other. Fires are frequently kindled by making a piece of iron red-hot by striking it smartly and repeatedly with a hammer. In most of the cases in which caloric is evolved by percussion, this evolution is ascribed to the condensation of the particles of the body struck. A condensation has been observed to take place, both in elastic fluids and liquids. 277 Flint and steel. 278 Heat produced, owing to condensation

1. The sudden condensation of air alone has been found to produce a change of several degrees in the thermometer. In some experiments by Dr Darwin, the condensed air from an air-gun, thrown on the bulb of a thermometer, uniformly sunk it about 2°. This shews that the air had given out some of its caloric; for during the operation of condensing it, the apparatus became sensibly hot *. 279 in airs;

Mr Dalton's experiments on the condensation and rarefaction of air, shew that an increase of temperature of 50° is produced, by admitting air into an exhausted receiver; and when the equilibrium is restored to condensed air, 50° of cold are produced. The suddenness of the fall and rise of the thermometer is very remarkable

* *Philos. Trans.* 1789, p. 44.

markable in these cases; and from this circumstance, Mr Dalton conjectures, that the real change of temperature of the air or medium was much greater than the thermometer indicated, but that the inequality existed only for a few seconds*. From these experiments, therefore, it appears that caloric is evolved during the condensation, and absorbed during the rarefaction of air.

* Manch. Mem. vol. v. p. 515.

A considerable rise in temperature takes place, when different gases unite together, and are condensed. Muriatic acid gas and ammoniacal gas, when combined together, form a solid salt; and during this combination a great quantity of caloric is evolved.

280 in hard bodies.

2. To the same cause is ascribed the caloric which is evolved by the percussion of hard bodies. This is particularly the case with metallic substances. Before hammering, the specific gravity of iron is 7.788; after it is hammered it increases to 7.840. In some other metals the increase of density is still more remarkable. Before hammering, platinum is only 19.5; and after hammering, its specific gravity is increased to 23.0. As a proof that the heat is evolved by condensation, iron, which has been once heated by hammering, cannot be subjected to a repetition of the same process till it has been again exposed to heat. It has become so brittle that it flies to pieces under the hammer.

281 Difficult to account for incombustibles giving out heat when struck.

3. It is perhaps more difficult to account for the caloric and light which are emitted by incombustible substances; as, for instance, in the case of two quartz stones struck against each other, which has been already alluded to in treating of light. The particles of these bodies which were struck off by percussion, are found, on examination, to be in a state of fusion; and it would appear that this is a case in which light and caloric are emitted without oxygen having any share in the action, as is supposed to happen in all cases of combustion.

In some observations on the appearances produced by the collision of steel with hard bodies, made by Sir H. Davy, he mentions that Mr Hawksbee shewed †, that no sparks could be produced *in vacuo*; a faint light was only perceived. Sir H. Davy thinks, that the vivid sparks obtained from steel in the atmosphere, are owing to the combination of the small abraded and heated metallic particles with oxygen; but it has been doubted, he observes, whether the faint luminous appearance, when the experiment is made *in vacuo*, be owing to the light produced by the fracture and abrasion of the particles of the flint, or only partly to this cause, and partly to the ignition of the minute filaments separated from the steel. When a fine and thin flint, which is easily broken, is used for the collision *in vacuo*, the light is more vivid than when a thick one is employed. From this he concludes, that the particles of steel are rendered luminous in consequence of combustion. This conclusion was proved by the following experiment.

† Philos. Trans. vol. xxxiv. p. 2165.

A thin piece of iron pyrites was inserted in a gunlock in place of the flint. By collision in the atmosphere it gave vivid sparks, chiefly white, but sometimes mixed with a few red sparks. The same experiment was repeated when the apparatus was introduced into the exhausted receiver of an air-pump; but no light whatever appeared.

28[…] Suppos[ed] to be [elec]tric.

Sir H. Davy further observes, that bodies which become luminous by being struck or rubbed together *in vacuo*, under water, or in gases that do not contain oxygen; such bodies, for instance, as fluate and carbonate of lime, siliceous stones, glass, sugar, and many of the compound salts, are both electrics *per se* and phosphorescent substances; so that the flashes they produce are probably occasioned, partly by electricity and partly by phosphorescence. In some cases, however, by the collision of very hard stony bodies, which are bad conductors of heat, there may be an actual ignition of the particles. This seems to be countenanced by various facts. Mr T. Wedgwood found, that a piece of window-glass, when brought into contact with a revolving wheel of grit, became red hot at its point of friction, and gave off luminous particles, which were capable of inflaming gunpowder and hydrogen gas †; and we are informed, Sir H. Davy adds, by a late voyager (s), that the natives of Oonalashka light their fires by striking together two pieces of quartz over dry grass, their surfaces being previously rubbed with sulphur *.

† Ibid 1795, 45.

* Jour[n.] Roy. [Inst.] vol. i. p. 264

Second source of Caloric,

Friction.

28[…] Combu[sti]ble bo[dies] inflam[ed].

1. A great quantity of caloric is also given out by friction. The intensity of the heat produced by friction depends on many circumstances, and varies chiefly in the ratio of the time employed and the nature and surface of the bodies which are rubbed together. When the bodies rubbed are combustible, as two pieces of dry wood, they may be inflamed; but even when they possess combustibility in a low degree, or are altogether incombustible, the temperature may be raised so high as to communicate a degree of heat sufficient to set fire to combustible bodies. Greater difficulty still attends the explanation of the phenomena of the evolution of caloric by friction, than by the percussion of hard, incombustible bodies. In many instances there can be no increase of density by the friction, for caloric is evolved by rubbing together two pieces of wood, or rubbing the hand on a piece of soft cloth where increase of density can scarcely be supposed. Nor can the increase of temperature by friction be accounted for by the diminution of the specific caloric of the

(s) Sauer's account of this fact is the following: "I observed in all the huts a basket containing two large pieces of quartz, a large piece of native sulphur, and some dry grass or moss. This serves them in kindling fires; for which purpose they rub the native sulphur on the stones over the dry grass, strewed lightly with a few feathers in the top where the sulphur falls; then they strike the two stones one against the other; the fine particles of sulphur immediately blaze like a flash of lightning, and communicating with the straw, set the whole in a flame. *Sauer's Account of Billings's Expedition to the northern parts of Russia*, p. 159.

the bodies which are rubbed together; for Count Rumford, who made some interesting experiments on this subject, could not discover any change in this respect, and supposing that this change had taken place, it could not have been sufficiently great to account for all the heat produced. In one of these experiments he took a brass six-pounder, cast solid, and rough as it came from the foundery; fixed it horizontally on the boring machine, and caused its extremity to be cut off; and by turning round the metal in that part, a solid cylinder was formed $7\frac{3}{4}$ inches in diameter, and $9\frac{8}{10}$ inches long. This when finished remained joined to the rest of the metal by a small cylindrical neck $2\frac{1}{5}$ inches in diameter, and $2\frac{8}{10}$ inches long. This short cylinder was bored with a horizontal borer used in boring cannon. Its bore, which was $3\frac{7}{10}$ inches in diameter, instead of being continued through its whole length $9\frac{8}{10}$ inches, was only $7\frac{2}{10}$ inches in length. A solid bottom of $2\frac{6}{10}$ inches in length was thus left. A blunt steel borer was pressed against the bottom of the bore of the cylinder with a force equal to 10,000 lb. avoirdupois; and the cylinder was turned round by horses at the rate of about 32 times in a minute. To prevent the dissipation of the heat, the cylinder was covered up with thick flannel. At the beginning of the experiment the temperature of the air and of the cylinder was 60°. At the end of 30′, when it had made 960 revolutions, a mercurial thermometer was introduced into the hole made to receive it in the side of the cylinder, and the mercury rose to 130°. When the borer was removed, and the metallic dust taken out of the bottom of the cylinder, it was found to amount to 837 grs. As the weight of this dust amounts to no more than $\frac{1}{948}$th part of that of the cylinder, it must have given off 948° to raise the temperature of the cylinder 1°, and consequently it must have given out 66,360° of heat in the course of the experiment.

2. But to determine whether the air of the atmosphere had any part or not in the generation of this heat, he contrived the following decisive experiment. The apparatus was inclosed in a wooden box, which was made water-tight, and filled with water, so as to exclude completely the external air. The quantity of water employed was 18.77 lb. avoirdupois, or $2\frac{1}{4}$ wine gallons, and the temperature at the commencement of the experiment was 60°. The machine was put in motion, and moved at the same rate as in the former experiment. At the end of an hour the temperature was 107°; in half an hour more, it rose to 178°, and at the end of two hours and 30′ from the beginning of the experiment the water actually boiled. By Count Rumford's calculation the caloric generated by friction in this experiment, and accumulated in two hours and 30′, would have heated ice-cold water 180°, or caused it to boil. From the results of his computation it appears, that the quantity of caloric thus generated equably, was greater than that produced equably in the combustion of nine wax-candles, each $\frac{3}{4}$ of an inch in diameter, burning clearly for the same length of time.

Reflecting on these experiments, Count Rumford recurs to the question, What is heat? Is there any such thing as an igneous fluid? And after stating that the quantity of caloric thus generated could neither be furnished by the particles of the metal detached from the solid masses, nor by the air, nor by the water, because it must have received its heat from the apparatus, he concludes, that caloric is not a material substance, but only a peculiar kind of motion produced among the particles of matter †.

287 Count Rumford concludes that heat is motion.

† Phil. Trans. 1798, p. 80.

3. The experiments of Professor Pictet also prove, that the caloric generated by friction is not owing to the combination of oxygen with any of the bodies. He contrived an apparatus which could be introduced into the receiver of an air-pump. By means of this apparatus, a piece of adamantine spar was rubbed against a steel cup in the open air. A thermometer, which was fixed in the inside of the cup, did not rise when the apparatus was set in motion, although abundance of sparks were produced. When the apparatus was placed in an exhausted receiver, and the experiment repeated, a phosphoric light, but no sparks, appeared, nor was the thermometer any way affected; but when a smaller brass cup was employed, and a piece of brass rubbed against it in the open air, the thermometer was not affected till the motion ceased, and then it rose 0.3°. The caloric, it would appear, was carried off as it was generated, by the motion of the air. When the same experiment was repeated *in vacuo*, the thermometer rose 1.2°, and it began to rise as soon as the friction commenced. When a piece of wood was made to rub on a wooden cup, the thermometer rose 2.1°, and *in vacuo* 2.4° †.

288 Heat generated by friction not owing to combination with oxygen.

† *Essai sur le Feu*, chap. ix.

These experiments, therefore, are sufficiently conclusive to prove that the caloric evolved by friction is not derived from the atmosphere; but still the question recurs, What is its origin! No satisfactory answer can be given to this question, if it cannot be resolved, as some have supposed, by having recourse to the agency of electricity; and considering the similarity of the effect of caloric and electricity in heating and cooling bodies, in producing the expansion and fusion of metallic substances, in effecting the actual combustion of inflammable matters, and that in other respects the one can be substituted for the other, it is not at all improbable that electric matter, which is generated in great abundance by friction, may be the chief agent in the evolution of caloric by the friction of bodies on each other.

289 Probably owing to electricity.

4. In some observations on spontaneous inflammations by Bartholdi, he mentions the experiments which were repeated by Dr Palcani, for obtaining fire by the friction of two pieces of wood, in which he gave to one of the rubbing pieces the form of a tablet, and to the other that of a spindle or cylinder; and as the results of some of these experiments are of importance to shew what attention ought to be paid to the choice of wood, in the construction of machines and instruments where there is considerable friction, we shall state the following.

290 Choice of wood in machines important on account of the friction.

Caloric.

Cylinders.	Tablet.	Duration	Effect.
Boxwood,	Box,	5′	Sensible heat.
do.	Poplar,	5	do.
do.	Oak,	5	do.
do.	Mulberry,	3	Considerable heat and smoke.
do.	Laurel,	3	do.
Laurel,	Poplar,	2	do.
do.	Ivy,	2	do.
Ivy,	Box,	3	do.
do.	Walnut,	3	do.
Olive,	Olive,	3	do.
Mulberry,	Laurel.	2	Considerable heat smoke and blackness.
Ash,	Oak,	5	Sensible heat.
do.	Fir,	5	do.
Peartree,	Oak,	5	do.
Cherry,	Elm,	5	do.
Plumtree,	Apple tree,	5	do.
Oak,	Fir,	5	do.

When the experiment was changed, and a cylinder of one of the kinds of wood was rubbed between two tablets of the other; as, for example, a cylinder of poplar between two tablets of mulberry wood, the increase of the rubbed surfaces which were in contact with the air, produced a temperatnre much more considerable; and almost the whole of the kinds of wood enumerated above took fire.

The effect of friction also varies according as the woods employed of the same kind are rubbed in the direction of the fibres, or when the fibres cross each other. In the first case the friction and heat generated are much more considerable than in the second †.

† *Annal. de Chim.* vol. xlviii. p. 252.

Third Source of Caloric,

Mixture.

291 Change of temperature by combination.

1. It is one of the characteristics of chemical action to produce a change of temperature. This happens in consequence of the increase or diminution of bulk of the bodies which have been the subject of combination, or a total change of their state and properties. Thus it has been established as a general law in chemical science, that all bodies which pass from the solid to the fluid state, absorb a quantity of caloric; and all bodies which pass from the fluid to the solid state, give out caloric. This law, therefore, will enable us to account for those changes which take place by the mixture of different bodies. In the course of the details of chemical science, we shall have frequent opportunities of pointing out the effects of this law. At present we shall only mention a few instances in which caloric is evolved by mixture attended with chemical action.

292 Gaseous bodies forming solids or liquids.

2. When two substances in the state of gas enter into union, and form a solid or liquid body, caloric is evolved.

a. Ammoniacal gas and muriatic acid gas, which, when mixed together, instantly combine, and form a solid salt, give out, at the same time, a quantity of caloric.

b. When oxygen gas and nitric oxide gas are mixed together, they combine and form a liquid, and at the moment of union give out caloric.

3. When two liquids are mixed together, provided the density of the mixture be greater than the mean of the two liquids, caloric is evolved during the combination.

a. When alcohol and water are mixed, the density is greater than the mean of the two liquids; caloric, therefore, is given out during the mixture.

b. A much greater degree of heat is produced by mixing sulphuric acid and water. If four parts of sulphuric acid be combined with one part of water, the density of the mixture is much greater than the medium density of the two liquids, and accordingly the quantity of caloric evolved is sufficient to boil water.

4. A great quantity of caloric is also given out when a fluid body combines with a solid. We have an instance of this in the slacking of lime.

a. When water is thrown upon quicklime, it instantly disappears; for part of it combines with the lime, and becomes solid; and thus passing from the liquid to the solid state, it gives out caloric.

b. If a quantity of sulphuric acid be poured upon quicklime, the caloric evolved is sufficient to raise part of the sulphuric acid into vapour.

5. Were we to reverse these experiments, and state instances of caloric being absorbed during the mixture of bodies, we should observe the operation of the same law, in the case of solid bodies becoming fluid, producing a great degree of cold. But it appears that the production of cold by the solution of salts in water is owing to the water which is in a previous state of combination with one of the salts, and thus water passing from the solid to the liquid state, must absorb caloric, and therefore produce cold. The salts which are best adapted for this purpose, contain a great proportion of water in the composition; for if the same salts are deprived of water by exposing them to heat, the same effect by no means follows. On the contrary, when they are dissolved in water in this state, heat is produced, because they combine with a portion of the water for which they have a strong affinity, and this water passing from the liquid to the solid state, gives out its caloric. 293 Cold produced by water becoming suddenly fluid.

6. A considerable quantity of caloric is also generated in other mixtures, in which the fermentation and putrefaction of animal and vegetable substances takes place. During these processes the substances which are held in solution enter into new combinations, and their chemical properties are totally changed. While this change is going on, there is a gradual and constant evolution of caloric. 294 Heat evolved in fermentation, &c.

It is an artificial heat of this kind which is generated by animal and vegetable matters, and on account of its uniformity and constancy is employed for promoting vegetation; as when horse dung and tanner's bark are used in making hot beds; or for the hatching of eggs, a practice which has been long in use in Egypt.

Fourth Source of Caloric,

The Sun.

1. But the great source of light and heat in the planetary system is the sun. When treating of light we mentioned

C[illegible]ric. mentioned a speculation of philosophers about the great and constant waste of light, which the sun, although a body of immense magnitude, must sustain. But since the nature and constitution of the sun were discovered by Dr Herschel, these speculations fall to the ground.

5 Th[illegible] an op[illegible] e bo[illegible] According to these discoveries, the sun is not, as was formerly supposed, an immense globe of fire, in which the materials composing it are continually wasting by combustion; but a solid opaque body, similar to the other planets, and surrounded by a very dense atmosphere, in which are observed two kinds of clouds. The lower region of clouds is similar to those in the atmosphere of the earth. The uppermost region of clouds is luminous, and from this proceed the light and heat which were supposed to come from the body of the sun. This luminous region, it appears from Dr Herschel's observations, in consequence of changes which seem to be constantly going on in it, exhibits different degrees of splendour, diminishing greatly the quantity of light and heat which are emitted at other times. To these variations he ascribes much of the difference of temperature in different seasons, and the consequent abundance or deficiency of crops.

6 D[illegible] co-lo[illegible] ab-so[illegible] eat 2. It is a familiar as well as a correct observation, that dark-coloured clothes, as black for instance, are much warmer than those which are of a lighter colour. The rays of light, and also probably those of caloric, are reflected in greater proportion by white bodies than by those of a deeper colour. The sun's rays enter the opaque body, and combine with it, and thus increase the temperature. These rays are permitted to pass through transparent bodies, which are very little affected by them; but combining with opaque bodies they heat them, and the deeper the colour of the body the greater is the increase of temperature.

7 H[illegible]e and Fr[illegible]lin's ex[illegible] m[illegible] 3. But this has not been left to the uncertainty of common observation. Experiments were made by Dr Franklin, and before him by Dr Hooke, to ascertain this curious point. Pieces of cloth of different colours were placed upon snow, and exposed to the light of the sun. The colours were white, red, blue, black; and it was fonnd that the darkest coloured pieces had admitted most heat, because they sunk deepest in the snow, and this was in proportion to the darkness of the colours.

8 Sir[illegible] D[illegible]s. Sir H. Davy made a similar experiment, to determine the correspondence between the increase of repulsive motion in bodies from the action of light and dark colours.

"Six similar pieces of copper, of equal weight, size, and density, each an inch square, and two lines thick, were coloured, one white, one yellow, one red, one green, one blue, and one black. A portion of a mixture of oil and wax, which became fluid at about 76°, was placed on the centre of each on the inferior side. They were then attached to a board painted white, and so placed with regard to the sun, that their upper surfaces were equally exposed to the light. Their inferior surfaces, to which the cerate was attached, were equally deprived of light and heat. The cerate on the black plate began to melt perceptibly before the rest, the blue next in order, then the green and the red, and lastly the yellow. The white was scarcely at all affected; the black was in a complete state of fusion*." It appears, therefore, from these experiments, that caloric enters bodies in different proportions; and in the greatest proportion in the darkest coloured bodies.

* *Beddoes' Contributions*, p 44.

299 Bodies which absorb most light become warmest. It appears too, that those bodies which absorb most light, acquire the greatest degree of temperature when exposed to the sun's rays. This has been demonstrated by the experiments of Wedgwood, Cavallo, and Pictet.

The former took two pieces of phosphorescent marble, one of which was blackened, and placed them on a hot iron. No light appeared from the blackened marble, but the other exhibited its usual phosphorescence. Upon a second exposure, the piece which was not blackened gave a faint light; the blackened one, as before, gave none at all. When the black was wiped off, and both pieces were again placed upon the heater, no light appeared either from the one or the other. This experiment shows, that the phosphorescent property was nearly destroyed without any visible light having appeared. But both pieces of marble before being heated, must have contained the same quantity of light and heat, and therefore the light from the blackened piece must have been absorbed by the black colour*.

* *Philos. Trans.* 1792, p. 278.

In Cavallo's experiments (υ), the bulb of a thermometer was painted black, and exposed along with other thermometers to the sun's rays. The blackened thermometer indicated a temperature 10° higher than the other; but this difference was not constant; for it varied according to the brightness of the sun, and the density and temperature of the atmosphere. Considerable variations were also observed, from the difference of colours which were employed, and from the difference of polish of the surface of the plate.

The same thing was observed when the thermometers were exposed to strong day light. The thermometer whose bulb was blackened indicated the highest temperature †.

† *Ib.* 1780, p. 587.

In an experiment made by Professor Pictet, two thermometers, one of which had its bulb blackened, when they were kept in a dark place, indicated the same temperature. These experiments prove the close connection between light and caloric; for the greater the proportion of light absorbed by any body, the higher is the temperature of that body. And when the light is totally excluded, as in the last mentioned experiment of Pictet, the temperature is the same ‡.

‡ *Essai sur le feu*, chap. iv.

300 Different heating power of the rays. 4. But it has been shewn that there is a very great difference in the heating power of the different rays of light. It appears, from the experiments of Dr Herschel, that this heating power increases from the middle of the spectrum to the red ray, and is greatest beyond it, where the rays are invisible. Hence it is inferred, that

(υ) The hint of these experiments, he says, was taken from the account of an experiment in a volume of the Philosophical Transactions, made with a thermometer whose bulb was painted black, and exposed to the rays of the sun. The experiment alluded to was made by Dr Watson, bishop of Llandaff. *Philosophical Transactions*, 1763, p. 40.

Caloric. that the rays of light and caloric nearly accompany each other, and that the latter are in different proportions in the different coloured rays.

It has also been shewn, that the different rays of light produce different chemical effects on metallic salts and oxides. These effects increase on the opposite direction of the spectrum, from the heating power of the rays. From the middle of the spectrum towards the violet end, they become more powerful; and produce the greatest effect beyond the visible rays.

301 Solar rays of three kinds. 5. From these discoveries it appears, that the solar rays are of three kinds. 1. Rays which produce heat. 2. Rays which produce colour; and, 3. Rays which deprive metallic substances of their oxygen. The first set of rays is in greatest abundance, or most powerful, towards the red end of the spectrum, and they are least refracted. The second set, or those which illuminate objects, are most powerful in the middle of the spectrum; and the third set produce the greatest effect towards the violet end, where the rays are most refracted.

302 Transparent bodies not heated by the solar rays. 6. The solar rays pass through transparent bodies without increasing their temperature. The atmosphere, for instance, receives little or no increase of temperature by transmitting the sun's rays till these rays are reflected from other bodies, or communicated to it by bodies which have absorbed them. This is also proved by the sun's rays being transmitted through convex lenses, producing a high degree of temperature when they are concentrated, but giving no increase of temperature to the glass itself. By this method, the heat which proceeds from the sun can be greatly increased. Indeed, the intensity of temperature produced in this way is equal to that of the hottest furnace. This is done either by reflecting the sun's rays from a concave polished mirror, or by concentrating or collecting them, by the refracting power of convex lenses, and directing the rays thus concentrated on the combustible body. See *Burning Glass*.

Fifth Source of Caloric,

Combustion.

303 Effects of combustion striking. It was impossible for men whose attention was directed to the phenomena of nature, long to pass unobserved the singular appearances which are exhibited in the combustion of bodies.

304 Important, As combustion is one of the principal sources of heat, it has long occupied the attention of men in general, both as to the means of its improvement and application in the arts of life, and in the discovery of

305 but of difficult explanation. a theory or explanation which will account for the phenomena. But the want of success in this branch of philosophical investigation, even at the present day, shews that the subject is attended with great difficulty.

306 Difference between increase of temperature and burning. When a piece of iron is exposed to a high temperature, it becomes red hot, and when it is removed from the heated body, it continues for some time to give out light and heat. But when it is suffered to cool, it returns to the same state in which it was before it was heated. When a piece of wood is burnt, it also gives out light and heat; but during this process it is totally changed. Great part is dissipated, and nothing remains but a small quantity of ashes.

When a piece of sulphur is exposed to a temperature between 300° and 400°, it takes fire and burns, gives out heat and light; and during this process the sulphur has acquired new properties, or has entered into new combinations.

When a metallic substance, zinc for instance, is exposed to a certain temperature, it also undergoes a very great change, during which heat and light are given out. The zinc is changed to a light flocculent substance; most other metals are reduced to the form of powder. To these substances was formerly given the name of *calces;* they are now denominated *oxides*. 307 Bodies totally changed by combustion.

Now, none of these changes can be effected without the presence of atmospherical air, or rather without the presence of oxygenous gas, which is one of its constituent parts, and that part of it which is necessary for the process of combustion. In all cases where combustion takes place, oxygen disappears or changes its state; light and heat are emitted, and the combustible body has changed its properties. Such are the phenomena of combustion, so far as observation and experiment have gone; but still the difficulty remains, to discover what share the different agents which are necessarily concerned in this process have in the changes which are effected. It is now universally agreed, that oxygen is fixed in the combustible body during the process of combustion, and that the caloric which was necessary to retain the oxygen in the state of an elastic fluid being emitted during the change, is the source of the heat which is given out by burning bodies. But what is the source of the light? Is it emitted by the oxygenous gas along with the caloric in its change from the fluid to the solid state? Or has it been a constituent part of the combustible body which is separated during combustion? On this point, different opinions have been entertained by philosophers, and the question in a great measure still remains undecided. Let us now consider the different theories which have been proposed to account for these phenomena. 308 Oxygen gas necessary in the process. 309 Source of the light not ascertained.

1. In the early dawn of chemistry, when the scattered facts were first collected, and it began to assume a scientific form, attempts to explain this process were soon made. Beccher was the first who gave any consistent form to a theory of combustion. Before his time, sulphur was considered as the universal inflammable principle; but he rejected this opinion, considering sulphur as an inflammable substance, containing the principle of inflammability, but not that principle itself. This theory was improved and extended by Stahl, who gave this principle the name of *phlogiston* (x), from which the theory is called the phlogistic, and from his own name the *Stahlian* theory. This principle was supposed to exist in all inflammable bodies, and to be the same in all. The diversity which is observed among them, in external appearance and other properties, is owing to the other principles or elements of which they are composed, and with which the common 310 Theories. 311 Stahlian.

(x) This principle was also called *terra secunda*, or *terra inflammabilis*.

Caloric.

common principle of inflammability, or phlogiston, is combined. Combustion, with the several phenomena that attend it, is supposed to depend on a gradual separation and dissipation of this principle; and this being once separated, what remains of the body is no longer combustible, but is similar to other kinds of matter. This principle is represented as a dry substance, of an earthy nature, composed of particles which more than all others are disposed to be affected with a swift whirling motion. When the particles of a body are agitated with this motion, the body becomes hot, is ignited, or undergoes combustion according to its violence. The heat and the light which are emitted during combustion, depend upon a peculiar motion of the particles of matter; phlogiston, which is supposed to be contained in all combusible substances, being most disposed to assume this motion *.

* [Bl]ack's [L]. vol. i. p. 232.

12 [Hook]e's

2. Before this time a different theory had been proposed by Dr Hooke, who published an account of it in 1665, in a work entitled *Micrographia;* and, in the year 1676, in another work called *Lampas.* According to this theory, the air of the atmosphere is the universal solvent of all combustibles. This solution takes place when the temperature of the combustible body is sufficiently raised, and during the violence of its action the heat is emitted. This dissolution of inflammable bodies is a substance inherent in the air, similar to that which is fixed in saltpetre, if not the very same. During this dissolution of bodies, part unites with the air and escapes; and part, after being mixed with it, forms a coagulum or precipitation, some of which being light, is carried away, while another part which is heavier remains behind.

13 [M]ayow.

Some time after, an account of the same theory was published by Dr Mayow, with some additional experiments, in a work entitled *De Sal-nitro et Spiritu Nitro-aëreo.* The nitro-aërial particles, or the spiritus nitro-aëreus of Mayow, was the same as the universal solvent of Hooke. According to Mayow, this spiritus nitro-aëreus consists of minute particles, from the motion of which it is produced, and when the motion is more rapid, not only heat but light also is extricated. The following abstract of the theory of Dr Hooke, with Professor Robison's observations, will not, we hope, be unacceptable to our readers.

14 [Abstr]act of [Hook]e's [theor]y.

"This theory, so opposite, as Dr Black observes, to the theory of Stahl, is not so recent as is generally imagined. It was seen in all its extent and importance by Dr Robert Hooke, one of the greatest geniuses, and most ardent inquirers into the operations of nature, who figured during the latter half of the 17th century, a period full of great discoveries.

"Dr Hooke proposed this theory in considerable detail in his *Micrographia*, published in 1665; and in his *Lampas*, published in 1676; and he makes it an important doctrine in his treatise on Comets, and in many passages of his Cutlerian Lectures. He promises to take it into serious consideration, and to publish a full exhibition of it. The allusions made to it in his lectures, make it evident that he had continued to make some desultory additions to his first conceptions. His *Lampas* contains a most accurate explanation of flame, which cannot be surpassed by any performance of the present day.

2

"In the Micrographia he states the theory in the following words:

"1. The air in which we live, and breathe, and move, and which encompasses and cherishes all bodies, is the universal solvent of all sulphurous (synonymous at that time with inflammable) bodies.

"2. This action it performs, not till the body be sufficiently heated, as we observe in other solutions.

"3. *This action of dissolution produces the great heat which we call fire.*

"4. It acts with such violence as to agitate the particles of the diaphanous body, air, and to produce that elastic pulse called light.

"5. This action, or dissolution of inflammable bodies, is performed by *a substance inherent in, and mixed with the air, that is like, if not the very same with that which is fixed in saltpetre.*

"6. In this dissolution of bodies by the air, a part of the body uniting with the air is dissolved or turned into air, and escapes and flies about.

"7. As one part is thus turned into air, so another is mixed with it, but forms a coagulum, or precipitation, some of which is so light as to be carried away with the air, while other grosser and heavier matters remain behind, &c. &c. This latter article is frequently employed in other parts of his writings, and is sometimes called a grosser *compound*, mixed with matters terrene, and originally insoluble in air, and incombustible.

"Can any thing more be wanting to prove that this is the same with the modern theory of combustion? Nothing but to shew that this coagulum contained the air which had formed it, by shewing an increase of its weight, or by separating it again. But the eager mind of Hooke, attracted by every appearance of novelty, was satisfied with the general notion of a great subject, and immediately quitted it in chase of some other interesting object. Had he not been thus led off by a new pursuit, this wonderful man would not only have anticipated, but completed many of the great discoveries of the last century. It was a bold conception, and only a vigorous mind could entertain it for a moment, that the vast heat of combustion was contained in a few grains of air. Yet this was his opinion, as appears by the explanation which he gives, in various meetings of the Royal Society, and in his lectures on comets, of the deflagration of combustible bodies with saltpetre, and of fiery motion.

"In the treatise called *Lampas*, he observes that this his treatise, published eleven years before, had been very favourably received, and that he had not seen any valid objection offered to it. It was in this interval that Dr Mayow at Oxford published his book *De Sal-Nitro et Spiritu Nitro-aëreo*, in which he holds precisely the same doctrine; but his exhibition of it is obscure, complicated, and wavering, mixed with much mechanical nonsense, of wedges, and darts, and motions, &c. according to the fashion of the times. Hooke's conception of the subject, on the contrary, is clear, simple, and steady. The only addition made by Mayow are some observations on the increase of weight observed in the preparation of diaphoretic antimony, &c. Hooke, explaining at a meeting of the Royal Society, some tricks of the plumbers

Caloric. bers workmen, who called the litharge which formed on the surface of the melted lead dross, and took it with them as their perquisite, says expressly that they can make dross of the whole, and that it is more than the lead by all the air which was its menstruum. But Mayow wrote on the subject expressly, and it appears in the title of his book. He is remembered, while Hooke is forgotten, because no one would think of looking into the Micrographia for chemical information. The theory comes in by chance, to explain the indestructibility of charcoal in close vessels by heat. Mayow also made many very ingenious experiments on the air which had contributed to inflammation, and has anticipated both the manipulations and the discoveries of modern pneumatic chemistry."

315 Phlogiston supposed to be light.

3. But in the progress of chemical science, the existence of the principle of phlogiston began to be called in question. It had been observed, and was proved by experiment, that substances became inflammable merely by being exposed to the light of the sun, and in this way having acquired the principle of inflammability, it was supposed to be the same as light. This opinion of phlogiston being light fixed in bodies, which was the first improvement or modification of the theory of Stahl, was adopted by Macquer and other chemists.

316 Farther modified.

4. In the progress of discovery, this theory was still farther modified. The introduction of pneumatic chemistry, and the accuracy and precision which it gave to the experiments and researches of chemists, enabled them to ascertain, with greater certainty, the changes which take place on bodies after being subjected to combustion, as well as on the air in which they are burnt. Some of these changes were observed by Dr Priestley, whose indefatigable labours contributed essentially to the extension of chemical science. He found, by experiment, that the air in which combustibles had been burnt was afterwards unfit for the support of flame, and equally so for the breathing of animals. He ascribed this change which the air had suffered, to its combination with the phlogiston which had separated from the burning body during the process of combustion. He considered air as necessary to combustion, because, having a strong affinity for phlogiston, it attracted it during the process, and combined with it; and by this combination the air was contaminated and rendered unfit for farther combustion, or for animal respiration. But still the difficulty remained to account for the heat and light which are extricated during this process.

317 Changes observed on the air by Priestley,

318 supposed that it combined with phlogiston.

319 Caloric and light exist in the air.

According to Dr Crawford, the caloric and light which appear during combustion, exist in the air in which the body is burnt; and during the process the phlogiston combines with the air, from which at the same time the light and caloric are separated.

320 Phlogiston the same with hydrogen.

5. Soon after Mr Kirwan proposed another opinion, which was pretty generally adopted by chemical philosophers. According to this opinion, hydrogen and phlogiston are the same; that it exists as a constituent part in all combustibles, separating from them during combustion, and combining with the oxygen of the air.

321 Scheele's hypothesis.

6. In the year 1777, Scheele published a work, which was entitled *Chemical experiments on Air and Fire*. Heat, according to him, consists of a certain quantity of oxygen united with phlogiston. Radiant heat, which moves in straight lines, is composed of oxygen combined with a greater proportion of phlogiston; and light, of oxygen combined with a still greater quantity.

322 Discoveries of Lavoisier.

7. But the labours and discoveries of the French chemists gave a new turn to chemical science. The unfortunate Lavoisier, who had devoted his time and his fortune to chemical pursuits, had long directed his attention to the phenomena of combustion, and after an extensive series of experiments, distinguished for their accuracy and precision, he established the general law, that oxygen combines with the burning body in all cases of combustion; and thus he was enabled satisfactorily to account for the phenomena of combustion without phlogiston, the existence of which had never been proved.

323 His theory.

8. The principles of this theory are the following. No combustion can take place without the presence of oxygen, for it consists in the combination of the combustible body with oxygen. The oxygen of the atmosphere, which is in the state of an elastic fluid, exists in combination with caloric and light; and during the combustion, that is, the combination of the oxygen with the combustible body, the caloric and light are separated.

324 Difficulties attending it.

This theory is applicable to the explanation of the phenomena of combustion, in the more limited meaning of that term, i. e. as taking place in oxygenous gas. But when it is considered, that the process of combustion goes on between two solids, one of which contains oxygen in its combination, as, for instance, sulphur and nitre, difficulties arise in accounting for the heat and light, when the oxygen which combines with the combustible body is in the solid state. When it is considered also that oxygen unites slowly with metals, being condensed from the state of gas, without any extrication of heat or light, difficulties of another kind present themselves.

To remove these difficulties, and to explain the appearances, the theory of Lavoisier has been greatly modified, or new theories proposed.

325 Theory of Brugnatelli.

10. With this view a theory has been proposed by Brugnatelli. This theory supposes that oxygen exists in combination with bodies, in two states. In the one it is entirely deprived of its caloric and light, and in the other, it retains great part of the caloric and light, even in its combined, concrete state. It is simply called *oxygen* in the first case, when it is deprived of its caloric and light; in the latter it is denominated *thermoxygen*, when the caloric and light are combined with it in the concrete state. Thermoxygen, then, is a compound of oxygen and caloric in the concrete state. This caloric is different from that which holds the thermoxygen in the state of gas, and it is in the same relation to thermoxygen gas, as water is to crystallized salts. This thermoxygen only enters into the composition of acids, when it is deprived of its concrete caloric. But it combines with the metals in the state of thermoxygen; that is, united with the concrete part of caloric. Metallic substances, therefore, are denominated *thermoxides*.

In its union with metals, thermoxygen is either previously formed, or is in its nascent state, during the combination.

loric.

combination. In the latter case, the caloric which is disengaged by the chemical action, or that which is ppliaed to assist the combination, furnishes the necessary portion for the formation of the thermoxide; that is, the combination of oxygen containing caloric in its concrete state, with a metal. Thus it is, that some metals require the application of heat for their solution in concreted acids.

The base of pure air is in the state of thermoxygen, in its combination with water. The metals, therefore, which have a stronger affinity for it than for hydrogen, the other component part of water, readily combine with it, without the aid of external heat, in acids diluted with this fluid. Gaseous thermoxygen always gives out caloric, when it passes from the elastic to the concrete state; but as thermoxygen requires little caloric for its expansion, little is separated when it is condensed. We shall only add the author's explanation of the difference between atmospherical air and those substances which have the same constituent parts in different proportion. The difference between atmospherical air and nitric oxide gas, he supposes, is ascribed to the proportion of the constituent principles, and consequently, according to this hypothesis, the atmospherical air might be converted into that gas, by augmenting the proportion of oxygen gas, or by diminishing that of the azotic. But the difference between these two gases, according to the theory of Brugnatelli, consists in this, that in atmospherical air the azotic gas is combined with thermoxygen gas; but in nitrous gas, the azotic gas is combined with simple oxygen *.

* ...nal. de C... vol. ... p. ...

326 T...ry w...h supp...the li...to b...ven ...y the c...usti-bl...

11. This theory, notwithstanding its ingenuity, is regarded by some merely as a plausible hypothesis, receiving little support from facts. We shall therefore leave it to the consideration of our readers, and proceed to state the principles of another, which is proposed to be substituted in place of the Lavoisierian theory, in explaining the phenomena of combustion. In this theory, it is supposed that the oxygen gas which is absorbed during combustion, furnishes the caloric, while the combustible body gives out the light which previously existed in it as a component part. In proof of this theory it is stated, that some bodies give out, during combustion, a greater quantity of light than others, even where the quantity of oxygen absorbed is less; that the colour of this light varies according to the nature of the combustible; and that vegetables which grow in the dark contain no combustible matter, being deprived of the light which is essentially necessary for its formation. This theory, which Gren calls *the theory of fire and combustion*, is distinctly detailed by him in the following words:

327 L... fur-ni...d by th...om-b...le.

"I take here the word *fire* in the usual sense of common language, and understand by it that light which is combined with free caloric. *Combustion* is the extrication of fire with and by the decomposition of oxygen gas. Take the example of phosphorus. On its combustion two new products, the phosphoric acid and fire, arise from phosphorus and oxygen gas.

328 A ...ory ex-pl... all th...heno-m...

"In order that the theory of combustion be admissible, it must explain every circumstance by which this phenomenon is accompanied, and be in contradiction with none of them. It, besides, must not be inconsistent with any other fixed invariable law of nature.

"According to the *antiphlogistic system*, a combustible body is such as is possessed of the power of attracting, in a certain temperature, the oxygen of vital air more strongly than it is attracted by the caloric. Besides, in that system, oxygen gas does not merely consist of oxygen and caloric, but it likewise contains light, in a fixed state, as a constituent part.

Caloric.

"If, therefore, phosphorus, at the temperature requisite to its inflammation, be brought into oxygen gas, it robs the latter of its oxygen, and makes with it phosphoric acid; whilst the caloric and the basis, or matter of light, previously *latent* in the gas, are restored to liberty; and, combining together, produce the fire which flies off. Thus the oxygen gas is decomposed.

329 New body generated by combustion.

"A new body, the phosphoric acid, is now generated; and, because in many cases an acid is produced by the combustion of inflammable matters, this circumstance has induced modern chemists to denote the basis of vital air by the words *acidifying principle*, or *oxygen*; not on the ground that it is supposed to be sour of itself, but because it forms an acid only when combined with an *acidifiable basis*, as in our experiment with phosphorus. And it is on this account that, in this system, combustion has likewise received the name of *oxygenation*. But in the case (very often occurring) where the combustible matter imbibes oxygen, yet without becoming thereby an acid, the product is called *oxide* (also denominated *half-acid*), and the process is termed *oxydation*.

330 Acquires an increase of weight.

"Since the combustible substance takes up the ponderable basis of oxygen gas, and since, according to this system, both the caloric and light are imponderable, it is thereby accounted for, why the residue of burnt matters, the phosphoric acid, for instance, acquires an increase of weight equal to that portion of vital air which was decomposed.—If the inflammable substance be saturated with oxygen, it is rendered incapable of decomposing more oxygen gas, and the combustion is ended.

"When the combustion is performed in atmospheric air, it is then the azotic, either mingled or mixed with the oxygen gas, that prevents those phenomena from going on with the same vivacity as in pure oxygen gas; and likewise, as the azotic gas is not affected or acted on by the inflammable body, it is left as the residue of the atmospheric air.

331 Combustion a case of simple affinity in the old theory.

"Hence, by that system, the combustion of phosphorus in oxygen gas is effected by a simple affinity, and the principle of fire is not in the combustible body, but in the oxygen gas.

332 Explained by double affinity.

"However, from what I have stated of the composition of light, I cannot help thinking, that in combustion a double affinity takes place; and to explain this theory I shall select the example of phosphorus. That substance consists of the basis of light, called by me *phlogiston*, and making a constituent part of all combustible bodies united to a peculiar body, the *phosphoric-radical*.—*Oxygen gas* is a compound of *oxygen* and *caloric*.

"Now, when phosphorus is heated in this gas, and by this means the force of attraction between the phlogiston and the phosphoric-radical is sufficiently weakened, so that the attractive power between the radical of phosphorus and the oxygen may prevail, then

Caloric. then the act of combustion ensues. The phosphoric basis attracts the oxygen, while the phlogiston of the phosphorus is attracted by the caloric of the oxygen gas. Thus, by virtue of this double affinity, two new compounds, the phosphoric acid and fire, arise from the two former combinations, phosphorus and oxygen gas.

"When the radical of phosphorus, and in general of any combustible body, has absorbed so much oxygen, that it is saturated with it, the combustion is arrived at its highest degree; and in the same manner it is ended, at the moment when all the quantity of oxygen gas, capable of being decomposed, is exhausted. By this it is explained, why, in a given volume of oxygen gas, only a certain quantity of phosphorus, and in general of every other combustible matter, can be consumed by fire.

"The increase of weight in the residue of the burnt substance is, in this phlogistic, or rather *eclectic system*, likewise explained by the access of oxygen; and the caloric and basis of light are likewise supposed to be both imponderable. The remaining azotic gas, not being acted upon by the combustible matter, is merely the residue of the atmospheric air.

333 Light given out without oxygen. "Those that wish to be impartial, must allow that the light, in the *antiphlogistic system*, acts a part quite superfluous; that it may be thoroughly set aside without impairing the system; that by this system those phenomena cannot be explained, where light issues from combustible bodies without any access of vital air, (some instances of which will hereafter be given (z); that the influence of light upon the growth and thriving of plants, upon the changes of their mixture during vegetation, and upon the alteration in the mixture of many other bodies, is by far too great, to allow oxygen gas to be considered as its only reservoir. Finally, it must be granted (an important point) that the antiphlogistic system does in no way explain the incidents preliminary to the process of combustion; and that it affords no argument to show why a certain degree of heat is necessary, in order that the combustible body be inflamed *."

* *Green's Chemistry*, vol. i. p. 135.

334 Three modifications. 11. Such then are the general facts with regard to combustion, and such are the theories which have been proposed, to account for the phenomena exhibited in this process. Three states or modifications have been distinguished in the act of combustion, namely, ignition, inflammation, and detonation.

335 Ignition. *a*. Ignition, properly speaking, is rather a preliminary step, than a part of the process of combustion itself. A metallic substance, for instance, may become red hot when exposed to a certain temperature; but when it is cooled, it returns without change to its former state. In this case caloric and light are given out, but the body undergoes no farther change. There is no absorption of oxygen, which is one of the ordinary phenomena of combustion. But, with an increase of temperature, this also is effected, and the whole phenomena of combustion are exhibited; namely, the union of oxygen with the combustible body, and the emission of light and heat.

b. The second state or modification of combustion is called *inflammation*. This depends on the nature of the combustible body, owing partly to its strong affinity for oxygen, and partly to the slight affinity which exists between the particles of the combustible body. 336 Inflammation. We have examples of this in the burning of sulphur or phosphorus, or a candle in the open air, or in oxygen gas.

c. Detonation is another modification of combustion. 337 Detonation. It is a rapid and instantaneous inflammation, accompanied with explosion. This arises from the sudden formation of a vacuum, by the change of elastic fluids into the liquid state, or by the sudden evolution of elastic fluids from the solid state. Of the first we have an instance in the composition of water by the inflammation of oxygen and hydrogen gases, which is attended with a violent explosion, great condensation and the extrication of light and heat. Of the evolution of elastic fluids from solid bodies, we have a good instance in common gunpowder, from which an immense volume of elastic vapour is instantaneously extricated, which, by its expansive force being suddenly exerted, produces the explosion, and the irresistible effects of this powerful agent.

12. All inflammable substances, Dr Black observes, 338 Combustible substances converted into acids are changed, during combustion, into one or more principles. From the combustion of some substances, as sulphur and phosphorus, an acid is obtained. From the combustion of others, as hydrogen with oxygen, water is the product; 339 or water, and in the case of metals, they are reduced to the state of oxide, or *calx*, as it was 340 or oxides. formerly called. After the combustible substance has been subjected to the process of combustion, it is totally changed in its properties, and no longer capable of exhibiting the phenomena of combustion.

Such, then, are the general properties and effects of light and heat, two of the most powerful agents, and of the most extensive influence, in all the changes and combinations which take place among bodies, by chemical actions. In many properties they resemble each other, but are totally different from all other kinds of matter. These bodies, possessed of a repulsive power among the particles of each other, are attracted by other bodies, and combine with them; and these combinations produce the most astonishing effects, giving new forms to matter, and inducing innumerable changes, which may be considered as constituting the principle and essence of some of the most sublime operations of nature, and many of the most important processes of art.

Connected with light and heat in many of their obvious properties, and also in many of the changes which they produce upon bodies, are electricity and galvanism; and with electricity at least, if not also with galvanism, the magnetic power possesses some common properties; and especially if some of these are to be considered, as some have supposed, only as modifications of the same substances which we have treated of, the discussion of these subjects would be properly introduced here; but according to the nature and arrangement of this work, each is to be fully detailed under its proper head. See Electricity, Galvanism, and Magnetism.

Chap.

(z) As in the case of the combination of sulphur and iron or copper.

Chap. IV. Of OXYGEN.

341 Great importance.

1. Oxygen is one of the most important agents in the chemical phenomena of nature, or in the processes of art. There is scarcely a single process in which it has not some share. Its nature and properties, therefore, ought to be early known.

342 Discovery of modern chemistry.

Oxygenous gas is one of the discoveries of modern chemistry. It was discovered by Dr Priestley in the year 1774, and received from him the name of *dephlogisticated air*. It was afterwards denominated *highly respirable air*. From Scheele, who discovered it in 1775, it received the name of *empyreal air*. It was called *vital air* by Condorcet; and Lavoisier gave it the name of *oxygen gas*, or *oxygenous gas*, by which it has since been generally distinguished.

343 Processes for obtaining it.

2. Oxygen gas is most easily obtained by the following process: *a*. Take a quantity of the native *oxide of manganese;* introduce it into the iron bottle A, fig. 3. to the neck of which apply the bent tube B, which is made to fit it exactly, and lute them together at the joining CD (A.). The bottle, thus prepared, is to be exposed to the heat of a furnace, or to that of an open fire. As soon as the heat is applied, the atmospheric air within the bottle is driven off; and, as the bottle becomes red hot, the quantity of air which passes over is greatly increased. Let the end of the tube connected with the bottle be introduced under the shelf in the pneumatic trough, and the bubbles of air will pass through the water, and may be received in jars filled with water, inverted over the opening in the shelf with their mouths immersed.

b. Oxygen gas may also be obtained by treating what is called in chemistry *the red oxide of mercury* in a similar manner.

c. This gas may be also readily procured, by introducing into a glass retort a quantity of the same substance (oxide of manganese) reduced to powder, adding an equal weight of sulphuric acid, and applying a moderate heat.

d. Or it may be obtained from the substance called *nitre* or saltpetre, exposed to a red heat, in an earthen or coated glass retort.

344 Nature of the process explained.

3. In all these methods of obtaining this gas, it is unnecessary to mention, that it must be received in the pneumatic apparatus, in the same way as has been directed for procuring it from the oxide of manganese, exposed to heat in the iron vessel; and, in whatever way it is obtained, the chemical change which takes place in these processes, is thus explained. Oxygen gas consists of two ingredients, the one, which is called its base, and the other *caloric*, or the matter of heat. In the oxide of manganese, this base is combined with the metallic substance; and when this compound is exposed to a sufficient temperature, the oxygen, having a greater attraction for caloric than for the metal, combines with it, and passes off in the state of gas. The same changes take place, when the process for obtaining the gas, by means of the red oxide of mercury, is employed. When the sulphuric acid, which is in the state of liquid, is added to the oxide of manganese, it combines with it at a lower state of oxidation, and becomes solid. But no liquid substance can become solid, without being deprived of the caloric necessary to retain it in the state of fluidity. The caloric which retained the sulphuric acid in the liquid state, combines with the oxygen of the manganese, assumes the fluid or gaseous form, and makes its escape. This is an example of double affinity. The sulphuric acid unites with a lower oxide of manganese, and forms a solid; while the caloric combines with the base of oxygen, and appears in the form of oxygen gas.

4. Oxygen gas, thus obtained, possesses many of the properties of common air. It is colourless, invisible, elastic, and may be indefinitely expanded or compressed. 345 Properties.

Oxygen gas possesses neither taste nor smell; its specific gravity, according to Mr Kirwan, is to that of water as 0.00135 to 1.0000. Being therefore 740 times lighter than its bulk of water, its weight to atmospherical air is in the proportion of 1103 to 1000; or 100 cubic inches of oxygen gas weigh 34 grs. while the same measure of atmospherical air weighs only 31 grs. the temperature being 60°, and the barometer being at 30 inches. According to Sir H. Davy's experiments, 100 cubic inches of oxygen gas weigh 35.05 grs.

Water does not sensibly absorb this gas. But by means of strong pressure, it may be made to combine with, and to retain in solution half its bulk. The water, thus impregnated, is not sensibly different from common water in taste or smell, but it is said to have proved a useful remedy in some diseases.

Combustible substances burn with greater brilliancy and rapidity in oxygen gas than in common air. Indeed it is owing to a certain quantity of the former, that the process of combustion goes on in the latter; and when the oxygen gas is exhausted, the process is interrupted. If a jar or phial is filled with this gas, a lighted candle introduced into it burns with greater splendour, and produces a greater degree of heat, than in a similar vessel filled with common air. If a candle be blown out, and while the snuff is red hot, introduced into a vessel filled with oxygen gas, it rekindles with a slight explosion, and burns with the same splendour. A candle in a vessel filled with oxygen gas burns much longer than in the same quantity of atmospherical air. 346 Combustion more brilliant in oxygen gas.

Oxygen gas is essentially necessary for respiration. No breathing animal can live in air which does not contain some proportion of oxygen gas. And the experiments of Dr Priestley and others prove, that animals live a much longer time in pure oxygen gas than in an equal bulk of atmospherical air. The experiments of Count Morozzo fully establish this fact. Into a vessel filled with common air, and inverted over water, he introduced a number of sparrows in succession, and observed the effects. The following are the results of his experiments: 347 Animals live a longer time in it.

	H.	M.
The first sparrow lived - -	3	0
The second - - - - -	0	3
The third - - - -	0	1

The

(A) A lute, which answers this purpose sufficiently well, is composed of pipe clay and linseed oil well beaten together, and reduced to the consistence of glaziers putty. This is neatly applied to the joining, and if allowed to remain for eight or ten hours before it is exposed to the heat, it will afterwards bear the highest temperature.

Oxygen.

The experiments were repeated by filling the same vessel with oxygen gas, and he obtained the following results:

	H.	M.
The first sparrow lived - -	5	23
The second - - -	2	10
The third - - -	1	30
The fourth - - -	1	10
The fifth - - -	0	30
The sixth - - -	0	47
The seventh - - - - -	0	27
The eighth - - - - -	0	30
The ninth - - - - -	0	22
The tenth - - - - -	0	21

Two sparrows were then put in together; the one lived for an hour, but the other died in about 20 minutes.

348 Oxygen combines with bodies.

5. Oxygen combines with a great number of bodies, and forms compounds with them. It is always presented to us in a state of combination. In examining its properties, it is always as a compound; and these properties are only cognizable to our senses in that state.

When oxygen combines with metallic substances, they acquire new properties, and this combination is in chemical language denominated an *oxide*. Combined with many other substances, the nature of the substance is also changed, and the compound exhibits new properties. One of the most remarkable of these is the taste of the compound substance, which is often sour or acid; and because this circumstance was observed to be one of the most frequent and most remarkable which attend its combinations, the name of oxygen, or acidifying principle, was invented for it by Lavoisier. Oxygen gas is also necessary for the germination of the seeds of plants; and as the process of vegetation advances, it is given out in great abundance by the leaves during exposure to the solar ray. By this means the great waste of oxygen gas, in the processes of combustion and respiration, has been supposed to be fully repaired, and the balance between its consumption and supply to be preserved.

349 Origin of the name.

6. The following is the order of its affinity for the substances with which it enters into combination.

OXYGEN.

Charcoal,
Titanium,
Manganese,
Zinc,
Iron,
Tin,
Uranium,
Molybdena,
Tungsten,
Cobalt,
Antimony,
Hydrogen,
Phosphorus,
Sulphur,
Azote,
Nickel,
Arsenic,
Chromium,
Bismuth,
Lead,
Copper,
Tellurium,
Platina,
Mercury,
Silver,
Oxide of arsenic,
Nitrous gas,
Gold,
Muriatic acid,
White oxide of manganese,
White oxide of lead.

Azotic G

CHAP. V. OF AZOTIC GAS.

1. AZOTIC gas was examined by Mr Scheele, the celebrated Swedish chemist, in 1776; and his experiments proved, that it is a fluid possessed of peculiar properties. It seems, however, to have been known to Dr Rutherford of Edinburgh, as early as the year 1772, as appears from his thesis published in that year, in which he treats of the effects of combustion and respiration on the atmosphere. 350 Discover

2. There are various methods by which this gas may be obtained. *a.* The process recommended by Berthollet is the following: Take a quantity of muscular flesh, or the fibrous part of the blood, which has been well washed. Cut the flesh into small pieces; introduce it into a retort, or a matrass to which a ground tube has been adapted. Pour over it diluted nitric acid, expose it to a heat of about 100°, and place the beak of the retort or the end of the tube in the pneumatic apparatus, that the gas which comes over may be received in proper vessels. The gas thus obtained, is *azotic gas*. *b.* If sulphuret of potash be exposed to the air of the atmosphere, inclosed in a bell-glass, over water; or, if sulphuret of iron be formed into a paste with water, and treated in the same way, and allowed to remain for some days, the quantity of air within the glass is greatly diminished, in consequence of part having been absorbed, and what remains is azotic gas. *c.* When the air of the atmosphere is inclosed in the same way, and exposed to the action of phosphorus, it also suffers diminution, part being absorbed. Azotic gas only remains. 351 Methods procuring it.

3. Azotic gas, like common air, is invisible and elastic, and may be indefinitely condensed and dilated. Its specific gravity is less than that of atmospheric air It is estimated by Mr Kirwan at 0.00120, which is in the proportion of 985 to 1000; but according to Lavoisier's experiments, it is to atmospheric air as 942.6 to 1000, which makes its specific gravity only 0.00115. 352 Properti

This gas is unfit for combustion. If into a jar or phial, filled with azotic gas, a lighted candle be introduced, it is immediately extinguished.

This gas is also extremely noxious to animals, and is therefore totally unfit for respiration.

4. No attempts which have yet been made have succeeded in decomposing azote, or the base of azotic gas. It must therefore be admitted among the number of simple substances. It has never been obtained in a separate state. It is therefore when it is combined with caloric, that is, in a gaseous state, that we are acquainted with its properties; and from its being unfit for respiration, it derived its name. From being the radical of the nitric acid, it is often named *nitrogen*. Some chemists have indeed considered it as a compound 353 Is a simp substanc

compound substance. Dr Priestley supposed that it consisted of phlogiston and oxygen gas. On this account he called it *phlogisticated air*. According to the Stahlian theory, the process of combustion is the separation of phlogiston from the burning body. Oxygen gas having a strong affinity for phlogiston, combines with it during the combustion, and is even supposed to contribute to the separation of the phlogiston, by its affinity for it. And when this air is saturated with phlogiston, the process of combustion is at an end. The air that remains after this process is azotic gas. This theory, when first announced by Dr Priestley, was pretty generally received; but future experiments soon demonstrated, that the quantity of air in which a combustible body was burnt, diminished both in bulk and in weight; and therefore proved that the air, instead of receiving any addition, was on the contrary deprived of something.

Achard, about the year 1784, concluded, from some experiments which he had made, that azotic gas consists of water and fire. This theory has been supported by Westrumb, and more lately by Wiegleb. According to the experiments on which these chemists rest the truth of their theory, azotic gas is always the result when steam is made to pass through red-hot earthen, or even metallic tubes; but a series of very accurate experiments, instituted by the associated Dutch chemists, clearly proved that no azotic gas was produced, when the instruments employed were impenetrable by air *. Dr Priestley had long before shewn, that in similar experiments, when he employed earthenware retorts, containing moist clay, and exposed them to a temperature above boiling heat; instead of vapour issuing from the beak of the retort, a quantity of air, which was nearly equal in weight to the quantity of water introduced, passed over. The conclusion which he drew from these experiments, was, that the water was converted into air; for he found that it possessed nearly the same properties as common air. But he proved afterwards, by more accurate experiments, that water had made its way through the pores of the vessels, and that its place was supplied by the external air which was forced in by the pressure of the atmosphere. For it was clearly ascertained by the experiments of the Dutch chemists, that no gas was obtained, while perfectly sound glass or metallic tubes were employed.

Another theory has been proposed, of the composition of azotic gas, by Girtanner †. He supposes that azotic gas consists of hydrogen and oxygen gas, having a smaller proportion of oxygen gas than what enters into the composition of water ‡. But the experiments of other chemists, as Berthollet and Bouillon Lagrange, have afforded no such results (B).

4 Combination with light.

5. There is no perceptible action between azotic gas and light. Combined with caloric, we have already seen it may be indefinitely expanded, but without undergoing any change in its properties.

5 With caloric.

Azotic gas, from its being found in such abundance in the air of the atmosphere, must act some important part in the economy of nature. It is given out, or seems to be given out, in great quantity, during the decomposition of animal and vegetable matters; but during these processes, it is the oxygen of the atmospherical air which is absorbed, and thus the residuary air is azotic gas. The base of azotic gas is unknown, and chemists are still unacquainted with its affinities.

Azotic gas combines with oxyen in different proportions, and forms compounds very different in their nature and properties. In one proportion it constitutes the air of the atmosphere; in another, what is called *nitrous oxide*, and in a third, *nitric oxide gas*. These we shall examine in their order in the following sections. 356 With oxygen in different proportions.

Sect. I. *Of Atmospheric Air.*

1. The air of the atmosphere is composed of azotic and oxygenous gases. It is an invisible elastic fluid, which may be indefinitely compressed and dilated. The specific gravity of atmospheric air is 0.0012, or about 816 times lighter than water. This is to be understood when the temperature is between 50° and 60°, and when the barometer is at 30 inches. The pressure of the air of the atmosphere is nearly equal to 15lb. on every square inch. 357 Properties.

2. Till the discoveries of modern chemistry, atmospheric air was considered one of the four simple elementary substances, of which all bodies are composed. But the experiments and researches of Priestley and of Scheele fully demonstrated the existence of two separate substances, totally distinct from each other in their nature and properties. Oxygenous gas, one of the component parts of atmospheric air, was, according to Dr Priestley, completely freed from phlogiston; and hence he calls it dephlogisticated air, which was in an eminent degree fit for respiration and combustion; but azotic gas, the other component part, was supposed to be saturated with phlogiston, and therefore unfit, as it was found to be, for these purposes. To the latter, the azotic gas, Scheele gave the name of *foul air*.

3. According to the experiments of Lavoisier, the proportions of the two gases which exist in atmospheric air, are 73 parts of azotic gas, and 27 of oxygen gas. But according to later experiments the proportions are found to be 78 of the former, and 22 of the latter, by bulk; or by weight, 74 and 26. 358 Proportions of azotic and oxygen gases

The proportions of these two gases in atmospheric air are uniform and constant. They have been found to be the same in all parts of the world, and in all seasons of the year. 359 always constant.

4. A question has arisen among philosophers concerning the constitution of the atmosphere, whether its component parts are to be considered merely as a mechanical mixture, or as a chemical combination. To the latter opinion the greater number of chemists are inclined, from the constancy of the proportions of the component parts of the atmosphere, these parts always being found in the same proportion at all heights, and never separating according to their specific gravities; from its possessing distinct properties; and from its continuing the same, whatever processes are carried on in 360 Constitution of the atmosphere. 361 Supposed to be a chemical combination,

* Jal. de Ch. vol. xx. p. 31.

† vol. xx. p. 3.

‡ vol. xx. p. 23.

(B) The component parts of water are oxygen and hydrogen, as we shall find afterwards.

Azotic Gas. in it, or whatever proportions of oxygen may be absorbed during these processes.

362 or a mechanical mixture. A contrary opinion has been adopted by Mr Dalton, which he has endeavoured to establish by some very acute mathematical reasoning. According to his ingenious hypothesis, the elastic fluids which exist in the atmosphere have no mutual action whatever. The particles of one fluid are only attracted and repelled by each other, but are not acted upon by the particles of another fluid. The particles of the different fluids, with regard to each other, are subjected to the laws of inelastic bodies *.

* *Manches. Mem* vol. v. p. 533.

Sect. II. *Of Nitrous Oxide Gas.*

363 Process for obtaining this gas. 1. This gas is most readily obtained by decomposing nitrate of ammonia, a salt composed of nitric acid and ammonia, the properties of which will be afterwards detailed. The crystals of this salt are put into a retort, and exposed to a temperature between 340° and 500°. It very soon melts after the heat is applied, and a great quantity of gas is emitted, at first in the form of white fumes, but afterwards transparent and colourless. This may be received in jars over water in the usual way. It is the nitrous oxide gas, the gaseous oxide of azotic, or, as it has been called by some, from the pleasurable sensations it excites on being respired, *the gas of paradise*. The first part of the gas which comes over is not quite so pure as the rest, which is given out slowly, and is transparent. When therefore it is respired, care should be taken to separate what comes off first, from the rest. This gas, as is obvious from the process, is obtained by the decomposition of the nitrate of ammonia; but the change which takes place will be better understood when we come to treat of the salt itself.

364 Discovery. 2. This gas was called by Dr Priestley dephlogisticated nitrous gas; and it was discovered by him in the year 1776. Its component parts were ascertained by the associated Dutch chemists; but its nature and properties were more fully and preeisely investigated by Sir H. Davy *.

* *Researches*, 1800.

365 Properties. 3. In its physical properties, this gas resembles common air. It is elastic, transparent, and colourless. The specific gravity, as it has been estimated by Sir H. Davy, is 0.00197. One hundred cubic inches of it weigh 50.20 grains. Its component parts are 63.58 of azote, and 36.42 of oxygen; by measure, two volumes of azotic to one of oxygenous gas.

Some combustibles burn in this gas nearly as well as in oxygen gas, but with this difference, that they must be previously in a state of ignition.

Pyrophorus, which spontaneously inflames so low as the temperature of 40° in atmospheric air, will not burn in nitrons oxide gas, till it is raised to a temperature above 212°. A burning taper introduced into pure nitrous oxide gas, burns at first with a brilliant white light, and sparkles as in oxygen gas; but as the combustion goes on, the flame gradually lengthens, and is surrounded with a pale blue light. Phosphorus burns in it with a brilliancy much inferior to its combustion in oxygen gas.

366 Effects in respiring it. 4. It was at first supposed that this gas is unfit for respiration, but the experiments of Davy have shown the contrary; and the singular effects which it produces on the animal frame have excited much interest. From these experiments, and from many others which have been since repeated, it appears that it may be respired for some minutes without injury. In some cases it produces no effect whatever; but, in general, the sensations it excites are similar to those of intoxication; though rarely followed by its unpleasant effects. Sir H. Davy describes his own feelings when he respired this gas in the following words.

"Having previously closed my nostrils and exhausted my lungs, I breathed four quarts of nitrous oxide from and into a silk bag. The first feelings were giddiness, sense of fulness of the head, and indistinct sensation; but in less than half a minute, the respiration being continued, they diminished gradually, and were succeeded by a sensation analogous to gentle pressure on all the muscles, attended by a highly pleasurable thrilling, particularly in the chest and the extremities. The objects around me became dazzling, and my hearing more acute. Towards the last inspirations, the thrilling increased, the sense of muscular power became greater, and at last an irresistible propensity to action was indulged in; I recollect but indistinctly what followed; I know that my motions were various and violent.

"These effects very soon ceased after respiration. In ten minutes I had recovered my natural state of mind. The thrilling in the extremities continued longer than the other sensations.

"This experiment was made in the morning; no languor or exhaustion was consequent, my feelings throughout the day were as usual, and I passed the night in undisturbed repose *."

* *Davy's Researches*, p. 457.

But although it may be respired for a short time with impunity, not more than 3 or 4 minutes, yet animals that are confined in it soon become restless and uneasy, and at last expire. It is unfit for the support of animal life, and perhaps could not at all be respired, if the lungs were previously exhausted of atmospheric air.

36[7] Taste and smell. 5. The taste of nitrous oxide gas, when in a state of purity, is distinctly sweet to the tongue and palate; and it has an agreeable odour. Davy observes, that he often thought it produced a feeling somewhat analogous, as he expresses it, to taste in its application to the lungs; for in one or two experiments he perceived a distinct sense of warmth in the chest †.

† *Ibid.* p. 460.

36[8] Is absorbed by water. 6. Water absorbs nitrous oxide gas in considerable proportion. When the water is agitated, 0.54 parts of its bulk, or 0.27 of its weight, combine with it. The water becomes sweetish, and the whole of the gas may be expelled from it unchanged, by boiling.

7. No change takes place upon this gas by the action of light; except when it is exposed to a high temperature, as when the electric spark is sent through it, or when it is made to pass through a red-hot porcelain tube; it is then decomposed, and converted into common air and nitric acid.

Sect. III. *Of Nitric Oxide Gas.*

36[9] How procured. 1. If a quantity of pure copper filings be put into a matrass or retort, and diluted nitric acid be poured over them, a violent effervescence takes place, and a great quantity of gas is evolved. This is *nitric oxide gas*; sometimes

Gas. sometimes called *nitrous gas.* It may be obtained also by substituting for the copper other metals, as iron, silver, and mercury.

This gas is mentioned by Dr Hales; but it is to the labours of Dr Priestley that we are indebted for a knowledge of its nature and properties.

Properties. 2. It is an elastic colourless fluid, without sensible taste, and does not redden the tincture of turnsole (c.)

According to Mr Kirwan, the specific gravity of nitrous gas is 0.001458, but by Davy's estimation it is 0.001343. The weight of 100 cubic inches of it is 34.26 grs. and it is composed of 53.40 oxygen, and 46.60 azote; or quantities which would make equal measures of these two principles in the state of gas ‡. This gas is totally unfit for respiration. Animals that breathe it are instantly suffocated.

Some combustibles burn in this gas. Phosphorus, when introduced into it in a state of active inflammation, burns with almost as much vividness as in oxygen gas ||. Homberg's pyrophorus, a substance which takes fire when exposed to the air, if introduced into this gas, instantly becomes red, and burns very vividly. In this experiment, and in the former with the phosphorus, these substances combine with the oxygen of the nitrous gas, while heat and light are emitted and azotic gas is left behind.

3. Nitric oxide gas, when exposed to the action of heat, by being made to pass through a red-hot porcelain tube, undergoes no change *. It is absorbed by water. When the water is freed from air, it absorbs about $\frac{1}{10}$ of its bulk of this gas, at the common temperature, and when it is boiled or frozen, the gas separates unchanged. The water thus impregnated has no peculiar taste, nor does it alter the colour of vegetable blues.

4. When a quantity of atmospheric air is introduced into a jar containing nitric oxide gas, a red colour appears from the mixture of the two gases; they are diminished in bulk, and heat is evolved. The product is nitrous acid. If oxygenous gas be employed instead of atmospheric air, the whole of the two gases will be converted into a liquid. The diminution of bulk is owing to the condensation of the elastic fluids, and the evolution of caloric must be ascribed to the change of state, from that of elastic fluid to that of liquid.

Azotic gas also enters into combination with oxygen in a different proportion from what has been stated above, forming nitrous and nitric acids; but these will come more properly to be treated of among the class of acids.

The following table exhibits at one view the different proportions of oxygen and azotic gases in the compounds formed by these two substances.

100 cubic inches.	Weight in grains.	In 100 grains, Proportions of	
		Azote.	Oxygen.
Atmospheric air	31.10	73.00	27.00
Nitrous oxide	50.20	63.58	36.42
Nitric oxide	34.26	46.60	53.40
Nitric acid	76.00	25.97	74.03

Chap. VI. Of HYDROGEN.

373 History. 1. This gas, in combination with carbon, has been long known under the name of the *fire-damp* of the miners. Its combustible property is described in the works of Boyle and Hales, of Boerhaave, and of Stahl; but it was not till the year 1766 that its properties were particularly ascertained, and the difference between it and atmospheric air pointed out by Mr Cavendish. Its properties and combinations were more fully investigated by Priestley and Scheele, Senebier, and Volta, under the name of *inflammable gas* or *air*. It is now distinguished by the name of hydrogen gas, and its base by that of hydrogen.

Like the two former, oxygen and azote, it is never obtained in an uncombined state. Its properties can only be examined in a state of gas.

374 Method of procuring. 2. Hydrogen gas may be obtained in a state of tolerable purity by the following process. Take one part of clean iron filings, and introduce them into a tubulated retort, and add two parts of sulphuric acid previously diluted with four times its bulk of water. A violent effervescence immediately takes place, and great abundance of air bubbles make their escape. Put in the stopper of the retort, place the beak of it under the shelf in the pneumatic trough, and let the gas which comes over be received in proper vessels. The gas thus obtained is *hydrogen gas*, which is distinguished by the following properties.

375 Properties. 3. In its physical character it resembles common air. It is invisible and elastic, and may be indefinitely compressed and expanded.

Its specific gravity has been variously estimated, owing, perhaps, to its different degrees of purity. According to Lavoisier, it is 0.000094, which is nearly 12 times lighter than atmospherical air; but according to Mr Kirwan, it is 0.00010.

Hydrogen gas is unfit for supporting combustion. If a lighted candle be suddenly plunged in a vessel filled with hydrogen gas, it is immediately extinguished; or if an inverted jar filled with it be suddenly brought over a lighted candle, it is extinguished in the same way. The latter experiment is the most effectual, on account of the small specific gravity of the gas, which is prevented from escaping by rising upwards when the jar is inverted.

It is also unfit for respiration.

When small animals are inclosed in a vessel filled with this gas, they are soon thrown into convulsions, and expire. Scheele, however, who first made the attempt, breathed it several times without much injury. Fontana made the same experiment, and he supposes that this was owing to the common air present in the lungs before respiration of the hydrogen gas: for when he made a full expiration, before he began to breathe the hydrogen gas, he could only inspire it three times, and these three produced great languor and oppression in the breast. This was confirmed by Sir H. Davy, who, in some experiments on himself found, that, after having exhausted the lungs as much as possible, he could

(c) This is a test for acid substances, which will be mentioned particularly afterwards.

Hydrogen. could not respire this gas for half a minute. It produced uneasy feelings in the chest, momentary loss of muscular power, and sometimes a transient giddiness *. From these experiments it may be concluded, that hydrogen gas is totally incapable of supporting animal life.

* Davy's Researches, p. 401.

376 Is combustible. 4. But although hydrogen gas be unfit for the support of combustion, or for respiration, yet it is itself a highly combustible substance. If a jar be filled with hydrogen gas, and a burning taper be applied, the gas will take fire, and burn with a flame which is more or less coloured according to the purity of the gas. When the gas is in the purest state that can be obtained, it is of a dilute or blackish white colour; but when it holds charcoal in solution, it is of a reddish or bright white colour.

377 Combines with water only by pressure. 5. Hydrogen gas, if other gases be entirely excluded, undergoes no change when it is kept in contact with water, nor is any part of it absorbed by the water: But when artificial pressure is employed, water is said

378 A remedy in disease. to absorb a third part of its bulk of the gas. No perceptible change is observed in the taste of the water thus impregnated with hydrogen gas; it is recommended by Mr Paul as beneficial in nervous disorders, and in inflammatory fevers †.

† Phil. Mag. vol. xv. p. 93.

379 Employed in balloons. Hydrogen gas, on account of its being so much lighter than atmospheric air, has been employed for the purpose of filling air balloons. When perfectly pure, it is 12 or 13 times lighter than the same bulk of atmospheric air; but, in the usual way of obtaining it, the specific gravity of hydrogen gas is only seven or eight times less than that of common air. See AEROSTATION.

380 Explodes. 6. If hydrogen gas and atmospheric air be mixed together, they remain unaltered; but if one part of oxygen gas, and two parts of hydrogen gas be introduced into a phial, and a burning taper be applied to its mouth, the mixed gases will explode with a loud noise, and the

381 With atmospheric air. bulk will be greatly diminished. The whole of the oxygen of the atmospheric air disappears, and the azotic gas only remains. If one part of oxygen gas and

382 And with oxygen gas. two parts of hydrogen gas be mixed together in a phial, and exploded in the same way, they both disappear. This may be proved by mixing the two gases in a jar over water or mercury, and exploding them by means of the electric spark. The gases disappear; a vacuum is consequently formed in the jar, and the water or the mercury, by the pressure of the air, is forced up. If the experiment has been made over mercury, and if the inside of the jar was previously free from moisture, drops of water will appear, which have been formed by the combination of the two gases. Water, therefore, is composed of oxygen and hydrogen gas. This is a case of true combustion. Oxygen combines with the combustible body; light and caloric are evolved, and the result of this action and combination is one of the products of combustion, namely water. The discovery of the composition of water, undoubtedly one of the most important in modern chemistry, will be the subject of the following section.

SECT. I. *Of Water.*

1. Water acts so important a part in many chemical combinations, that its nature and properties should be early known. Before the discoveries of modern chemistry, it was considered as a simple substance, and one of the four elements which enter into the constitution of all bodies in nature. 383 Importance in chemistry.

The fortunate discovery of the composition of water, is undoubtedly one of the most important which has been made in chemical science. We have already mentioned, that the product of oxygen and hydrogen gases, when exploded together, is water; but in a subject of so much importance, it will be necessary to enter more into detail; and this we shall do, 1st, by stating the experiments forming the proofs of its composition; and, 2dly, by giving a short historical view of the progress of the discovery.

2. Various experiments have been made to ascertain this fact; but those which were made by Lavoisier being on a larger scale, and performed with such precautions as to insure accuracy and precision, an account of them will be the more satisfactory.

1. *Proof of the Composition of Water.*

Exper. a. Take a porcelain or glass tube from 8 to 12 lines diameter, and place it across the furnace EFCD, with a gentle inclination from E to F (D). The higher extremity of the tube is then luted to the glass retort A, containing a known quantity of distilled water. To the lower extremity F is luted the worm SS, the lower end of which is fixed in the neck of the bottle H, which bottle has the bent tube KK fixed to a second opening. This bent tube is intended to carry off any elastic fluids which may escape into the bottle H. A fire is then lighted in the furnace EFCD, sufficient to keep the tube EF red hot, but not to melt it. The water in the retort A is kept boiling by a fire in the furnace VVXX. The water is gradually changed into steam by the heat of the two furnaces. It passes through the tube EF into the worm SS, where it is condensed, and then drops into the bottle H. When the whole water is evaporated, and all the communicating vessels are emptied into the bottle H, it is found to contain exactly the same quantity which was put into the retort. This experiment therefore is a simple distillation. 384 Proof of the composition of water by analysis. Plate CXLI. Fig. [illegible]

Exper. b. Every thing being disposed as in the last experiment, let 27 grains of pure charcoal, broken into small parts, and which has been exposed to a red heat in a close vessel, be introduced into the tube EF. The experiment is then performed in the same manner as the former. The water is evaporated, and a portion of it is again condensed in the worm SS, and then falls into the bottle H; but at the same time a considerable quantity of an elastic fluid escapes through the tube KK, which is received in vessels. When the water

(D) The tube EF, if of glass, should be such as can bear a strong heat without melting. It should also be coated over with a lute composed of clay and powdered stone-ware; and to prevent it from bending during the experiment, it must be supported about the middle by an iron bar.

Hydrogen. ter is entirely evaporated, and the tube examined, the 28 grains of charcoal have wholly disappeared.

When the water in the bottle H is examined, it is found to have lost 85.7 grains of its weight; and when the elastic fluid which passed off by the tube KK is weighed, it is found to weigh 113.7 grains, which is exactly the weight which the water has lost, added to the 28 grains of charcoal which had disappeared. The elastic fluid, on examination, is discovered to be of two kinds; namely, 144 cubical inches of carbonic acid gas weighing 100 grains, and 380 cubical inches of a very light gas weighing only 13.7 grains. Now 100 grains of carbonic acid gas consist of 72 grains of oxygen, combined with 28 grains of carbon. It is therefore evident, that the 28 grains of charcoal must have acquired 72 grains of oxygen from the water. It is also evident, that 85.7 grains of water are composed of 72 grains of oxygen, combined with 13.7 grains of a gas capable of being burned.

Exper. c. Every thing being put in the same order as in the two former experiments, with this difference, that instead of the 28 grains of charcoal, 274 grains of soft iron, in thin plates rolled up spirally, are introduced into the tube EF. The tube is kept red hot while the water is evaporating from the retort.

After the water has been distilled, it is found to have lost 100 grains. The gas or elastic fluid weighs 15 grains, and the iron has gained 85 grains of additional weight, which put together make up 100 grains, the weight which the water has lost. The iron has all the qualities which it would have received by being burned in oxygen gas. It is a true oxide (or calx) of iron. We have the same result as in the last experiment, and have therefore another proof for concluding, that 100 grains of water consist of 85 grains of oxygen, and 15 of the base of hydrogen gas.

We have now exhibited two sufficient proofs, that water is composed of oxygen and hydrogen; but as the composition of water is so interesting and important a subject, M. Lavoisier was not satisfied with these proofs alone. He justly concluded, that if water be a compound of two substances, it ought to follow, that by reuniting these two substances, water would be produced. He accordingly proved the truth of this conclusion by the following experiment.

385 P[roved] by [s]y[nthe]sis.

Exper. d. He took a large crystal balloon A, fig. 4. containing about 30 pints, and having a large mouth; round which was cemented the plate of copper BC, pierced with four holes, through which four tubes pass. The first tube H *h* is intended to exhaust the balloon of its air, by adapting it to an air pump. The second tube *g g* communicates with a reservoir of oxygen gas placed at MM. The third tube *d* D ∂ is connected with a reservoir of hydrogenous gas at NN. The fourth tube contains a metallic wire GL, having a knob at its lower extremity L, from which an electric spark is passed to ∂, in order to set fire to the hydrogen gas. The metallic wire is moveable in the tube, that the knob L may be either turned towards ∂, or away from it, as there is occasion. We must also add, that the three tubes H *h*, *g g*, *d* D ∂ are furnished with stopcocks.

It is necessary that the oxygen gas, before being put into the reservoir, should be completely purified from carbonic acid. This may be done by keeping it for a long time in contact with a solution of caustic potash. The hydrogen gas ought to be purified in the same manner. The quantity employed ought to be double the bulk of the oxygen gas. It is best procured from water by means of iron, as was described in Experiment Third.

Great care must also be taken to deprive the oxygen and hydrogen gas of every particle of water. For this purpose they are made to pass in their way to the balloon A, though salts which have a strong attraction for water; as the acetite of potash (a compound of vinegar and vegetable alkali), or the muriate or nitrate of lime (the muriatic or nitric acid combined with lime). These salts are disposed in the tubes MM and NN of one inch diameter, and are reduced only to a coarse powder, that they may not unite into lumps, and interrupt the passage of the gases.

Every thing being thus prepared for the experiments, the balloon is exhausted of its air by the tube H *h*, and is filled with oxygen gas. The hydrogen gas is also pressed in through the tube *d* D ∂ by a weight of one or two inches of water. As soon as the hydrogen gas enters the balloon, it is kindled by an electric spark. The combustion can be kept up as long as we please, by supplying the balloon with fresh quantities of these two gases. As the combustion advances, a quantity of water is collected on the sides of the balloon, and trickles down in drops to the bottom of it. By knowing the weight of the gases consumed, and the weight of the water produced, we shall find that they are precisely equal. M. Lavoisier and M. Meusnier found that it required 85 parts by weight of oxygen gas, and 15 parts of hydrogen gas, to produce 100 parts of water.

Thus we have complete proofs, both analytical and synthetical, that water is not a simple elementary substance, as it had been long supposed, but is compounded of two elements, oxygen and hydrogen.

But although the knowledge of the component parts of water was finally confirmed by Lavoisier and his friends, we shall find that science is indebted for the origin and progress of this discovery, chiefly, if not entirely, to the English philosophers.

2. *History of the Discovery of the Composition of Water.*

1. So early as the year 1776, an experiment was made by Macquer, to ascertain what would be the product of the combustion of hydrogen gas. He accordingly set fire to a bottle full of it, and held a saucer over the flame, but no soot appeared upon it as he expected, for it remained quite clean; and was bedewed with drops which were found to be pure water. Various conjectures were now formed about the nature of the product of the combustion of oxygen and hydrogen gases. By some it was supposed to be carbonic acid gas; by others it was conjectured it would be the sulphurous or sulphuric acid. The latter was the opinion of M. Lavoisier. Such were the experiments and opinions of the French chemists, previous to the year 1781.

386 Combustion of hydrogen yields water.

387 Conjectures.

2. About the beginning of that year, Mr Warltire, a lecturer in natural philosophy, had long entertained an opinion that the combustion of hydrogen gas with atmospheric air might determine the question, whether heat

388 Experiment by Warltire and Priestley.

Hydrogen. heat be a heavy body. Apprehensive of danger in making the experiment, he had for some time declined it; but was at last encouraged by Dr Priestley, and accordingly prepared an apparatus for the purpose. This was a copper vessel properly fitted, and filled with atmospherical air and hydrogen gas, which was exploded by making the electric spark pass through it. A loss of weight of two grs. was observed after the combustion. A similar experiment was repeated in close glass vessels, which, though clean and dry before the combustion, became immediately wet with moisture, and lined with a sooty matter. This sooty matter, Dr Priestley afterwards supposed, proceeded from the mercury which had been employed in filling the vessel.

389 By Cavendish.

3. During the same year, Mr Cavendish repeated the experiments of Mr Warltire and Dr Priestley. He performed them several times with atmospheric air and hydrogen gas, in a vessel which held 24,000 grs. of water, and he never could perceive a loss of weight more than $\frac{1}{5}$ gr. and often none at all. In all these experiments, not the least sooty matter appeared. To examine the nature of the dew which appeared in the inside of the glass, he burnt 500,000 grain measures of hydrogen gas with about $2\frac{1}{2}$ times that quantity of common air; and in this combustion he obtained 135 grs. of water, which had neither taste nor smell; and when it was evaporated, left no sensible sediment.

In another experiment, he exploded in a glass globe, 19,500 grain measures of oxygen gas, and 37,000 of hydrogen gas, by means of the electric spark. The result of the experiment was 30 grains of water, which contained a small quantity of nitric acid. The experiments of Mr Cavendish were made in the year 1781, and they were undoubtedly conclusive with regard to the composition of water.

390 Mr Watt's views.

4. It would appear, that Mr Watt entertained the same ideas on this subject. When he was informed by Dr Priestley of the result of these experiments, he observes; "Let us consider what obviously happens in the deflagration of hydrogen and oxygen gases. These two kinds of air unite with violence, they become red hot, and when cooling totally disappear. When the vessel is cooled, a quantity of water is found in it equal to the weight of the air employed. The water is then the only remaining product of the process; and water, light, and heat, are all the products, unless there be some other matter set free, which escapes our senses. Are we not then authorised to conclude, that water is composed of oxygen and hydrogen gases, deprived of part of their latent or elementary heat; that oxygen gas is composed of water, deprived of its hydrogen, and united to elementary heat and light; and that the latter are contained in it in a latent state, so as not to be sensible to the thermometer or to the eye. And if light be only a modification of heat, or a circumstance attending it, or a component part of the hydrogen gas, then oxygen gas is composed of water deprived of its hydrogen, and united to elementary heat*."

Thus it appears that Mr Watt had a just view of the composition of water, and of the nature of the process by which its component parts pass to a liquid state from that of an elastic fluid.

* *Philos. Trans.* 1784, p. 383.

5. Towards the end of the same year, M. Lavoisier had made some experiments, the result of which surprised him; for the product of the combustion of the oxygen and hydrogen gases, instead of being sulphuric or sulphurous acid, as he expected it, was pure water. This led him to procure an apparatus, with which the experiment might be performed on a large scale, and with more accuracy and precision. Accordingly the experiments, which we have already detailed were performed on the 24th of June 1783, in presence of several academicians, and also of Sir Charles Blagden, who who was at that time in Paris. A similar experiment was afterwards performed by M. Monge, with the same result; and it was repeated again by Lavoisier and Meusnier, on a scale so large as to put the matter beyond a doubt. The conclusion, therefore, from the whole was (as has been stated in detailing the experiments themselves), that water is composed of oxygen and hydrogen; and this fact, we believe, since Dr Priestley's death, is universally admitted.

39[.] Lavoisier's experiments.

39[.] Fourcroy, &c.

6. If farther proofs were necessary to establish the fact, we might refer the reader to an elaborate memoir on the combustion of hydrogen gas in close vessels by the celebrated chemists Fourcroy, Vauquelin, and Seguin, which was read at the academy of sciences in the year 1790 *.

* *Ann. de Chim.* viii. p. [.]

39[.] Water in three states.

7. Water exists in three different states; in the solid state or state of ice; in the liquid, and in the state of vapour or steam. Its principal properties have already been detailed, in treating of the effects of caloric. It assumes the solid form when it is cooled down to the temperature of 32°. The specific gravity of ice is less than that of water.

39[.] Ice.

39[.] Water liquid.

When ice is exposed to a temperature above 32°, it absorbs caloric, which then becomes latent, and is converted into the liquid state, or that of water. At the temperature of 40°, water has reached its maximum of density. According to the experiments of Lefevre Gineau †, a French cubic foot of distilled water, taken at its maximum of density, is equal to 70lb. 223 grs. French, = 529,452.9492 troy grains. An English cubic foot at the same temperature weighs 437,102.4946 grains troy. By Professor Robison's experiments it is ascertained, that a cubic foot of water at the temperaturere of 55° weighs 998.74 avoirdupois ounces, of 437.5 grains troy each, or about $1\frac{1}{4}$ ounce less than 1000 avoirdupois ounces.

† *Journ. de Phys.* xlix. p. [.]

39[.] Vapour.

When water is exposed to the temperature of 212°, it boils; and if this temperature be continued, the whole is converted into an elastic invisible fluid, called vapour or steam. This, as has been already shewn, is owing to the absorption of a quantity of caloric, which is necessary to retain it in the fluid form. In this state it is about 1800 times its bulk when in the state of water. This shews what an expansive force it must exert when it is confined, and hence its application in the steam engine, of which it is the moving power.

Sect. II. *Of Ammonia.*

Hydrogen also enters into combination with azote, and forms a compound of great importance. When hydrogen and azotic gases are mixed together, no change takes place, nor has any process been yet discovered by which these two gases can be directly combined; but when bon.

when in their nascent state, as it is called, or in the moment of evolution from the bodies with which they are formerly in combination, they unite together and form ammonia, or the volatile alkali. It is demonstrated also, by direct experiment, that this substance is composed of these two gases; but for the properties of it, we must refer to the chapter on alkalies, where they will be fully detained.

Chap. VII. Of CARBON.

397 T dia- l com- ble.

1. It may appear at first sight surprising, that the diamond, one of the hardest and most indestructible substances in nature, should be arranged among combustible bodies. This, however, was conjectured by Newton, when he considered its great refracting power, referring it to the general law, that combustible bodies have this power in greatest perfection. The sagacious conjecture of this great philosopher has been fully verified. The first experiment to ascertain the combustibility of the diamond was made in the year 1694, in the presence of Cosmo III. grand duke of Tuscany, by the Florentine academicians. In this experiment, the diamond, exposed to the heat of a burning-glass, first became dull and tarnished, lost weight, and was at last entirely dissipated, without the smallest residue. Some years afterwards, a series of experiments was made before Francis I. emperor of Germany, in which diamonds were consumed in the heat of a furnace. In the year 1771, Macquer first observed the diamond swell up and burn with a very sensible flame. Rouelle the younger, Cadet, Mitouart, and Darcet, repeated the same experiments, all which tended to establish the volatility and combustibility of the diamond.

398 ed by i-

But it is to the celebrated Lavoisier that we are indebted for ascertaining the nature and product of this combustion.

399 d in rrid

2. But for the sake of comparison we shall mention some of the general properties of the diamond. This precious stone is found in the warmer regions of the earth, and chiefly in the East Indies and the Brazils. It is found crystallized in regular octahedrons, which is its primitive form; that of the integrant molecules is the regular tetrahedron. The most common form is the six-sided prism, terminating in a six-sided pyramid. What are called spheroidal diamonds have 48 curvilineal, triangular faces, which form of crystal is owing, according to Hauy, to a regular decrement, which may be determined by caculation. The lapidaries are well acquainted with the direction of the laminæ of the diamond, because in that direction it is found to be most easily polished. The hardest diamonds are found to have their fibres twisted, which by the lapidaries are called *natural* diamonds.

400 F.

401 Properties.

3. The diamond is the hardest body known. It can only be polished with the powder of itself, which is procured by rubbing one diamond against another. The specific gravity of the diamond is 3.5, water being 1. Its most remarkable property is brilliancy. When exposed to the light of the sun for some time, and afterwards carried into a dark place, it appears luminous, so that it has the property of absorbing light. It becomes very sensibly electric by friction, and is therefore a nonconductor of electricity. Carbon.

402 Product of its combustion.

4. As it was now ascertained, that the diamond exposed to a strong heat was susceptible of combustion, and might be entirely dissipated, Lavoisier directed his attention in the year 1772 to discover the product which was thus obtained; and he found by experiment, that the quantity of the diamond, exposed to the heat of a burning-glass in oxygen gas, consumed, was in exact proportion to the quantity of air absorbed. The air was converted into carbonic acid gas (F). The quantity of the carbonic acid obtained being found proportional to the quantity of diamond consumed, it was concluded that diamond was nothing else but pure carbon. This furnished a striking analogy between the diamond and charcoal, from the combustion of which a similar product is obtained. An experiment made by Guyton in the year 1785, and a similar one repeated in 1797 by Mr Tennant, proved that the diamond is combustible, and that it burns like charcoal when thrown into melted nitre. The conclusion from which was, that the diamond and charcoal consist of the same substance.

403 A simple substance.

5. We shall find, in investigating the properties of charcoal in the following section, that the one is a simple the other a compound substance, which will enable us to explain the remarkable difference between many of the properties of the diamond and charcoal.

404 Compared with charcoal, which is a compound.

Charcoal burns in the heat of an ordinary fire, but the diamond requires for its combustion a temperature not less than 5000°; nor is the difference between these two bodies in specific gravity, hardness, and colour, less striking. Lavoisier had ascertained that 100 parts of carbonic acid contained

28 charcoal,
72 oxygen.

100

In the experiments made by Guyton on the diamond, it appeared that carbonic acid gas is composed of

17.88 diamond,
82.12 oxygen.

100.00*.

* *Ann. de Chim.* tom. xxi. p. 99.

If then 100 parts of carbonic acid gas are composed of the same proportions of constituent parts, and these proportions are obtained both by the combustion of the diamond and charcoal, it must necessarily follow that the charcoal, which requires a smaller proportion of oxygen to make up the 100 parts of carbonic acid gas, must contain the difference of the quantity of oxygen between the quantity with which it combines, and the quantity necessary to saturate the diamond. Hence it was inferred, that 100 parts of charcoal consist of 63.86 diamond, and 36.14 oxygen. But in more recent and more

(F) Carbonic acid gas, as will appear afterwards, is composed of carbon and oxygen.

Carbon.

more accurate experiments, it is found that the purest charcoal contains no oxygen whatever; and that it differs from diamond only in compactness of texture. From this account, therefore, of the nature and properties of the diamond, it must be considered as a simple substance, and that substance which has received the name of carbon in the new chemical nomenclature; or pure charcoal in a highly condensed form.

405 Charcoal very abundant.

1. Charcoal exists in great abundance in animal and vegetable matters, and it is obtained by the partial decomposition of these substances. It may be procured by burning wood in close vessels; and the matter that remains after this combustion is a black, shining, brittle substance, which is well known under the name of charred wood, or charcoal.

406 Method of preparing and purifying.

To obtain charcoal pure, it must be repeatedly washed with pure water, and be afterwards exposed for some time to a strong heat in close vessels. Thus prepared, if it be entirely deprived of moisture and excluded from air, it may be exposed to the strongest heat without any change.

407 Properties.

2. Charcoal is a good conductor of electricity. When it is new made, it is found to have the property of removing the disagreeable odour with which animal matters beginning to putrify, clothes and other substances, are tainted. On account of this property, perhaps, and also on account of its mechanical effects, it is greatly recommended as an excellent tooth powder. Charcoal seems to be quite indestructible. Hence charring is the best method of preserving wood from decay, which is exposed to the effects of air and moisture. Stakes charred on the outside have remained in the ground for some thousand years, and are still in perfect preservation. This seems to have been a common practice among the ancients.

3. Charcoal has neither taste nor smell. It is insoluble in water, but it absorbs moisture in considerable proportion. When well dried, charcoal attracts the air very greedily. A piece of charcoal well dried, placed under a jar over mercury, absorbs the air, and the mercury ascends rapidly; but if a little water be introduced into the jar, the charcoal absorbs the moisture, gives out the air, and the mercury descends. In some experiments made with this view, it appeared that charcoal absorbed four times its bulk of air; and when the charcoal was plunged into water, a fifth part of this air was disengaged, which being examined, a quantity of oxygen had disappeared. In another experiment, the charcoal was introduced into a vessel filled with oxygen gas, when it absorbed eight times its bulk of the gas, and being plunged into water, gave out a fourth part. These experiments were made by Delametherie †.

† *Journ. de Phys.* vol. xxv.

The experiments of Senebier seem to prove, that it was only the oxygen gas of the atmospheric air that was absorbed by charcoal; but it has been since demonstrated, that this only takes place when the charcoal is hot. The atmospheric air is absorbed unchanged when the charcoal is cold.

408 Chemical habitudes.

4. When the temperature of pure charcoal is raised to redness, and if it be then introduced into a jar of oxygen gas, it burns rapidly, giving out brilliant sparks, but with little flame. The charcoal disappears, and the oxygen gas is totally changed. By its combination with the charcoal during the combustion, it is converted into a peculiar gas, which has received the name of *carbonic acid gas*, the component parts of which were discovered by M. Lavoisier, to be

28	charcoal,
72	oxygen.
100	

The properties of this acid will be fully described in its place among the class of acids.

There is no direct action between carbon and azotic gas; but by the action of a third substance. Compounds of azote, hydrogen and carbon, which are combined also with a greater or lesser proportion of oxygen, frequently exist among vegetable and animal matters.

SECT. I. *Of the* COMBINATIONS *of* CARBON *with* OXYGEN, *particularly* CARBONIC OXIDE GAS.

Carbon enters into combination with oxygen in two proportions. 1. In that which forms carbonic oxide gas. 2. In that which forms carbonic acid gas. Of the first of these we are now to treat: the other will be considered under the head of ACIDS.

1. A peculiar inflammable gas, which was at first considered of the same nature with the carbonated hydrogen gas to be described in the next section, was announced by Dr Priestley, from the manner of its production and properties, as a confirmation of the truth of the phlogistic theory. His experiments were soon repeated by many other chemists, and particularly by Mr Cruickshank of Woolwich, who published a very satisfactory account of the nature, composition, and properties of this gas. He gave it the name of the *gaseous oxide of carbon*. He considered it as consisting of carbon united with oxygen; the oxygen and carbon existing in it being nearly in the proportion of two to one. Dr Priestley obtained it from the grey oxide or forge scales of iron and charcoal. Mr Cruickshank also obtained it by a similar process. He employed the oxides of zinc and copper; the black oxide of manganese and litharge. The gas which is obtained from these substances is a mixture of carbonic acid and carbonic oxide. Mr Cruickshank found, that the oxides which most readily part with their oxygen, afford the greatest proportion of carbonic acid; but the oxides which retain their oxygen more strongly, give the greatest proportion of the carbonic oxide. At the beginning of the process, carbonic acid comes over in greatest abundance; it then diminishes, and afterwards carbonic oxide is extricated pure.

409 History.

410 Method of procuring.

It is also obtained by exposing to a strong heat one part of pure charcoal and three parts of carbonate of lime, strontites, or barytes, in an iron retort. The carbonic acid which is in combination with the earths is partly disengaged unchanged, and partly decomposed by the charcoal, and converted by the action of this substance into the carbonic oxide. The gas which is obtained in this process is composed of one part of carbonic acid and five parts of oxide ‡.

‡ *Ann. de Chim.* xxxix. 45.

The same gases are also obtained, by employing iron filings with the earthy carbonates, and the quantity is considerably increased when pure iron is used. Mr Cruickshank and the French chemists also obtained ed it, by making carbonic acid gas pass through red-hot charcoal in an iron or porcelain tube. The carbonic acid is decomposed, and the gaseous oxide is formed.

The carbonic acid which is mixed with the carbonic oxide obtained in all these processes, may be separated by washing the gas with lime water, and the oxide remains in a state of purity.

Properties. 2. This gas is invisible and elastic like common air. Its specific gravity is 0.001167; 100 cubic inches weigh 30 grains.

It is unfit for respiration. Small animals introduced into it are instantaneously suffocated; and in some persons who attempted to breathe it, it produced faintness and giddiness. Desormes and Clement think that it is probably owing to this gas disengaged from burning charcoal, that sudden death is induced in close apartments. It is not altered by passing it through a red-hot tube, nor does it undergo any change by being exposed to light; and it is neither inflamed nor diminished by passing the electric spark through it. This gas in contact with common air, when set fire to, burns with a blue flame. When made to traverse a red-hot tube full of air, it produces slight detonations. The residue of these combustions is carbonic acid and azote.

3. With oxygen gas, if in considerable proportion, the combustion is very rapid; a red flame is produced, and the whole of the gas is consumed. The residue in this combustion is carbonic acid †.

According to Mr Cruickshank, the carbonic oxide is a compound of carbon and oxygen. Thirty grains of it obtained from charcoal and metallic oxides, required 15 grains of oxygen to saturate it, and the quantity of carbonic acid produced was 35.5. Thirty grains obtained from iron filings and earthy carbonate, required 13.6 grains of oxygen, which gave 43.2 grains of carbonic acid.

4. But according to the experiments and conclusions of Berthollet, this gaseous oxide of carbon contains a certain portion of hydrogen in its composition. This quantity, he thinks, amounts to about $.04 = \frac{1}{25}$. He distinguishes two species of inflammable gas, which contain carbon; the one consists entirely of hydrogen and carbon, which he proposes to denominate *carbonated hydrogen gas*, which will be treated of in the next section. The other species of inflammable gas is also formed of hydrogen and carbon, but contains a certain portion of oxygen. To this he proposes to give the name of oxycarbonated hydrogen gas. But the results of the experiments of Cruickshank and others do not correspond with the experiments and conclusions of Berthollet, in admitting any proportion of hydrogen as a component part of his oxycarbonated hydrogen gas, or of carbonic oxide gas. For an account of his observations and reasonings on this subject, see *Memoires de l'Institut. Nationale*, tom. iv. p. 269. 319, and 325.

Sect. II. *Of Carbureted Hydrogen Gas.*

Mode of preparing. 1. If a quantity of wet charcoal be introduced into a retort, and exposed to a red heat, a great quantity of gas passes over, which may be collected in jars in the pneumatic apparatus in the usual way. It may be also obtained by making the vapour of water pass through red-hot charcoal in a porcelain or iron tube placed across a furnace. The water is decomposed; the hydrogen, one of its component parts, combines with the carbon of the charcoal. The gas obtained by these processes has been called *light inflammable air*. A similar gas may be procured from ether, spirits of wine, or camphor, by making the vapour of these substances pass through red-hot porcelain tubes. This gas, from its greater specific gravity, has been called *heavy inflammable air*. The proportions of the substances which enter into the composition of this gas vary considerably, according to the process employed, or the materials from which it is obtained. It is the same gas which is given out in great abundance during hot weather, from stagnant waters.

413 Properties. 2. This gas, like common air, is invisible and elastic. When a candle is applied to it, it burns with a blue, lambent flame. If it be mixed with atmospheric air, the combustion is more rapid and brilliant, and still more so when it is mixed with oxygen gas, but without any detonation. The products of this combustion are carbonic acid and water. The oxygen combines partly with the carbon to form carbonic acid; and partly with the hydrogen to form water.

3. It is totally unfit for respiration. Animals introduced into it are instantly suffocated. It is also unfit for supporting combustion.

One of the most remarkable properties of this gas is, when it is mixed in a tube with common air or oxygen gas, about $\frac{2}{3}$ds its bulk of the latter, and fired by the electric spark, there is a considerable increase of volume.

414 Composition. The component parts of carbureted hydrogen gas obtained from different substances, as they have been ascertained by Mr Cruickshank, are the following. When it is procured from ether, camphor, or stagnated water, it contains the largest proportion of carbon. The specific gravity is 0.000804, and it is to common air nearly as two to three. One part by weight of hydrogen gas holds in solution $5\frac{1}{2}$ parts of carbon;

100 parts contain	52.35	carbon,
	9.60	hydrogen,
	38.05	water instead of vapour.
	100.00	

When it is obtained from ether, the specific gravity is 0.000787:

100 parts contain	45	carbon,
	15	hydrogen,
	40	water.
	100	

When it is obtained from spirit of wine, the specific gravity is 0.00063:

100 parts contain	44.1	carbon,
	11.8	hydrogen,
	44.1	water.
	100.0	

The lightest is obtained from distilling wet charcoal, or passing the vapour of water through red-hot charcoal. It contains one part by weight of hydrogen gas, holding three parts of carbon in solution. The specific

Carbon. fic gravity is 0.000554. It is to common air nearly as one to two;

100 parts contain	28	carbon,
	9	hydrogen,
	63	water. †
	100	

† Nichol-son's Jour. vol. v. p. 1.

Mr Cruickshank has discovered a very easy method of distinguishing carbonic oxide from the carbureted hydrogen gas. A mixture of the latter and oxymuriatic acid gas may be exploded by passing electric sparks through it. But a mixture of oxymuriatic acid gas and carbonic oxide suffers no change by the action of electricity.

The following table, drawn up by Mr Cruickshank, exhibits the results of his experiments on these two gases.

A Table, shewing the Analysis, &c. of the different Species of Carbureted Hydrogen Gas, or Hydrocarbonates, and of Carbonic Oxides.

Chap. VIII. Of PHOSPHORUS.

415 History. 1. This singular substance was accidentally discovered in 1677, by an alchemist of Hamburgh, named Brandt, while engaged in searching for the philosopher's stone. Kunkel, another chemist, who had seen the new product, associated himself with one of his friends named Krafft, to purchase the secret of its preparation; but the latter deceiving his friend, made the purchase for himself, and refused to communicate it. Kunkel, who at this time knew nothing farther of its preparation, than that it was obtained by certain processes from urine, undertook the task, and succeeded. It is on this account that this substance long went under the name of Kunkel's phosphorus. Mr Boyle is also considered as one of the discoverers of phosphorus. He communicated the secret of the process for preparing it to the Royal Society of London in 1680. It is asserted, indeed, by Krafft, that he discovered the secret to Mr Boyle, having in the year 1678 carried a small piece of it to London, to shew it to the royal family; but there is little probability, that a man of such integrity as Mr Boyle would claim the discovery of the process as his own, and communicate it to the Royal Society, if this had not been the case.

Mr Boyle communicated the process to Godfrey Hankwitz, an apothecary of London, who for many years supplied Europe with phosphorus; and hence it went under the name of *English phosphorus*. Many chemists now attempted to produce phosphorus, and different processes had been published for the purpose; but it would appear that they rarely succeeded.

In the year 1737, a stranger having sold to the French government a process for making phosphorus, the Academy of Sciences charged Dufay, Geoffroy, Duhamel, and Hellot, to superintend it. The latter published an account of the experiment, which succeeded. Rouelle the Elder exhibited phosphorus which he had prepared, in a course of lectures which he opened at Paris some years after. In the year 1743, Margraaf made a great improvement in the process, but still it continued to be obtained with difficulty, and in very small quantity. It was not till 30 years after that considerable improvement was made in the process for procuring phosphorus.

In the year 1774, the Swedish chemists Gahn and Scheele, made the important discovery, that phosphorus is contained in the bones of animals, and they improved the processes for procuring it. 41[illegible] Exists [illegible] bones.

2. The most convenient process for obtaining phosphorus seems to be that recommended by Fourcroy and Vauquelin ‡. Take a quantity of burnt bones, and reduce

‡ Mem. [illegible] l'Inst. [illegible] ii. p. [illegible]

duce them to powder. Put 100 parts of this powder into a porcelain or stone-ware bason, and dilute it with four times its weight of water. Forty parts of sulphuric acid are then to be added in small portions, taking care to stir the mixture after the addition of every portion. A violent effervescence takes place, and a great quantity of air is disengaged. Let the mixture remain for 24 hours, stirring it occasionally, to expose every part of the powder to the action of the acid. The burnt bones consist chiefly of phosphoric acid and lime; but the sulphuric acid has a greater affinity for the lime than the phosphoric acid. The action of the sulphuric acid uniting with the lime, and the separation of the phosphoric acid, occasion the effervescence. The sulphuric acid and the lime combine together, being insoluble, and fall to the bottom.

Pour the whole mixture on a cloth filter, so that the liquid part which is to be received in a porcelain vessel may pass through. A white powder, which is the insoluble sulphate of lime, remains on the filter. After this has been repeatedly washed with water, it may be thrown away, but the water is to be added to that part of the liquid which passed through the filter.

Take a solution of sugar of lead in water, and pour it gradually into the liquid in the porcelain bason. A white powder falls to the bottom, and the sugar of lead must be added so long as any precipitation takes place. The whole is again to be poured upon a filter, and the white powder which remains is to be well washed and dried. The dried powder is then to be mixed with one-sixth of its weight of charcoal powder. Put this mixture into an earthen-ware retort, and place it in a sand bath with the beak plunged into a vessel of water. Apply heat, and let it be gradually increased, till the retort becomes red hot. As the heat increases, air-bubbles rush in abundance through the beak of the retort, some of which are inflamed when they come in contact with the air at the surface of the water. A substance at last drops out similar to melted wax, which congeals under the water. This is phosphorus.

8 (…and purifying it.) In this state the phosphorus is not quite pure. It is generally mixed with some charcoal powder, and a portion of half burnt phosphorus, which give it a brown colour. To have it quite pure, melt it in warm water, and strain it several times through a piece of shamoy leather under the surface of the water. The leather should only be employed once, for phosphorus strained through it afterwards will be coloured. To mould it into sticks, take a glass funnel with a long tube, which must be stopped with a cork. Fill it with water, and put the phosphorus into it. Immerse the funnel in boiling water, and when the phosphorus is melted, and flows into the tube of the funnel, then plunge it into cold water, and when the phosphorus has become solid, remove the cork, and push the phosphorus from the mould with a piece of wood. Thus prepared, it must be preserved in close vessels containing pure water.

9 (Properties.) 3. Phosphorus, when perfectly pure, is semitransparent, and has the consistence of wax. It is so soft that it may be cut with a knife. Its specific gravity is from 1.770 to 2.033. It has an acrid and disagreeable taste, and a peculiar smell resembling that of garlic. When a stick of phosphorus is broken, it exhibits some appearance of crystallization. The crystals are needle-shaped, or long octahedrons; but to obtain them in their most perfect state, the surface of the phosphorus, just when it becomes solid, should be pierced, that the internal liquid phosphorus may flow out, and leave a cavity for their formation.

4. When phosphorus is exposed to the light, it acquires a reddish colour, which appears to be the effect of an incipient combustion. It is therefore necessary to preserve it in a dark place. 420 (Action of light.) At the temperature of 99° it becomes liquid, and if air be entirely excluded, it evaporates at 219°, and boils at 554°. 421 (Of heat.) At the temperature of 43° or 44°, it gives out a white smoke, and is luminous in the dark. This is a slow combustion of the phosphorus, which becomes more rapid as the temperature is raised. When heated to the temperature of 148°, phosphorus takes fire, burns with a bright flame, and gives out a great quantity of white smoke.

Phosphorus enters into combination with oxygen, azote, hydrogen, and carbon.

Sect. I. *Of the Combinations of Phosphorus with Oxygen.*

Phosphorus enters into combinations with oxygen in different proportions.

1. Oxide of Phosphorus.

Phosphorus, when exposed to the light, or kept in water that is not freed from air, soon acquires an opaque white colour, and afterwards changes to a brown. This is the first combination of oxygen with it, and being in the smallest proportion, and giving no acid properties to the compound, it has been denominated an *oxide of phosphorus*. This shews that it is necessary to keep it excluded from air and light. 422 (To separate the oxide.) But phosphorus thus changed on the surface may be freed from that part which is oxidated by a very simple process. Dissolve the phosphorus in warm water, the whole melts except the oxidated part, which remains at the surface, not being fusible at the same temperature.

2. Acids.

423 (Production.) 1. When phosphorus is burned in common air confined in a vessel, the combustion is pretty rapid, and continues till the whole of the oxygen is consumed. A great quantity of white fumes are produced, and when these fumes are mixed with water which absorbs them, it is found to have acid properties. This is the *phosphorous acid*, in which the oxygen is in smaller proportion than in the following, but greater than in the oxide.

2. But when a small bit of phosphorus is introduced into a jar filled with oxygen gas at the temperature of 60°, it dissolves slowly, but does not appear luminous till the temperature be raised to 80°, which shews that phosphorus requires a higher temperature to burn in oxygen gas than in common air. And if the phosphorus be introduced into the oxygen gas, which is perfectly pure at a lower temperature, it undergoes no change, gives out no smoke, and is not luminous in the dark. But when it is immersed in a state of ignition into oxygen gas, it exhibits a most brilliant combustion. 424 (Splendid combustion.) The light emitted is almost as splendid as that of the sun, and too powerful for the eye. During this combustion the oxygen gas disappears, loses its gaseous form,

Phosphorus. form, and becomes solid in combination with the phosphorus. It is during this change from the fluid to the solid state that the caloric is emitted; and the light, according to Gren's theory of combustion, is given out by the phosphorus. The product is a concrete substance which adheres to the sides of the jar. This is the *phosphoric acid*, in which there is a greater proportion of oxygen in combination with the phosphorus. These acids will be treated of in the chapter on acids.

Sect. II. *Of Phosphureted Azotic Gas.*

425 Phosphorus combines with azotic gas without emitting light.

1. At first sight it seems difficult to explain the reason that phosphorus requires a higher temperature for its combustion in oxygen gas than in common air. But the cause of this singular phenomenon appears by examining the effects of azotic gas on phosphorus. The phosphorus, which is readily converted into vapour at a low temperature, combines with the azotic gas without combustion, and therefore without giving out any light. The azotic gas is thus saturated with the phosphorus, and its bulk is increased about $\frac{1}{40}$. The combination is denominated *phosphureted azotic gas*. In this state the phosphorus being minutely divided, takes fire at a lower temperature.

2. When oxygen gas is introduced into a jar filled with this gas, it becomes luminous, because there is a combustion of the phosphorus which is held in solution by the azotic gas. The combustion is more rapid and brilliant when the phosphorated azotic gas is let up into the jar of oxygen gas.

Sect. III. *Of Phosphorized and Phosphureted Hydrogen Gas.*

426 Phosphorus dissolved in hydrogen gas.

1. When a piece of phosphorus is put into a jar filled with hydrogen gas, it does not appear luminous in the dark. But, after having remained for several hours, part of the phosphorus is dissolved. When this gas, to which Fourcroy and Vauquelin have given the name of phosphorized hydrogen gas, is introduced into a jar of oxygen gas, each bubble, as it passes up and comes in contact with the gas, produces a very brilliant bluish flame, which fills the whole vessel. This effect does not take place in atmospheric air. This gas holds in solution only a small proportion of phosphorus; but it is owing to the combustion of this portion that the flame appears in the oxygen gas. This gas has a less fetid odour than that which is next to be described. It has, however, a slight smell of garlic §.

§ *Ann. de Chim.* vol. xxi. p. 203.

427 History.

2. Phosphureted hydrogen gas was discovered by M. Gengembre in 1783, by boiling a solution of potash on phosphorus; and by Mr Kirwan in the following year. Its nature and properties have been more completely investigated by M. Raymond, in two papers in the *Annales de Chimie* for 1791 and 1800. It may be obtained by introducing a bit of phosphorus into a jar of hydrogen gas standing over mercury, and melting the phosphorus by means of a burning glass. The phosphorus is thus converted into the state of vapour, when the hydrogen gas dissolves a much greater proportion. But a more simple process has been recommended by Raymond.

Take two ounces of quicklime, slaked in the air, about 60 grs. of phosphorus, and half an ounce of water; reduce the whole to a paste, and put it immediately into a small glass or stone-ware retort, the body of which may be filled with the materials. Immerse the beak of the retort under water in the pneumatic trough, and apply a moderate heat. As soon as the retort is heated, the gas begins to come over; and when the bubbles come to the surface of the water in contact with the air, they explode with flame and smoke. When the gas passes off slowly the bubbles are larger; and when they reach the surface they exhibit an elegant appearance, forming, after explosion, a beautiful coronet of white smoke, which rises with an undulatory motion to the ceiling, when the air is still. When this gas is brought into contact with oxygen gas, the combustion is more rapid and more brilliant. 428 Process of obtaining it.

The products of the combustion of this gas are phosphoric acid and water. The phosphorus, held in solution by the hydrogen, combines with the oxygen, and forms phosphoric acid; while the hydrogen unites with another portion of oxygen and forms water. 429 Products by combustion.

This gas has a very fetid odour, which has some resemblance to the smell of putrid fish. Pure water agitated in contact with this gas, absorbs about one-fourth of its bulk at the temperature of 50°. The colour of the solution is not quite so deep as that of roll sulphur. The smell is strong and disagreeable, and the taste extremely bitter. It does not appear luminous in the dark. But when it is exposed nearly to the temperature of boiling, the whole of the phosphorated hydrogen gas is driven off unchanged, and the water remains behind perfectly pure. When the solution is exposed to the air, the oxide of phosphorus is deposited, and the hydrogen gas escapes †. 430 Properties.

† *Annal. de Chim.* vol. xxx p. 234.

Sect. IV. *Phosphuret of Carbon.*

Phosphorus enters into combination with charcoal, and forms what Proust, who discovered it, denominates *phosphuret of carbon*. It is produced during the distillation of phosphorus, and remains behind on the leather, when it is strained through it to purify it from this substance. It is of a red colour, and does not melt like pure phosphorus. If it be distilled with a gentle heat, a small portion of phosphorus, which it contains in excess, is separated. But the true compound of phosphuret of carbon is not decomposed without a very strong heat. When the vessels have cooled, there is found a light, flocculent powder, of a lively orange red, which M. Proust considers as the phosphuret of carbon. If it be exposed to a red heat in the retort in which it is formed, the whole of the phosphorus is driven off, and the charcoal remains behind. When this phosphuret is exposed to the open air on a heated metallic plate, it burns rapidly; but the charcoal which absorbs the phosphoric acid, as it is formed, escapes the combustion. It loses, in a short time, the property of burning, by being exposed to the air, and then it may be preserved without any risk of spontaneously catching fire. ‡ 430 How produced. 431 Action of heat.

Chap. IX. Of SULPHUR.

1. Sulphur is a simple undecompounded combustible substance, which is universely diffused in nature; but 432 A simple substance.

but most commonly in a state of combination with mineral, vegetable, or animal matters. It is found in some mineral waters, but in greatest abundance in volcanic countries, where it is a valuable article of commerce.

33 Properties. 2. Sulphur, as it is extracted from minerals and purified by art, is a hard brittle substance of a yellow colour, which can easily be reduced to powder. It is always opaque, has a lamellated fracture, and becomes electric by friction. The specific gravity, after it is melted, does not exceed 1.9907. It has no smell, and very little perceptible taste. When rubbed some time, it is volatilized, and diffuses a peculiar and slightly fetid odour, by which it is easily distinguished. It leaves on the skin which has been in contact with it a very strong smell, which remains for some hours. It is insoluble in water.

434 3. Light has no sensible effect on sulphur. But if a roll of sulphur be held in the hand for a little, it begins to crackle, and at last it breaks to pieces. When a temperature equal to that of boiling water is applied to sulphur, it melts, becomes liquid and transparent, and changes to a brown red colour; but, in cooling, if the fusion is not too long continued, it resumes the yellow colour. When permitted to cool slowly, it crystallizes in prismatic needles. The crystals are better formed by pouring out part of the liquid sulphur as soon as the surface has become solid.

436 4. If the heat be continued, it becomes thick and viscid; and if it be then poured into cold water, it retains its softness, and in this state is employed for taking impressions of seals and medals, which are called *sulphurs*. When sulphur is exposed to heat in close vessels, it is volatilized or sublimed in the form of a very fine powder, known under the name of FLOWERS OF SULPHUR.

Sulphur enters into combination with oxygen, azote, hydrogen, carbon, and phosphorus.

438 The combination of sulphur with azotic gas has been little examined. Part of the sulphur is dissolved, when it is heated in a vessel filled with the gas. This *sulphuratea azotic gas*, as it is called, has a fetid odour. When the temperature is diminished, part of the sulphur is deposited. It has been lately discovered in the mineral waters of Aix-la-Chapelle.—We shall consider the other combinations of sulphur in the following sections.

Sect. I. *Sulphur combined with Oxygen.*

39 1. When sulphur is kept some time in fusion in an open vessel, it assumes a red colour, and becomes viscid. When cooled, it retains its red colour, which is owing to the combination of oxygen in small proportion with the sulphur. In this state it has been denominated the *oxide of sulphur*. According to the experiments of Dr Thomson, the oxide of sulphur, formed by melting the substance in a deep vessel, is of a dark violet colour, fibrous fracture, and tough consistence; the specific gravity is 2.325. It contained $2\frac{1}{10}$ per cent. of oxygen. Another oxide, containing 6.2 per cent. of oxygen, was formed by passing a current of oxymuriatic acid gas through flowers of sulphur †.

40 2. Sulphur, when burnt in the open air, emits a pale blue flame, with a great quantity of white smoke. When these fumes are mixed with water, the liquid is found to possess acid properties. This is a combination of sulphur with a greater proportion of oxygen than exists in the oxide, and is called *sulphurous acid*.

441 In oxygen gas. 3. But when sulphur is burnt in oxygen gas, a very rapid combustion takes place with a reddish white flame, and it combines with a larger proportion of oxygen. When the fumes which are copiously emitted during this combustion are collected and mixed with water, it exhibits the properties of an acid, which is the *sulphuric acid*. Thus it appears, that sulphur combines with oxygen in four different proportions. In two of these, in which the proportions are smallest, the compounds are denominated oxides; but in the two others, in which the proportion of oxygen is increased, the compounds are acids, the properties of which will be afterwards investigated.

† ...of ...vol. ...763.

Sect. II. *Sulphureted Hydrogen Gas.*

442 Method of procuring. 1. This gas may be procured by various processes. It may be obtained by making hydrogen gas pass through melted sulphur. In this way the hydrogen gas enters into combination with sulphur. The same gas may also be obtained by melting together in a crucible equal parts of iron filings and sulphur, by which means a black brittle mass is formed, which is to be reduced to powder, and introduced into a glass vessel (fig. 6.) with two mouths, the one of which has a stopper A, and the other a bent tube B, accurately ground to fit the mouths C, D. When the mixture of iron filings and sulphur has been introduced into the phial, the bent tube is to be fitted into the mouth, with the other end under the surface of the water in the trough E. The apparatus being thus prepared, pour in muriatic acid through the other opening, and immediately close it with the ground stopper. The sulphureted hydrogen gas is copiously disengaged, and fills the glass jar F, which is previously placed on the shelf to receive it. This gas was formerly known by the name of *hepatic gas*.

443 Properties. 2. The odour is extremely fetid, resembling that from the washings of a gun, or from rotten eggs, which arises from the extrication of the same gas. The specific gravity of this gas is 0.00135.

It is unfit for respiration, and for supporting combustion. A taper immersed in it is extinguished. When it is inflamed in contact with atmospheric air or oxygenous gas, it burns with a reddish flame, and deposits a quantity of sulphur. Sulphur also is deposited by simple exposure to the air. From this it appears, that the affinity of hydrogen for oxygen is stronger than for sulphur. During the combustion, the hydrogen unites with the oxygen, and the sulphur is deposited. It is from this deposition that the sulphur found about mineral springs, the waters of which contain this gas, is derived.

444 Composition. 3. According to the experiments of Thenard, 100 parts by weight of sulphureted hydrogen gas contain

70.857 sulphur,
29.143 hydrogen.

100.000 *.

4. Sulphureted hydrogen gas has the property of dissolving phosphorus. Fourcroy and Vauquelin introduced

* Ann. de Chim. vol. xxxii. p. 267.

Sulphur.

ced pieces of phosphorus into a jar filled with this gas over mercury. After the phosphorus had been exposed to the gas for twelve hours, the atmospheric air was admitted, and a bluish voluminous flame instantly appeared.

445 Dissolves phosphorus.

The bubbles of the gas diffused in the air, presented by day light a white vapour, which seemed to adhere like viscid matter to the surface of the mercury; but in the dark, exhibited a very brilliant light. The mercury in the trough in which the experiment was made, continued for some minutes to give out sparks of light by agitation. The hands plunged into this gas, continued luminous for some minutes, and a sponge introduced into it retained the same property for some time in the air †.

† *Ibid.* vol. xxi. p. 207.

5. Sulphureted hydrogen gas is very readily absorbed by water, and in this state it changes vegetable blues to a red colour, and forms neutral salts with different bases. On this account it is now justly ranked among the acids.

Sect. III. *Carburet of Sulphur.*

446 With carbon in different proportions.

1. Sulphur and carbon combine together at a high temperature, and probably in different proportions; one of these combinations is liquid at the ordinary temperature and pressure of the atmosphere. This is the carburet of sulphur. The following method of preparing it is given by Clement and Desormes, who have particularly investigated the action of sulphur and charcoal.

447 Preparation.

2. Put a quantity of charcoal in small pieces, or in powder previously dried, into a porcelain tube, which is to pass through a furnace that it may be exposed to a red heat. The gas from the charcoal is to be allowed to escape, before the other part of the apparatus is adjusted. To that extremity of the porcelain tube which contains the charcoal, fit a long glass tube, sufficiently wide to contain a number of small pieces of sulphur, which may be pushed successively into the porcelain tube with an iron rod passing through a cock which closes the end of the tube. To the other extremity there is to be fitted another glass tube, bent at the end, that it may be immersed in a vessel of water in the pneumatic trough. Heat is then to be applied till the porcelain tube and the charcoal become red hot, when the pieces of sulphur are to be pushed slowly forwards into the tube, and when it acts on the charcoal a yellow liquid of an oily appearance passes through the tube. The heat being continued, it evaporates, and is condensed in the water of the vessel in which the tube terminates, traversing it in globules, which collect together at the bottom.

448 Precautions.

The success of this experiment is somewhat precarious. When sulphur is exposed suddenly to a strong heat, instead of being sublimed, it appears in some measure fixed, and becomes soft by fusion. Sometimes it passes too rapidly through the charcoal to unite with it; the pieces of sulphur, therefore, should be slowly introduced, and the tube, in passing through the furnace, should be inclined from that extremity at which the sulphur is introduced.

449 Properties.

3. The carburet of sulphur, when pure, is transparent and colourless, but frequently has a greenish-yellow tinge. It has a disagreeable pungent odour. The taste is at first cooling, but afterwards becomes extremely pungent. It is heavier than water, does not mix with it, and therefore remains at the bottom of the vessel. The specific gravity of this liquor is various. In one trial it was found to be 1.3.

450 Evaporates.

4. This compound evaporates at the ordinary temperature of the atmosphere, and increases its volume nearly as much as ether. When a quantity of this liquor in a vessel of water is placed under the receiver of an air pump, and the air exhausted, it rises through the water in bubbles, and assumes the gaseous form; and when the pressure of the air is restored, the gas is instantly condensed, and returns to the liquid state.

451 Combustible.

5. The carburet of sulphur burns with great facility, and during combustion emits a strong odour of sulphurous acid, deposites a little sulphur, which afterwards burns, and some black charcoal remains in its usual combustible state. Air holding carburet of sulphur in solution, burns quietly; but when impregnated with oxygen gas, and brought in contact with a burning body, explodes with prodigious violence, and not without considerable danger.

6. This substance unites with phosphorus, which it very readily dissolves, but the solution is not more inflammable than the phosphorus itself. It combines also with a small quantity of sulphur, but without any other change in its properties than becoming a little deeper coloured. It seems to have no action on charcoal *.

* *Ann. Chim.* v. xlii. p. [illegible]

Sect. IV. *Sulphuret of Phosphorus.*

452 Preparations.

1. Sulphur and phosphorus combine together in all proportions. If one part of phosphorus with eight times its weight of sulphur, be put into a matrass, with 32 parts of distilled water; on the application of a gentle heat, the phosphorus melts and dissolves the sulphur. The new compound assumes a yellow colour, and remains fluid, till it is cooled down to the temperature of 77°, when it becomes solid. This substance is the *sulphuret of phosphorus*. In other cases, when the proportion of phosphorus exceeds that of the sulphur, it is called a *phosphuret of sulphur*.

453 Combinations with sulphur more fusible.

2. The compounds of sulphur and phosphorus have been particularly investigated by Pelletier, and he has found that the compound is always more fusible than either of the uncombined constituents. The following table exhibits the results of his experiments †.

† Fourcroy Connais. Chim. t. i. p. 20[illegible]

8 Phosphorus, 1 Sulphur	remain fluid at 95°
4 Phosphorus, 1 Sulphur	59
1 Phosphorus, ½ Sulphur	50
1 Phosphorus, 1 Sulphur	41
1 Phosphorus, 2 Sulphur	72
1 Phosphorus, 3 Sulphur	99

Thus, all these compounds are more fusible than the phosphorus itself, and much more so than the sulphur.

454 Danger in the process.

3. In making these combinations, great caution should be observed; for if the heat be applied suddenly, even

ds. even when the substances are under water, a violent explosion sometimes takes place, from the sudden formation and extrication of the sulphureted and phosphureted hydrogen gases.

Chap. X. Of ACIDS.

5 Ox s. 1. We have seen, in describing the different substances which have been treated of in the five preceding chapters, that they all, excepting one, combine with oxygen in different proportions. Hydrogen combines with oxygen only in one proportion, and this compound is water. The first portion of oxygen which combines with the other four substances, namely azote, carbon, phosphorus, and sulphur, forms with them compounds which, possessing no acid properties, have received the name of oxides.

6 Ac 2. But when these substances combine with a greater proportion of oxygen, the compounds exhibit very different properties; and possessed of these properties, they are ranked among the class of acids. The following are the properties of the substances referred to this class.

7 D ictive ch cters. *a.* They redden blue vegetable colours (K).

b. They possess a peculiar taste, which is well known by the terms *acid* or *sour*.

c. They combine with water in all proportions.

d. They enter into chemical combination with alkalies, with earths, and metallic oxides, and form with them compounds which have been denominated *salts*.

8 Im tance of ds. 3. The acids are a very important class of bodies, and not merely on account of their peculiar properties, and the singular and useful compounds which they form with other substances, but also as they are the instruments of analysis in the hands of the chemist for discovering the properties and combinations of the objects of his science. It is therefore necessary to become early acquainted with their nature.

9 N ncla- tu 4. Acids which have the same radical or base, contain oxygen in different proportions. Thus, for instance, sulphur combines with oxygen in two proportions. 100 parts of one compound contain 32 of oxygen, and 100 parts of the other contain 38 parts. The characteristic properties of these compounds are totally different. It is therefore necessary that they should be distinguished by some appropriate name, and this accordingly has been attended to in the construction of the present chemical nomenclature. The name of the acid is derived from the base, and this name has a different termination according to the proportion of the oxygen combined with its radical. With the smallest proportion the name terminates in the syllable *ous:* with the greater proportion, it terminates in the syllable *ic.* Thus, in the case of the acid formed with sulphur, that compound in which there is the smaller proportion of oxygen is denominated the *sulphurous acid;* the other, which has the greater proportion of oxygen is the *sulphuric acid.* In the same way when phosphorus combines with oxygen in the smallest proportion which gives it acid properties, it is called the *phosphorous acid;* Acids. in the greater proportion, the *phosphoric acid.* And thus by the simple change of the termination, the name becomes descriptive of the peculiar state of the proportions in the compound.

Sect. I. *Of Sulphuric Acid.*

1. The name of sulphuric acid is given to the combination of sulphur and of oxygen, with the greatest 460 Names. proportion of the latter. It was formerly called vitriolic acid, because it was obtained by distillation from vitriol, which is a compound of sulphuric acid and an oxide of iron. When it is strongly concentrated, it has a sluggish appearance; hence it was called *oil of vitriol.* It has also been denominated *oleum sulphuris per campanam*, because it was obtained by burning sulphur under a glass bell.

2. The ancients were unacquainted with this acid. 461 History. Pliny speaks of vitriols, which were used for different purposes, in some of which it was probably decomposed. Sulphur was burnt in sacrifices, but in neither case was the product attended to. Basil Valentine is the first who mentions this acid, about the end of the 15th century. Agricola and Paracelsus have also spoken of it, but Dornæus is the first who described it distinctly, in the year 1570.

3. If a quantity of flowers of sulphur be exposed to a degree of heat sufficient to inflame it, and if, when it is in a state of ignition, it be introduced into a jar filled with oxygen gas, it burns with great splendour, and emits a great quantity of white fumes. These fumes 462 Formation by experiment. may be condensed, by pouring a small quantity of water into the jar, and when this is examined, it is found to possess acid properties. This is the *sulphuric acid.* It is procured, as appears by this experiment, by burning sulphur in oxygen gas.

4. The process for obtaining sulphuric acid in the 463 And in the large way. large way is the following. A mixture of sulphur and nitre is burnt in leaden chambers. The use of the nitre is to supply a quantity of oxygen for the combustion of the sulphur. There is a little water in the bottom of the vessel, which serves to condense the vapours given out during the combustion. The acid which is obtained in this way is very weak, for it is diluted with the water in which it was condensed, which water may be separated by distillation. Even after this it is usually contaminated with a little lead from the vessels, some potash, and sometimes nitric and sulphurous acids. To obtain it perfectly pure, the 464 Purification. sulphuric acid of commerce must be distilled. This process is conducted by putting a quantity of the acid into a retort, and exposing it to a degree of heat sufficient to make it boil. The beak of the retort is put into a receiver, in which the acid, as it comes over, is condensed.

5. The acid, thus purified, is a transparent colour- 465 Properties. less liquid, of oily consistency. It has no smell, but a strong

(K) Hence vegetable blue infusions, or paper stained with them, are employed as tests to discover acids. These are sometimes called re-agents. A great variety of substances are employed for this purpose, such as the infusion and tincture of litmus and of turnsole, the syrup of violets, and the infusion of the flowers of mallow or red cabbage.

Acids.

strong acid taste. It destroys all animal and vegetable substances. It reddens all vegetable blues. It always contains water. When this is driven off by a moderate heat, the acid is said to be concentrated. When as much concentrated as possible, the specific gravity is 2, or double that of water; but it can rarely be obtained of greater density than 1.84.

466 Action of heat.

6. Sulphuric acid suffers no change from being exposed to the light. It boils at the temperature of 546°, or, according to Bergman, 540°. When this acid is deprived of its caloric, it is susceptible of congelation, and even of crystallization, in flat, six-sided prisms, terminated in a six-sided pyramid. It crystallizes most readily, when it is neither too much concentrated, nor diluted with water. Of the specific gravity of 1.65 it crystallizes at the temperature of a few degrees below the freezing point of water. Of the specific gravity of 1.84 it resists the greatest degree of cold. Chaptal observed it crystallize at the temperature of 48°, and Mr Keir found that it froze at 45° of the specific gravity of 1.78.

467 Attracts water strongly.

7. Sulphuric acid has a strong attraction for water. In some experiments that have been made, this acid, when exposed to the atmosphere, attracted above six times its weight of water. When four parts of concentrated sulphuric acid, and one part of ice at the temperature of 32°, are mixed together, the moment they come in contact the ice melts, and the temperature rises to 212°. A greater quantity of caloric is given out when the two bodies are mixed together in the liquid state. If four parts of the acid and one of water are suddenly mixed together, the temperature of the mixture rises to about 300°. This extrication of caloric, it is obvious, arises from the sudden condensation of the two liquids, the medium bulk of which is considerably less than the two taken together.

468 Method of determining the quantity.

8. So great is the attraction of this acid for water, that the strongest that can be prepared can scarcely be supposed to be entirely free from it. It has therefore greatly occupied the attention of chemical philosophers to determine the proportions of real acid and water, in sulphuric acid of any given specific gravity. This subject has been investigated by Wenzel, Wiegleb,

469 Mr Kirwan's.

and Bergman, and more lately and successfully by Mr Kirwan. His method was the following. Eighty-six grains of potash, dissolved in water, were saturated with sulphuric acid of a known specific gravity. The solution being turbid, water was added till the specific gravity was 1.03 at temperature 60°. The whole weight was now equal to 3694 grains. Forty-five grains of sulphate of potash dissolved in 1017 grains of distilled water, had the same specific gravity at the temperature 60°. Hence the proportion of salt in each solution was equal. But in the last, the quantity of salt was $\frac{1}{22.6}$, then the quantity of salt in the former was $\frac{3694}{22.6}=$ 163.45 grains. Of this quantity only 86 were alkali; the remainder, therefore, viz. 77.45 grains, were acid, or acid and water. The quantity of acid employed in the saturation amounted to 79 grains standard; but the quantity of acid taken up was only 77.45 grains; therefore 1.55 were rejected, and consequently were mere water, therefore the acid taken up is stronger than standard; and since 79 parts standard lose 1.55 by combining with pure potash, 100 parts standard should lose 1.96; or 98.04 parts of acid of the strength of what is found in sulphate of potash, contains as much real acid as 100 parts standard. Hence 100 parts of this strong acid are nearly equivalent to 102 of standard. Therefore, 100 parts of potash take up nearly 92 of standard sulphuric acid, or 82 of the strongest, and afford 182 of sulphate of potash. Mr Kirwan thinks there is no reason to suppose that the sulphate of potash contains any water of crystallization. One hundred grs. exposed to a red heat for half an hour, fell into powder and lost only a single grain *.

* Irish Trans. iv. p. 18

It having been suggested by Guyton Morveau, Mr Kirwan observes, that the densities of mixtures of sulphuric acid and water being greater than what is found by calculation, should be ascribed to the condensation of the aqueous part, rather than to that of the acid; this led him to consider of a different method from what he had formerly employed in determining the quantity of real acid in sulphuric acid of different densities. Sulphuric acid of the specific gravity of 2.000, which is the strongest that can be produced by art, was taken as the standard of the strength of all other acids. He could not procure the acid of this strength at the temperature of 60°. But from many experiments made with acids of inferior density, as 1.8846, 1.8689, 1.8042, 1.7500, he concludes, that the condensation of equal weights of this standard acid and water amounts to $\frac{1}{73}$th of the whole. Then by applying Mr Pouget's formula (L) for investigating the increased densities of inferior proportions of acid and water, the successive increments of density will be found as in the following table.

Parts

(L) The formula here alluded to was invented by M. Pouget in the investigation of the specific gravity of alcohol mixed with water in different proportions; and he has given a detailed account of his method in a letter addressed to Mr Kirwan, which is inserted in the Transactions of the Royal Irish Academy, vol. iii. p. 157.

Having purified alcohol by repeated distillations, the specific gravity at the temperature 65.75* was found to be 0.0399. This he took for his standard. And considering the specific gravity as the means of discovering the increase of density, or the diminution of volume, he thought the quantities in the mixture would be best determined, not by the difference of weight, but of volume. He therefore took ten mixtures, the first containing nine measures of alcohol and one of water, the second eight measures of alcohol and two of water, and so on to the last, which contained only one measure of alcohol and nine of water. But as the real measures are always uncertain, he weighed them to ascertain the specific gravity. Thus 10,000 grains of water, and 8199 of alcohol formed a mixture of equal parts in bulk. Knowing the real specific gravities of mixtures of alcohol and water, taking a mean of a great number of observations made at the same temperature,

Parts Water.	Standard.	Increment of Density.
5	95	,0252
10	90	,0479
15	85	,0679
20	80	,0856
25	75	,0699
30	70	,1119
35	65	,1213
40	60	,1279
45	55	,1319
50	50	,1333

"By adding, says Mr Kirwan, these increments to the specific gravities found by calculation, and taking arithmetical mediums for the intermediate quantities of standard, I made out the first 50 numbers of the following table; the remainder was formed by actual observation in the following manner, premising that the specific gravities were always taken between 59,5° and 60°, or at most 60,5° of Fahrenheit.

"1st, I found by the preceding part of the table that 100 parts of sulphuric acid, whose specific gravity was 1.8472, contained 88.5 parts standard; consequently 400 grs. of this acid contain 354.

"2dly, I then took six portions of this acid, each containing 400 grs. and added to them as much water as made them contain respectively 48. 46. 44. 42. 40. and 38. grains standard. To find the proportion of water that should be added to each portion of acid, in order that it should contain the given proportion of standard, I

---

temperature, and comparing them with the specific gravities found directly by calculation, he thus deduces the increase of density, or the diminution of volume produced in the whole mass by the mutual penetration of the fluids. For calling A the real specific gravity, and B the specific gravity found by calculation, n the number of measures which compose the whole mass, $n-x$ that to which it is reduced by mutual penetration, it is evident, since this increase of density does not diminish the weight of the whole mass, that $n\,B=\overline{n-x}\times A$. Then $x=\frac{A-B}{A}\times n$, or making $n=1\ \frac{A-B}{A}$, which expresses the diminutions of bulk, or the quantity of fluid absorbed during the mixture.

The following table contains the result of Pouget's experiments, or the diminutions of volume which is supposed to be = 1 of the mixtures, calculated according to the formula.

Number of measures of Water.	Number of measures of Alcohol.	Diminution of the whole volume = 1 by experiment.	By Calculation.
1	9	0.0109	0.0103
2	8	0.0187	0.0184
3	7	0.0242	0.0242
4	6	0.0268	0.0276
5	5	0.0288	
6	4	0.0266	0.0276
7	3	0.0207	0.0242
8	2	0.0123	0.0184
9	1	0.0044	0.0103

From this table it appears that the numbers which express the diminution of bulk follow a regular progression. The greatest correspond to the mixtures of equal parts, and they decrease towards each end of the progression. They must therefore be regulated by some general law. M. Pouget thinks that the alcohol may be conceived as being dissolved in the water which has absorbed or retained part of it in its pores. The quantity absorbed ought to be in the ratio of that of the solvent and the body dissolved, and each measure of water will retain quantities of alcohol proportional to the number of measures of this fluid in the mixture. Thus, for example, in a mixture formed of nine measures of alcohol and one of water, this measure of water will absorb a quantity of alcohol = 9: and in another mixture of eight measures of alcohol with two of water, each measure of water will contain a quantity of alcohol = 8. Consequently the diminutions of bulk of each mixture are in a ratio compounded of the number of measures of alcohol and of water which form it; and in the table above, as 1×9, 2×8, 3×7, 4×6, 5×5, &c. And in general taking for a constant quantity the diminution of bulk with equal measures, and calling it e; calling the whole number of measures n; the number of

I used the following analogy: Let the quantity of water to be added to 400 parts of the acid, that the mixture may contain 48 per cent. standard be x.

Then $400+x. 354 :: 100. 48$, then $19200+48x=35400$.

And $48x=35400-19200=16200$. And $x=\frac{16200}{48}=337,5$.

"In this manner I found the quantities of water to be added to each of the other portions. The mixtures being made, they were set by for three days, stirring them with a glass rod (that remained in them) each day, and the 5th day they were tried; after which the half of each was taken out and as much water added to them, and then set by for three days, by which means the specific gravities corresponding to 24. 23. 22. 21. 20. and 19. per cent. standard were found. after which six more portions of 400 grs. each of the concentrated acid, whose specific gravity was 1,8393, were taken, the proper proportion of water added to each, and after three days rest and repeated agitation, their densities in temperature 60° were examined as above, by which means the specific gravities corresponding to 36. 34. 32. 30. 28. and 26. per cent. standard were obtained, and half these portions mixed with half water exhibited, after three days rest and agitation, the densities corresponding to 18. 17. 16. 15. 14. and 13. per cent. standard in the above temperature. The balance I used turned with $\frac{1}{12}$ of a grain when charged with two ounces, and the solid employed was a small glass ball containing mercury, which lost 27,88 grs. of its weight when weighed in water in temperature 56°, suspended commonly by a horse hair, but when dipped in strong nitrous and marine acids it is suspended by a fine gold wire, and then lost 27,78 grs of its weight in water.

"I also examined and rectified, in some instances, many parts of the first 50 numbers of the table in the same manner, but in general I found them just.

TABLE

---

of measures of alcohol in any mixture, x, and the increase of density or diminution of volume z, we shall have $c : n :: \frac{n}{2} \times \frac{n}{2} : \overline{n-x} \times x$: and $z = \frac{4c}{n2} \times \overline{nx-x^2}$: or making $n=1$, $4cx-4cx^2$. The increase of density, calculated according to the formula, corresponds pretty nearly with experiments; for in all mixtures in which the alcohol is in greater quantity than water, but not in those cases in which the water is in greatest proportion, the real increase of density is much less than by calculation, and the differences become more considerable as the quantity of water is increased. M. Pouget thinks, that when the quantity of water is greater than that of alcohol, the law of absorption is disturbed; and he conjectures that it is owing to the attraction of the particles of the water among themselves, which consequently oppose their union with any other substance. But when the alcohol forms at least the half of the whole mass, the diminutions of bulk are as the products of the numbers which express the proportions of alcohol and water forming the mixture: they may be represented by the formula $z=\frac{4cnx-4cx^2}{n^2}$. By this formula may be determined the strength of spirits of wine of commerce, or the number of parts of water and standard alcohol of which they are composed.

The number of measures of the whole mass or the bulk -	$=1$
The number of measures of alcohol in any mixture - -	$=x$
The diminution of bulk of equal parts by experiment - -	$=c$
The diminution of bulk of a mixture containing x measures of alcohol by hypothesis	$=4cx-4cx^2$
The specific gravity of water - - - -	$=a$
Specific gravity of alcohol - - - -	$=b$
Specific gravity of the unknown mixture - - -	$=y$

Since the increase of density does not change the weight of the mass, we shall have $\overline{1-x} \times a + bx = \overline{1-4cx+4cx^2} \times y$.

By this equation may be found the value of x or the proportion of alcohol, having previously ascertained the specific gravity of the mixture, and to determine this specific gravity, or the value of y by knowing the property of alcohol. Hence,

$$x=0.5\frac{a-b}{8cy}+\sqrt[2]{\frac{a-y}{4cy}+\left(\frac{a-b}{8cy}-0.5\right)^2}$$

$$y=\frac{a-ax+bx}{1-4cx+4cx^2}$$

And making $a=1$, $b=0.8199$, $c=0.0288$

$$x=0.5\frac{0.1801}{0.2304y}+\sqrt[2]{\frac{1-y}{0.1152y}+\left(\frac{0.1801}{0.2304y}-0.5\right)}$$

$$y=\frac{1-0.1801x}{1-0.1152x+0.1152x^2}.$$

TABLE of the Quantity of the Standard Sulphuric Acid 2,000 in Sulphuric Acid of inferior Density.

100 Parts.	Standard Temp. 60°	100 Parts.	Standard.	100 Parts.	Standard.
2,000	100	1,6217	67	1,2847	34
1,9859	99	1,6122	66	1,2757	33
1,9719	98	1,6027	65	1,2668	32

1,8787	91	1,5385	58	1,2009	25
1,8660	90	1,5292	57	1,1918	24
1,8542	89	1,5205	56	1,1836	23
1,8424	88	1,5112	55	1,1746	22
1,8306	87	1,5022	54	1,1678	21
1,8188	86	1,4933	53	1,1614	20
1,8070	85	1,4844	52	1,1531	19
1,7959	84	1,4755	51	1,1398	18
1,7849	83	1,4666	50	1,1309	17
1,7738	82	1,4427	49	1,1208	16
1,7629	81	1,4189	48	1,1129	15
1,7519	80	1,4099	47	1,1811	14
1,7416	79	1,4010	46	1,0955	13
1,7312	78	1,3875	45	1,0896	12
1,7208	77	1,3741	44	1,0833	11
1,7104	76	1,3663	43	1,0780	10
1,7000	75	1,3586	42	1,0725	9
1,6899	74	1,3473	41	1,0666	8
1,6800	73	1,3360	40	1,0610	7
1,6701	72	1,3254	39	1,0555	6
1,6602	71	1,3149	38	1,0492	5
1,6503	70	1,3102	37	1,0450	4
1,6407	69	1,3056	36	1,0396	3
1,6312	68	1,2951	35	1,0343	2

"The last eleven numbers were only found by analogy, observing the series of decrements in the four preceding densities, and therefore are to be considered barely as approximations.

"To reduce vitriolic acids of given densities, at any degree of temperature between 49° and 70°, to that which they should have at temperature 60°, in order that their proportion of standard may be thereby investigated, I made the following experiments:

Degrees of Temperature.	Sp. Gr. of A.	Sp. Gr. of B.	Sp. Gr. of C.
70°	1,8292	1,6969	1,3845
65	1,8317	1,6983	1,3866
60	1,8360	1,7005	1,3888
55	1,8382	1,7037	1,3898
50	1,8403	1,7062	- -
49	1,8403	- -	1,3926

"Hence we see that vitriolic acid, whose density at any degree between 49° and 60° resembles or approaches the corresponding density in the column A, gains or loses 0,00126 of its specific gravity by *every two* degrees between 60° and 70° of Fahrenheit, and 0,0086 by *every two* degress between 49° and 60°.

"Secondly, That any vitriolic acid, whose density at any degree between 50° and 70° resembles or approaches to the corresponding density in the column B, gains or loses 0,00158 for every two degrees between 60° and 70°; and 0,0017 by every two degrees between 50° and 60°. Whence it appears that the stronger acid is less altered by variations of temperature than the weaker, which formerly appeared to me an irregularity, but now seems to proceed from the increase of the accrued density, when larger proportions of water are mixed with the stronger acid.

"3dly, Sulphuric acid, whose density at any degree between 50° and 70° resembles the corresponding at the same degree in the column C, gains or loses 0.00086 for every two degrees between 60° and 70° inclusively, and 0.00076 between 50° and 60°. Between 45° and 50° I could perceive no difference *.

* *Irish Trans.* vol. iv. p. 7.

47° Composition.

9. Attempts have been made to determine the proportion of oxygen and sulphur, which enter into the composition of sulphuric acid. According to the experiments of Lavoisier, in which he measured the quantity of oxygen absorbed, by a given weight of sulphur during combustion, the proportions are,

71 sulphur,
29 oxygen.

100

But other methods have been adopted, which promise more accurate results. These are, by decomposing other substances which contain oxygen, by means of sulphur. According to the experiments of Mr Chenevix, conducted in this way, the sulphuric acid consists of

61.5 sulphur,
38.5 oxygen.

100.0

10. Sulphuric acid does not combine with oxygen, nor has it any action with azotic gas.

471 Action with hydrogen.

11. It appears that hydrogen has a greater affinity for oxygen, than the sulphur has, and therefore the sulphuric acid is decomposed by means of hydrogen gas. In the cold there is no action between hydrogen gas and sulphuric acid; but if they are made to pass through a red-hot porcelain tube, the acid is decomposed; water is formed and sulphur is precipitated. When hydrogen gas is employed in a greater proportion than the half of the acid, the superabundant gas dissolves the sulphur, and is disengaged in the form of sulphureted hydrogen gas.

472 Charcoal.

12. Charcoal has no action on sulphuric acid in the cold; but at the boiling temperature, it decomposes it, and converts it into sulphurous acid. If a piece of red-hot charcoal be immersed in a quantity of concentrated sulphuric acid, part of the acid is suddenly disengaged under the form of thick white fumes, accompanied with sulphurous acid gas. The sulphuric acid is decomposed; part of its oxygen is attracted by the charcoal, forming carbonic acid, and thus it is reduced to

to the lowest proportion of oxygen, in the state of sulphurous acid.

473 Phosphorus. 13. A similar effect is produced by phosphorus. Phosphorus, with the assistance of heat, partially decomposes the sulphuric acid, by abstracting part of its oxygen. Phosphoric acid is formed, and sulphurous acid driven off.

474 Sulphur. 14. In the cold, sulphur has no action on sulphuric acid; but, when they are boiled together, the sulphur is partly dissolved in the acid, and converts it into sulphurous acid. The sulphur which has been added combines with the oxygen, which is necessary for the constitution of sulphuric acid, and thus the whole is converted into sulphurous acid.

475 Sulphates. 15. Sulphuric acid combines with alkalies, the earths, and the metals, forming salts; which, in the present language of chemistry, are denominated *sulphates*.

476 Uses. 16. This acid is employed in great quantity in many arts and manufactures. It is employed also in medicine and pharmacy; the preparation of it, therefore, has long been an object of considerable importance.

477 Affinities. 17. The order of the affinities of sulphuric acid is the following:

Barytes,
Strontites,
Potash,
Soda,
Lime,
Magnesia,
Ammonia,
Glucina,
Yttria,
Alumina,
Zirconia,
Oxide of Zinc,
Iron,
Manganese,
Cobalt,
Nickel,
Lead,
Tin,
Copper,
Bismuth,
Antimony,
Arsenic,
Mercury,
Silver,
Gold,
Platina.

Sect. II. *Of Sulphurous Acid.*

478 Names. 1. According to the received nomenclature of the acids, the term *sulphurous* signifies that this acid contains a smaller proportion of oxygen. It was formerly called *spirit of sulphur*, and *volatile sulphurous acid*.

479 History. Although the ancients must have been acquainted with some of its properties, as it is formed during the slow combustion of sulphur, Stahl is the first chemist who examined it with attention. He supposed that it was the sulphuric acid combined with his imaginary principle of phlogiston. Hence he called it *phlogisticated* sulphuric acid. It was not till the year 1774 that its nature and composition were discovered by the labours of Priestley and Lavoisier. Berthollet afterwards investigated the formation, decomposition, combinations, and uses of this acid. Fourcroy and Vauquelin * also have examined many of its properties, especially the saline compounds which it forms.

* Ann. Chim. xxiv. p. 229.

48[0] Abund[ance] in nat[ure]. 2. The sulphurous acid exists in nature in great abundance, particularly in the neighbourhood of volcanoes. It is disengaged from some lavas while in a state of fusion, and from the soil which is impregnated with sulphur, when a sufficient degree of heat is applied.

48[1] Fatal [to] Pliny. It was by the vapours of sulphurous acid that Pliny the naturalist was suffocated in the eruption of Mount Vesuvius, which destroyed Herculaneum, in the 79th year before the Christian era.

48[2] Forma[tion]. 3. When sulphur is burnt in the open air, the fumes generated by this slow combustion, are sulphurous acid. It was in this way that this acid was formerly obtained. The method of procuring it, which is now followed, is to decompose the sulphuric acid by means of any substance which deprives it of part of its oxygen. If one part of mercury and two parts of concentrated sulphuric acid be exposed to heat in a glass retort, the mixture effervesces, and a gas is disengaged, which may be collected in jars over mercury. In this process the mercury attracts part of the oxygen of the sulphuric acid, and leaves behind that portion which constitutes the sulphurous acid.

48[3] In the [state] of gas. 4. Sulphurous acid thus obtained is in the state of gas, and it is an elastic, invisible, and colourless fluid, like common air.

48[4] Prope[rties]. It is rather more than double the weight of atmospheric air. Its specific gravity is 0.00246; 100 cubic inches weigh nearly 63 grains. It has a pungent smell; is unfit for respiration, and for supporting combustion. It at first reddens vegetable blues, and then destroys the greater number of them. It is on account of this property that the fumes of sulphur are employed to remove the stains of fruit from linen, and that the sulphurous acid is often used in bleaching.

4[85] Actio[n] with [ca]loric. 5. Sulphurous acid gas refracts the light strongly, without undergoing any change. When strongly heated, as in a red-hot porcelain tube, it remains unaltered, according to the experiments of Fourcroy. But Dr Priestley and Berthollet found that it deposited sulphur after long exposure to heat. At the temperature of — 31° it becomes liquid. This property, which distinguishes it from other gases, and which was discovered by Monge and Clouet, is ascribed by Fourcroy to the water it holds in solution.

4[86] With [oxy]gen &c. 6. When sulphurous acid is in the form of gas, it does not readily combine with oxygen. In its fluid form it unites with it more freely, and is converted into sulphuric acid. A mixture of sulphurous acid gas and oxygen, in passing through a red-hot tube, combine together, and are converted into sulphuric acid. There seems to be no action between sulphurous acid and azotic gas.

4[87] With [hy]drog[en gas]. 7. Hydrogen gas has no action on sulphurous acid gas in the cold; but when a mixture of these gases is made to pass through a red-hot tube, sulphurous acid is decomposed; the hydrogen combines with the oxygen and forms water, and sulphur is deposited. If the hydrogen gas be in greater proportion than the oxygen contained

Acids.

contained in the sulphurous acid, it dissolves part of the sulphur, and passes off in the form of sulphurated hydrogen gas.

8. Its action with charcoal is somewhat similar. In the cold there is none; but exposed together to a red heat, carbonic acid is formed by the union of carbon and oxygen, and sulphur is deposited.

9. There is no action whatever between phosphorus and sulphurous acid gas; but phosphureted hydrogen gas is decomposed by this acid. When the two gases come in contact, a white thick vapour is produced; sulphur combined with phosphorus in the solid state is deposited, and water is formed.

10. Sulphur has no action on this acid; but sulphureted hydrogen gas, at the instant it comes in contact with sulphurous acid gas, is condensed; solid sulphur is deposited, and water is formed, with the extrication of caloric.

11. Water has a strong attraction for sulphurous acid gas. A piece of ice brought in contact with it, is immediately melted without any perceptible change of temperature. Water saturated with this gas is known by the name of *liquid sulphurous acid*. The specific gravity is 1.040. At the temperature of 43° water combines with $\frac{1}{3}$ of its weight of sulphurous acid gas †; but as the temperature increases, it absorbs it in smaller proportions. It freezes at a temperature a few degrees below 32°, and it passes into the solid state without parting with any of its acid. Liquid sulphurous acid has the smell, taste, and other properties of the gas; and particularly that of destroying vegetable colours. When exposed to the atmosphere, it gradually absorbs oxygen, and passes into the state of sulphuric acid. This change goes on more rapidly when it is diluted with water, and agitated in contact with the air.

12. Sulphuric acid separates the sulphurous acid in the gaseous form from its combinations, and even from water. Concentrated sulphuric acid absorbs this gas, which imparts to it a yellowish brown colour, and renders it pungent and fuming. The two acids strongly attract each other, so that when they are exposed to the action of heat, the first vapour which rises crystallizes in long, white, needle-shaped prisms. This is a compound of the two acids. It smokes in the air, dissolves with effervescence in it, and when thrown into water produces a hissing noise, like a red-hot iron. It has the strong smell of sulphurous acid. This substance was formerly called *glacial sulphuric acid**.

13. Sulphurous acid is very much employed in the arts, and sometimes in medicine. In the state of gas it is used for the bleaching of silk and wool, by extracting the colouring matter. It removes also the stains arising from vegetable juices, and spots of iron, from linen.

14. According to the analysis of Dr Thomson, 100 parts of this acid are composed of

68 sulphur,
32 oxygen.

100

15. The compound salts formed by this acid are denominated *sulphites*.

16. The following is the order of its affinities:

Barytes,
Lime,
Potash,
Soda,
Strontites,
Magnesia,
Ammonia,
Glucina,
Alumina,
Zirconia.

Sect. III. *Of Nitric Acid.*

1. This acid was formerly known by the name of aquafortis, and spirit of nitre. Raymond Lully, who lived in the 13th century, seems to have been acquainted with it; and Basil Valentine, who lived in the 15th, describes the process for preparing it. He calls it *water of nitre*. But till the discoveries of modern chemistry, little was known of the nature, properties, and composition of this acid. It is to the experiments and researches of Cavendish and Priestley, of Lavoisier and Berthollet, that we are indebted for the knowledge we possess of it. 497 Names. 498 History.

2. Nitric acid exists in great abundance in nature. It is formed by the union of its constituent parts which are evolved during the putrefactive process of animal and vegetable matters; but it is never found, except in combination with some base, from which it must be extracted by art. The component parts of nitric acid are azote and oxygen. The name in this case is not derived from the base, which is azote, but from nitre, from which it is generally obtained. This acid cannot be formed merely by bringing in contact the two gases which are its constituent parts; but if they are mixed together in certain proportions, and electric sparks sent through the mixture, the gases disappear, and are converted into a liquid. This is *nitric acid*. By a similar experiment Mr Cavendish discovered the composition of the acid. 499 Abundant in nature.

3. This acid may be obtained by putting three parts of nitre with one of sulphuric acid into a glass retort, and distilling with a strong heat. The gas which comes over is condensed in a glass receiver, to which the retort is to be luted. The gas which is condensed is nitric acid. Nitre is composed of this acid and potash: but potash has a stronger affinity for sulphuric acid than for nitric acid; it therefore combines with the sulphuric acid in the retort, and the nitric acid is disengaged, and passes over in the gaseous form. 500 Method of procuring it.

4. The acid thus obtained is contaminated with muriatic, and sometimes with sulphurous acid. It is purified by distillation with a gentle heat. At first too it is of a yellow colour, which is owing to the fumes of nitric oxide gas with which it is combined. These fumes are driven off by heat, after which the acid remains pure, and is transparent and colourless. 501 Of purifying it.

5. Thus prepared, it has a strong acid taste; a disagreeable pungent odour, and gives a yellow colour to the skin. The specific gravity of strong nitric acid is 1.583, or, according to Mr Kirwan, at temperature 60°, 1.554. 502 Properties.

6. Nitric acid and one of its compounds, nitre, have long been the subject of the experiments and researches of 503 Discovery of its composition.

† Fourcroy, Conn. Chim. ii. 76.

* ... ii. p. ...

Acids.

of chemical philosophers. In investigating the nature of nitre, Mayow found that it possessed a common property with atmospheric air; namely, the property of giving a red colour to the blood. And, from observing that air was deprived of this property by the process of combustion and respiration, he drew the curious conclusion, that nitre contained that part of the air which is necessary for respiration and combustion.

7. When nitric acid dissolves metallic substances, a great quantity of a peculiar gas makes its escape, and the metal acquires considerable weight during this process. According to the phlogistic theory, it was supposed that the metal was deprived of its phlogiston, and that this phlogiston had combined with the nitrous gas which had escaped. This was Dr Priestley's explanation. But it was differently explained by Lavoisier. He took 1104 grs. of mercury, and added to it 945 grs. of nitric acid. Nitrous gas was emitted during the solution, and when he exposed the mercury which had been converted into an oxide, to a red heat, oxygen gas was given out, and the mercury appeared in the metallic state. He therefore concluded, that the nitric acid in this case was decomposed, and that it consisted of oxygen which combined with the metal, and of nitrous gas which was driven off. The proportions, he supposed, were, 64 parts of nitrous gas by weight, and 36 of oxygen gas. He found, however, that the quantity of oxygen obtained in this process, was sometimes greater than what was necessary to saturate the nitrous gas; and he was at a loss to account for this quantity. His own experiments, as well as some of Dr Priestley's, proved, that azote is a component part of nitre.

Mr Cavendish, who discovered the composition of water, in his experiments and researches on that subject, found, that nitric acid was produced during the explosion of oxygen and hydrogen gases; and that he could increase this quantity by adding azotic gas to the mixture before combustion. From this he concluded, that the formation of the acid depended on the azotic gas. He proved this by passing electrical sparks through common air in a glass tube. The air diminished in bulk, and nitric acid was formed. Repeating a similar experiment with oxygen and azotic gases in certain proportions, he found that the whole could be converted into nitric acid †. Mr Cavendish repeated the same experiments, with a view to remove some objections which had been made to his conclusions. They were followed by the same result, and the fact of the composition of nitric acid was thus fully established ‡.

† *Phil. Trans.* 1784.

‡ *Ibid.* 1788, p. 261.

To perform this experiment, take a glass tube of about one sixth of an inch in diameter. Close one end with a cork, through which let a metallic conductor with a ball at each extremity be passed. Fill the tube with mercury; immerse the open end into the mercurial trough; introduce a mixture of .13 parts of azotic gas, and .87 of oxygen gas, occupying three inches of the tube, and a solution of potash filling one-half inch more. Let electrical explosions be sent through the tube till the air ceases to be diminished in bulk. If the experiment succeed, the potash will be found converted into nitre, which shews that the nitric acid, which is a component part of nitre, has been formed during the process.

8. Nitric acid, having a strong affinity for water, is never found entirely deprived of this liquid. When exposed to the air, it attracts moisture from it, and heat is given out when it is mixed with water. Mr Kirwan has endeavoured to ascertain the relative strength of nitric acid of different densities or specific gravities; and the method which he adopted was the following. He saturated 36 grs. of carbonate of soda with 147 grs. of nitric acid, of specific gravity 1.2754, which contained 45.7 per cent. of standard acid, of specific gravity 1.5543. The carbonic acid which escaped amounted to 14 grs.; and by adding 939 grs. of water, the specific gravity of the solution, at the temperature of 58.5°, was 1.0401. By a similar test with that employed in ascertaining the strength of sulphuric acid, namely, by comparing this solution with one of nitrate of soda of the same density, he found the quantity of salt amounted to $1.\frac{16}{901}$ parts. There was an excess of acid of about 2 grs. The whole weight was 1439 grains. The quantity of salt, therefore, was $\frac{1439}{16.901}=85.142$ grs. The quantity of pure alkali was .50—14=36.05 grs. The quantity of standard acid was 66.7; the sum of both =102.75. Of this quantity only 85.142 entered into combination with the salt, the remaining 17.608 were mere water, given out by the standard acid. If then 66.7 parts standard acid lose 17.608 parts water combining with the alkali, 100 parts should lose 26.38. And, as Mr Kirwan has made it probable, that nitrate of soda contains very little water in its composition; 100 parts of standard nitric acid is composed of 73.62 of pure acid, and 26.38 of water §.

504 Absorbs water.

505 Method of determining the quantity.

§ *Irish Trans.* vol. iv. p. 34.

The following table, drawn up by Mr Kirwan, shews the quantity of pure acid in nitric acid of different specific gravities.

100 Parts. Sp. Gravity.	Real Acid.	100 Parts. Sp. Gravity.	Real Acid.
1.5543	73.54	1.4171	53.68
1.5295	69.86	1.4120	52.94
1.5183	67.12	1.4069	52.21
1.5070	68.39	1.4018	51.47
1.4957	67.65	1.3975	50.74

Sir H. Davy has, from his own experiments, deduced the real quantities of nitric acid in solutions of different specific gravities, and has assigned the following proportions *.

TABLE of the quantities of True Nitric Acid in solutions of different Specific Gravities.

100 Parts Nitric Acid, of specific gravity.	True Acid (M).	Water.
1,5040	91,55	8,45
1,4475	80,39	19,61
1,4285	71,65	28,35
1,3906	62,96	37,04
1,3551	56,88	43,12
1,3186	52,03	47,97
1,3042	49,04	50,96
1,2831	46,03	53,97
1,2090	45,07	54,73

9. When colourless nitric acid is exposed to the light, it undergoes a partial decomposition. Some oxygen gas is separated, the acid assumes an orange yellow colour, and part of it passes into the state of nitrous acid.

10. It boils at the temperature of 248°, and is entirely dissipated without alteration, if the heat be continued. When it is made to pass through a red-hot porcelain tube, it is decomposed, and converted into its constituent parts, oxygen and azotic gases †. When nitric acid is cooled down to the temperature of —55°, it begins to crystallize in a few minutes, assumes a deep-red colour, and congeals into a thick mass resembling butter, by agitating the vessel which contains it †.

† Annal. de Chim. vol. xxix. p. 282.

11. There is no action between nitric acid and oxygen or azotic gases; but when concentrated nitric acid is exposed to the air, the vapour which it exhales combines with the moisture of the atmosphere, forms white fumes, and is condensed into a liquid. 507 Of oxygen.

12. Hydrogen gas has no action on nitric acid at the ordinary temperature of the atmosphere; but, if they are made to pass through a red-hot porcelain tube, there is a violent combustion with detonation. Water is formed by the combination of the hydrogen with the oxygen of the acid; and azotic gas, its other constituent part, is evolved. 508 Hydrogen. Of combustible bodies.

13. Nitric acid is also decomposed by charcoal at a high temperature. Carbon combines with the oxygen, and forms carbonic acid, while the azotic gas is set at liberty.

14. It is also decomposed in the same way by phosphorus and sulphur. When the acid is poured upon these combustibles at a high temperature, inflammation takes place, and they are converted into phosphoric and sulphuric acids.

15. When nitric and sulphuric acids are mixed together, heat is evolved. The sulphuric acid attracts the water which existed in the nitric acid, and this water being more condensed in combination with sulphuric acid, the caloric with which it was combined along with the nitric acid, is given out. Thus, the nitric acid becomes more concentrated by the addition of the sulphuric acid. 509 Of sulphuric acid.

When nitric and sulphurous acids are mixed together, a very different action takes place. The nitric acid separates it from water and its other combinations; parts with its oxygen, and thus converts it into sulphuric acid, and passes itself into the state of nitric oxide gas. 510 Of sulphurous acid.

16. According to Lavoisier, the proportions of the component parts of nitric acid are, one part azote and four parts oxygen. This was the result of his experiments on the decomposition of nitre by charcoal. According to Mr Cavendish, the proportions of the azote and oxygen combined by electricity are one part azote and 2.346 of oxygen. The result of Sir H. Davy's experiments shews that 100 parts of pure nitric acid are composed of 511 Composition.

29.5 azote.
70.5 oxygen.

100.0

17. The combinations which are formed with the nitric acid, and the alkalies, earths, and oxides of metals, are denominated *nitrates*. 512 Combination.

(M) The quantities of oxygen and nitrogen in any solution, may be thus found: Let A = the true acid, X the oxygen, and Y the nitrogen,

$$\text{Then } X = \frac{238A}{239} \text{ and } Y = \frac{A}{239}.$$

Acids.

513 Affinities. 18. The order of the affinities of nitric acid is the following.

Barytes,
Potash,
Soda,
Strontites,
Lime,
Magnesia,
Ammonia,
Glucina,
Alumina,
Zirconia,
Oxide of Zinc,
Iron,
Manganese,
Cobalt,
Nickel,
Lead,
Tin,
Copper,
Bismuth,
Antimony,
Arsenic,
Mercury,
Silver,
Gold,
Platinum.

514 Uses. 19. This is one of the most important of the acids, considered as an instrument of analysis in the hands of the chemist. It is employed in many arts. It is also used in medicine, for diseases of the skin; and sometimes as a cure in venereal affections. Perhaps it may be regarded as a useful auxiliary to the ordinary remedies.

Sect. IV. *Of Nitrous Acid.*

515 Method of procuring. 1. Nitrous acid bears the same relation to nitric acid that sulphurous acid bears to sulphuric; that is, the constituent parts of nitric acid are in different proportion from those of nitrous acid. Nitrous acid may be formed by combining nitric oxide gas with nitric acid: and it was at one time contended, that it is a mere mixture of these two substances. It is now, however, generally admitted, that the nitrous acid is as much a distinct compound, as any other of the compounds of azote.

516 Composition. 2. Sir H. Davy finds, that two measures of nitric oxide gas and 1 of oxygen (= 1 azote and 2 oxygen) are condensed into half their volume, forming nitrous acid gas. One hundred grains of this contain, by weight,

Azote	30.32
Oxygen	69.68.

517 Liquid acid. 3. When absorbed by water to saturation, it constitutes liquid nitrous acid; the water first becomes green, then blue, and then orange, depending on the quantities absorbed. This acid boils at 160, while the nitric boils at 236.

518 Action of light and heat. 4. Light has no action on nitrous acid; but when heat is applied, nitric oxide gas is driven off, and nitric acid remains behind. In the state of vapour, nitrous acid remains unchanged by the action of heat.

5. Neither oxygen gas, azotic gas, nor atmospheric air, produce any change on nitrous acid.

6. On combustible bodies the action of this acid is nearly similar to that of the nitric; but many substances are more rapidly inflamed by nitrous acid. This seems to depend on the nitrous acid being more easily decomposed, and giving up its oxygen, which is less strongly attracted by the azote, on account of the greater proportion of caloric united with it. It decomposes phosphureted and sulphureted hydrogen gases, and precipitates the phosphorus and the sulphur. 519 Combustibles.

7. Sulphuric acid combines with the vapour of nitrous acid, which communicates the property of disposing the sulphuric acid to crystallize. Nitrous acid converts sulphurous into sulphuric acid, and, at the same time, parts with its nitric oxide gas. 520 Sulphuric acid.

8. Nitrous acid enters into combination with the alkalies and earths. The compounds are distinguished by the name of *nitrites*. These compounds are not made by direct combination, and therefore the affinities of this acid are little known. 521 Compounds.

Sect V. *Of Muriatic Acid and Chlorine.*

1. The composition of this acid is at the present moment matter of controversy; but before entering on this, we shall state the facts known relative to it. The name of muriatic acid is derived from the Latin word *muria*, which signifies sea-salt, the substance from which the acid is usually extracted. It was formerly denominated *spirit of salt*, *acid of salt*, and *marine acid*. 522 Composition disputed. 523 Names.

2. Muriatic acid may be obtained by putting 100 parts of dry common salt, and 35 of sulphuric acid, into a retort or matrass with a bent tube. The beak of the retort at the end of the tube must communicate with a receiver containing water, that the muriatic acid may be condensed as it passes into the receiver. In this way liquid muriatic acid may be obtained. 524 Method procuring.

3. But if the gas which comes over is received in a jar inverted in the mercurial apparatus, its properties may be examined in the state of gas. When it first passes over, it is in the form of white smoke. 525 In the state of gas.

4. Muriatic acid gas possesses the physical properties of common air. It is an invisible elastic fluid. It has a strong acid taste, and a very pungent smell. The specific gravity, according to Kirwan, is 0.002315. 526 Properties.

5. It is unfit for respiration, and equally so for supporting combustion.

6. This gas has a strong attraction for water. If a little water be introduced into a jar filled with this gas, standing over mercury, the whole of the gas will be absorbed, and the mercury will instantaneously rise to the top. Or if a jar filled with muriatic acid gas be inverted into a vessel of water, coloured with vegetable blue, the water suddenly rushes into the jar, which it completely fills, and the blue colour is changed to red, exhibiting the usual effects of acids on vegetable colours. 527 Action of water.

7. Light has no action whatever on this gas, nor does it undergo any change when it is made to pass through a red-hot porcelain tube. In the state of gas, it has no action upon oxygen gas. When this gas comes in contact with atmospheric air, thick white fumes are produced, with the extrication of caloric. This is a combination 528 Light and heat.

 combination of the gas with the water in the atmosphere, by which they are mutually condensed.

8. There is no action between muriatic acid gas and azote, hydrogen, charcoal, phosphorus, or sulphur.

:9 Co ines w water in eat p rtion.

9. The quantity of muriatic acid which water absorbs is very considerable. Ten grains of water combine with ten grains of the gas. The liquid acid thus formed occupies the space of 13.3 grains, and hence its specific gravity is 1.500; and the specific gravity of the purest muriatic acid in its condensed state is 3.300.

The specific gravity of the strongest muriatic acid that can easily be procured and preserved, is 1.196. One hundred parts of this, Mr Kirwan calculates, will contain about 49 of acid, whose specific gravity is 1.500, which he calls the standard acid.

30 P rties.

10. Liquid muriatic acid, in its ordinary state, is of a pale yellow colour; but when pure, it is transparent and colourless.

31 A n of li and h

11. Light has no action whatever on muriatic acid. When heat is applied, it readily assumes the gaseous form. Neither oxygen nor azotic gases are absorbed by muriatic acid, nor has this acid any action on hydrogen, charcoal, phosphorus, or sulphur.

32 C lphu ri id.

12. Sulphuric acid separates the muriatic acid from its compounds, and even from its combination with water; but the muriatic acid drives off the sulphurous acid from this liquid.

33 C tric a

13. One of the most remarkable characters of muriatic acid, is its combination with nitric acid. When these two acids are mixed together, they act upon each other, are strongly heated, and produce effervescence, with a change of colour to an orange red. A mixed acid is thus formed, which possesses properties which existed neither in the one acid nor the other when in a state of separation. It was formerly called *aqua regia*, from its property of dissolving gold, which was distinguished by the name of *king of the metals*. It is now denominated *nitro-muriatic acid*. This acid is not to be considered as a simple mixture of the two acids. A double attraction takes place in their mutual action; the muriatic acid attracts part of the oxygen of the nitric acid, and the nitric combines with the nitrous gas. The muriatic acid thus combined with a portion of oxygen, is disengaged with effervescence in yellow fumes; the undecomposed nitric acid seizes the nitric oxide gas which is formed, and when it is saturated with it, the action ceases. Hence arises the colour of the mixed acid. The peculiar effect of the nitro-muriatic acid on metallic substances, will be described in treating of the metals.

34 N -mu ri acid.

35 A n of e ricity.

14. The bulk of muriatic acid gas is greatly diminished by the action of electricity, and hydrogen gas is given out; but this action is limited. Dr Henry has shewn that it is not owing to the decomposition of the acid, as might at first sight be supposed, but to the decomposition of water which it holds in solution; so that the action continues as long as there is any moisture in the gas. The oxygen of the water combines with the acid, and forms oxymuriatic acid: while the hydrogen of the water is evolved.

36 U in de st ing n us va p .

15. Muriatic acid gas has been successfully employed in destroying noxious, putrid exhalations. It was applied in this way in the year 1773 by Morveau, in purifying the cathedral of Dijon from these exhalations, on account of which it had been altogether deserted.

537 Compounds

16. The compounds which are formed by muriatic acid, with alkalies, earths, and metallic oxides, are distinguished by the name of *muriates*.

538 Affinities.

17. The following is the order of the affinities of this acid.

Barytes,
Potash,
Strontites,
Lime,
Ammonia,
Magnesia,
Glucina,
Alumina,
Metallic oxides.

539 Oxymuriatic acid, or chlorine.

1. Oxymuriatic acid, now called chlorine, was discovered by Scheele in the year 1774, and he gave it the name of *dephlogisticated marine acid*. On account of its singular properties, and the important uses to which it was soon applied, it has been much examined by chemical philosophers.

540 Method of procuring.

2. This substance is obtained by the following process: Take three parts of common salt, and one part of the black oxide of manganese reduced to powder. Introduce them into a tubulated retort; place the retort in a sand bath, and immerse its beak under the surface of warm water in the pneumatic trough. Pour upon it two parts of sulphuric acid a little diluted with water. An effervescence takes place, and a lemon-coloured gas is evolved, which may be received in jars, or preserved in large vessels with ground stoppers.

The nature of this process seemed till lately sufficiently obvious. Common salt is composed of muriatic acid and soda; the affinity of sulphuric acid for soda is stronger than that of muriatic acid; it therefore combines with the soda, and the muriatic acid is disengaged in the state of gas. The black oxide of manganese is composed of oxygen and the metallic substance. The sulphuric acid combines with the manganese at a lower stage of oxidation, and sets oxygen at liberty in the state of gas. But there is also an affinity between the muriatic acid and oxygen, so that in the moment of evolution they unite, and pass off in the state of oxymuriatic acid gas. This rationale of the process is now however disputed. We shall state the grounds of dispute, after we have detailed the properties of the substance obtained.

541 Properties.

3. This gas is of a yellowish green colour, and is hence called chlorine; has a strong penetrating odour, and excites violent coughing, when a mixture of it with atmospheric air is respired. The pure gas is totally unfit for respiration. This gas supports combustion. It diminishes and reddens the flame of a taper; much smoke is evolved, and the taper consumes rapidly.

542 Unchanged by light and heat.

4. Neither light nor heat have any action on the gas. When passed through red-hot porcelain tubes, it remains unchanged.

543 Action on inflammable substances.

5. It has no action whatever on oxygen or azotic gases.

6. In the cold no effect is produced from a mixture of this gas with hydrogen gas; but when they are passed

Acids. passed through a red-hot tube, a violent detonation takes place.

7. In the cold there is no action between charcoal and this gas. When a mixture of equal bulks of this gas and carbureted hydrogen gas is inflamed, there is only a combustion of the hydrogen gas, with a deposition of charcoal. If two measures of oxymuriatic acid gas, and one measure of carbureted hydrogen gas, are mixed together in a close phial, and allowed to remain for 24 hours, they decompose each other. Water, muriatic acid, carbonic acid, and carbonic oxide, are the products. When water is admitted, the whole is nearly absorbed.

8. A bit of dried phosphorus introduced into this gas, is instantly inflamed, and converted into phosphoric acid. It also sets fire to phosphorated hydrogen gas, which has lost the property of spontaneous inflammation in the air.

9. Melted sulphur, plunged into this gas, is immediately inflamed, and converted into sulphuric acid. Sulphureted hydrogen gas is decomposed, but without inflammation, and sulphur is deposited.

544 Sulphurous acid.

10. There is no action between this gas and sulphuric acid; but, when sulphurous acid gas is mixed with it, a thick white vapour is formed, which is the sulphurous acid converted into sulphuric acid, by depriving the oxymuriatic gas of its oxygen. It has no effect on nitric acid; but nitric oxide gas brought into contact with it, is reddened, and converted into nitrous acid.

545 In the liquid state.

11. What is commonly known by the name of *oxymuriatic acid*, is water saturated with this gas. It has a pale green colour, and exhales the same odour as the gas. According to Berthollet, a cubic inch of water absorbs $1\frac{6}{10}$ grs. French of the gas. The quantity absorbed by the water is in proportion to the temperature and the pressure. When vessels containing water, and receiving this gas, are surrounded with ice, while the water is saturated, the gas crystallizes at the surface, and even at the bottom of the liquid, in the form of six-sided plates, of a greenish white colour; but the slightest heat dissolves them, and they rise through the liquor in the form of gas.

Water saturated with this gas at the temperature of 43° has the specific gravity of 1.003.

546 Destroys vegetable colours.

12. This substance does not redden vegetable blues, like the acids. It has the singular property of destroying vegetable colours, on account of which it has been much employed in the art of bleaching. The effect which takes place in this process, has been supposed to be the combination of the colouring matter with the oxygen of the chlorine; for the chlorine seems to be deprived of its oxygen, as it is converted into muriatic acid. For the full account of this process, see BLEACHING.

547 Action of light.

13. This substance, when exposed to the light, is decomposed; it gives out oxygen gas, becomes colourless, and passes into the state of muriatic acid. But, when heat is applied, the chlorine is disengaged in the state of gas, without any perceptible separation of its oxygen. Exposed to the air, it is gradually separated; exhaling at the same time, its pungent, disagreeable odour.

548 Composition.

14. The constituent parts of oxymuriatic acid, according to Berthollet, are of 89 muriatic acid, to 11 of oxygen. According to Mr Chenevix, it is composed of 84 of muriatic acid, and 16 of oxygen.

54[illegible] Views of Gay Lussac and Davy.

In consequence of some elegant experiments of Gay Lussac, however, very strong reasons have appeared for taking a totally different view of the nature of chlorine. Many eminent chemists, accordingly, as Sir H. Davy, Dr Thomson, Gay Lussac, Thenard, and perhaps the majority at the present moment, deny the compound nature of this substance, and maintain it to be a simple body, forming one of the constituents of muriatic acid, while hydrogen is the other. In every case in which oxygen has appeared to be yielded by chlorine, water was present; and when deprived of water, it is found much steadier in its constitution, not altered by light, and giving off no oxygen. The conclusion is, that the oxygen comes from the water, while the hydrogen of the water combines with the chlorine to form muriatic acid. Besides, it is incontrovertibly proved that, if chlorine gas differs from muriatic acid gas, by containing oxygen, this cannot be the only difference. In no case can we, by simply removing oxygen, convert chlorine into muriatic acid gas. When chlorine is made to act on hydrogen gas with detonation, muriatic acid is formed; but no oxygen is removed, for no water is produced capable of being separated from the gas. Muriatic acid gas is in fact the only product. It therefore contains whatever was contained in the chlorine, and the hydrogen besides. Those who adhere to the old opinion, therefore, say that water is an essential part of muriatic acid gas, but not of oxymuriatic; that the latter is dry acid in union with oxygen, while the former is the acid in union with water; and that the cause of the difficulty of obtaining muriatic acid gas, by removing oxygen without the aid of hydrogen, is the impossibility of the muriatic acid assuming a separate and gaseous state without the presence of a portion of water, which is necessary to it, in the same manner as it is to the sulphuric and the nitric acids. The question would be decided in favour of the old opinion, if it could be proved, either 1. That chlorine yields oxygen, or, 2. That muriatic acid gas, free from hygrometric vapour, contains combined water, and is capable, under any circumstances, of yielding it. The affirmative of these two last questions has been maintained by the late Dr Murray, who ably defends the old doctrine, both by arguments drawn from analogy, and by the results of his experiments. For these we refer to the last edition of the Elements of Chemistry of that author. We are certainly indebted to him for some careful and ingenious experiments directed to this object. Minute quantities of water were yielded by muriate of ammonia subjected to sublimation, after the muriatic acid and ammoniacal gases of which it was formed had been freed from hygrometric water, by passing over deliquescent salts. It also was apparently yielded by muriatic acid gas when made to act on metals. The only reply made to these results is, that the water was yielded by the glass vessels employed, a source which had never been before suspected of interfering in such cases. These rigid interrogations of nature are always useful, but we do not consider them in the present instance as completed. We wait for a repetition of them, with some variations. At all events, it is to be remarked, that, according to the old opinion, pure muriatic acid, uncombined

uncombined with oxygen, or with water, has never been procured. It is also to be remarked, that where chlorine, called oxymuriatic gas, appears readily to part with oxygen, it is not its own oxygen that it yields; it is the oxygen of the water that is present, which is evolved in consequence of the mutual attraction subsisting between chlorine and the hydrogen of the water; for dry chlorine does not give off oxygenous gas, but dry chlorine readily combines with dry hydrogen when heat is applied. If chlorine is a compound, its compound nature is not easily demonstrated. Those eminent chemists of our cotemporaries, who regard it as a simple body, have introduced a new nomenclature, not only as applied to it, but to its compounds. The French chemists call it a combustible substance, and apply to its compounds a set of terms corresponding to this view. Its compounds with the metals are called by them *chlorurets*, as those of other inflammables are called *sulphurets*, *carburets*, &c. Its compound with oxygen being found to possess some qualities in common with the acids, is called *chloric* acid, and the salts which this acid form, *chlorates*. The muriatic acid being formed of chlorine and hydrogen, is called the *hydrochloric* acid, and its salts *hydrochlorates*. The British chemists, who maintain the simple nature of chlorine, regard it as a supporter of combustion, and therefore rank it in the same class with oxygen. They at first designated its compounds by the termination *ane*, as *sodane*, *cuprane*, &c. Now they call them *chlorides*, as a term analogous to the compounds of oxygen, the *oxides*. These chlorides of the British, and chlorurets of the French chemists, are, as we shall afterwards see, the muriates of the previously used and still prevalent nomenclature.

50 Mur. More recently, however, a still different and very interesting view has been taken of these substances by Dr Murray, as contained in the Transactions of the Royal Society of Edinburgh, and in the last edition of his System of Chemistry. He supposes chlorine to be a compound of oxygen with an unknown simple body as its radical (which may be called *murion*), and muriatic acid as the same substance, acidified by the further addition of hydrogen. This last principle he regards as an acidifying principle like oxygen, and producing along with it more powerful acids than those formed by oxygen alone. Some combustible bodies form acids by uniting with hydrogen alone; such is sulphureted hydrogen, which is now known to possess acid properties. These are the weakest acids. Others are formed by the union of the radical with oxygen alone; such is sulphurous acid. These have stronger acid powers. Of this kind is chlorine or oxymuriatic acid; a substance the acid powers of which are feeble and scarcely recognizable, but which presents this strong analogy with the sulphurous acid, that they both have the property of destroying vegetable colours. Other acids are formed by the union of the radical both with oxygen and hydrogen; such is the case with the sulphuric acid, and such, he suggests, may be the nature of the muriatic. This doctrine is consistent with the results of his experiments, in which water was yielded by muriatic acid. It contains both oxygen and hydrogen, which may be obtained in the form of water, though existing in the acid not as water, but as two acidifying powers, heightening one another's efficiency. The author supports this view by many beautiful and striking analogies, and likewise by the application of the doctrine of definite proportions or fixed combining weights; and he maintains, by some ingenious calculations, that this view removes some of the anomalies which that doctrine, as applied to certain compounds, otherwise presents. This writer, therefore, still retains the old nomenclature, calling chlorine oxymuriatic acid, &c. which indeed may be done in sufficient consistency with all the facts. It is a suitable enough name for the compound formed of oxygen with the radical of the muriatic acid. It may even be used, though we should consider chlorine as a simple body, if we view it as a supporter of combustion. It is the oxygen or the acidifier to which muriatic acid owes its power.

SECT. VI. *Of the Compounds of* CHLORINE *with* OXYGEN.

1. When hyperoxymuriate or chlorate of potash, (a salt to be afterwards described,) is distilled at a gentle heat with weak muriatic acid, a gas is collected over mercury, differing from chlorine. It has a dense yellow colour, and a smell resembling that of burnt sugar. It has been called by Sir H. Davy, its discover, *euchlorine*. It explodes by a gentle heat with a further evolution of heat and light, and yet presents the remarkable phenomenon of an expansion rather than a condensation of its elements. Five volumes are expanded to six, being composed of two volumes of chlorine and one of oxygen; and the latter, being condensed to half its bulk. It does not act on mercury at ordinary temperatures as chlorine does. 551 Euchlorine.

2. Another compound is procured by distillation from hyperoxymuriate of potash, treated with a small quantity of concentrated sulphuric acid, and exposed to a moderate heat. This has a still livelier colour, and more bland odour than euchlorine. It explodes more violently than euchlorine when decomposed by heat, and the expansion produced is greater, amounting to an addition of nearly one half. It seems to consist of two volumes of oxygen to one of chlorine. 552 Peroxide of chlorine.

3. A compound is also obtained, consisting of a still larger proportion of oxygen with chlorine. It is in fact the same compound which, when united to potash, forms the hyperoxymuriate or chlorate of that alkali. It is obtained in a state of liquid or absorption by water, by detaching it from the chlorate of barytes by means of diluted sulphuric acid carefully introduced to avoid excess or deficiency. This compound, however, does not admit of being driven off by heat unchanged, and thus examined in the gaseous state. Such a distillation is always accompanied with a partial decomposition into chlorine and oxygen. 553 Hyperoxymuriatic or chloric acid.

The order of the affinities of hyper-oxymuriatic or chloric acid, is the following, as they have been ascertained by Mr Chenevix†. 554 Affinities.

Potash,
Soda,
Barytes,
Strontites,
Lime,
Ammonia,
Magnesia,
Alumina.

† Philos. Trans. 1802, p. 126.

SECT.

Sect. VII. *Of Iodine and its Acids.*

555 History. 1. Iodine was discovered in 1813 by M. Courtois, a Parisian manufacturer of soda from kelp, whose attention was first directed to it by an unaccountable corrosion of his iron vessels, which he endeavoured to understand by experiment.

2. It is obtained from the lixivium of kelp. This lixivium, after repeated concentration and removal of the crystallizing salts, is treated with concentrated sulphuric acid under a gentle heat. Beautiful purple vapours now come over. These consist of iodine, and from that colour the substance derives its name. They condense in a brown crust or crystalline plates similar to plumbago. To purify it from the acid which comes over with it, the iodine may be redistilled from water containing a very little potash, and afterwards dried by blotting paper. It melts at 225, and is volatilized about 350. The volatilization which takes place in its first extrication under a moderate heat, arises from its affinity for aqueous vapour.

556 Hydriodic acid. 3. Iodine combines readily with hydrogen to form an acid, which is called the hydriodic. This acid may exist in the state of gas, but cannot be retained long pure, as it acts on liquid substances used for confining it; being absorbed by water and decomposed by mercury, which combines with the iodine, and sets the hydrogen gas at liberty.

This acid forms neutral salts with alkaline and other bases. These are called hydriodates. Hydriodate of soda exists in kelp, and from this the iodine is obtained.

557 Oxiodic acid. 4. Iodine is capable of combining with oxygen when presented to euchlorine. The compound formed, is a white semi-transparent solid, very soluble in water, capable of combining with alkalies and oxides. It is called oxiodic acid, and its salts oxiodates.

558 Nature of iodine, &c. 5. Iodine and its compounds present some striking analogies with chlorine and its compounds; and the same difference of opinion about its nature, whether simple or compound, exists regarding it.

Sect. VIII. *Of Fluoric Acid.*

559 History. 1. This acid was supposed to have been discovered by Scheele in 1771. But the substance then discovered is now found to consist of a compound of this acid with silex. In its uncombined state, or combined only with water, it was first obtained by Gay Lussac, and Thenard.

560 Method of Preparing. 2. It is obtained by distillation from fluate of lime, *i. e.* fluor spar (which must be pure and in a particular manner free from silex,) acted on by thrice its weight of concentrated sulphuric acid. This must be done in a leaden retort, to which a leaden or silver receiver is fitted, and the receiver must be surrounded with ice to ensure the condensation of the acid which comes over, as it possesses great volatility.

561 Properties. 3. The acid thus obtained is distinguished by some remarkable properties. It readily combines with water, emitting a strong heat even to boiling, and giving off dense and noxious fumes. When water is added to it slowly, its specific gravity is increased, and at last exceeds that of water itself; a property altogether unique as applied to fluids. It powerfully affects the skin. A small quantity of it instantly raises a painful blister; a larger quantity produces a deep ulcer, by exciting a morbid action which extends far beyond the seat of its corroding agency. It acts instantly and rapidly on glass, and therefore cannot be prepared nor preserved in glass vessels. It may be employed for removing the polish of glass surfaces, and for etching on glass.

3. This action arises from the strong affinity of the acid for silex, with which it forms a compound called silico-fluoric acid, which presents this singular property, as distinguished from pure fluoric acid, that it is readily obtained in the form of a gas, which the latter has never yet been. In the state of gas it does not attack glass. The gas is readily absorbed by water, to the extent of 263 times the bulk of the latter. It unites with ammonia, depositing its silex. 56 Silico- ric aci

4. The fluoric acid has never been decomposed. But the great success of modern chemists in analysing bodies, has given rise to anticipations of its composition; some supposing it to consist of a peculiar body, a supporter of combustion, which, like chlorine, forms an acid by combining with hydrogen. This they have called fluorine: while others suppose it to consist of a peculiar radical combined with oxygen. 56 Natur

5. The compounds with the alkalies, earths, and metallic oxides, are called *fluates*. 56 Compounds

6. The order of its affinities is the following: 56 Affiniti

Lime,
Barytes,
Strontites,
Magnesia,
Potash,
Soda,
Ammonia,
Glucina,
Alumina,
Zirconia,
Silica.

Sect. IX. *Of Boracic Acid.*

1. Boracic acid was first discovered by Homberg in 1702, who gave it the name of *narcotic* or *sedative salt*. The substance called borax of the shops is a compound of this acid and soda. 56 Disco

2. The process for obtaining this acid is the following: Dissolve a quantity of this substance in hot-water, and filter the solution. Gradually pour on it sulphuric acid, till the liquor acquires a slight degree of acidity. The sulphuric acid combines with the soda; and the boracic acid, as the solution cools, is precipitated in small shining white scales. To purify the acid thus obtained, it is to be washed with cold water; which removes the more soluble salts with which it is mixed. 56 Prepara tion.

3. Boracic acid is in the form of silvery white hexagonal scales, which have a greasy feel, and some resemblance to spermaceti. It has a sourish taste, which afterwards gives the sensation of coolness. It has no smell. It changes vegetable blues to red. In the scaly form, the specific gravity is 1.479; but when it is fused, it is 1.803. It has been decomposed by the agency of potassium (a substance afterwards to be described), by being heated along with an equal quantity of that substance 5 Compo tion a proper

stance in a green glass tube, and found to consist of a peculiar radical, termed *boron*, in union with oxygen. This radical is a greenish brown powder, the other chemical habitudes of which are little known. It seems to have little tendency to combine with other substances besides oxygen.

4. This acid, when exposed to heat, froths up, which is owing to the separation of the water of crystallization, and assumes the form of a viscid paste. In this state
569 it is known by the name of *calcined borax*. When it is exposed to a red heat, it is converted into a hard transparent glass, which, without attracting moisture from the air, becomes opaque when exposed to it, but undergoes no essential change: for when it is re-dissolved in warm water, it resumes its former properties, by cooling and crystallization *.

570 5. Boracic acid has very little attraction for water: boiling water only dissolves about a 50th part of its weight, and cold water much less. When the solution in water is evaporated in close vessels, part of the acid rises in the state of vapour along with the water, and crystallizes in the receiver; but when the whole of the water is dissipated, the process stops; so that it is only by means of it that the acid is volatilized; otherwise it is perfectly fixed. The solution in water has little taste, but it reddens the tincture of turnsole.

6. Neither oxygen, azotic, nor hydrogen gases, produce any effect upon it; and with charcoal, phosphorus, and sulphur, it also remains unchanged. When burnt with phosphorus, indeed, a earthy yellow matter is left behind.

571 7. At a red heat it drives off some of the acids from their combinations, even those acids which have a stronger affinity for the same substances in the cold. Boracic acid has some peculiar action with the sulphuric and nitric acids; for when it is heated with these acids, it deprives them of a portion of their oxygen.

572 8. The boracic acid is employed in chemistry, not directly as an instrument of analysis, because its affinities and action have little energy compared with other acids, but to discover its peculiar combinations and compounds. It is also employed in the arts, as in soldering, to assist the fusion of metallic substances. It is of great importance to the mineralogist, in promoting the fusion of substances under the blow-pipe.

573 9. It forms an interesting compound with the fluoric acid. When one part of it, and two of fluate of lime, are subjected to strong heat in an iron tube, a gas is given off in great quantity. This gas, which is called *fluo-boric* acid, contains no water, but possesses a singularly powerful affinity for it. Hence it is used as a test of the presence of hygrometric vapour in any other gas on which it does not chemically act. When aqueous vapour is present, a cloudiness is shown on the introduction of fluo-boric acid gas; water takes up 700 times its bulk, and acquires a specific gravity of 1.77.

10. The compounds which boracic acid forms with the alkalies, earths, and metallic oxides, are distinguished by the name of *borates*.

574 11. The affinities of boracic acid are the following:

Lime,
Barytes, &c. as in Fluoric; then
Zirconia,
Water,
Alcohol.

Sect. X. *Of Phosphoric Acid.*

1. When phosphorus undergoes combustion in oxygen gas, a great quantity of white fumes are produced, which are deposited in white flakes. These are phosphoric acid; so that it is a compound of phosphorus and oxygen. 575 Formation.

2. The phosphoric acid was first shewn to be distinct from all other acids, in the year 1743, by Margraaff. 576 History. He found that it existed in the salts which were taken from human urine, and that phosphorus could only be obtained from this acid, as well as that it could be converted into phosphoric acid. This acid was found to exist in some vegetable substances, although it was formerly supposed to be peculiar to animal matters. It was discovered by Scheele and Gahn in bones, in the year 1772. Bergman, Proust, and Tenant, detected it in several fossils; and Lavoisier proved, by a series of accurate and ingenious experiments, that it was composed of phosphorus and oxygen.

3. Phosphoric acid may be obtained, not only by the method just mentioned, but also by transmitting a current of oxygen gas through phosphorus melted under water. 577 Preparation. The acid, as it is formed, combines with the water, from which it may be obtained in a state of purity by evaporation. It may be procured also by dropping small bits of phosphorus into nitric acid moderately heated. An effervescence takes place, and nitrous gas is evolved. Phosphorus combines with the oxygen, and forms phosphoric acid. The precaution of adding but a little phosphorus at a time, and of applying a moderate heat to the acid, should be carefully observed. The liquid is then evaporated, and the phosphoric acid remains behind in the solid state. The water that may be combined with it is driven off, by exposing it to a red heat.

4. In this state phosphoric acid is a transparent, colourless, solid substance, resembling glass, known under the name of *phosphoric glass*. 578 Properties.

The specific gravity of this acid varies, according to the different states in which it exists. In the liquid state it is 1.417; in the dry state it is 2.697; in the state of glass 2.8516. It changes the colour of vegetables blues to red; has no smell, but a very acid taste.

5. When it is exposed to the air, it attracts moisture, and is converted into a thick viscid fluid, like oil. 579 Attracts moisture. It is very soluble in water. When in the form of dry flakes, it dissolves in a small quantity of this liquid, producing a hissing noise like that of a red-hot iron plunged into water, with the extrication of a great quantity of heat. In the state of glass it dissolves more slowly, but the concentrated liquid phosphoric acid unites with water with very little disengagement of caloric.

6. Phosphoric acid being fully saturated with oxygen, has no action whatever on oxygen gas; nor is there any action between hydrogen or azotic gases, or sulphur, with the phosphoric acid. 580 Action of charcoal. Charcoal has no effect on phosphoric acid in the cold; but when they are exposed together to a red heat, the phosphoric acid is decomposed; the oxygen combines with the carbon of the charcoal, forming carbonic acid, and the phosphorus is set at liberty. This is the process already described in treating of phosphorus, which is generally employed for obtaining that substance.

Acids.

7. Sulphuric acid has no action on phosphoric acid; but when the two acids are mixed together in the liquid
581 Of acids. state, the sulphuric acid, on account of its strong affinity for water, combines with the water in the phosphoric acid; and if heat be applied, the sulphuric acid is dissipated, and the phosphoric acid remains behind in the state of a transparent viscid matter, or in that of glass. Sulphurous acid is separated from its combinations by the phosphoric acid. Nitric acid separates the phosphoric from its combinations. Muriatic acid has the same effect.

582 Composition. 8. The component parts of this acid have been accurately ascertained by Lavoisier, and it consists of,

60 oxygen,
40 phosphorus.

100

583 Importance. 9. The accuracy of our information with regard to the component parts and properties of phosphoric acid, renders it of great importance in many chemical operations; and if it could be obtained with less difficulty and expence, its uses might be extended to medicine and the arts.

584 Compounds. 10. It combines with the alkalies, earths, and metallic oxides, and forms salts which are denominated *phosphates*.

585 Affinities. 11. The following is the order of its affinities.

Barytes,
Strontites,
Lime,
Potash,
Soda,
Ammonia,
Magnesia,
Glucina,
Alumina,
Zirconia,
Metallic oxides,
Silica.

Sect. XI. *Phosphorous and Hypophosphorous Acid.*

1. Phosphorous acid bears the same relation to phosphoric as sulphurous acid does to sulphuric. It is com-
586 Formation. bined with oxygen in the smaller proportion. This was demonstrated by Lavoisier in 1777, when he pointed out the difference between the product from the slow or rapid combustion of phosphorus. This acid is obtained by the slow combustion of phosphorus at the common temperature of the air. If phosphorus, in small pieces, be exposed to the air in a glass funnel placed in a bottle, it attracts the oxygen and moisture from the atmosphere, and the phosphorous acid runs down into the bottle. By this process, about three times the weight of the phosphorus is obtained. It is mixed, however, with phosphoric acid; and, according to some, the two acids are chemically combined, or rather we have in this instance a separate definite compound, to which the name of *phosphatic* acid has been given. When alkaline bases are presented to it, we have always a mixture of phosphates and phosphites.

A pure phosphorous acid is obtained by the agency of a chloride of phosphorus on water. That chloride is formed by subliming phosphorus through corrosive muriate of mercury (considered as a compound of that metal with chlorine). The chlorine combines with the phosphorus, and when the compound thus formed (the chloride) is moistened, water is decomposed, the hydrogen unites with the chlorine to form muriatic acid, and the oxygen unites with the phosphorus in that exact proportion which forms the pure phosphorous acid. For this process we are indebted to Sir H. Davy.

2. It is then in the form of a white thick liquid, 587 Properties.
adhering to the sides of the vessel. It varies in consistence according to the state of the air. Its specific gravity is not known. It has an acid, pungent taste, not different from phosphoric acid. It also reddens vegetable blue colours.

3. Phosphorous acid is not altered by light. When 588 Action of
exposed to heat in a retort, part of the water combined heat.
with it is first driven off; and when it is concentrated, bubbles of air suddenly rise to the surface, and collect in the form of white smoke, and sometimes inflame, if there be any air in the apparatus. If the experiment be made in an open vessel, each bubble of air, when it comes to the surface, produces a vivid deflagration, and diffuses the odour of phosphorated hydrogen gas. This inflammable gas continues to be evolved for a long time, and when the action ceases, phosphoric acid only remains behind. It ought to be observed, that the phosphorated hydrogen gas is not disengaged till the phosphorous acid is concentrated and brought to a high temperature, which seems to prove that the phosphorus which is not saturated with oxygen, strongly adheres to it.

4. There is little attraction between oxygen and 589 Oxygen.
phosphorous acid, which seems to be owing to the great affinity between phosphorus and phosphoric acid. It absorbs, however, very slowly, a small quantity of oxygen; and even after long boiling, it is not completely converted into phosphoric acid.

5. Hydrogen gas has no action on phosphorous acid; 590 Hydrogen.
but this acid is decomposed at a red heat, by means of charcoal, which separates from it a greater quantity of phosphorus than from phosphoric acid. There is no action between these bodies in the cold. Sulphur has no action on this acid at the ordinary temperature of the atmosphere, and they cannot be combined by means of heat, because the phosphorus is dissipated before it unites with the sulphur.

6. There is no action between phosphorous acid and 591 Of acids.
sulphuric acid in the cold; but when they are heated together to the boiling temperature, the phosphorous acid deprives the sulphuric of part of its oxygen, and is converted into phosphoric acid, while part of the sulphuric acid, thus decomposed, is disengaged in the state of sulphurous acid gas. Phosphorous acid produces a similar effect on nitric acid. The phosphorous is converted into phosphoric acid, and part of the nitric acid is converted into nitrous gas.

7. Phosphorous acid forms compounds with alkalies, earths, and metallic oxides, which are known under the name of *phosphites*. 592 Compounds.

8. The order of its affinities is the following. 593 Affinities.

Lime,
Barytes,
Strontites,

Strontites,
Potash,
Soda,
Ammonia,
Glucina,
Alumina,
Zirconia,
Metallic oxides.

94 ...phos- ...ous a...

9. Another acid, with a still smaller proportion of oxygen, and therefore called hypophosphorous acid, is formed when a phosphuret of an alkali or an earth is made to act on water by heat. The water is decomposed, the hydrogen is evolved, and carries with it a portion of phosphorus. The oxygen combines with another portion of phosphorus, forming two distinct acids, the phosphoric and the hypophosphorous, which both form at the same time neutral salts, a phosphate and a hypophosphite of the base employed. The hypophosphite is the most soluble of the two. When a phosphuret of barytes has been employed, the hypophosphite is obtained pure in solution, the phosphate of that earth being entirely precipitated; and now the earth may be separated from this acid by the sulphuric acid, which thus gives us the hypophosphorous acid uncombined.

Sect. XII. *Of Carbonic Acid.*

1. When a piece of charcoal, in a state of ignition, is plunged into a jar of oxygen gas, it burns with great brilliancy; and after the combustion has ceased, the
99 ...ation. air in the vessel is totally changed. If a little water is introduced into the jar, and agitated, the air combines with it; and this water, when examined, exhibits acid properties. This is *carbonic acid*. It is formed by the combination of carbon and oxygen. This is one of the most important acids, both on account of its numerous combinations, and also on account of the discovery of it having occasioned a total revolution in chemical science.

2. It was regarded by the ancients, on account of the noxious effects which it produced, as a pestilential vapour, and they gave it the name of *spiritus lethalis*.
96 ...es. Paracelsus and Van Helmont considered it as a peculiar matter, to which they gave the name, *spiritus sylvestris*, or *gas*. Hales, although he considered it merely as contaminated air, distinguished it by the name of *fixed air*, because it entered into the composition of many bodies. Dr Black demonstrated, that it is a peculiar substance, different from the air; that lime, magnesia, and the alkalies, were deprived of their causticity, by being combined with this air, and therefore he gave it the name of *fixed air*. It was afterwards found, by the experiments of Keir and Bergman, to be an acid, and hence Bergman gave it the name of *aërial acid*. The nature and properties of this acid were investigated by many chemical philosophers, and from them it received various names, as *mephitic acid*, *calcareous* or *cretaceous acid*, thus distinguished from its effects, or from the substances from which it was obtained. In the present chemical nomenclature it has the name of *carbonic acid*, from its base *carbon*.

97 A...st sup- ...t sim- pl...

3. For some time after the discovery of the difference between carbonic acid and common air, and its properties as an acid, it was considered by many as a simple elementary substance, and was even regarded as the acidifying principle. In the progress of investigation it was found to be a compound substance, containing oxygen as one of its constituent parts, and it was generally believed that phlogiston constituted the other. When hydrogen was considered as the same with phlogiston, it was supposed that oxygen and hydrogen constituted carbonic acid. The discovery of Mr Cavendish proved that water, not carbonic acid, was the product of the combination of oxygen and hydrogen. The experiments of Lavoisier established the fact of its real composition, and placed it beyond dispute. He demonstrated that the weight of the carbonic acid which was obtained, was exactly equal to the quantity of the oxygen and charcoal which had disappeared.

598 Method of obtaining.

4. Carbonic acid may be obtained by taking a quantity of chalk, limestone, or marble, and reducing them to a coarse powder. Introduce it into a matrass, pour over it a quantity of diluted sulphuric or nitric acids; a violent effervescence takes place, carbonic acid gas is disengaged, which passes over, and may be received in vessels in the usual way. The chemical action that takes place in this change is obvious. The affinity of the sulphuric acid for the lime is stronger than that of the carbonic acid, which is previously in combination with it; the sulphuric acid, therefore, seizes the lime, and the carbonic acid is disengaged in the state of gas.

599 Properties.

5. Carbonic acid thus obtained in the state of gas, is an invisible, elastic fluid. Its specific gravity is 0.0018. One hundred cubic inches of it weigh 46.5 grs. It is nearly double the weight of common air. It has no smell; it is totally unfit for respiration, and equally so for supporting combustion. It reddens the tincture of turnsole, which has its blue colour restored on being exposed to the air, by the separation of the acid.

600 Absorbed by water.

6. Water absorbs a considerable proportion of this acid, which is increased by agitation. At the temperature of 41° water absorbs its own bulk. When artificial pressure is employed, the quantity of gas absorbed may be greatly increased. It is in this way that what are called the aërated alkaline waters are prepared, some of which, it is said, contain no less than three times their bulk of the gas. Water impregnated with this gas, acquires an acidulous taste, and when poured from one vessel to another, has a sparkling appearance. When water impregnated with this acid is exposed to the air, it soon disappears. The air of the atmosphere attracts it from the water, having a stronger affinity for it than the water.

When water containing this gas is raised to the boiling temperature, the whole is driven off; and if water impregnated with it be exposed to the temperature of 32°, the whole of the gas separates during the freezing.

601 Not altered by light or heat.

7. Carbonic acid undergoes no change by the action of light. It is not changed by the action of heat in close vessels, nor by passing it through a red-hot tube.

602 Attracted by the air.

8. There is no action between this gas and oxygen. Exposed to the air of the atmosphere, it is gradually dissipated. The air of the atmosphere generally contains from .01 to .02 parts of this gas.

Acids.

603 Absorbed by charcoal. 9. There is no action between this acid and azote. Charcoal has no chemical action on carbonic acid; but when it is heated, it has the property of absorbing and condensing within its pores the carbonic acid; but the acid is again separated by plunging the charcoal under water.

10. Phosphorus has no action on carbonic acid; but can decompose it by the aid of compound affinity.

11. Sulphur has still less action on carbonic acid than phosphorus. It is said, indeed, that a small quantity of sulphur is dissolved by this gas by means of heat, which gives it partly the fetid odour of sulphureted hydrogen gas.

604 Diminishes combustibility. 12. Carbonic acid gas mixed with carbureted, phosphoreted, and sulphureted hydrogen gases, diminishes the combustibility of these inflammable gases.

605 Compounds. 13. The carbonic acid combines with the alkalies, some of the earths, and metallic oxides, forming compounds known by the name of *carbonates*.

606 Affinities. 14. The following is the order of the affinities of this acid:

Barytes,
Strontites,
Lime,
Potash,
Soda,
Magnesia,
Ammonia,
Glucina,
Zirconia,
Metallic oxides.

607 Very abundant. 15. Carbonic acid exists in great abundance in nature. It is produced during the processes of combustion, respiration, and the fermentation of vegetable matters. Hence it is found in pits and caverns, where there is a stagnation of the air, and being specifically heavier than common air, it remains at the bottom. This is the reason why small quadrupeds, as dogs, are instantly suffocated, because they respire only this gas, when they enter places where it is accumulated. This has been long observed in the celebrated Grotto del Cani in Italy, where dogs are instantly suffocated; while men, whose heads are in the stratum of common air near the top of the cavern, receive no injury. Men have been suddenly killed by going down into large vats, in which the process of fermentation had been carried on. In consequence of the greater specific gravity of the carbonic acid gas, and the great quantity generated during the process, when the fermented liquor is drawn off, it sinks to the bottom of the vessel, and there remains till it is displaced by a denser fluid, or slowly attracted by the air. Similar accidents have happened to persons going down into pits or wells which have been long shut up, and where the air has been long stagnant. It is by respiring this gas that persons are suffocated who have been exposed to the fumes of burning charcoal in close places. During the combustion of the charcoal, the carbon combines with the oxygen of the atmosphere; and carbonic acid is formed, which soon fills the apartment. In these cases, where life is not totally extinguished, the best method of recovery is said to be, to dash cold water on the head and body; a practice which is commonly followed in accidents of this kind, in northern countries, where charcoal is burnt in close apartments.

608 Fatal effects produced by it.

609 Mode of recovery.

Sect. XIII. *Of Arsenic Acid.*

1. This acid, and the four following, have metallic substances for their radical. Most metallic substances combine with oxygen in different proportions, and the compounds formed with these substances and oxygen, are denominated *oxides*, because they possess no acid properties; but some of the metals combine with oxygen in such a proportion as gives them the characteristic properties of acid substances. 610 Five metallic acids.

2. The metallic substance arsenic, combines with oxygen in two proportions; the first, which is usually called the *white oxide of arsenic*, has been denominated by Fourcroy, the *arsenious acid*. Macquer discovered some of the combinations of arsenic acid, previous to the year 1746; for he shews that a mixture of white oxide of arsenic and nitre, subjected to the action of a strong fire, yields a neutral salt, to which he gave the name of the neutral salt of arsenic. But it was by the investigation of Scheele in 1775 that its properties were fully known.

3. The process for obtaining it which was pointed out by Scheele, is the following. Take three parts of the white oxide of arsenic, and dissolve it in seven parts of muriatic acid. Add five parts of nitric acid to the solution, and distil it to dryness. The arsenic acid remains behind. It may also be procured by dissolving the white oxide in liquid oxymuriatic acid, or by making a stream of oxymuriatic acid gas pass through a solution of the white oxide of arsenic. The chemical action which takes place in these processes, is the union of the arsenic with an additional portion of oxygen, which it derives from the nitric acid, the liquid oxymuriatic, or the oxymuriatic acid gas. 611 Process of obtaining it.

4. By whatever process it is obtained, the arsenic which is not crystallized has an acid, caustic, and metallic taste. It reddens the syrup of violets, and its specific gravity is 3.91. When it is exposed to a strong heat in a retort or crucible, it fuses, attacks the glass of the retort, or the earth of the crucible; it remains transparent and pure at a high temperature, gives out a little oxygen, and is partly converted into white oxide. 612 Properties.

5. Exposed to the air, it attracts the moisture from it, and absorbs two thirds of its own weight of water from the atmosphere, which is sufficient to hold it in solution.

6. The arsenic acid is much more soluble in water than the white oxide. Three or four parts of water are sufficient to dissolve it. When it is evaporated, it assumes a thick consistence like honey. 613 Action of water.

7. Combustible substances decompose arsenic acid, by depriving it of part of its oxygen, and converting it into the white oxide. Hydrogen gas, mixed with a solution of this acid, has the property of precipitating it. Charcoal, phosphorus, and sulphur, produce a similar effect. Exposed in a retort to heat with charcoal; the charcoal is inflamed, and the arsenic acid is reduced to the metallic state. Sulphur heated with arsenic acid, is partly converted into sulphurous acid gas, and partly sublimed into the red sulphuret of arsenic. When heated 614 Of combustibles.

heated with phosphorus, part of the phosphorus is converted into phosphoric acid, and the arsenic reduced to the metallic state, unites with another part of the phosphorus, with which it forms a phosphuret of arsenic, which sublimes.

5 8. The arsenic acid is composed of the white oxide of arsenic and oxygen. The proportion of its constituent parts, according to the experiments of Proust, are

65	arsenic,
35	oxygen,
100	

6 9. The componnds which arsenic acid forms with alkalies, earths, and some metallic oxides, are known by the name of *arseniates*.

7 10. The order of its affinities is the following:

Lime,
Barytes,
Strontites,
Magnesia,
Potash,
Soda,
Ammonia,
Glucina,
Alumina,
Zirconia.

Sect. XIV. *Of Tungstic Acid.*

8 1. In the year 1781, Scheele and Bergman, in investigating the natnre of a heavy stone (called tungsten by the Swedes), discovered that it is composed of lime combined with a peculiar acid. Their discovery was afterwards confirmed by several chemists, and particularly by the experiments of the D'Elhuyarts, who detected the same acid in the mineral wolfram.

9 2. This acid always exists in combination with lime and iron. It may be obtained by reducing the former to a fine powder, and treating it with nitric or muriatic acids, which unite with the lime, and then by alkalies, which dissolve the acid. The alkaline solution is to be precipitated by the nitric or muriatic acid; the precipitate is to be carefully washed and dried, which is the tungstic acid in the solid state.

3. Tungstic acid, thus prepared, is in the form of a white powder, which has an acid and metallic taste; changes the colour of vegetable blues into red; and has a specific gravity according to Bergman, equal to 3.600. Heated under the blow pipe, this tungstic acid becomes first yellow, then brown, and at last black; it affords no smoke, and gives no sign of fusion. When it is calcined for some time in a crucible, it is deprived of the property of dissolving in water.

4. Exposed to the air, it suffers no change. It is soluble in 20 parts of boiling water, but it is partially separated on cooling. This solution has an acid taste, and reddens the tincture of turnsole. Heated with charcoal, it is reduced, but with difficulty, to the metallic state. With sulphur and phosphorus it becomes of a gray colour, but without reduction.

5. The acids do not dissolve the tungstic acid in the form of white powder, but they change completely its properties. The sulphuric acid changes it to a blue, and the nitric and muriatic acids convert it into a fine yellow colour. In this state it has lost its taste and solubility, has become specifically heavier, and has acquired the property of forming salts with the same bases distinctly different from those formed with what was called the white acid. The Spanish chemists D'Elhuyarts, consider the latter as an acidulous triple salt, and yellow oxides as real tungstic acid.

6. Vauquelin and Hecht, who instituted a set of experiments on these oxides, as they propose to denominate them, obtained the same results. They consider the tungstic acid of Scheele as a triple salt, which has retained a portion of the acid by which it was precipitated in its composition, and when the oxide of tungsten is pure, it possesses none of the properties which are admitted and acknowledged as the characteristics of the acids, but that it has a strong tendency to form triple combinations, in which only it exhibits acid properties. The compounds which it forms with the alkalies, earths, and metallic oxides, are a species of neutral salts; but the chemical combination is not fully completed to hide the alkaline properties of the former †. In forming these compounds, it is the only property in which it agrees with the acids. The compounds are denominated tungstates. 624 Only an oxide.

† *Jour. de Mines*, No. xix. p. 26.

625 Tungstates.

7. The order of its affinities is the following: 626 Affinities.

Lime,
Barytes,
Strontites,
Magnesia,
Potash,
Soda,
Ammonia,
Glucina,
Alumina,
Zirconia.

Sect. XV. *Of Molybdic Acid.*

1. This acid was discovered by Scheele in the year 1778. It is a compound of the metallic substance molybdena and oxygen. Scheele supposed that it existed in the mineral from which he obtained it, and that this mineral was a compound of the acid, sulphur, and iron. The experiments of later chemists have shown that the acid is formed in the process of preparing it, by the metal combining with oxygen. 627 History.

2. There are various processes for the preparation of this acid.

a. Scheele found that by treating a little of the sulphuret of molybdena (sulphur combined with the metal) on a silver plate, the white fumes which exhaled from it, adhered to the plate in form of a small scale of a brilliant yellowish white colour, which was the trne molybdic acid. But a very small quantity can only be obtained in this way. 628 Processes for obtaining it.

b. Another process is by means of nitric acid. On one part of sulphuret of molybdena in powder, pour five parts of nitric acid, and distil it to dryness. The same process is repeated three or four times. The dry residuum is a white powder, which is the molybdic acid mixed with the sulphuric acid, which is also formed during the process with the nitric acid. The sulphuric acid.

Acids. acid may be washed off with hot water, and the molybdic acid remains behind in a state of purity.

c. It may be also prepared by projecting into a red-hot crucible three parts of nitrate of potash, and one part of sulphuret of molybdena, reduced to fine powder and well mixed together. A red mass remains after the detonation, composed of the oxide of iron, of the sulphate of potash, and the molybdate of potash. By throwing the mass into water, the two salts are dissolved, and the oxide of iron is precipitated. Evaporate the solution to obtain the sulphate of potash, and drop into the liquid which refuses to crystallize, and which should be diluted with water, sulphuric acid, till there is no farther precipitation. The precipitate is molybdic acid, but not in a state of perfect purity; for it is combined with a certain portion of potash.

629 Properties. 3. Molybdic acid prepared in this manner, and sufficiently purified, is a white powder of a sharp metallic taste. According to Bergman, the specific gravity is 3.4.

630 Action of heat. 4. When heated in a large glass retort, it yields a little sulphurous acid. But when it is exposed to a strong heat in a close vessel, it fuses, attaches itself to the sides of the vessel, and crystallizes on cooling in rays going out from a centre. But if at the moment the acid is in fusion the vessel be uncovered, it rises into a white smoke by contact with air, and this vapour attaches itself to cold bodies in form of brilliant scales of a golden-yellow colour.

631 Of water. It is readily soluble in warm water. One part of the acid requires about 500 grs. The solution is of a yellow colour, has little smell, and reddens litmus paper.

632 Of charcoal and sulphur. 5. Molybdic acid is decomposed by charcoal, with the assistance of heat; it is also decomposed by sulphur, with the extrication of sulphurous acid, and the formation of sulphuret of molybdena.

633 Of acids. 6. The concentrated sulphuric acid dissolves a considerable quantity of molybdic acid, with the aid of heat. The solution on cooling becomes of a violet blue colour, which disappears when it is heated. The muriatic acid dissolves a considerable proportion by boiling. When this solution is distilled to dryness, one part of the acid is sublimed, of a blue and white colour. The nitric acid has no effect whatever *.

* *Philos. Trans.* 1789, p. 389.

634 Compounds. 7. Molybdic acid combines readily with the alkaline and earthy bases, which have the name of *molybdates*.

8. This acid has not been applied to any use.

Sect. XVI. *Of Chromic Acid.*

635 Discovery. 1. This acid was discovered by Vauquelin in the year 1797. It has only been found in small quantity, in combination with lead or iron.

636 Preparation. 2. Chromic acid may be obtained by boiling the red lead ore of Siberia in a solution of carbonate of potash, and precipitating it by means of another acid, which has a stronger attraction for the potash. A red or yellow orange powder falls to the bottom, which is chromic acid.

3. It has an acrid and peculiar metallic taste, more perceptible than any other metallic acid.

4. When exposed to the action of light and caloric, in open vessels, it assumes a green colour; but in close vessels, it gives out pure oxygen gas, and losing its acid properties it returns to the state of green oxide. This is the only metallic acid, which by the action of caloric, easily parts with its oxygen.

5. Strongly heated with charcoal, chromic acid becomes black, and is easily reduced to the metallic state without fusion. It is probable also, that it may be decomposed with equal facility by hydrogen, phosphorus, and sulphur. 63[illegible] Action [of] charco[al].

6. Chronic acid is soluble in water, and crystallizes by cooling and evaporation, in prisms of a ruby red colour. 63[illegible] Water.

7. The muriatic acid by distillation with a moderate heat with the chromic acid, passes to the state of oxymuriatic acid, and the mixture acquires the property of dissolving gold. In this respect it resembles the nitric acid, and it is the only metallic acid which is distinguished by this property. 63[illegible] Muriat[ic] acid.

8. The chromic acid combines readily with the alkalies, and has the peculiar property of giving an orange colour to the crystals: from this it derived its name. The compounds are called *chromates*. 64[illegible] Compounds.

9. The chromic acid, from its peculiar colour, and the beautiful colours which it communicates to other bodies, promises to be useful in painting on porcelain and glass, or even in dyeing. 64[illegible] Uses.

Sect. XVII. *Of Columbic Acid.*

1. The last of the metallic acids is the columbic, which was discovered by Mr Hatchet in 1801. In the ore from which it was extracted, it is combined with oxide of iron, from which it was separated, by exposing it to a strong red heat, with five times its weight of carbonate of potash. The alkali combined with part of the acid, and from this it was separated by water. By repeatedly fusing the residuum with potash, he separated the whole of the acid from the iron, which latter combined with muriatic acid that was added to it. By treating the alkaline solution with nitric acid, a precipitate of a white, flaky, insoluble substance was obtained. This is the columbic acid. 64[illegible] Discov[ery]. 64[illegible] Preparation.

2. It is of a pure white colour, but not very heavy, and has scarcely any perceptible taste; it is not soluble in boiling water. When some of the powder is placed upon litmus paper, moistened with distilled water, the paper in a few minutes becomes red. When exposed to the blow-pipe, it is not fusible, but only becomes of a less brilliant white. 64[illegible] Proper[ties]. 64[illegible] Action [of] heat.

3. It is dissolved in boiling sulphuric acid, and forms a transparent colourless solution, which is only permanent while the acid is in a concentrated state; for if it be diluted with water, it assumes a milky appearance; a white precipitate is deposited, which, as it dries on the filter, changes when completely dry to a brownish gray. It is then insoluble in water, has no taste, is semitransparent, and breaks with a glossy, vitreous fracture. This compound appears to be formed of the sulphuric and columbic acids. Nitric acid has no effect on the columbic acid *. 64[illegible] Of aci[ds].

* *Phi[l]. Trans.* 1802, [p.] 4[illegible].

Sect. XVIII. *Of Acetic Acid.*

1. Acetic acid, or vinegar, was one of the earliest known. This indeed was to be expected, from the manner 64[illegible] Histo[ry].

manner and the abundance in which it is produced, as it is the first change to which wine and similar liquids are subject. The sourness which exists in these liquids, is owing to the production of this acid. It has different names, according to the state in which it is found. When it is first prepared, it is known under the name of *vinegar;* when purified by distillation, it is called *distilled* vinegar; and when it is strongly concentrated, it is called *radical* vinegar, or *acetic acid.*

2. The process by which vinegar is obtained is the fermenting process of many vegetable matters, what is usually denominated the acetous fermentation, or the second stage of the fermentative process of vegetable matter. The circumstances in which this fermentation takes place are, a temperature between 70° and 80°, the addition of some fermenting substance, and exposure to the air.

The process which is recommended by Boerhaave is generally followed. Two large hogsheads are prepared, by fixing about a foot from the bottom, a grating of rods, on which vine branches are to be placed. The wine to be fermented is poured into the vessels; the one is to be filled to the top, and the other only one half. They are both left exposed to the air. Fermentation begins in the vessel which is half full; when it is completely begun, fill it up from the other vessel, which interrupts the fermentation in the full hogshead, and it commences in that which is half full. When this has continued for a little time, it is filled up from the other vessel, in which the fermentation again commences, and is interrupted in the other.

Thus, the process is carried on by alternately emptying and filling the vessels till vinegar is formed, which generally requires a period of from 12 to 15 days.

3. Vinegar is generally of a yellowish colour, an acid taste, and agreeable smell. It reddens vegetable blues, and when exposed to heat, it is entirely dissipated. The specific gravity varies from 1.005 to 1.0251. It varies considerably in colour, specific gravity, and other properties, according to the substances from which it has been obtained. Vinegar in this state is extremely apt to be decomposed. Scheele has pointed out a very simple process, by which it may be preserved for a long time. Put the vinegar into bottles, and place them over the fire in a vessel filled with water. Let the water boil for a moment, and then take out the bottles, after which it may be kept for several years.

4. To separate the impurities with which vinegar is contaminated, it is distilled with a moderate heat; the temperature must not exceed that of boiling water, and the process should be carried on only till about $\frac{2}{3}$ of the quantity have passed over. This is distilled vinegar, or the acetous acid of the chemists. It is then perfectly transparent and colourless, has an agreeable odour, and a strong acid taste. The vinegar in this state, when exposed to a sufficient degree of cold, is partly frozen. As the ice which is formed consists almost entirely of water, when it is separated the fluid which remains is the vinegar highly concentrated

5. To prepare what has been denominated radical vinegar, a salt, of which this acid forms a component part, must be decomposed. The acetate of copper, or verdigris, is generally employed for this purpose. It is reduced to powder, and distilled in a retort with a strong heat. The liquid which first comes over is insipid and colourless, and must be kept separate from the remaining part of the product, which is the acetic acid in a highly concentrated state. It has generally a green colour, being contaminated with a little copper, but it may be purified by distillation with a moderate heat, by which it is rendered colourless.

653 Acetous and acetic acids supposed to be different.

6. The acid in this state was at first considered by chemists as different from the acetous acid in its properties, affinities, and in the compounds it forms with other bodies. This was the opinion of the celebrated Berthollet, and the same opinion was adopted by almost all chemists. It was supposed that it was the acetous acid in combination with another portion of oxygen, and hence it was denominated, according to the present nomenclature, *acetic acid.*

654 Found to be the same.

7. The nature and properties of these two supposed acids were at last investigated fully by Adet and Darracq, who proved that there was no difference in the proportion of oxygen in the acetous and acetic acids. This conclusion was controverted by Chaptal and Dabit, who endeavoured to support the opinion of Berthollet, that the two acids are distinguished from each other by different properties and different combinations with other bodies. It is now generally admitted, that what have been called the acetous and acetic acids, are essentially the same, their apparent difference depending on the quantity of water, mucilage, and other substances with which the acetous acid is combined.

655 Properties.

8. This acid, when pure, is transparent and colourless. In the state of acetous acid, it has an agreeable, aromatic odour. In the state of acetic acid, or when it is highly concentrated, it acquires a sharp, penetrating odour, different from that of the vinegar, and in this state it is extremely acrid. Applied to the skin it reddens and destroys it. It is highly volatile; and when exposed to the open air, it is soon dissipated. When heated in contact with the air, it inflames.

656 Crystallizes.

9. This acid may be obtained in crystals, by forming distilled vinegar into a paste with charcoal, and subjecting the mixture to a temperature which does not exceed 212°. By this heat the watery part is dissipated, and the acid remains behind; but when a stronger heat is applied, the acid itself is driven off. By repeating the process the acid may be obtained crystallized.

657 Action of heat.

10. Acetic acid undergoes no perceptible change by the action of oxygen, hydrogen, or azotic gases; and it is not altered by charcoal, phosphorus, or sulphur.

658 Of acids.

11. Acetic acid is decomposed by the sulphuric acid. It absorbs carbonic acid, and dissolves boracic acid. It is also decomposed by nitric acid, and is converted into carbonic acid and water. Dr Higgins analyzed the acetic acid by decomposing it in combination with an alkali. He distilled in a glass retort 7680 grs. of acetate of potash, that is, potash combined with acetic acid, and he obtained the following products.

659 Analysis.

Potash, - -	3862.9940
Carbonic acid gas, -	1473.5640
Carbonated hydrogen gas,	1047.6018
Charcoal, - -	0078.0000
Oil, - -	0180.0000
Water, - -	0340.0000
Deficiency, - -	0726.9402

Dr

Acids.

Dr Higgins was at a loss to account for this deficiency, till by repeated experiments he found that it is always owing to the water and oil, and chiefly to the water which is carried off by the elastic fluids. He states the quantity of water carried off in vapour at 700 grs. and the quantity of oil carried off in the same way at 26.9402, which together make up the whole deficiency †. The potash remained behind unaltered; the acetic acid, therefore, has been decomposed, and has yielded the products which were obtained by distillation. But the constituent principles of these products are oxygen, hydrogen, and carbon; and from the proportions of oxygen and carbon which enter into the composition of carbonic acid, the proportions of carbon and hydrogen in carbonated hydrogen gas,
660 Composition. and of oxygen and hydrogen in the composition of water, 100 parts of acetic acid are composed of about,

† Experiments and observations, p. 27.

50	oxygen.
36	carbon,
14	hydrogen.
100	

661 Compounds. 12. The compounds which acetic acid forms with alkalies, earths, and metallic oxides, are denominated *acetates*.

662 Affinities. 13. The order of its affinities is the following:

Barytes,
Potash,
Soda,
Strontites,
Lime,
Ammonia,
Magnesia,
Metallic oxides,
Glucina,
Alumina,
Zirconia.

Sect. XIX. *Of Oxalic Acid.*

663 Found in plants. 1. This acid exists ready formed in the *oxalis acetosella* or wood-sorrel, and some other species belonging to the same genus of plants. From this it derives the name of *oxalic acid*. It was originally denominated the *saccharine acid*, or the acid of sugar, because it was obtained from that substance. Its properties were first particularly investigated by Bergman and Scheele, and the method of preparing it is given by the former.

664 Method of obtaining. 2. An ounce of white sugar in powder is put into a retort, with three ounces of strong nitric acid. During the solution, a great quantity of fumes of the nitrous acid escapes. Apply heat till the liquor boils, and nitrous gas is then driven off. When the liquor in the retort acquires a reddish brown colour, add three ounces more of nitric acid, continue the boiling till the fumes cease, and the colour of the liquor vanishes. Pour out the liquor into a wide shallow vessel; and, when it cools, crystals will be formed in slender four-sided prisms, which may be collected and dried in blotting paper. The crystals thus obtained may be again dissolved in distilled water, and evaporated to obtain new crystals. Oxalic acid may be obtained by a similar process from other vegetables, and from some animal substances, as gum arabic, alcohol and honey.

3. Prepared in this way, oxalic acid is in the concrete state, crystallized in four-sided prisms, terminating in two-sided summits. They are white and transparent, and have a considerable lustre. They have a strong sharp taste, change vegetable blues into a red colour, and produce the same effect on all vegetables except the indigo. 665 Proper

The acid properties of this substance are so strong, that one part of concrete oxalic acid gives to 3600 parts of water, the property of reddening paper stained with turnsole.

4. When oxalic acid is exposed to heat, it is volatilized, partly in a liquid, and also in a solid and crystalline form. It is not decomposed, but at a high temperature; but, when it is exposed to a moderate heat, it dries, is covered with a white crust, and is soon reduced to powder. It loses $\frac{3}{10}$ of its weight when put upon burning charcoal; it exhales a pungent, irritating smoke, and there remains behind a white alkaline residue. 666 Action heat.

5. This acid is deliquescent in the air, when it is loaded with moisture. Cold water dissolves about $\frac{1}{2}$ its weight of the acid; boiling water dissolves a quantity equal to its own weight. 667 Of wat

6. Oxalic acid is decomposed by the sulphuric acid with the assistance of heat, and charcoal is deposited; at the boiling temperature it is decomposed by the nitric acid, and converted into water and carbonic acid. According to Fourcroy, the component parts of oxalic acid, as they have been ascertained by him and Vauquelin, are 668 Composition.

77	oxygen,
13	carbon,
10	hydrogen.
100*	

* Conn. Chim. vii. p. 66

7. Oxalic acid combines with the alkalies, earths, and metallic oxides, and the salts thus formed are distinguished by the name of *oxalates*. 66 Compound

8. The affinities of this acid are in the following order: 66 Affinit

Lime,
Barytes,
Strontites,
Magnesia,
Potash,
Soda,
Ammonia,
Alumina.

Sect. XX. *Of Tartaric Acid.*

1. This acid was procured by Scheele in a separate state, in the year 1770, the process for which he communicated to M. Retzius, who published the account of it in the Swedish Memoirs for that year. It was the first discovery in the bright career of that distinguished chemist. 67 Histo

2. The process which he followed was by boiling a quantity of the substance called *tartar*, or *cream of tartar*, 6 Preparation.

tartar, in water, and adding powdered chalk till effervescence ceases, and the liquid no longer reddens vegetable blues. It is then allowed to cool; the liquor is filtered; and a white insoluble powder remains on the filter, which is carefully removed and well washed. This is put into a matrass, and a quantity of sulphuric acid, equal in weight to the chalk employed, diluted with water, is poured upon it. The mixture is allowed to digest for 12 hours on a sand bath, stirring it occasionally with a glass rod. The sulphuric acid combines with the lime, and forms a sulphate of lime, which falls to the bottom. The liquid contains the tartaric acid dissolved in it. This is decanted off, and a little acetate of lead is dropt into it, as a test to detect the sulphuric acid, should any remain. With it it forms an insoluble precipitate; and if this be the case, it must be digested again with more *tartrate of lime*, to carry off what remains of the sulphuric acid. It is then evaporated, and about $\frac{1}{3}$ of the weight of tartar employed is obtained, of concrete tartaric acid. To purify this, the crystals may be dissolved in distilled water, and again evaporated and crystallized. It seems probable, Fourcroy observes, that this acid exists in a state of purity in some vegetables. Vauquelin has found a 64th part in the pulp of the tamarind.

672 Crystals. 3. Tartaric (or tartarous) acid, thus obtained, is in the form of very fine needle-shaped crystals; but they have been differently described by different chemists. According to Bergman, they are in the form of small plates attached by one extremity, and diverging at the other. They have been found by others grouped together in the shape of needles, pyramids, regular six-sided prisms, and square and small rhomboidal plates. The specific gravity is 1.5962.

673 Properties. 4. This acid has a very sharp, pungent taste; diluted with water, it resembles the taste of lemon juice; and it reddens strongly blue vegetable colours.

674 Action of heat. 5. When it is exposed to heat on burning coals, it melts, blackens, emits fumes, froths up, and exhales a sharp, pungent vapour. It then burns with a blue flame, and leaves behind a spongy mass of charcoal, in which some traces of lime have been detected. Four ounces of the concrete crystallized acid, carefully distilled, gave the following products *:

Cub. In.	
431	carbonic acid gas,
120	carbureted hydrogen gas.

* Fourcroy Connaiss. Chim. tom. vii. 255.

675 Action of heat. 6. In the decomposition of tartaric acid by heat, one of the most remarkable products which particularly characterizes it, is an acid liquid of a reddish colour, which amounts to one-fourth part of the weight of the former. This was formerly known by the name of pyrotartarous acid. It has a slightly acid taste, produces a disagreeable sensation on the tongue, is strongly empyreumatic, and reddens the tincture of turnsole. But it has been found by the experiments of Fourcroy and Vauquelin, to be the acetic acid impregnated with an oil † (Q).

† Ann. de Chim. tom. xxxv. p. 161.

7. Tartaric acid is very soluble in water. The specific gravity of a solution formed by Bergman, was found to be 1.230. This solution in water is not soluble to spontaneous decomposition, unless it is diluted. While it is concentrated, it loses nothing of its acid nature or its other properties. 676 Water.

8. Bergman supposed that tartarous acid could not be changed by the strongest mineral acids, and more especially by the nitric; but Hermstadt has succeeded in converting it into oxalic acid by several successive distillations, with six times its weight of nitric acid. Three hundred and sixty parts of tartaric acid yielded 560 parts of oxalic acid, which shews that it had combined with a great additional proportion of oxygen ‡. 677 Converted into oxalic.

‡ Fourcroy Connaiss. Chim. tom. vii. p 256.

9. According to the analysis of Fourcroy and Vauquelin, 100 parts of this acid are composed of 678 Composition.

70.5 oxygen,
19.0 carbon,
10.5 hydrogen.

100.0

10. The affinities of this acid are in the following order: 679 Affinities.

Lime,
Barytes,
Strontites,
Magnesia,
Potash,
Soda,
Ammonia,
Alumina.

Sect. XXI. *Of Citric Acid.*

1. The sour acid or taste of the juice of lemons and oranges is well known. This is *nitric acid*, but it is mixed with water and mucilage; and various processes have been proposed to obtain it in a state of purity. 680 Found in fruits.

2. The first which succeeded was proposed by M. Georgius, an account of which was published in the Swedish Memoirs for the year 1774. His process was the following. It consisted in filling bottles with lemon juice, shutting them up close, and placing them for some time in a cellar to separate the mucilage. He afterwards exposed it to a temperature of about 24°; the watery part froze, and carried with it a portion of mucilage. This was removed, and the liquid part which remained was again frozen, till the solid part had a perceptible acid taste. The juice thus reduced to one-eighth part of its original bulk, is eight times stronger, and requires the same quantity of potash for saturation. In this state of concentration it was preserved. 681 Preparation.

3. But in this state it is not pure. We are indebted to Scheele for the discovery of the process by which it is obtained in a state of purity, and for ascertaining the 682 Process of Scheele.

(Q) The pyromucous and the pyroligneous acids are to be regarded in the same light. The peculiar properties which were supposed to distinguish them from other acids were found by the same philosophers to be owing to a similar impregnation.

Acids. the characters by which it is distinguished from tartaric acid, with which it was formerly confounded. Lemon juice which has been filtered, is saturated with powdered chalk. While the chalk is added, an effervescence takes place, which is owing to the combination of the citric acid with the lime, and the separation of the carbonic acid from it in the state of gas. When the effervescence ceases, a white powder falls to the bottom. This is the lime combined with the citric acid. Wash this powder with warm water till it passes off colourless, then put the salt which has been washed into a matrass with a little water. Take such a quantity of concentrated sulphuric acid, diluted with six or seven parts of water, as may be necessary to saturate the lime which has been employed; boil it for a few minutes, then let it cool, and filter the liquor. The sulphate of lime, formed by the decomposition of the calcareous citrate, remains upon the filtre. The filtered liquor contains the pure citric acid, which is to be evaporated to the consistence of a syrup,[s] and to be set by in a cool place to crystallize. The citric acid is thus obtained in small crystals.

683 Excess of acid to be added. Scheele thinks that is necessary to add a small excess of sulphuric acid, to take up the whole of the lime from the citric acid. But Dizè is of opinion that this excess of sulphuric acid is only necessary, to destroy the remaining portion of mucilage which adheres to the citric acid, and thus to separate from it every extraneous substance *.

684 Supposed to be unnecessary. But it has been observed, that when an excess of sulphuric acid is employed, it may act upon the citric acid itself, decompose it, and produce the black matter which was supposed to be owing to the mucilage which adhered to it. And it appears, from an investigation by Proust on the preparation of this acid, that when too much sulphuric acid is employed, it decomposes the citric acid, and prevents it from crystallizing. To prevent this, a small quantity of chalk is added. He found that four ounces of chalk were necessary for the saturation of 94 ounces of lemon juice, and that the product which he obtained amounted to $7\frac{1}{2}$ ounces of citrate of lime; and to decompose this, he added 20 ounces of diluted sulphuric acid †.

* *Fourcroy, Connaiss. Chim.* tom. vii. p. 204.

† *Journ. de Phys.* iii.

685 Properties. 4. When citric acid is pure, it crystallizes in rhomboidal prisms, whose sides are inclined to each other at angles of 60° and 120°, terminating at each end in four trapezoidal faces, which include the solid angles. By slow cooling of large quantities of the solution of the pure acid, evaporated to the consistence of syrup, Dizè obtained very fine crystals.

5. Citric acid has a very strong acid taste, and even seems to be caustic; but when it is diluted with water, the taste is cooling and agreeable. It has a very slight odour of lemons, and it reddens blue vegetable colours.

686 Action of heat. 6. When exposed to heat, it melts rapidly in its own water of crystallization. When the solid acid is put upon burning coals, it quickly fuses, froths up, exhales a sharp penetrating vapour, and is reduced to the state of charcoal. Distilled in a retort, it is partly disengaged without decomposition, seems to be converted partly into vinegar, and then yields carbonic acid gas, carbonated hydrogen gas, and there remains in the retort a mass of light charcoal.

2

7. Exposed to the air, it effloresces in a dry, warm atmosphere; but when the air is moist, it absorbs water, and loses its crystalline form. It is very soluble in water. Seventy-five parts of water dissolve 100 of the acid. 687 Water.

8. Sulphuric acid, when concentrated, converts it into acetic acid. It is also decomposed by the nitric acid, which converts it partly into oxalic acid, but the greater proportion into acetic acid. 688 Acids.

9. From the experiments which have been made with this acid, by decomposing it by means of other acids, and the products which it affords, and its conversion into acids whose component parts are known, it seems to be pretty certain that oxygen, hydrogen, and carbon enter into the composition of citric acid. 689 Composition.

10. This acid enters into combination with alkalies, earths, and metallic oxides, and forms salts which are denominated *citrates*. 690 Compounds.

11. The affinities of citric acid are the following: 691 Affinities.

Lime,
Barytes,
Strontites,
Magnesia,
Potash,
Soda,
Ammonia,
Alumina,
Zirconia.

Sect. XXII. *Malic Acid.*

1. Malic acid is found in considerable proportion in the juices of a great number of fruits. In them it exists ready formed, and particularly in the juice of apples, from which it has derived its name. In some fruits it exists in small quantity, mixed with a great proportion of citric acid, as in two species of *vaccinium*, *oxycoccos* and *vitis idæa*, *prunus padus*, and *solanum dulcamara*. These acids are found in nearly equal proportions in some other fruits, as in the gooseberry, cherry, and strawberry; but it exists in greatest abundance, and in the greatest purity, in the juice of apples. 692 History.

2. It is prepared by the following process, which was discovered by Scheele. Bruise a quantity of sour apples, express the juice, and filter it through a linen cloth. Saturate this juice with potash, add to the solution acetate of lead (sugar of lead) dissolved in water, and continue the addition till there is no more precipitation. The acetic acid combines with the potash, and remains in the liquid, while the malic acid unites with the lead, and being insoluble, falls to the bottom. Wash the precipitate with water, and pour upon it diluted sulphuric acid. The sulphuric acid combines with the lead, and forms an insoluble salt, which falls to the bottom. The malic acid remains uncombined in the liquid. Care should be taken to add a sufficient quantity of the sulphuric acid to separate the whole of the malic acid from the lead, which may be known by the pure acid taste unmixed with the sweet taste of the salt of lead. 693 Method of preparing it.

3. When this acid is mixed with citric acid, as is the case in the juices of many fruits, Scheele contrived the 694 Of separating it from cit

ds. the following process to separate them. The juice is first evaporated to the consistence of honey; alcohol is poured upon it, by which the two acids are dissolved, and a great quantity of mucilage is separated; the alcohol is then evaporated; the residue after evaporation is diluted with two parts of water, and saturated with chalk, which combines with both the acids. The citrate of lime, which is the least soluble, is separated by evaporation; the malate of lime, or the combination with the malic acid, may be also separated, by adding another portion of alcohol, which does not dissolve the salt, but a saccharine matter which had combined with the malate of lime. The malic acid may then be separated as before, with the solution of the sugar of lead.

5 Ob..ed fro..ouse-leel 4. Vauquelin has extracted a very pure and nearly colourless malic acid from the juice of house-leek, (*sempervivum tectorum*, Lin.) It exists in this juice combined with lime. He extracted it by evaporating the juice, pouring alcohol upon the residue to separate a small quantity of sugar which it contained, and by adding to the remaining matter an equal weight of concentrated sulphuric acid, previously diluted with seven or eight times the quantity of water. But as some traces of sulphate of lime are always found in the malic acid prepared in this way, he prefers the following method.

Add to the juice a solution of sugar of lead; a precipitate is formed, which is to be decomposed by means of diluted sulphuric acid *.

5 Pro..ties. 5. Malic acid, thus obtained, is a reddish brown liquid, of a pungent acid taste, leaving afterwards the sensation of sweetness. It reddens blue vegetable colours. It never assumes a crystalline form, but becomes thick and viscid like syrup; and when exposed to dry air, it dries in thin strata like a brilliant varnish, for which purpose it might be employed on polished surfaces †.

7 Act.. of hea. 6. Malic acid is very readily decomposed by heat. It becomes of a dark colour, swells up, exhales a thick acrid vapour in the open air, and leaves behind a bulky mass of coal. When distilled in a retort, it yields an acid water, a great deal of carbonic acid gas, a little carbonated hydrogen gas, and a light spongy coal.

3 De..po-sed ..n-tan..sly 7. It is spontaneously decomposed in the vessels in which it is kept; undergoes a kind of vinous fermentation, and deposits a mucous, flaky substance. This decomposition is owing to the intimate re-action of its constituent parts.

) by ..ic aci.. 8. All the strong acids decompose it. Concentrated sulphuric acid chars it; and it is converted into oxalic acid by nitric acid. Scheele discovered, that mucous matters treated with nitric acid, passed to the state of malic acid, or were converted into this acid, and into oxalic acid.

) Pro..tion of i..on-stit..ts unk..vn, 9. The proportions of the constituent parts of this acid have not been ascertained; but from its decomposition, and the products which are thus obtained, it is obvious that it is composed of oxygen, hydrogen, and carbon, of which the latter is supposed to be in great proportion.

and ..o its ..i-ties. 10. The affinities of this acid are not determined. The compounds which it forms with alkalies, earths, and metallic oxides, are denominated *malates*.

11. It is very soluble in water.

Acids.

Sect. XXIII. *Of Gallic Acid.*

1. This acid exists most abundantly in a well known substance, *nut galls*, and hence it has obtained the name of gallic acid. It is also found in the bark and wood of many other plants. It was first examined by the academicians of Dijon in 1772, and its acid properties clearly ascertained; but it is to Scheele that we are indebted for the discovery of the process by which it may be obtained pure and crystallized. The account of this process was published in 1780, which is the following. 702 History.

2. To one part of nut galls, reduced to a coarse powder, add six parts of pure water. Let the infusion macerate for 15 days at the temperature of between 70° and 80°; filter it, and put the liquid into a large glass or earthen vessel, expose it to the air, and allow it to evaporate slowly. A thick glutinous pellicle forms on the top; a great quantity of mucous flakes are precipitated, and the solution has no longer an astringent, but a perceptibly acid taste. At the end of two or three months, Scheele had observed on the sides of the vessels in which the solution was contained, a brown crust covered with shining crystals of a yellowish gray colour. He found also a great quantity of these crystals under the thick pellicle which covered the liquid. He then decanted it, and added alcohol to the precipitate, the pellicle and the crystalline crust, and applied heat. The alcohol dissolved the crystallized acid, without touching the mucilage. The solution was now evaporated, and the gallic acid was obtained pure, in small shining crystals of a yellowish gray colour. 703 Preparation.

3. Deyeux has pointed out another method, by which, with proper precautions, gallic acid may be more readily obtained. He introduces into a large glass retort, a quantity of nut galls reduced to powder, and applies heat slowly and cautiously, by which he obtains a large quantity of laminated, brilliant, silvery crystals, sufficiently large, and which have all the properties of gallic acid. But in following this process, it is necessary to observe, that the heat must be very moderate, and not continued till an oil is disengaged, which instantly disolves all the crystals sublimed before its appearance *. 704 Another process.

4. Sir H. Davy prepares it by boiling together for some time carbonate of barytes, and a solution of gall nuts. This affords a bluish green liquor. When diluted sulphuric acid is dropt into it, it becomes turbid; sulphate of barytes is deposited, and after filtration, if the saturation of the earth be complete, a colourless solution of gallic acid, apparently pure, is obtained †. 705 Davy's.

5. Gallic acid is crystallized in transparent octahedrons, or brilliant plates; it has a sharp, pungent, and austere taste, but less strong and astringent than that of the gall nut. 706 Properties.

6. This acid is not sensibly affected by exposure to the air. It requires 24 parts of cold water, and about two-thirds of its weight in boiling water, to dissolve it, from which it can only be crystallized by a very slow evaporation. 707 Action of water.

7. With a moderate heat, it rises into vapour, which on cooling is condensed and crystallized. In the state of vapour, it has a sharp, aromatic odour, resembling that 708 Of heat.

* *Connaiss. Chim.* viii. p. 181.

† *Journ. Roy. Inst.* vol. i. p. 274.

Acids. that of the benzoic acid. Every time that it is sublimed, even with a moderate heat, it is partially decomposed; water is formed, an acid liquid, carbonic acid gas, carbonated hydrogen gas, and some drops of a brown coloured oil; and there remains behind, a great quantity of coaly matter.

709 Of acids. 8. Concentrated sulphuric acid decomposes and chars the gallic acid. Nitric acid converts it into the malic and oxalic acids. Oxymuriatic acid produces peculiar changes on the gallic acid, but these have not been distinctly ascertained †.

† *Fourcroy, Connaiss. Chim.* tom. vii. p. 183.

710 Of metallic oxides. 9. Although we have not yet treated of metallic substances, it may be necessary to anticipate a little, and mention the effects of gallic acid on metallic oxides. This indeed is its chief characteristic. On this account, it is much employed by chemists, to discover metallic substances, which are held in solution along with other bodies. Its effects on the metallic oxides are extremely various, and with different metals it affords different coloured precipitates. The more readily the metallic oxides give up their oxygen, the greater is the change produced by the gallic acid. On some metallic solutions it has no effect; such are, solutions of platina, of zinc, of tin, of cobalt, and of manganese. The precipitates of the different metals produced by means of gallic acid, exhibit the following colours:

Gold,	Brown.
Silver,	Brown.
Mercury,	Orange-yellow.
Copper,	Brown.
Bismuth,	Citron-yellow.
Iron,	Black.
Lead,	White.
Nickel,	Gray.
Antimony,	White.
Tellurium,	Yellow.
Uranium,	Chocolate.
Titanium,	Reddish-brown.
Chromium,	Brown.
Columbium,	Orange.

711 Composition. 10. The component parts of gallic acid are the same as those of the other vegetable acids, but having a greater proportion of carbon; but these proportions have not been ascertained.

712 Compounds. 11. The compounds which the gallic acid forms with alkalies, earths, and metallic oxides, are denominated *gallates*.

713 Affinities. 12. The affinities of this acid have not been ascertained.

Sect. XXXIV. *Of Benzoic Acid.*

714 History. 1. Benzoic acid is obtained from several plants, and particularly from the *styrax benzoë*, a tree which grows in Sumatra; from the balsam of Peru and Tolu; from vanilla, and liquid amber. It also exists in the urine of children, and sometimes in that of adults, but constantly in the urine of quadrupeds which live on grass and hay, especially in that of the horse and cow. It is suspected also that it exists in many of the grasses, and that it is derived from them by means of the aliment to the urine of the animals in which it is found. Fourcroy and Vauquelin suspect that it exists in the sweet-scented grass, (*anthoxanthum odoratum*, Lin.) which gives the fine flavour to hay ‡.

‡ *Fourcroy, Connaiss. Chim.* tom. vii. p. [illegible]

The first mention of benzoic acid is made by Blaise de Vigenere, who wrote about the commencement of the 17th century (R). He says, that he obtained by distilling benzoin, an acid salt which crystallized in needles, of a penetrating odour. It was then called *flowers of benzoin*, but at present *benzoic acid*.

715 Preparation. 2. To obtain this acid by the most common process, put into an earthen pot a quantity of benzoin grossly powdered. Cover the vessel with a cone of paper, and apply a very gentle heat. The benzoic acid is sublimed, and attaches itself to the sides of the cone, which may be renewed every two hours. Continue the process till the acid sublimed begins to be coloured by the oil which is disengaged. By a process proposed by Geoffroy, the benzoin reduced to a powder is digested in warm water, and this being filtrated, yields on cooling needle-shaped crystals of benzoic acid; but the quantity obtained in this way is very small, which led Scheele to adopt the following process. He took 1 part of quicklime, to which were added 3 parts of water, and afterwards about 30 parts more, which is then to be gradually mixed with 4 parts of powdered benzoin. Heat the whole on a moderate fire for half an hour, continually agitating the mixture; then remove it from the fire, and let it remain at rest for several hours. Decant the clear supernatant liquor, and add 8 parts more water to the residuum. Boil it for half an hour, and mix it with the former. Reduce the liquor by evaporation to two parts; add drop by drop, to a slight excess, muriatic acid, which causes the benzoic acid to precipitate, by separating it from the lime. Wash the precipitate well on a filter; and to obtain it in crystals, dissolve it in 5 or 6 times its own weight of boiling water, which, on cooling, yields crystals in the form of long compressed prisms.

716 Properties. 3. Pure benzoic acid is either in the form of a light powder, perceptibly crystallized, or in the form of very small needles, of which it is extremely difficult to determine the shape. It is white and brilliant, and has some degree of ductility and elasticity. It has an acrid, pungent, acidulous, and very bitter taste. In the cold the odour is slight, but is aromatic, and this is sufficient to characterize it. It reddens the tincture of turnsole, but has no effect on the syrup of violets. The specific gravity of benzoic acid is 0.667.

717 Action of heat. 4. Exposed to a moderate heat, it melts, forms a soft brown and spongy body, which cools into a solid crust, exhibiting on the surface some appearance of crystallization. With a stronger heat it is sublimed, and exhales a white acrid vapour, which affects the eyes. It burns when brought into contact with flame, and the whole is consumed without any residuum. When it is distilled in close vessels, great part sublimes unchanged, but part is decomposed and yields a viscid liquid, a considerable quantity of oil, and a much greater quantity of carbonated hydrogen gas than any other

(R) *Traité du feu et du sel*, which was printed at Paris in 1608.

ids other body of this nature. A very small portion of coaly matter remains in the retort.

18 ater. 5. It is not sensibly changed by exposure to the air. It is scarcely soluble in cold water. Four hundred parts of boiling water dissolve 20 parts of the acid, 19 of which are separated on cooling.

19 ids. 6. Concentrated sulphuric acid readily dissolves this acid, and one part of the sulphuric acid passes into the state of sulphurous acid. Benzoic acid may be separated from this solution without having undergone any change, by adding water. The nitric acid dissolves it in the same way, and it is also separated by means of water. Guyton found, by distilling nitric acid on the concrete benzoic acid, that nitrous gas was disengaged, only towards the end of the process, and that the acid itself then sublimed without alteration.

20 osi-. 7. As this acid yields by distillation oil and carbonated hydrogen gas, it is obvious that it must be composed of carbon and hydrogen, and probably also oxygen, although this latter has not been discovered in any experiments that have been made on this substance.

21 ls. 8. Benzoic acid unites very readily with alkalies, earths, and metallic oxides, and the compounds which are thus formed are denominated *benzoates*.

22 ties. 9. The order of the affinities of benzoic acid is the following:

White oxide of arsenic,
Potash,
Soda,
Ammonia,
Barytes,
Lime,
Magnesia,
Alumina.

Sect. XXV. *Of Succinic Acid.*

23 ry. 1. Succinic acid, formerly called volatile salt of amber, was long regarded as an alkaline salt. It was not till towards the end of the 17th century, that its acid properties were discovered. As amber, the substance from which the acid is obtained, is found in considerable quantity under strata of substances which contained pyrites, it was thought that this acid was formed by sulphuric acid. This was the opinion of Hoffman and Neuman. Amber is found on the sea-coast of different countries, especially in the Prussian territory on the shores of the Baltic. The name of the acid is derived from *succinum*, the Latin name for this substance.

24 ra. 2. Succinic acid may be obtained by the following process. Introduce a quantity of amber in powder into a retort, and let it be covered with dry sand. Adapt a receiver, and distil with a moderate heat in a sand bath. There passes over first a liquid which is of a reddish colour, and afterwards a volatile acid salt, which crystallizes in small, white, or yellowish needles in the neck of the retort; and if the distillation be continued, a white light oil succeeds, which becomes brown, thick, and viscid. The acid which is obtained in this way is contaminated with the oil; and therefore to separate this oil, it may be dissolved in hot water, and passed through a filter on which has been placed a little cotton moistened with oil of amber, which retains the oil, and prevents it from passing through along with the acid. The acid may then be evaporated and crystallized. Guyton has observed, that the acid may be rendered quite pure, by distilling off it a sufficient quantity of nitric acid, but with this precaution, that the heat employed is not strong enough to sublime the succinic acid *.

* *Ann. de Chim.* tom. xxx. p. 162.

3. The acid thus obtained is in the form of white, shining, transparent crystals, which are foliated, triangular, and prismatic. The taste is acid, but not corrosive. It reddens the tincture of turnsole, but has no effect on the infusion of violets. 725 Properties.

4. With the heat of a sand bath, the crystals of succinic acid first melt, and are then sublimed and condensed in the upper part of the vessel. There is, however, a partial decomposition, for there is a coaly matter left behind in the vessel. 726 Action of heat.

5. At the temperature of 212°, two parts of water dissolve one of this acid, which crystallizes on cooling. When the water is cold at the temperature of 50°, it requires 96 parts of water to dissolve one of the acid. 727 Of water.

6. This acid, like other vegetable acids, is composed of oxygen, hydrogen, and carbon; for when it is distilled in a retort with a strong heat, carbonic acid gas and carbonated hydrogen gas are evolved, and charcoal remains behind in the retort. The proportions of the component parts have not been ascertained. 728 Composition.

7. This acid enters into combination with alkalies, earths, and metallic oxides, and forms with them compounds, which are denominated *succinates*. 729 Compounds.

8. The affinities of this acid are in the following order: 730 Affinities.

Barytes,
Lime,
Potash,
Soda,
Ammonia,
Magnesia,
Alumina,
Metallic oxides.

Sect. XXVI. *Of Saclactic Acid.*

1. To this acid Fourcroy has given the name of *Mucous acid*, because it is obtained from gum arabic and other mucilaginous substances; and it was formerly called *acid of sugar of milk*. This latter name it received from Scheele, who discovered it in the year 1780, while he was employed in making experiments on the sugar of milk, in order to obtain from it oxalic acid, which he procured from sugar. 731 History.

2. This acid may be obtained by the following process. To 1 part of gum arabic, or other mucilaginous substance, add 2 parts of nitric acid in a retort, and apply a gentle heat. There is at first disengaged a little nitrous gas and carbonic acid gas, after which let the mixture cool. There is then precipitated a white powder which is slightly acid. This powder is the saclactic acid. 732 Preparation.

3. Thus obtained, saclactic acid is in the form of a white powder, a little gritty, and with a weak acid taste. 733 Properties.

4. It is readily decomposed by heat, and yields an acid liquor which crystallizes by rest in the shape of needles, 734 Action of heat.

needles, a small quantity of an acrid caustic oil, of a blood-red colour, carbonic acid gas, and carbonated hydrogen gas; and there is left behind a considerable quantity of coaly matter. It is partly sublimed in needles or brown plates, with an odour similar to that of benzoic acid †.

† Fourcroy Connaiss. Chim. tom. vii. p. 147.

735 Of water.

5. Saclatic acid in the state of powder is not very soluble in water. Cold water does not take up more than 200 or 300 parts of its weight; boiling water does not take up above one half more. On cooling, the acid is deposited in brilliant scales, which become white in the air. The solution has an acid taste. It reddens the tincture of turnsole. Its specific gravity at the temperature of 59° is 1.0015 ‡.

‡ Encyc. Method. i. p. 290.

736 Compounds.

6. This acid enters into combination with earths, alkalies, and metallic oxides; and the salts which it forms are known by the name of *saccolates*.

737 Affinities.

7. The order of its affinities, according to Bergman, is the following:

Lime,
Barytes,
Magnesia,
Potash,
Soda,
Ammonia,
Alumina,
Metallic oxides.

Sect. XXVII. *Of Camphoric Acid.*

738 History.

1. This acid is obtained, as the name imports, from *camphor*, a concrete substance procured from a species of laurel (*Laurus camphora*, Lin.) which is a native of the East Indies.

739 Preparation.

2. Camphoric acid was first obtained by Kosegarten, by distilling nitric acid 8 times successively off camphor. This experiment was repeated by Bouillon Lagrange with the same result. He introduced into a glass retort, 1 part of camphor, and he poured over it 4 parts of nitric acid. A receiver was adapted to the retort, and the joinings were well luted. The retort was placed on a sand-bath, and a gradual heat was applied. A great deal of nitrous gas and carbonic acid gas was disengaged. One part of the camphor is sublimed, and another part seizes on the oxygen of the nitric acid. The same process must be repeated till the whole of the camphor is acidified, which is known by its crystallizing when the liquor cools which remains in the retort. These crystals are camphoric acid. To purify it, it must be dissolved in distilled warm water, and the liquor is then to be filtered and evaporated to nearly half its volume, or till a thin pellicle is formed on it. When it cools, crystals of pure camphoric acid will be obtained.

740 Properties.

3. Camphoric acid has a slightly acid, bitter taste. It reddens the tincture of turnsole. The crystals resemble, when, in a mass, those of the muriate of ammonia. Exposed to the air the mass effloresces.

741 Action of water.

4. Cold water dissolves this acid with great difficulty. An ounce of water at the temperature of between 50° and 60°, cannot dissolve more than 6 grs. while water at the boiling temperature will hold in solution eight times that quantity.

742 Of heat.

5. When this acid is put upon burning coals, it exhales a dense, aromatic vapour; with a less degree of heat, it melts, and is sublimed. When put into a heated porcelain tube, and if a stream of oxygen gas be passed through it, the acid remains unchanged, but it is sublimed from the sides of the tube. When distilled alone, it first melts and then sublimes. This sublimation produces some change in its properties. It no longer reddens the tincture of turnsole, and acquires a strong aromatic odour, and a less pungent taste; becomes insoluble in water, and in the sulphuric and muriatic acids. The nitric acid heated, makes it yellow, and dissolves it *.

* Annal. Chim. t. xxiii. p. 1

743 Compounds.

6. Camphoric acid enters into combination with the alkalies, earths, and metallic oxides, and the compounds thus formed are denominated *camphorates*.

744 Affinities.

7. The affinities of this acid are the following †:

† Ibid. xxvii. p.

Lime,
Potash,
Soda,
Barytes,
Ammonia,
Alumina,
Magnesia.

Sect. XXVIII. *Of Suberic Acid.*

745 History.

1. This acid is obtained from cork, a well-known substance, which is the bark of a tree (the *quercus suber* Lin. or cork-tree). From the Latin name of this substance, *suber*, the name of the acid is derived, and hence it is called *suberic acid*. The acid which is obtained from cork, by treating it with nitric acid, was supposed to be the oxalic acid, on account of possessing some common properties, and particularly that of forming with lime an insoluble salt. But the experiments of Bouillon Lagrange have shewn, that this is a peculiar acid.

746 Preparation.

2. This acid is obtained by the following process. Take a quantity of clean cork, grated down. Introduce it into a retort, and pour on it six times its weight of nitric acid; the acid ought not to be too concentrated. It is then to be distilled with a moderate heat. The cork swells up and becomes yellow, and there is disengaged a quantity of red vapours; and as the distillation goes on, the cork is dissolved, and swims on the surface like foam. If this scum is not formed, the cork has not been acted upon by the acid. In this case, when the distillation begins to stop, return into the retort the acid which had passed over into the receiver, and distil as long as any red vapours appear, and then immediately remove the retort from the sand bath, and pour out the contents while yet hot into a glass or porcelain vessel; put it into a sand bath and apply a gentle heat, stirring it constantly with a glass rod. The matter gradually thickens, and as soon as white vapours are disengaged, which excite a tickling in the throat, it is to be removed from the sand bath, and constantly stirred till the mass is nearly cold. In this way a substance is obtained of the consistence of honey, of an orange-yellow colour, of a sharp penetrating odour while it is warm, but which gives out a peculiar aromatic smell when it is cold.

To procure the acid which is contained in this substance, put it into a matrass, and pour upon it double its

its weight of distilled water. Apply heat till the mass becomes liquid, and separate by filtration that part which is insoluble in water. The liquor which is obtained is of a clear amber colour, and of a peculiar odour. The filtered liquor on cooling becomes muddy, is covered with a thin pellicle, and deposits a powdery sediment. The precipitate is to be separated from the liquid by filtration, and it is to be dried with a gentle heat. This precipitate is the suberic acid. The remaining liquor is then to be evaporated to dryness with a moderate heat, to obtain the whole of the acid which it holds in solution.

The acid which is prepared by this process is a little coloured, and may be purified, either by saturating the suberic acid with potash, and precipitating with an acid, or by boiling it with charcoal powder.

[..]7 Pr[ope]rties. 3. Suberic acid is in the solid form, but it is not crystallized. When it is obtained by precipitation, it is in the state of a powder, and by evaporation it is in the form of thin irregular pellicles.

4. It has a slightly bitter and acid taste. Dissolved in a small quantity of boiling water, it tickles the throat, and excites coughing. It reddens vegetable blues.

[..]8 Ac[tion] of ligh[t]. 5. Exposed to the light, it becomes brown after a certain time; but this effect is more speedily produced when it is exposed to the sun's rays. Heated in a matrass, the suberic acid is sublimed, and the glass remains marked with zones of different colours. If the sublimation be stopped in time, the acid is obtained on the sides of the vessel, in small points formed of concentric circles. When exposed to the heat of the blowpipe on a spoon of platina, it first melts, then falls down into a powder, and at last is totally dissipated by sublimation.

[..]9 Of [hea]t.

[..]0 Of [aci]ds. 6. It undergoes no change from the action of oxygen gas. The action of the acids on suberic acid is very weak. The solution is not complete, especially when it is impure.

[..]1 Of [wat]er. 7. Water at the temperature of 60° or 70° dissolves the concrete acid only in the proportion of 10 grs. to the ounce. When the acid is very pure, the water will not dissolve more than 4 grs. Boiling water dissolves half its weight; but as the liquor cools, it becomes muddy, and the acid is deposited*.

[..]2 Co[m]pou[nds]. 8. This acid combines with the alkalies, earths, and metallic oxides, and forms with them compounds which are known by the name of *suberates*.

[..]3 Affi[niti]es. 9. The order of its affinities is the following †:

Barytes,
Potash,
Soda,
Lime,
Ammonia,
Magnesia,
Alumina,
Metallic oxides.

* [Ann]al. de Chi[m.] tom. xxi[.] p. 42.

† I[..] p. 57.

Sect. XXIX. *Of Mellitic Acid.*

[..]4 Dis[cov]ery. 1. The acid is procured from a mineral substance which was discovered about the year 1790. Werner gave it the name of *honigstein*, (honeystone) from its colour. By other mineralogists it has been denominated mellite, from the Latin name of honey, and hence the acid which it affords has been called *mellitic* acid. The mineral from which this acid is obtained seems to be of vegetable origin. It is found in small crystals among the layers of wood coal at Arten in Thuringia. In the first analysis to which this mineral was subjected, no new acid was detected. But in the year 1799 the acute and accurate Klaproth examined its nature and component parts, and found that it is a compound of a peculiar acid and alumina. His experiments have been since repeated by Vauquelin, and the result of his analysis has been fully confirmed.

2. It is procured from mellite by the following process. The mineral is to be reduced to powder, and boiled with about 72 times its weight of water. The alumina is precipitated in the form of flakes, and the acid combines with the water. By filtration and evaporation, crystals are deposited, which are the crystals of mellitic acid. 755 Process for obtaining.

3. This acid crystallizes in the form of fine needles, or in small short prisms with shining faces. They are considerably hard. It has a slightly acid taste, accompanied with some degree of bitterness. 756 Properties.

4. This acid has very little solubility in water, but it has not been ascertained to what degree; or what proportion of water it requires for its solution. 757 Action of water.

5. A small quantity of this acid, exposed to the flame of the blow-pipe, at first gave out sparks like nitre; and then swelled up, and left a matter which penetrated the charcoal. Heated in a crucible of platinum, it swells up at first, is then charred, without the production of any oily vapour, and leaves behind a light coaly alkaline matter*. 758 Of heat.

6. When the nitric acid is added to this acid, it produces no other change than giving it a yellowish colour. It has not yet converted it into any of the vegetable acids, to which it is nearly allied in its properties and constituent parts. 759 Of acids.

7. According to Klaproth's analysis the mineral from which the acid is obtained consists of 760 Composition.

46	metallic acid,
16	alumina,
38	water.
100	

When it was distilled in a retort the acid was completely decomposed; and the products obtained by Klaproth in this way from 100 grains of mellite were the following:

54 cubic inches of	carbonic acid gas,
13	hydrogen gas,
38 grs. of	acidulous water,
1	aromatic oil,
9	charcoal,
16	alumina.

The constituent parts of mellitic acid are obviously carbon, hydrogen, and oxygen. But the proportions have not been ascertained.

8. Mellitic acid enters into combination with the earths, alkalies, and metallic oxides, and forms compounds with them which are called *mellates*. 761 Compounds.

* Annal. de Chim. vol. xxxvi. 210.

Sect.

Sect. XXX. *Of Lactic Acid.*

762 Discovery. 1. In investigating the changes which spontaneously take place in milk, the celebrated Scheele discovered that it contains a peculiar acid. To this has been given the name of *lactic acid*. The formation of this acid depends on the change of the sugar of milk or of the saccharine mucous matter; for after the acid is once well formed, when the serous part of the milk being very sour reddens vegetable blues, no more is obtained by evaporation and crystallization.

763 Preparation. 2. Scheele did not succeed in separating the acid from the serons part of the milk by distillation. He therefore contrived the following process. He evaporated a quantity of sour whey to $\frac{1}{8}$th of its bulk, and then filtered it to separate the whole of the coagulated cheesy matter. He then added lime-water to precipitate the phosphate of lime, and dilnted the liquid with three times its weight of pure water. He then precipitated the excess of lime by means of the oxalic acid, adding no more of the latter than what is necessary. He evaporated the solution to the consistency of honey, poured on a quantity of alcohol, which separates the portion of sugar of milk and of other extraneous matter, and dissolves the lactic acid; and distilled the clear filtered liquor till the whole of the alcohol employed be driven off; what remains in the retort is the lactic acid.

764 Properties. 3. This acid is never crystallized; but always appears in the form of a viscid mucilaginous substance. It has a strong sharp taste, which is far from being agreeable. It reddens the tincture of turnsole, and gives a reddish violet shade to the syrup of violets.

765 Composition. 4. When it is distilled in a retort it yields an empyreumatic acid which is very strong and analogous to the tartaric, very little oil, carbonic acid gas, and carbonated hydrogen gas, and a small quantity of coaly matter which adheres to the glass. This shews what are the constituent parts of this acid, but the proportions of these have not been determined.

766 Compounds. 5. The compounds with alkalies, earths, and metallic oxides which are formed with the lactic acid, are denominated *lactates*.

767 Affinities. 6. The affinities of this acid are in the following order:

Barytes,
Potash,
Soda,
Strontites,
Lime,
Ammonia,
Magnesia,
Metallic oxides,
Glucina,
Alumina,
Zirconia.

Sect. XXXI. *Of Laccic Acid.*

768 History, 1. The substance from which this acid is obtained, is collected in the neighbourhood of Madras. It was first described by Dr Anderson, who says that nests of insects resembling small cowry shells were brought to him from the woods by the natives, who eat them with avidity. These supposed nests he shortly afterwards discovered to be the coverings of the females of an undescribed species of coccus; and having noticed in Abbé Grosier's account of China, that the Chinese called a kind of wax, much esteemed by them, under the name of *péla*, from a coccus deposited for the purpose of breeding on certain shrubs, and managed exactly in the same manner as the Mexicans manage the cochineal insects, he followed the same process with his new insects, and found means to propagate them with great facility on trees and shrubs in the neighbourhood.

769 and natu[re] of the su[b]stances from whi[ch] it is obtained. This substance, which he called white lac, was found on examination to have a considerable resemblance to bees wax. Dr Anderson supposes, that the animal which secretes it provides itself, by some means or other, with a small quantity of honey, resembling that produced by our bees. The sweetness of it tempted the children who were employed to collect it, to eat so much of it as very mnch to diminish his crop. A small quantity of this matter was sent to Europe in 1789. It was examined by Dr Pearson, who published an acconnt of his analysis in the Philosophical Transactions for 1794, from which we have extracted the information which we now lay before our readers.

A piece of white lac, which weighs from three to fifteen grains, is supposed to be produced by each insect. These pieces are about the size of a pea, of a gray colour, opaque and roundish, but with a flat side, by which they adhere to the bark. In its dry state, white lac is soft and tough, and has a saltish and bitterish taste. A watery liquid, which has a slight salt taste, oozes out on pressing a piece of this substance. White lac has no smell, unless it be pressed or rubbed, when it becomes soft, and then it emits a peculiar odour. When it is gathered from the tree, the pieces of lac are lighter than bees-wax; but after being melted and purified, it sinks in water. It melts in alcohol and in water at the temperature of 145°, and very readily in boiling water.

770 Preparation. 2. Dr Pearson exposed 2000 grains of white lac to such a degree of heat as was sufficient to melt them. They became soft and fluid, and there oozed out 550 grains of a reddish watery liquid, which emitted the smell of newly baked bread. The liquid was filtered and purified from extraneous matter. This liquid is *laccic acid*.

771 Propert[ies]. 3. It has a slightly saltish taste, with some degree of bitterness. It smells when heated like newly baked hot bread. It reddens the tincture of turnsole. Its specific gravity, at the temperature of 60°, is 1.025. When this liquid remains for some time at rest, it becomes turbid, and deposits a sediment. When it is evaporated, it becomes more turbid; and, allowed to remain at rest, it affords small needle-like crystals in mucilaginous matter.

772 Action [of] heat. 4. Two hundred and fifty grains of this liquid were exposed to heat in a small retort. As the liquor grew warm, mucilage-like clouds appeared, but when it grew hot, they disappeared. At the temperature of 200° it distilled over very fast. On distillation to dryness, a small quantity of extractive matter remained. The distilled liquid was transparent and yellowish, and while hot, had the smell of newly baked bread. Paper stained with turnsole, which had been put into the receiver, was

was not reddened. One hundred grains of yellowish transparent liquid being evaporated till it became turbid, afforded in the course of a night, acicular crystals which had a bitterish taste. Under a lens they appeared in a group, somewhat resembling the umbel of parsley. One hundred grains of yellowish transparent liquid being evaporated in a low temperature to dryness, a blackish matter remained behind, which did not entirely disappear when exposed to pretty strong heat; but on heating oxalic acid to a less degree, it evaporated and left no trace behind.

From these properties, and from its peculiar action with alkaline, earthy, and metallic salts, Dr Pearson concludes, that this acid is different from any of the acids already known.

73 Composi-ti...

5. The experiments which have been made on white lac, and on the acid obtained from it, show that it is closely allied to the vegetable acids. Its component parts, therefore, probably are, carbon, hydrogen, and oxygen; but experiments are still wanting fully to ascertain its nature and properties *.

Sect. XXXII. *Of Prussic Acid.*

74 ...ory.

1. This is one of the most important acids, both to the chemist and to the manufacturer. It has been alledged, that the ancients were acquainted with Prussian blue, which they employed in painting; but Landriani has shown, in his dissertation on this substance, from the evidence of Theophrastus and Pliny, and from the analysis of an Egyptian mummy, that the ancients employed ultramarine blue and the smalt or azure of cobalt; and that Prussian blue, which is readily acted on by the substances to which it must have been exposed in these countries, could not have resisted their influence for so many ages, and retain the beautiful colours which are admired in the paintings of Herculaneum.

75 ...dis-co...y.

2. Stahl relates, in his 300 experiments, that the discovery of Prussian blue was owing to an accident. About the beginning of the 18th century, Diesbach, a chemist of Berlin, wishing to precipitate a decoction of cochineal with an alkali, borrowed from Dippel some potash, on which he had distilled several times his animal oil; but as there was some sulphate of iron in the decoction of cochineal, the liquor instantly exhibited a beautiful blue in place of a red precipitate. Reflecting on the circumstances which had taken place, he found that it was easy to produce at pleasure the same substance, which afterwards became an object of commerce. It obtained the name of *Prussian blue*, from the place where it was discovered.

76 ...an-...ed.

3. This discovery was announced in the Memoirs of the Academy of Berlin, for the year 1710; but the process by which it was obtained was kept secret, that those who were in possession of it might derive the whole advantage from the manufacture. It was published for the first time by Woodward in the Philosophical Transactions for the year 1724, who declared, that it had been sent to him from Germany, by one of his friends. This is all that is known of the manner by which this process was made public. It is not certain whether it came originally from the first inventors, or was owing to the researches of some other chemist.

4. The method which is described by Woodward succeeds very well. It is by preparing an extemporaneous alkali, by detonating four ounces of nitre, with an equal quantity of tartar; then to add four ounces of bullock's blood, well dried, and to calcine the whole with a moderate heat, till the blood be reduced to a coal, or emit no smoke capable of blackening any white body that is exposed to it. Towards the end of the process the fire is to be increased, till the crucible which contains the materials shall be moderately red. Throw the red-hot matter into water, and boil it for half an hour; and having poured off the first water, add another quantity, and boil it again. Repeat this operation till the last water comes off insipid, then add all the quantities of water together, and evaporate to the quantity of two pints. To this liquid the Germans have given the name of *blood ley*. By others it has been denominated *phlogisticated alkaline ley*. 777 Process.

5. A solution of 2 ounces of sulphate of iron, and 8 ounces of alum, in two pints of boiling water, is to be mixed with the former solution while both are hot. A great effervescence takes place; the liquor becomes muddy, assumes a greenish colour, inclining more or less to blue; and a precipitate is formed of the same colour. Separate this precipitate, and to heighten the colour, pour upon it carefully muriatic acid till it no longer increases the intensity of the blue colour; then wash it with water, and dry it slowly.

6. Such was the process by which Prussian blue was obtained, before the theory was discovered, to account for the different changes and effects which it presented. The same year in which Woodward published an account of the process, Brown instituted a set of experiments to discover the nature of this substance, and the circumstances which attended its formation. He found that flesh, as well as bullock's blood, possessed a similar property. He thought that Prussian blue was the bituminous part of iron, developed by the alkaline ley, and fixed in the aluminous earth. Geoffroy adopted the same explanation. He found that, in the animal kingdom, oils, wool, hartshorn, sponge, had the same effect as blood with the alkali, in precipitating iron of a blue colour; and that some vegetable charcoal treated with the alkali, in some measure communicated to it a similar property. Neuman discovered that the animal empyreumatic oils might be employed for the same purpose. The abbé Menon was of opinion, that the colour of iron is blue; and that this colour, usually disguised by same saline matter, reappears, when it is separated by the phlogisticated alkaline ley, and thus Prussian blue was only iron precipitated in its natural state. The aluminous earth, he saw, served only to diminish the intensity of the colour, and to give it a more agreeable shade. 778 Nature of it investigated by several chemists.

7. It is to the celebrated Macquer that we are indebted for the first correct views in developing the theory of this process. He observed, 1. That pure alkalies precipitated iron from its solution of a yellow colour. 2. That this precipitate is soluble in acids. 3. That the blue fecula obtained from the blue phlogisticated ley after the addition of muriatic acid, was not acted on by acids. He therefore concluded that the first green precipitate was not a homogeneous substance, but 779 By Macquer,

Acids.

but a mixture of two precipitates, the one yellow and the other blue; and that it was sufficient to remove the first by any acid, to give to the second its full intensity of colour. Hence he supposed, that the acid of the alum employed in this process was useful in saturating, in a great measure, the pure alkaline portion of the ley, and diminishing proportionally the yellow precipitate of iron. Having found that it was impossible to saturate the alkali with a colouring matter by means of calcination; and, having discovered that the pure alkali deprived iron (which was converted into Prussian blue) of its characteristic properties; and finally, having ascertained that the alkali which was employed in the process became exactly similar to that which was calcined with combustible matters, to prepare it for the precipitation of iron of a blue colour, and that alkaline properties disappeared as it was more or less saturated with the colouring matter, he attempted to saturate it fully. He therefore saturated an alkali so completely with the colouring matter, that it underwent no change by boiling, and exhibited none of its alkaline properties by chemical tests. By this discovery we are now in possession of this valuable substance which had been hitherto known under the name of the *saturated ley of the colouring matter of Prussian blue*.

Macquer found, in the course of his experiments, that the saturated ley could not be decomposed by sulphuric acid, or by the solution of alum; but, on the contrary, that every metallic substance dissolved in an acid, separated the phlogistic matter from all the fixed and volatile alkalies. Hence he concluded, that in the process of the formation of Prussian blue, it is necessary that the affinity of the iron should co-operate with that of the acid with the alkali, to form a sum of affinities capable of effecting the separation. This luminous explanation of so striking a process, has not a little contributed to establish the theory of compound affinities.

780 and others.

8. After the publication of Macquer's dissertation, almost all chemists were occupied in researches into the nature of Prussian blue, either to discover the nature of its principles, or to improve the process for preparing the colouring matter: but they were chiefly occupied in examining those bodies which were capable of phlogisticating the alkali, as it was called; and this property was found to exist in a great number of substances. Till the year 1775, no change or modification was proposed on the theory of Macquer.

781 By Bergman.

9. About this time Bergman, in his dissertation on elective attractions, threw new light on this subject, by considering the colouring matter of Prussian blue as a distinct acid, and possessed of peculiar attractions. According to Sage, the alkali which precipitated Prussian blue was nothing but an alkali saturated with phosphoric acid; but Lavoisier justly remarked, that according to this theory, the salt formed of phosphoric acid and an alkali ought to precipitate a solution of sulphate of iron, of a blue colour, which was not the case.

Many chemists examined the nature of this substance by means of heat; and among others Delius and Scopoli, Deyeux and Parmentier, Bergman and Erxleben, subjected it to distillation, the product of which was a quantity of ammonia. By others an oil was obtained in this process, and sometimes a peculiar acid, which had the properties of sulphuric acid. The difference of these results probably arose from the different states of purity of the Prussian blue which was employed in the experiment.

Fontana discovered that the sulphuric acid distilled on Prussian blue passed to the state of sulphurous acid, and that the colouring matter produced detonation with nitre. Landriani found that it yielded by distillation, besides ammonia, a small portion of liquid perceptibly acid, and some oil, and a great quantity of elastic fluids, which consisted of azotic and hydrogen gases, the latter burning with a blue flame, and detonating strongly with oxygen gas. 782 By Fontana.

10. But the most important step in the progress of the discovery of the nature and properties of this singular substance, was made by Scheele, an account of which he published in two dissertations in the Stockholm transactions for 1782 and 1783. He began by examining the blood ley, and he found by exposing it for some time to the air, that it lost the property of precipitating iron of a blue colour, and that the precipitate which it then yields is soluble in acids. To discover what change had taken place on the air, he put some of the ley fresh prepared into a large glass globe close shut up, and he found some time after, that neither the air nor the ley had undergone any change. He concluded, therefore, that the colouring matter was not pure phlogiston. He suspected that carbonic acid might have some effect in changing the nature of the alkali when exposed to the open air. He filled a globe with carbonic acid gas, and having introduced a quantity of Prussian alkali, he kept it close shut up for 24 hours, after which, on examining the alkali, it gave a precipitate which was soluble in acids; the change then must have been occasioned by the carbonic acid gas. He repeated this experiment by adding to the colouring matter a small quantity of sulphate of iron. This matter was not changed by the action of the carbonic acid gas. The same result was observed when he boiled the colouring matter in an oxide of iron precipitated by an alkali. It suffered no change in the carbonie acid gas, but precipitated the iron as before. The iron then has the property of fixing the colouring principle, of defending it against the action of carbonic acid gas; and hence it happens that the neutral colouring salt formed with an alkali boiled on Prussian blue, does not so easily lose its properties. But if the colouring ley be digested on an oxide of iron, as that which is obtained from the sulphate of iron boiled in nitric acid, and afterwards precipitated by an alkali, no effect is produced. By this digestion the action of the gas is not prevented, and if the sulphate of iron be added, even with an excess of acid, there is no longer a production of Prussian blue.

783 By Scheele. 784 He examines the ley. 785 Effect of carbonic acid. 786 Iron fixing the colouring principle.

To discover what happened to the colouring principle, when it was charged with carbonic acid gas, Scheele introduced into a globe filled with this gas, some of the Prussian alkali, and suspended in it a bit of paper, previously dipped in a solution of sulphate of iron, and on which he had let fall two drops of alkaline liquor to precipitate the iron. The paper was removed at the end of two hours, and, with the addition of a little muriatic acid, was covered with a fine blue colour. The same experiments repeated with alkali

saturated

saturated with excess of sulphuric acid, gave the same result; that is to say, the paper charged with oxide of iron and suspended as above, acquired a blue colour on adding muriatic acid. Hence it follows, that the colouring principle is disengaged by acids, without decomposition, for it still has the property of being fixed with oxide of iron with which it comes in contact. Thus he found that the colouring matter might be separated from the substances with which it was generally in combination, and without undergoing decomposition.

38 parate olour- natter.

11. To obtain it, therefore, in a separate state, he contrived the following process. He put into a glass vessel two parts of Prussian blue reduced to powder, one part of red oxide of mercury, and six parts of water. He boiled the mixture for some minutes, continually stirring it. It then assumes a yellowish green colour. He put the whole on a filter, and poured upon the residuum two parts more of boiling water, to wash it completely. This liquid is a solution of mercury combined with the colouring matter, which has the metallic taste, and is neither precipitated by acids nor alkalies. Pour this liquid into a glass vessel upon one half part of clean iron filings, and a smaller quantity of concentrated sulphuric acid. Shake the mixture well for some minutes, when it becomes black by the reduction of the mercury. The liquid then loses its metallic taste, and gives out the odour which is peculiar to the colouring matter. Having allowed it to remain at rest for some time, it is poured off, put into a retort to which a receiver is adapted, and distilled with a gentle heat. One-fourth part of the liquid only should be allowed to pass over, for the colouring matter is much more volatile than water, and consequently rises first. The liquid in the receiver is commonly mixed with a little sulphuric acid, from which it may be separated by distilling again off a little powdered chalk, which takes up the sulphuric acid. The liquid then passes over in a state of purity; and this liquid is *prussic acid.*

39 ic ıed.

90 re of ro-

12. In this process the oxide of mercury which was mixed with the colouring matter, takes it from the iron with which it is combined in the state of Prussian blue, and is then a crystallizable prussiate of mercury. The iron which is added in the metallic state, reduces the oxide of mercury; and at the moment it combines with the sulphuric acid, which has also been added, the heat applied sublimes the prussic acid which has been disengaged from the mercury, which is now reduced to the metallic state. The prussic acid thus obtained, partly in the liquid, and partly in the gaseous state, combined with alkalies, produces the same effects as the blood ley, and the colourless Prussian blue.

91 osi-

13. Having obtained the prussic acid in a separate state, it was his next object to discover its component parts. He had observed in the process for procuring it, that the air in the receiver was inflammable; and in decomposing the prussiates, he obtained ammonia and carbonic acid, and found that some metals were reduced by distillation with the metallic prussiates. He concluded from this, that prussic acid was composed of ammonia and oil, and he endeavoured to prove this by the test of experiment; but he soon found that he could not succeed in forming the colouring compound, by combining ammonia and the different oils heated together. Seeing that water was an obstacle to the formation of the prussic acid, he conducted his experiments in a different way, by combining the ammonia with the dry combustible principle, which he supposed existed in oils, and with the carbonic acid, equally in the dry state. He saw that charcoal alone, strongly heated with fixed alkalies, gave them the property of colouring iron blue. Having heated these two substances in crucibles, he added to the one muriate of ammonia, at the moment when the first mixture had acquired a white heat, and he continued the heat till no more vapour was disengaged. This process furnished him with a pure Prussian alkali, whilst the combination of the alkali and the charcoal, without the addition of the muriate of ammonia, afforded none.

792 Berthollet's experiments.

14. Such was the state of our knowledge with regard to the colouring matter of Prussian blue, when Berthollet, at the end of 1787, communicated to the Academy of Sciences, the result of his investigations into the nature and properties of this substance. He repeated the experiments of Scheele, improved and extended his views, and confirmed his conclusions. The result of his researches on this substance was closely connected with the light which he had thrown on the nature and composition of ammonia some years before. He proved that the alkaline prussiate is a triple salt, which is composed of prussic acid, the alkali and iron; that when it is evaporated and re-dissolved, it affords crystals in the form of octahedrons; and mixed with sulphuric acid, and exposed to the sun, there is precipitated Prussian blue, which does not happen in the dark. After these preliminary experiments, he proceeded to the examination of prussic acid, by the action of oxymuriatic acid. This acid, in proportion as it is dissolved in the prussic acid, is deprived of its oxygen, and is converted into the state of muriatic acid. The prussic acid becomes more odorous and volatile, and less susceptible of combination with the alkalies, precipitating iron from its solutions, of a green colour. This green precipitate recovers its blue colour when exposed to the light, by contact with sulphurous acid, by iron. It is the oxy-prussic acid. When the oxymuriatic acid is still continued to be added in the state of gas, and is exposed to the light, the new acid separates from the water, and is precipitated to the bottom in the form of an aromatic oil, which is converted by heat to an insoluble vapour, which is no longer capable of combining with iron. Thus superoxygenated, this acid can no longer return to its original state. It is totally different in its properties.

793 Oxy-prussic, or chloro-cyanic acid.

When the oxyprussiate of iron, which is prepared by treating Prussian blue with the oxymuriatic acid, and which is distinguished by its green colour, is deprived of its acid, by being brought into contact with a caustic fixed alkali, it is instantly decomposed, and is converted into carbonate of ammonia. It is now, however, found that this oxy-prussic acid consists of prussic acid combined with chlorine. Hence the French chemists call it the chloro-cyanic acid, and its salts chloro-cyanates.

15. Scheele and Bergman were of opinion, that prussic acid contained ammonia ready formed. Berthollet, however, concludes from his experiments, that it only contains the elements, namely, the azote and hydrogen,

Acids.

494 Prussic acid a triple compound.

hydrogen, both in combination with carbon; and thus he considers prussic acid to be a triple compound of hydrogen, carbon, and azote, but he has not been able to ascertain the proportions. He thinks, however, that the hydrogen and azote come near to the proportions which exist in ammonia *.

*Fourcroy. *Connaiss. Chim.* tom. ix. p. 89.

16. In some experiments by M. Clouet, on the colouring matter of Prussian blue, he attempted to combine the elements of ammonia with charcoal, with the view of producing prussic acid; but in whatever proportion he employed them, no colouring matter was obtained. He therefore concluded, that it was necessary to combine directly the ammonia with the charcoal, for the production of this substance. He took $2\frac{1}{2}$ parts of quicklime in powder, and mixed them with one part of sal ammoniac dried, and also in the state of powder. He put the mixture into a porcelain retort, which he placed upon a sand-bath. To the beak of the retort was adapted a porcelain tube filled

795 Prussian blue formed of carbon and ammonia.

with dry powdered charcoal. The porcelain tube passed across a furnace, in which it might be strongly heated. It was then made red hot, and heat being afterwards applied to the retort, the ammonia was disengaged in the state of gas, which passed through the red-hot porcelain tube containing the charcoal. The product was received in proper vessels, and when examined, was found to be the colouring matter of Prussian blue †.

† *Ann. de Chim.* tom. xi. p. 30.

It is obtained in a purer state by decomposing the prussiate of mercury, by means of the muriatic acid, under the application of heat. It passes over in vapour, and is condensed by cold.

796 Properties of prussic acid.

17. It is a colourless liquid, of the specific gravity of 0.705, has the odour of peach blossom, or bitter almond, substances which actually contain it, and owe to it their peculiar smell and their narcotic power. The acid is extremely baneful to animal life. A single drop applied to the tongue of a small animal is fatal, and we are even told that it has proved destructive by mere external application.

Its freezing point is 5°. It boils at 80°, and is so volatile as to freeze by the cold of its own evaporation in the open air. From this cause a drop held on the end of a glass rod instantly freezes; a fact of which it furnishes an unique example. This acid has scarcely any effect on vegetable blues.

797 Composition.

The composition of it, as consisting of carbon, azote, and hydrogen, has been demonstrated by analysis, by passing it in the state of vapour through an ignited tube containing iron. The products are hydrogen, and azote in the state of gas, charcoal deposited on the iron, but without any oxidation of this metal, showing that it contained no oxygen.

It is further found that the carbon and azote which it contains can be obtained in a state of mutual combination, free from the hydrogen, and then form a well-marked and definite compound. This is effected by subjecting the prussiate of mercury to a powerful heat. The oxygen of the mercurial oxide, and the hydrogen of the acid, combine, and the carbon and azote of the latter assume the state of a separate compound, which passes over in the gaseous form, and has received the name of *cyanogen;* and the French chemists now call the prussic acid, formed by the union of it with hydrogen, the *hydro-cyanic*.

This acid combines with difficulty with alkalies and earths, and without destroying their alkaline properties.

798 Action of carbonic acid, &c.

19. The carbonic acid drives it off from these combinations. It deprives oxymuriatic acid gas of its oxygen, and by this addition changes its properties. It has no action on the metals; but it combines with their oxides, changing the colour, and forming salts which are in general insoluble.

799 Triple compounds.

20. This acid has the greatest tendency to form triple salts with the alkaline and metallic bases. These complex combinations are more permanent and fixed than the simple alkaline prussiates. They are not decomposed by carbonic acid, light, air, or the other acids.

800 not easily decomposed.

801 Affinities.

21. The affinities of prussic acid are the following:

Barytes,
Strontites,
Potash,
Soda,
Lime,
Magnesia,
Ammonia.

Sect. XXXIII. *Of Sebacic Acid.*

802 History.

1. The penetrating fumes which are exhaled from melted tallow, and which affect the eyes, the nostrils, and even the lungs, had been long ago observed, and Olaus Borrichius has thrown out some hints, warning against the danger of being exposed to these fumes. But little attention was paid to their nature and properties. Grutzmacher was the first who demonstrated the existence of this acid, in a dissertation *de ossium medulla*, printed at Leipsic in the year 1748. Rhodes published a small work in 1753 at Gottingen, in which he makes particular mention of this acid. The following year appeared a dissertation by M. Segner, *on the acid of animal fat*, which contained a number of well-conducted experiments. Crell endeavoured to improve the process for the separation and purification of this acid, and to ascertain the properties of its combinations. These were published in the Philosophical Transactions for the years 1780 and 1782.

But it appears, as Thenard, who made experiments on this acid, observes, that the acid obtained by those who first treated of the subject, was either the acetic acid, or some acid different from the sebacic, the properties of which are quite distinct from those which had been formerly described.

803 Preparation.

2. The process by which this chemist obtained the sebacic acid is the following. He distilled a quantity of hogs lard, and washed the product several times with hot water. He then dropt into it acetate of lead; there was formed a flaky precipitate, which was collected and dried, put into a retort with sulphuric acid, and heated. The liquor in the receiver had no acid character; but there appeared in the retort a melted matter analogous to fat. This is carefully separated; and after being washed, is boiled with water. By the action of heat the whole is dissolved by the water, and when it cools, crystals in the shape of needles are deposited. These are sebacic acid. To be certain that these were not

not produced by means of the sulphuric acid, he washed the fat which had been distilled with water, which was filtered and evaporated, and needles were formed, exhibiting exactly the same properties. Or, after having washed with water the distilled fat, he saturated the filtered liquor with potash, evaporated it, and dropt into it a solution of lead. There was instantly formed a salt composed of the sebacic acid and lead. This is to be decomposed as before with sulphuric acid. This acid has the following properties.

3. It has no smell, a slight acid taste, and reddens strongly the tincture of turnsole. When heated, it melts like tallow.

4. It is much more soluble in warm than in cold water. Boiling water saturated with this acid forms a solid mass on cooling. It crystallizes in small needles, but with certain precautions may be obtained in the form of long, large, and very brilliant plates *.

Sect. XXXIV. *Of Uric Acid.*

1. This acid was discovered by Scheele in the year 1776. It was at first called *lithic acid.* It constitutes one of the component parts of urinary calculi, and is also found in human urine. There is one species of calculus which is almost entirely composed of this substance. It is that species which resembles wood in appearance and colour.

2. This acid, as its properties have been described by Scheele, is thus characterized. It is insipid, inodorous, almost insoluble in cold water, and soluble only in about 360 parts of boiling water. It separates from this when it cools, into small yellow crystals. The solution in water reddens the tincture of turnsole.

3. There is scarcely any action between uric acid and sulphuric and muriatic acids. It is soluble in the concentrated nitric acid, to which it communicates a red colour. It would appear that in this change of colour the nature of the acid is also changed, for part of it is converted into oxalic acid. Oxymuriatic acid very readily acts upon uric acid, either by suspending a calculus in the liquid acid, or, which is easier, by passing a stream of oxymuriatic acid gas through water, at the bottom of which is placed the uric acid in powder. Its colour becomes pale, the surface swells up, it softens, and is at last converted into a jelly. This part disappears, and is soon dissolved, giving a milky colour to the liquid. There is extricated by slow effervescence small bubbles of carbonic acid gas. The liquid by evaporation gives muriate of ammonia, acidulous oxalate of ammonia, both crystallized; muriatic acid, and malic acid. Thus the oxymuriatic acid decomposes the uric acid, and converts it into ammonia, carbonic, oxalic, and malic acids.

4. When uric acid is distilled, there is a little of it sublimed without decomposition. It yields also a very small quantity of oil and water, crystallized carbonate of ammonia, carbonic acid gas; and there remains behind a very black coal without any alkali, and without any lime.

5. All these facts shew that uric acid is a compound of a very peculiar kind, formed of azote, of carbon, of hydrogen and oxygen, and susceptible of a great number of different changes by chemical agents.

Sect. XXXV. *Of Rosacic Acid.*

1. During certain diseases, the urine, when it cools, deposits a peculiar substance, which has been denominated from its colour, which resembles bricks, *lateritious sediment.* During fevers, this appearance of the urine takes place; and in gouty persons, at the termination of the paroxysms, it is very abundant. And when this suddenly disappears, and the urine at the same time continues to deposit this substance, a relapse may be dreaded. It appears in the form of red flakes, and adheres strongly to the sides of the vessel. If the urine be heated, this sediment is again dissolved. 811 Origin.

2. This substance was formerly considered by chemists as uric acid. If into fresh urine a little nitric acid is dropt, it becomes muddy, and a precipitate is formed. The nitric acid, and the substance to which the name of *rosacic acid* has been given, combine together, and are deposited. The uric acid being much less soluble than the rosacic acid, it is very easy to separate them. All that is necessary is to pour boiling water on the sediments, and to wash them on the same filter, in which case the uric acid remains behind. 812 Preparation. 813 Properties.

Proust, who made experiments on this substance, considers it as another characteristic of rosacic acid, that it produces with a solution of gold, a cloudy precipitate of a violet colour *.

* Ann. de Chim. tom. xxxvi. p. 265.

Sect. XXXVI. *Of Amniotic Acid.*

1. A peculiar acid has been detected in the liquor of the amnios of the cow. This was discovered by Buniva and Vauquelin. This acid is concrete, white, and brilliant, has a very slight acid taste, and reddens the tincture of turnsole. It is little soluble in cold water, but dissolves more readily in boiling water, from whence it is deposited, by cooling, in long needle-shaped crystals. When this acid is exposed to heat, it swells up, and exhales an odour of ammonia sensibly mixed with prussic acid. It leaves behind a voluminous coal. 814 Properties.

2. It seems at first to have some analogy with the saclactic and uric acids, but this is not really the case. The saclactic acid does not furnish ammonia by distillation; the uric acid yields ammonia and prussic acid by heat, but it is not equally soluble in warm water, and does not crystallize in long, white, brilliant needles, nor is it soluble in boiling alcohol, as the amniotic acid is †. 815 And distinctive characters.

Chap. XI. Of INFLAMMABLE SUBSTANCES.

The class of bodies which we are to examine in this chapter, under the title of inflammable substances, are *alcohol*, *ether*, and *oils*. These substances are closely allied to many of the bodies which were treated of in the last chapter. Their constituent parts are the same with those of many of the vegetable acids, arranged, however in different proportions, and totally different in their properties and effects. The elements of these inflammable substances are chiefly carbon and hydrogen, but 816 Introduction.

Inflammable Substances.

but in some there is a triple compound of carbon, hydrogen and oxygen; the last does not exist in such a quantity as to exhibit acid properties, or these properties are concealed by the proportions of the other constituent parts. It was therefore thought necessary to treat of these substances in this place, that we might be early acquainted with their properties, some of which are of great importance in chemical researches, particularly their effects on many saline bodies. They are valuable instruments of chemical analysis. We shall consider the inflammable substances in the four following sections, namely; 1. Alcohol, 2. Ether, 3. Fixed oils, and 4. Volatile oils.

Sect. I. *Of Alcohol.*

817 Preparation.

1. When vegetable matters have been subjected to the vinous fermentation, the fluid is totally changed. It is converted into a substance called *wine* or *beer*, according to the nature of the materials from which it has been prepared. When this product, the wine or beer, is subjected to another process, a very different product is obtained. By distillation a fluid is obtained of very different properties from the beer or wine from which it is extracted. This liquid, when is perfectly pure, is known in chemistry by the name of *alcohol*, or *spirit of wine*, because it is produced from wine. It is sometimes denominated also *ardent spirit*, from its effects. Ardent spirit, as it is first obtained by distillation, is to be considered as a mixture of alcohol and water, because the alcohol in the process of distillation is condensed by water. In this state, ardent spirit is different in flavour, in colour, and in strength, according to the nature of the materials from which it is obtained,

818 Different names.

and hence in common language it is distinguished by different names. When it is obtained from the fermented juice of the grape, it is known by the name of *brandy;* from that of the sugar-cane, by that of *rum;* and from that of farinaceous substances, by that of *whisky*. All these substances, therefore, are to be considered as composed of alcohol, or pure spirit of wine, water, and a peculiar oil, to which the flavour is owing.

819 History.

Ardent spirit, it is supposed, was known in the dark ages. It does not appear, from any of the writings of the Greeks or Romans, that they were acquainted with such a liquor. The preparation of it from wine, and even the discovery of alcohol, or pure spirit itself, is ascribed to Arnold de Villa Nova, who lived in the 13th century.

820 Purification.

2. To purify the alcohol or pure spirit, from water and colouring matter, it is again distilled; and, to have it perfectly pure, this process must be repeated several times. When ardent spirit is distilled for the first time, after it is extracted from the fermented liquors, it is distinguished by the name of rectified spirits. The process which is recommended by some is the following. Distil it in a water bath, till one fourth of the quantity has passed over; then distil it again for several times, taking only the first half of the product. Mix all these products together, and distil them with a very gentle heat; the first half of the liquor which passes over, is the purest alcohol that can be obtained; the remainder may be reserved for ordinary purposes†. Even in this state, the alcohol, thus obtained, contains a certain proportion of water, to separate which, Boerhaave has given a very good process, by means of an alkali. Take a quantity of carbonate of potash which has been exposed to a red heat, to separate the moisture; reduce it to powder, and put it into the spirit. This salt, on account of its strong attraction for water, combines with the water of the alcohol; and this solution of the alkali having the greater specific gravity, falls to the bottom. The alcohol which remains at the top may be easily separated. To purify this alcohol from a small quantity of potash which it holds in solution, it may be redistilled in a water bath. It ought to be observed, however, that the distillation should not be carried on till the whole of the alcohol is driven off, because, towards the end of the process, it carries part of the potash along with it. The salt called muriate of lime, may be employed for the same purpose.

† Fourcroy Connaiss. Chim. tom. viii. p. 143.

821 Propert

3. Alcohol, thus prepared and purified, is a light, transparent, and colourless liquor, of a sharp, penetrating, agreeable smell, and of a warm, stimulating, acrid taste. It has the property, in a much greater degree than wine, of producing intoxication. The specific gravity of alcohol, when perfectly pure, is 0.800, but the strongest spirit which is afforded by mere distillation, according to Mr Nicholson, is 0.820 at the temperature of 71°. The alcohol or rectified spirit of commerce, has rarely a specific gravity below 0.8371.

82 Volatil

4. When alcohol is exposed to the air at a temperature between 50° and 60°, it evaporates, and when it is pure, leaves no residuum. By this rapid evaporation it produces great cold, which is very sensibly felt by dipping the fingers in alcohol, and exposing them

823 Action heat.

to the air. It boils at the temperature of 176°, and is then converted into an elastic fluid. In the vacuum of an air-pump it boils at 56°. It has never yet been frozen by the greatest degree of cold to which it has been exposed. It remains fluid when the thermometer stands at —69°. When passed through a red-hot porcelain tube, it is decomposed, and converted into carbonic acid gas, carbureted hydrogen gas, and water.

824 Phosph

5. With the aid of heat, alcohol dissolves a small quantity of phosphorus. When this solution, which has a fetid odour, is precipitated, by dropping a little of it into water, it becomes luminous in the dark. Jets of flame arise from the surface of the water; and an oxide of phosphorus is formed in the state of white powder. Alcohol seems also capable of dissolving phosphureted hydrogen gas.

82 Sulphu

6. There is no action between alcohol and sulphur at ordinary temperatures, nor even when they are boiled together; but when the two bodies are brought in contact with each other in the state of vapour, they combine readily, and a fetid sulphureted alcohol is formed, which deposits a small quantity of white sulphur, and becomes muddy in cooling. The sulphur is precipitated by water, and gives about $\frac{1}{60}$th part. Alcohol combines still more readily with sulphureted hydrogen gas, which communicates to the alcohol a little colour, and in this combination is decomposed with more facility by oxygen gas, and all other oxygenated bodies, than when it is in the state

Inflammable Substances.

state of gas. Alcohol combines with sulphureted hydrogen gas, which is contained in mineral waters, and deprives them of this gas by distillation.

7. The strong acids have a very powerful effect on alcohol. It is decomposed by the sulphuric, the nitric, the oxymuriatic, and the acetic acids: and the product of this decomposition varies according to the nature of the acid, its strength, and the proportions in which it is employed. Some of the acids are soluble in alcohol. With the aid of heat, it dissolves the boracic acid, which communicates to it the property of burning with a green flame. It also holds in solution carbonic acid gas in greater proportion than its own bulk. It precipitates from water, on the contrary, the phosphoric acid, almost in the concrete state, and also the metallic acids which are soluble in this liquid.

8. Alcohol combines with water in all proportions. The affinity between the two fluids is so strong that water is capable of separating from alcohol many bodies with which it is combined, while the alcohol decomposes many aqueous saline solutions, and precipitates the salt. When water and alcohol are combined together, there is an increase of temperature, which shews that there is a condensation of the two liquids. Accordingly it is found, that the density or specific gravity of the mixture is greater than the mean of the uncombined liquids. The density varies according to the different proportions of the alcohol and water which are employed. In consequence of this variation, it becomes an object of considerable importance, both in a political and commercial view, to be able to ascertain the strength of spirits; that is, the proportions of alcohol and water of different degrees of density or specific gravity. For the purposes of commerce, various instruments have been contrived, and tables constructed, for the convenience of those who are concerned in the purchase and sale of spirituous liquors. For the purposes of revenue, a most elaborate and minute set of experiments was instituted by Sir Charles Blagden, who was expressly employed by the British government to ascertain the relative value or strength of ardent spirit at different temperatures and different specific gravities. An account of these experiments was published in the Philosophical Transactions for the year 1790. Tables which shew the result of the experiments were published by Mr Gilpin in 1793; but as these are not immediately connected with the elements of chemistry, we refer our readers to the original papers, to the article *Spirituous Liquors*, in this work, and to a long note in the present article, under the head of sulphuric acid, p. 508—510.

9. Alcohol dissolves the fixed alkalies in the pure state, and forms with them an acrid solution of a reddish colour. The solution of potash in alcohol was formerly denominated *the acrid tincture of tartar*. It is in this way that the fixed alkalies are obtained in their purest state. Alcohol, therefore, becomes a valuable instrument of analysis for separating the fixed alkalies from a great number of extraneous substances. Ammonia also combines with alcohol by the assistance of heat. The ammonia with a higher temperature is driven off, and carries with it part of the alcohol. Many of the saline bodies may be dissolved in alcohol, and on this account also it is valuable to the chemist in his researches. Tables have been constructed, shewing the quantities of different salts which may be dissolved at different temperatures. The following tables were drawn up from the experiments of M. Guyton *.

I. *Table of Salts which are readily Dissolved.*

	Temperature.	Grains.	
240 grains of alcohol dissolve at	54.5°	240	Nitrate of cobalt:
	54.5	240	copper.
	54.5	240	Muriate of zinc.
	54.5	240	alumina.
	54.5	240	Nitrate of alumina.
	113.	240	Acetate of lead.
	180.5	694	Nitrate of magnesia.
	180.5	1313	Muriate
	180.5	240	of iron.
	180.5	240	of copper.
			Nitrate of zinc decomposed.
			Nitrate of iron partly decomposed.
			Nitrate of bismuth.

II. *Table of Salts that are little Soluble.*

	Grains.	
240 grains of alcohol at the boiling temperature dissolve	240	Muriate of lime.
	214	Nitrate of ammonia.
	212	Oxymuriate of mercury.
	112	Acetate of soda.
	100	Nitrate of silver.
	23	Nitrate of soda.
	18	Acetate of copper.
	17	Muriate of ammonia.
	9	Arseniate of potash.
	7	Superoxalate of potash.
	5	Nitrate of potash.
	5	Muriate of potash.
	4	Arseniate of soda.
	1	Tartrate of potash.

III. *Salts that are Insoluble.*

Borax,
Tartar,

829 Composition,

10. A great variety of different opinions have been proposed with regard to the composition of alcohol. It had been observed, in burning this combustible substance, in close vessels, that water was formed. Some philosophers had even observed that the quantity of water obtained by the combustion of alcohol was greater than the whole weight of the alcohol consumed. From observing this circumstance, it was supposed to consist of water, combined with an acid, an oil, or phlogiston, according to the views and theories of different philosophers.

830 According to Lavoisier.

It is to the experiments of Lavoisier that we are indebted for ascertaining the real constituent parts of this substance. He burnt in a proper apparatus, with a known quantity of oxygen gas, 76.7083 grs. troy of alcohol, and, after the combustion, carbonic acid gas and water were found to be the only products; and by estimating the oxygen gas consumed, the quantity of carbonic acid and of water which were formed, it appeared that the quantity of alcohol consumed was composed of

22.840 carbone,
6.030 hydrogen,
47.830 water.

76.700

831 To Fourcroy.

But it has been since proved, by the experiments of Fourcroy and Vauquelin, that oxygen is a component part of alcohol; for when they mixed together equal parts of alcohol and concentrated sulphuric acid, and while ether was formed from it, there was also at the same time a production of water; the alcohol in this case was decomposed, but the sulphuric acid suffered no change. The oxygen, therefore, which combined with the hydrogen in the formation of water, must have come from the alcohol *.

* Nich. Jour. p. 191

Sect. II. *Of Ether.*

83 Forma

By the action of different acids with alcohol, the latter is decomposed, and different products are obtained, according to the proportions of the acid employed, and the heat which is applied. When the acid and the alkali are in a certain proportion, and are exposed to a moderate temperature, the product is a peculiar substance, which has received the name of *ether*. Ether has been obtained by the action of different acids on alcohol, and hence it has received different names, as *sulphuric ether*, *nitric ether*, *muriatic ether*. The first, namely, sulphuric ether, which seems to have been longest known, and is most easily obtained, has excited the greatest attention among chemists. We shall therefore consider it first.

83 Name

1. Of Sulphuric Ether.

83 Histo

1. It appears from different passages in the writings of the earlier chemists, that the knowledge of sulphuric ether was in the number of their secrets. It was then called *oleum vitrioli dulce*. The method of preparing it is described in a book published at Nuremberg about the year 1540. But the nature of this substance was not much attended to till the year 1730, when a quantity was presented to the Royal Society by Dr Frobenius, with a paper which was published in their Transactions for that year, containing an account of a number of experiments which were made upon it.

Inflammable Substances.

it. It was long known among the German chemists under the name of *naphtha*.

834 Preparation. 2. The following is the process by which sulphuric ether may be obtained. Equal parts of concentrated sulphuric acid and alcohol are put into a retort, to which a receiver is to be adapted and luted. Or perhaps it is better to add the acid by small portions at a time, that the action may not be too violent, and the heat produced too great. The receiver should be immersed in cold water, or surrounded with ice, or it may be kept cool by the application of wet cloths, over which a small stream of water is directed. Heat is then applied, and the first product which comes over is a fragrant spirit of wine; but as soon as the mixture begins to boil, the ether comes over, is condensed by the cold, and runs in streams down the sides of the receiver. When the quantity obtained amounts to about one half of the alcohol employed, the process should be stopped, and the receiver unluted and removed; but if it be continued, white fumes begin to come off, which are known to be the fumes of sulphurous acid. After this there rises a light yellowish coloured oil, which has been called *the sweet oil of wine*. The heat should now be moderated after the ether has passed over, because the matter contained in the retort becomes black, thick, and swells considerably. When the whole of the sweet oil has come over, there is still an evolution of sulphurous acid, which becomes constantly thicker, till at last there is nothing but a dark coloured sulphuric acid.

835 Purification. 3. The ether obtained by this process is impure, being generally contaminated with sulphurous acid. To purify it, it has been usual to mix a quantity of potash with the fluid, and to distil it over again. The acid in this case combines with the potash, and the ether being separated, passes over into the receiver. Dizè, however, considering this process as tedious and uncertain, has proposed other substances in the room of potash, and he has tried several metallic oxides, such as the red oxide of lead, the yellow oxide of iron, the red oxide of mercury, and the black oxide of manganese. After a variety of experiments, he is of opinion that the black oxide of manganese is the most convenient for the purification of ether. It is mixed with ether, allowed to remain some time, and is to be frequently agitated. The oxygen of the manganese combines with the sulphurous acid, and converts it into sulphuric acid, which is a more fixed body than the sulphurous acid *.

To separate the liquid from the sulphurous acid, Proust recommends the following method, which he says is employed in the large way, as by far the most preferable. Introduce into a bottle which is ¾ths filled with impure ether, some water, and a portion of slaked lime. Agitate the bottle strongly, and do not open it to examine its odour, till after it has remained for some minutes in cold water, and when the vapour within the bottle has ceased to exert its elastic force against the cork; if the sulphurous smell is not entirely removed, the process is to be repeated till it is completely destroyed. This method, which was employed by Woulfe, Proust prefers on account of its economy, particularly as it affords at the same time a sulphite of lime, which is formed by the combination of the sulphurous acid with the lime. When the liquids have separated, the ether which swims on the top, may be drawn off by means of a syphon, and it may be introduced into a retort to be rectified by distillation †.

* Journ. de Phys. xlvi.

4. The ether which is thus obtained, is a transparent colourless fluid, of a very fragrant smell, and a hot pungent taste. The specific gravity is only 0.7581, so that it is considerably lighter than alcohol. It is extremely volatile, so that when it is agitated, or poured from one vessel to another, it is instantly dissipated. It produces so great a degree of cold, that water may be frozen by means of it. It rises in the state of gas which burns with great rapidity, and the air which holds ether in solution may be passed through water without being deprived of its combustibility or fragrance. 836 Properties.

† Ann. de Chim xlii. p. 257.

5. It boils in the open air at the temperature of 98°, and in the vacuum of an air-pump at —20°, so that it would constantly remain in the state of gas if the pressure of the air were removed. 837 Action of heat.

When ether is kindled in the open air, it burns very readily. The electric spark also inflames it. It burns with a copious white flame, and leaves behind it a black trace on the surface of any body exposed to the flame. Lavoisier has observed that an acid is always formed during the combustion of this liquid; and Scheele says that the residuum of ether burnt over a little water, contains sulphuric acid. When the ether is exposed to a cold of —46°, it freezes and crystallizes. It is decomposed when the vapour is passed through a red-hot porcelain tube, and the product is carbonated hydrogen gas.

6. Dr Priestley discovered that ether agitated with any kind of gas, greatly increased its volume, and in most cases doubled it. Mr Cruickshank made a similar experiment, by agitating some oxygen gas with a little ether. The bulk was exactly doubled. In this state the gas did not explode, but when one part of this mixture was added to three parts of oxygen, an ignited body or the electric spark produced a dreadful explosion. The products were water, with 2⅓d carbonic acid gas. Hence it would appear, Mr Cruickshank observes, that one part of this vapour requires about seven of oxygen to saturate it; and according to this experiment, the proportion of carbon to hydrogen in the vapour of ether or ether itself, should be as five to one ‡. 838 Increases the volume of gases.

‡ Nich. Journ. v. p. 205.

7. Phosphorus is dissolved in small quantity in ether, and produces a transparent solution; but when alcohol is added to the solution, it becomes milky. 839 Action of phosphorus.

8. Sulphuric acid has a peculiar action on ether, by converting it into a kind of oil, which is called *the sweet oil of wine*. This is one of the products in the preparation of sulphuric ether. When a small quantity of ether is introduced into a bottle filled with oxymuriatic acid gas, it explodes, and inflames; or if paper moistened with ether be introduced, the same effect follows. Carbonic acid gas is produced, and charcoal is deposited on the sides of the bottle. 840 Of Acids.

9. Various theories have been proposed, to account for the production of ether. From the manner of its production by means of sulphuric acid, it was natural to suppose that this acid formed one of its component parts. This accordingly became a general opinion, till it was found that the sulphuric acid suffered no change in the process, but merely assisted or disposed the alcohol to 841 Composition.

that change which it undergoes when it is converted into ether. According to Macquer, the alcohol has not been changed, but merely deprived of the whole of its water. Scheele supposed, that ether was alcohol deprived of its phlogiston; and when the new theories were introduced, ether was considered as a combination of alcohol and oxygen.

10. The experiments and researches of Fourcroy and Vauquelin have thrown new light on this subject, and have led to different views of the nature and composition of ether. According to the result of these experiments, ether contains a smaller proportion of carbon, but a greater proportion of hydrogen and oxygen. From their experiments, and from those of others, it appears that the changes induced by the action of sulphuric acid on alcohol, depend on the quantity and strength of the acid, and the temperature.

A. Equal parts of concentrated sulphuric acid and alcohol mixed together raise the temperature to 189°. Bubbles of gas are emitted; the liquid becomes turbid, and at the end of some hours assumes a deep red colour.

B. A mixture of two parts sulphuric acid, and one part alcohol, produces a temperature of 200°. The mixture becomes instantly of a deep red colour, passes to black a few days after, and diffuses an odour which is perceptibly that of ether.

C. When equal parts of sulphuric acid and alcohol are exposed to the action of heat, in a proper apparatus, such as is employed for the preparation of ether, the following phenomena are observed.

a. When the temperature is raised to 207°, the liquid boils; there is produced a fluid which is condensed by cold, into a light, colourless, and fragrant liquor, which from its properties has received the name of ether. If the process be properly conducted, no permanent gas is evolved, till about $\frac{1}{4}$ of the alcohol is converted into ether.

b. If, as soon as the sulphurous acid appears, the receiver be changed, there is no longer any production of ether; but the sweet oil of wine, water, and acetic acid are formed, without a single particle of carbonic acid. When the sulphuric acid makes about $\frac{4}{5}$ths of the mass which remains in the retort, there is evolved an inflammable gas, which has the odour of ether, and which burns with a white oily flame. This is the gas which the Dutch chemists have called *carbureted hydrogen gas*, or *olefiant gas*, because when it is mixed with oxymuriatic acid it forms oil. At this period, the temperature of the matter contained in the retort is elevated to 230° or 234°.

c. When the sweet oil of wine ceases to flow, if the receiver be again changed, there is only sulphurous acid emitted, water which was previously formed, carbonic acid gas; and there remains only in the retort, a mass which consists chiefly of sulphuric acid thickened with charcoal.

842 Inferences.

The operation of ether, then, may be divided into three periods; the first, in which a small quantity of ether and water is formed, without the assistance of heat; the second period, in which the greatest quantity of ether which can be obtained without the evolution of sulphurous acid at a temperature of 207°; and the third, in which the sweet oil of wine, olefiant gas, acetic acid, sulphurous and carbonic acid, are produced while the temperature of the mixture is raised to 230° and 234°. To all these three periods there is only one circumstance in common, and this is, the continual formation of water from the beginning to the end of the operation.

84[3] Theor[y].

On these observations, Fourcroy and Vauquelin have established their theory of the formation of ether. In the case in which ether is formed by the simple mixture of alcohol and sulphuric acid, without the aid of heat, the formation which appears by heat as well as by the black precipitate, the charcoal which is separated without the production of sulphurous acid, proves that the sulphuric acid acts in a different manner on alcohol from what was supposed. This acid is not decomposed by charcoal at that temperature. There is no action between these two bodies in the cold, nor is there any action between this acid and alcohol; for in that case, sulphurous acid would be formed, of which not the smallest trace can be perceived at the beginning of the operation. Recourse then must be had to a different action, namely, the strong affinity which exists between sulphuric acid and water. It is this which determines the union of the constituent principles of water existing in the alcohol, and with which this acid comes in contact: but this action must be very limited. A balance of affinities is soon established, and no farther change takes place.

If then it be proved that ether is formed by the mixture of certain quantities of sulphuric acid and alcohol, it must obviously follow, that a mass of alcohol may be completely converted into ether, water, and acetic acid, by increasing the quantity of sulphuric acid; and it is equally obvious, that this acid would undergo no change but that of being diluted with water.

It is not necessary to suppose, according to this theory, that ether is alcohol deprived of a certain portion of oxygen and hydrogen, for there is separated at the same time a quantity of charcoal proportionally greater than that of the hydrogen; and it may be conceived, that the oxygen which is combined in this case with the hydrogen, to form water, would not only saturate this hydrogen in the alcohol, but that it would saturate at the same time the carbon which has been precipitated. Thus, then, instead of considering ether as alcohol with a smaller proportion of hydrogen and oxygen, if we take into account the carbon which is precipitated, and the small quantity of hydrogen contained in the water that is formed, it must be considered as alcohol with a greater proportion of hydrogen and oxygen. Such seems to be the nature of the spontaneous action between sulphuric acid and alcohol without the aid of heat.

But when the mixture is subjected to heat, the production of ether is more complicated, and the products more numerous.

It ought to be observed, that the mixture of sulphuric acid and alcohol in equal proportions, boils only at the temperature of 207°, whilst alcohol alone boils at 176°; whence we must conclude, that the alcohol is retained by the affinity of the sulphuric acid, which fixes it. Now, if we compare what happens in this case to the change produced on all other vegetable matter

Inflam-mable Sub-stances.

matter exposed to the action of heat, in which the principles are volatilized, according to the order of their affinity for caloric, carrying with them a small quantity of the more fixed elements, in proportion as the sulphuric acid attracts the alcohol and the water, of which it favours the formation, the ether which is evolved attracts caloric, and is sublimed; and when the greatest part of the alcohol has been changed into ether, the mixture becomes denser, the heat more considerable, and the affinity of the sulphuric acid for the undecomposed alcohol being increased, the acid is decomposed, so that on one hand its oxygen combines with the hydrogen of the alcohol, and forms water, which rises gradually into vapour, whilst, on the other, the ether retaining a greater quantity of carbon, with which it rises in vapours at this temperature, affords the sweet oil of wine, which ought to be considered as an ether with a greater proportion of carbon. This seems to be proved by its greater specific gravity, less volatility, and its citron colour.

11. From this theory the ingenious authors have deduced the following practical conclusions.

a. The formation of ether is not owing, as was supposed, to the immediate action of the principles of the sulphuric acid on those of alcohol, but to the reaction of the principles of the latter on each other, and particularly of its oxygen and hydrogen, occasioned by the sulphuric acid.

b. A portion of alcohol may be converted into ether without the aid of heat, by increasing sufficiently the proportion of sulphuric acid.

c. With regard to the change which takes place on alcohol in the production of ether, the process may be divided into two periods. In the one, ether and water are only produced; in the other, sweet oil of wine, water, and sulphuric acid.

d. During the formation of ether, the sulphuric acid is not decomposed, and there is no production of the sweet oil of wine. When the latter makes its appearance, there is given out no more, or at least very little, ether; and at the same time the sulphuric acid is decomposed by hydrogen solely; whence sulphurous acid is formed.

e. The formation of the sweet oil of wine may be avoided, by keeping the temperature of the mixture between 200° and 207°. This is managed by introducing a few drops of water into the retort.

f. And lastly, alcohol differs from ether, in containing more carbon, less hydrogen and oxygen; and the sweet oil of wine is to ether very nearly what alcohol is to the former *.

* [F]ourcroy [and Vauquelin, Ann. de Ch]im. tom. [x]xiii. 161.

II. Of Nitric Ether.

1. Nitric acid, or rather nitrous acid, acts with much greater violence on alcohol than sulphuric acid. In this case the action must be moderated, either by diluting the two liquids, or by cooling the mixture. The first easy process which was proposed for the preparation of nitric ether, was given by Navier, a physician of Chalons.

844 Preparation by Navier.

2. The process of Navier is the following. He put into a strong bottle 12 parts of pure alcohol, and plunged it into cold water, or rather surrounded it with ice. To this he added, in different portions, eight parts of concentrated nitric acid, agitating the mixture, after every addition. The bottle is then stopped with a cork, which is secured with leather, and the mixture is set in a convenient place, to avoid the danger of accidents from the bursting of the bottle, which sometimes happens. At the end of some hours, bubbles rise from the bottom of the vessel, and drops are collected on the surface of the liquid, which gradually form a stratum of ether. This action continues for the space of six days. When it ceases, the cork is to be pierced with a needle, to permit the escape of a quantity of nitric oxide gas, which, without this precaution, would rush out rapidly on uncorking the bottle, and would carry along with it the ether, which would be lost. When the gas is dissipated, the cork is to be drawn out, and the whole liquid in the bottle is to be poured into a funnel. The ether swims on the top, and the remaining liquor being heavier, is allowed to pass off, and the ether is retained.

845 Beaumè.

3. This process was improved by Beaumè. He found that the greatest produce of ether was from two parts of acid to three of alcohol. He directed both ingredients to be used in the coldest state, by keeping each in melting ice, and the bottle in which the mixture is made, to be kept equally cold. In this proportion of ingredients, the danger of explosion is avoided, and the low temperature greatly moderates the violent action. The mixture in the bottle is always to be well agitated before any new addition of acid is made, and by this means the accumulation in any particular spot is prevented. The ether begins to form, as in the former process, in the course of a few hours; and if the bottle is allowed to remain undisturbed for eight or ten days, a quantity of ether equal to one half the weight of the alcohol is obtained, after which no more is produced.

846 Black's process.

4. Dr Black's process is described by himself in the following words. "Into a strong phial, having a ground stopper, I first pour four ounces of strong hale nitric acid. I then add three ounces of water, pouring it in so gently, that it swims on the surface of the acid. I then pour in after the same manner six ounces of alcohol. I put in the stopper slightly, and I set the phial in a tub of water or ice. The acid mixes slowly with the water, and in a diluted state comes in contact with the alcohol, on which it immediately acts, and ether is produced slowly and quietly. The liquor gets a dim appearance, because imperceptible bubbles are formed, which get to the top, and having collected to a certain degree, they lift the stopper, and escape (s). After eight or ten days, I find upwards of three ounces of nitric ether, though I am certain by the smell, that much escapes with the vapour. This is, however, a certain, easy, and safe process, though it is slow and imperfect *."

* *Black's Lect.* ii. 324.

847 Laplanche's.

6. Many other processes have been proposed for the preparation

(s) Dr Black, we believe, contrived a spring for the stopper which kept down the cork till it was pushed up by the elastic vapours; and when they had escaped, it returned to its place by the force of the spring.

Inflammable Substances.

preparation of nitric ether. Laplanche, a Parisian apothecary, has employed nitre, which he introduced into a tubulated stone-ware retort, and first pouring the concentrated sulphuric acid, and then the alcohol upon it, there is an immediate production of ether; but by this process it is suspected that the nitric ether may be mixed with sulphuric ether. He has therefore proposed another process, which is more complicated †.

† *Fourcroy Connaiss. Chim.* tom. viii. p. 170.

848 Chaptal's.

6. The process which has been proposed by Chaptal, is, according to Proust, the best that can be adopted. This process, with some additions and alterations, which he has found it necessary to make from his own experience, is the following. The proportions which he employs are, 32 ounces of alcohol, and 24 of nitric acid. These are introduced into a large retort, which is to be luted to a globular glass vessel, furnished with a tube of safety. A tube passes from this globe to a second, which is also furnished with a tube of safety. One or two ounces of water should be introduced into the second globe to shut up its tube of safety. Three bottles of Woulfe's apparatus, containing from 64 to 80 ounces of liquid, are then to be connected with the second globe. These bottles are half filled with alcohol. The alcohol and the acid are poured into the retort, and are mixed by agitation. The retort is luted to the glass globe, and heat is applied, with this precaution, that it must be removed as soon as there is any effervescence. The process now goes on, and requires no farther attention than occasionally cooling the globes and the bottles with cloths moistened with snow-water. The greatest part of the ether which is formed, condenses in the first bottle, and gives the alcohol a yellow colour. It then passes to the second, in which the colour is lighter, and at last to the third, where there is little perceptible change. To separate the ether of the first bottle, the mixture is to be saturated with an alkali, and distilled ‡.

‡ *Annal. de Chim.* tom. xlii. p. 261.

849 Purification.

7. But by whatever process nitric ether is obtained, it requires to be purified, to separate the acid and alcohol, which are generally mixed with it. This is done by distilling it from potash, which reduces its quantity; for the distillation must not be continued longer than when two-thirds or one-half of the first ether has come over. To purify this still more, it is directed to be mixed with one-fifth of nitrous acid, and distilled again, taking two-thirds of the product set apart, and rectify it from an alkali. The remainder which comes over is a less pure ether, which has been known under the name of *Hoffman's mineral anodyne liquor*. What remains in the retort has been called *dulcified spirit of nitre*.

850 Properties.

8. Nitric ether, thus obtained, is a yellowish coloured liquid, equally volatile as sulphuric ether. Its odour, though stronger and less sweet, is analogous to the sulphuric ether. The taste is hot and more disagreeable. It is often of a deeper yellow colour, and always contains a small excess of acid and nitrous gas. The stopper is frequently driven out of the bottle in which it is kept, for there is a constant evolution of a considerable quantity of gas.

851 Burns with a brilliant flame.

9. When kindled, it gives out a more brilliant flame, and a denser smoke, than sulphuric ether, and deposits a greater quantity of charcoal. When it is long kept in a close vessel, some water is formed, holding a small quantity of oxalic acid in solution, which falls to the bottom of the vessel.

852 Analogous to sulphuric ether.

10. Nitric ether is not only analogous to sulphuric ether in its properties, but also in the nature of the process by which it is obtained, and in the other products which accompany this process. But in the production of nitric ether, there is no deposition of charcoal, and the acid itself is decomposed. This appears from the great quantity of nitric oxide gas evolved during the process; and the reason assigned for the disappearance of the charcoal is, that the oxygen of the acid combines with it, and forms carbonic acid, which escapes in the form of gas. The products which are generally obtained in the processes for the preparation of nitric ether are nitrous gas, ether, oil, acetic acid, oxalic acid, and carbonic acid gas.

If equal parts of nitric acid and alcohol are mixed together, a violent effervescence immediately takes place, which is owing to the evolution of a great quantity of gas, which being a compound of ether and nitric oxide gas, has been denominated *etherised nitrous gas*. The same gas is obtained by employing a diluted acid; but then the mixture requires the assistance of heat. This gas may be collected in vessels over water. It has a disagreeable ethereal odour, quite different from the odour of nitric ether, and exactly similar to that kind of ether which is furnished by the oily carbureted hydrogen gas, treated with oxymuriatic acid gas. If a candle be applied to this gas, it burns slowly with a yellow flame. This gas is soluble in water, and is wholly absorbed; but the absorption is slow. The water acquires the odour of the gas. Alcohol also dissolves it completely, and more rapidly. Oxygen gas mixed with this gas, provided it be pure, produces no change; but when the mixture is kindled, there is a violent detonation. When this gas was exposed to sulphuric, nitric, and muriatic acids, the ether was absorbed by the acids, and the nitrous gas remained behind. The sulphurous acid in the state of gas, combined with an equal bulk of the inflammable gas, also decomposed it; but this effect did not take place till after several days §.

§ *Jour. Phys.* xl. p. 245.

If the alcohol and nitric acid be mixed together in the proportion of one of the former to three of the latter, and a gentle heat applied, there is a copious evolution of gas, which is composed of the etherised nitrous gas and nitric oxide gas. If towards the end of the process, when a small part of the liquid remains in the retort, it is allowed to cool, crystals are formed; and these crystals are found to be oxalic acid. They were formerly called *crystals of Hierne*, from the name of a Swedish chemist, who first discovered them ‖.

‖ *Ibid.* p. 346.

If one part of nitric acid be added to its own weight of alcohol, and one part of sulphuric acid be added soon after, the mixture is suddenly inflamed, and burns with great violence. In this case, when the products are collected, they are found to be ether and oil.

From this statement of facts, therefore, it appears, that the mode of production of nitric and sulphuric ethers is nearly the same; that the differences which take place, are owing to the different nature of the acids; the violent action which follows in the formation of

Inflammable Substances. of nitric ether, depending on the nitric acid itself being decomposed, and by the operation of new affinities, new actions having taken place.

III. Of Muriatic Ether.

3 Processes for obtaining. 1. Muriatic acid has no sensible action on alcohol, either by simple mixture, or by distilling them together, as in the former case. Beaumé obtained a small quantity of muriatic ether, by combining together muriatic acid and alcohol in the state of vapour. But other means were thought of for this purpose, and particularly the oxymuriate of antimony, and the oxide of zinc dissolved in muriatic acid, and to distil this salt, concentrated by evaporation, in close vessels with alcohol. By this process muriatic ether has been obtained. But the most successful method of procuring this ether, was proposed by Courtanvaux. His process is the following.

4 From salts of tin. 2. One part of alcohol is mixed with three parts of oxymuriate of tin, or the fuming liquor of Libavius, in a glass retort. A strong heat is produced, with the production of a white suffocating vapour, which disappears when the mixture is agitated. There is then emitted an agreeable odour, and the liquor assumes a lemon colour. The retort is then to be placed on a sand bath; two receivers are to be attached, one of which is to be immersed in cold water. There passes over at first some pure alcohol, and soon after the ether, which is known by its fragrant odour, and the streams which run down the sides of the retort. When the odour changes, and becomes sharp and suffocating, the receiver must be changed; and if the distillation be continued, a clear acid liquor is procured, on the surface of which are observed some drops of sweet oil, which is succeeded by a yellow matter of the consistence of butter, which is a true muriate of tin, and at last a brown heavy liquid, which exhales very copious white vapours; and there remains in the retort a gray matter in the state of powder.

5 Purification. 3. To purify this ether, it is put into a retort over carbonate of potash. A brisk effervescence takes place, and a very copious precipitate is produced. This is owing to the oxide of tin which the acid had carried off during the distillation. A little water is to be added, and distilled with a gentle heat. About the one-half of the product of the ether is thus obtained. All the fluids which come over after the muriatic ether, are loaded with oxide of tin; they attract moisture from the air, and combine with the water without any precipitation.

6 Prepared from common salt, 4. Another method has been proposed for the preparation of muriatic ether by Laplanche. He pours into a tubulated retort sulphuric acid and alcohol on common salt which has been strongly dried. The muriatic acid gas, disengaged by the sulphuric acid, meeting the vapours of the alcohol in the retort, combines with them. In this way an ether is obtained, which may be purified in the usual way. But, in this process, Fourcroy thinks that the production of ether is owing to a small portion of oxymuriatic acid which is formed during the process.

7 and manganese. 5. Pelletier has succeeded in obtaining muriatic ether, by distilling in a large tubulated retort, a mixture of oxide of manganese, common salt, concentrated sulphuric acid, and alcohol. The quantity of ether obtained by this process is equal to one half the weight of the alcohol employed.

6. Another process has been proposed by Berthollet, by distilling with a gentle heat alcohol which has been saturated with oxymuriatic acid gas, and by distilling the oxide of manganese, a mixture of alcohol, and strongly concentrated muriatic acid. 858 and oxymuriatic acid gas.

7. Muriatic ether, thus obtained, is transparent and very volatile. It has nearly the same odour as sulphuric ether. It burns like it, and gives out a similar smoke; but it differs in two of its properties; the one is, that it exhales, while burning, an odour as pungent and acrid as sulphurous acid; and the other is, that the taste is astringent like that of alum. This difference in odour and taste is owing, it is supposed, to some extraneous substances with which it is contaminated; for in the whole process of its formation it appears to be exactly the same; a constant product of the decomposition of alcohol, by whatever re-agent this is effected. 859 Properties.

IV. Acetic Ether.

1. An ether has also been obtained by distilling a mixture of acetic acid and alcohol. This was the first process which was employed in the production of this ether. It was discovered by the count de Lauraguais in 1759. It has been improved by Pelletier, who distilled equal quantities of acetic acid, obtained from acetate of copper, and alcohol. It was then poured back into the retort, and distilled a second time. When this process is finished, it is distilled a third time, and the product of the third distillation is a mixture of acetic acid and ether. To separate the acid from the ether, it is saturated with potash, and distilled with a gentle heat. The acetic ether passes over in a state of purity. 860 Preparation.

2. Another process has been proposed to obtain the same ether. Take 16 parts of acetate of lead, six parts of concentrated sulphuric acid, and nine parts of alcohol. Let it be distilled till ten parts come over. Let this liquid be agitated with one third of its bulk of lime water; the ether separates and swims on the top. The quantity generally amounts to about six parts.

3. This ether is similar to the other ethers in its properties, excepting that it has a slight odour of acetic acid.

4. Ether has also been formed by several other acids, and it appears, that these acids possess one common property in their action on alcohol, for all the ethers produced by the different acids are nearly the same, and indeed it is supposed would be exactly the same, were it not that they are contaminated with extraneous matters derived from the acids, the alcohol, or other substances, which are employed in their formation.

Sect. III. *Of Fixed Oils.*

1. Oils, which are copious productions of nature, have been long known; and their extensive utility in domestic economy and the arts, has always rendered them objects of great importance. The general characters of oils are combustibility, insolubility in water, and fluidity. From the peculiar properties of different oils, 861 Oils of two kinds.

Inflammable Substances. oils, they are naturally divided into two kinds; fixed or fat oils, and volatile or essential oils. The fixed or fat oils require a high temperature to raise them to the state of vapour, a temperature above that of boiling water; but the volatile or essential oils are volatilized at the temperature of boiling water, and even at a lower one. Both the volatile and fixed oils are obtained from plants, and sometimes from the same plant, but always from different parts of it. While the seeds yield fixed oil, the volatile oil is extracted from the bark or wood.

862 Found only in the seeds of vegetables. 2. One of the most distinguishing characteristics of the fixed oils is, that they exist only in one part of the vegetable. They are only found in the seeds. No trace of fixed oil can be detected in the roots, the stem, leaves, or flowers of those plants, whose seeds afford it in great abundance. The olive may seem an exception to this. The oil which it yields is extracted, not from the seed, but from its covering. Among plants too, fixed oils are only found existing in those whose seeds have a peculiar structure. The seeds of plants have sometimes one lobe, in which case they are called *monocotyledonous* plants; and sometimes they have two, when they are denominated *dicotyledonous*. The formation of fixed oil in plants is exclusively limited to the latter class. There is no instance of fixed oils being found in the seeds of plants which have only one lobe †. Those seeds which yield the fixed oils, contain also a considerable portion of mucilage, so that when such seeds are bruised and mixed with water, they form what is called an *emulsion*, which is a white fluid containing a quantity of the oil of the seed mixed with the mucilage. One of the most common emulsions, that of almonds, is an instance of this.

† *Fourcroy, Connaiss.* vii. 319.

Fixed oils are extracted from the seeds of a great number of plants. Those which yield it in greatest abundance are, the olive, thence called *olive oil;* the seeds of lint, and the kernels of almonds, called *linseed*, or *almond oil.* Fixed oils are also obtained from animals; such is *train oil*, as it is called, which is extracted from the fat or blubber of the whale. They are obtained in great abundance from the livers of animals, and a fixed oil is found to exist in the eggs of fowls.

863 Have different properties. 3. These different kinds of fixed oils, although they possess many common properties, are very different in others. Many of the vegetable oils have no smell, and scarcely any perceptible taste. The animal oils are generally nauseous and offensive. These differences are supposed to be owing to the admixture of extraneous bodies, or to certain chemical changes arising from the action of those bodies upon each other, or on the oil itself.

864 Preparation. 4. As the fixed oils exist ready formed in the seeds of plants, they are generally obtained by *expression*, and hence they have been called *expressed oils.* This is done by reducing the seeds to a kind of pulp, or paste, which is inclosed in bags, and subjected by means of machinery, when it is obtained in the large way, to strong pressure, so that the oil flows out, and is easily collected. The oil obtained by this process, which has been called *cold drawn;* because it is procured without the application of heat, and merely by pressure, is the purest; but the quantity of this which seeds in general yield is comparatively small, and some seeds, which contain a considerable portion of oil, scarcely afford any when treated in this way. It therefore becomes necessary for extracting the oil from seeds of the latter description, and to have it in greater abundance from all seeds, to employ heat, to facilitate the separation of the oil from the mucilage or other matters with which it is combined. For this purpose heat is applied, either to the apparatus which is employed in pressing out the oil, or the bruised seeds are exposed to the vapour of water, and sometimes they are boiled in the water itself, by which means those substances which are soluble in water, are separated, and thus the oily part which adhered to these substance, is disengaged.

5. Oils obtained in this way are very impure. They are mixed with mucilage, and other parts of the substances from which they have been extracted. Many of these matters separate from the oils when they are left at rest. They are sometimes mechanically purified by filtration through coarse cloths, by which means the grosser parts are separated. Different oils too, it is said, are subjected to different kinds of purification by different manufacturers, but these processes are kept secret. After they have remained at rest for some time, they are filtered and agitated with water, by which the parts that are soluble in this fluid are separated from the oil. Sometimes they are gently heated, for a shorter or longer time, according to the nature of the substances with which the oil is contaminated. Acids diluted with water are employed to separate the mucilage; lime and the alkalies are also used to combine with an acid which holds this mucilage in solution, and thus to favour its precipitation. Alum, chalk, clay, and ashes, are also employed in the purification of oils. 865 Purification.

6. Fixed oils are generally liquid, but of a thick, viscid consistence. They are mild or insipid to the taste; sometimes, however, they have a peculiar taste, which is analogous to that of the plant from which they have been extracted. When pure, they have no smell, but are sometimes impregnated with the odour of the seed which produces them. The fixed oils are rarely quite colourless, but are generally green or yellowish. If they are green when fresh prepared, this colour changes to a yellow, and in time to an orange or red. Fixed oils in general are lighter than water. The specific gravity varies from 0.9153, which is that of olive oil, to 0.9403, that of linseed oil. The boiling point of the fixed oils is not under the temperature of 600°. When exposed to cold, they congeal, and even crystallize. There is, however, a considerable variety in this respect, among fixed oils; some become solid at the temperature of a few degrees above the freezing point of water; while others, on the contrary, require a degree of cold $= 5°$; and some remain fluid when exposed to the greatest cold. Those oils, it has been observed, which most readily become solid, such as olive oil, are least subject to change, while those which congeal with difficulty have a greater tendency to spoil and become rancid. 866 Properties.

7. When fixed oil is exposed to heat, it does not evaporate, till it is raised to the temperature of boiling, or 600°; but when it is thus raised in vapour its properties are changed. It is decomposed by the separation of some of its principles. The part that is volatilized has a greater proportion of hydrogen; charcoal is deposited 867 Action of heat.

Inflammable Substances.

deposited, and water and sebacic acid are formed, while carbureted hydrogen gas is disengaged. By this distillation an oil was produced, denominated by the older chemists *philosophical oil*.

When oil is exposed to the open air, and a burning body is brought in contact with it, it readily takes fire, and burns rapidly, with a yellowish white flame. It is on this conversion of oil into vapour, and the inflammation of this vapour, that the application of oil in lamps and candles depends. The oil is gradually, and in small quantities, brought in contact with the burning part of the wick; it is converted into vapour, which is immediately inflamed, and continues to burn till new portions are supplied to undergo the same change, and thus keep up a constant and uniform light and heat.

8 Composition.

8. According to the analysis of olive oil by Lavoisier, it is composed of hydrogen and carbon. In the experiment which he instituted to ascertain its component parts, he burnt

oil	15.79 grs. troy.
oxygen gas	50.86
	66.65

The products of this combustion were water and carbonic acid. The weight of the water could not be ascertained with much precision, but the quantity of carbonic acid which was formed amounted to 44.50 grs. This quantity subtracted from the whole weight of the substances consumed, namely the oil and oxygen gas, left 22.15 grains for the weight of the water. The proportion of oxygen in this quantity of water is 18.82 grs. which leaves 3.33 grs. of hydrogen, the other component part. The proportion of oxygen in 44.50 grs. carbonic acid gas is 32.04 grs. which leaves 12.46 of carbon. The oxygen of the water and of the carbonic acid, namely 18.82 grs. of the one, with 32.04 grs. of the other, make up the whole quantity of oxygen, namely 50.86 grs. that was consumed. From this analysis, therefore, 15.79 of olive oil are composed of

12.46	carbon,
3.33	hydrogen.
15.79	

The component parts, therefore, of 100 grains of olive oil are

78.92	carbon,
21.08	hydrogen.
100.00	

Insoluble in water.

9. The fixed oils are insoluble in water. When it is necessary to combine them with this liquid, it is by means of mucilaginous substances, in which case the mixture is known under the name of *emulsion*, or with alkaline substances, when it is distinguished by the name of soap.

Action of air.

10. When fixed oils are exposed to the air, they undergo peculiar changes; and these changes are different, according to the nature of the oil.

11. Some of these oils become thick, opaque, white, granulated, and are analogous in appearance to tallow. Oils subject to this change are called *fat oils*, such, for instance, is olive oil, almond oil, and rapeseed oil. This change is more or less rapid in different circumstances. If a thin layer of oil be spread on the surface of water, and exposed to the air, it takes place in a few days, and this effect is owing to the absorption of oxygen, which combines with the oil. It was supposed by Berthollet, that it depended on the action of light; but his experiments were repeated by Senebier, who found that olive oil when kept in the dark became rancid, while the same kind of oil exposed to the light, but excluded from the air, remained unchanged *.

* *Seneb. Ann. de Chim.* xi. 91.

871 Drying.

12. Other soils, when exposed to the air, dry altogether, yet have the property of retaining their transparency. Those which have this peculiar property are called *drying oils*. The oil of poppies, hempseed oil, and particularly linseed oil, are possessed of this property. The nature of the change which takes place in these drying oils, is supposed to depend on the absorption of oxygen; and this oxygen combining with the hydrogen of the oil forms water. This opinion is supported by the practice which is followed to increase the drying property of linseed oil. It is usually boiled with litharge, before it is employed by painters. The litharge in this case is partly reduced to the metallic state, by being deprived of its oxygen, which is supposed to combine with the oil.

872 Rancidity.

13. But many of the fixed oils, when exposed to the air for a sufficient length of time, undergo a farther change, and acquire very different properties. They are then said to become *rancid*. During this change, they assume a brown colour, have the property of changing vegetable blues to red, and acquire a peculiar smell and taste. In this change, the sebacic acid is formed, which depends on a new combination of the hydrogen and carbon of the oil, in certain proportions with the oxygen absorbed from the atmosphere. To this acid, therefore, the rancidity of oils seems to be owing. Part of the hydrogen of the oil too, it would appear, combines with the oxygen, and forms water †.

† *Fourcroy Connaiss. Chim.* vii. 328.

873 Action of charcoal.

14. Carbon in the state of charcoal has no action upon oils; but they are purified and rendered colourless by being passed through charcoal powder.

874 Of phosphorus.

15. Phosphorus combines with oils, with the assistance of heat. A small portion of the phosphorus is dissolved, which communicates a luminous property to the oils, so that when they are spread upon any surface, they shine in the dark. When the oil is completely saturated with the phosphorus, with the assistance of heat, and is allowed to cool, part of the phosphorus is deposited, and crystallized in transparent octahedrons. When this phosphureted oil is distilled, phosphureted hydrogen gas is disengaged.

875 Of sulphur.

16. Sulphur easily combines with fixed oil, with the assistance of heat. The solution, which was formerly called *ruby of sulphur*, is of a reddish colour. When it cools, the sulphur crystallizes, by which process Pelletier obtained sulphur in the form of octahedrons. When the cooling is too rapid, the sulphur is precipitated

tated of a yellow colour, in the shape of needles. If this sulphurated oil, which has a peculiarly fetid odour, be distilled, it affords a great quantity of sulphurated hydrogen gas †.

† Fourcroy, Connaiss. Chim. vii. 329.

876 Of Acids.

17. The acids have a powerful effect on the fixed oils. The sulphuric acid, when concentrated, decomposes them. They become brown, thick, and at last of a black colour. Water is formed, charcoal is precipitated, and even an acid is formed. Nitric acid in the cold, thickens fixed oils by communicating part of its oxygen. In the state of nitrous acid it produces a more violent action. There is a considerable effervescence, with the evolution of a great quantity of nitrous gas. If a mixture of nitrous acid and concentrated sulphuric acid be thrown upon fixed oils, they instantly inflame, and leave behind a spongy mass of charcoal. Muriatic acid has little effect on fixed oils, but the oxymuriatic acid thickens and bleaches them, in the same way as tallow or wax.

877 Uses.

18. The various purposes to which fixed oils are applied, are too well known to require particular enumeration. They are employed in domestic economy as articles of food, and for this purpose are used alone, or in combination with other substances. They are employed for giving light, by being burnt in lamps. They are used in medicine, either on account of the active properties which peculiar oils possess, or on account of the mechanical properties which they communicate to other substances with which they are combined. In this state the use of oils is well known in the form of unguents, plasters, and liniments. In the arts, fixed oils are of the most extensive utility. They are employed in the fabrication of soaps, for mixing colours in painting, for some kinds of varnish, and for defending substances from the action of air and moisture ‡.

‡ Ibid. vii. p. 330.

878 Affinities.

19. The order of the affinities of fixed oils is the following:

Lime,
Barytes,
Fixed alkalies,
Magnesia,
Ammonia,
Oxide of mercury,
Other metallic oxides,
Alumina.

Sect. IV. *Of Volatile Oils.*

879 Characters.

1. Volatile oils are distinguished from the fixed oils by their volatility, fragrance, and acrid taste. They are also known under the name of *aromatic oils*, from their odour; or *essential oils*, or simply *essences*, from being supposed to constitute the *essence* of the vegetable matters which furnish them.

880 Names.

2. Volatile oils are not limited to particular parts of plants, but are found to exist in every part of the plant,

881 Found in all parts of plants but the lobes of the seeds.

excepting in the seed, which furnishes the fixed oils. A great number of roots which are generally distinguished by an aromatic odour, and have more or less of an acrid taste, afford volatile oils. They are furnished also by many woods, such as those of the pine and fir tribe, and by many of those which are natives of warm climates. The leaves of a great number of plants belonging to the didynamia class also afford volatile oil, as well as many of the umbelliferous plants. It is obtained from many flowers of vegetables, and from the covering of many fruits, as the skin of oranges and lemons. It is also obtained from a great number of seeds; it is never found in the cotyledons or lobes themselves, but only in the external covering. The quantity of volatile oil which is obtained from vegetables, varies according to the age, the soil in which they grow, and the state of the plant. Some plants, while green, furnish it in greatest abundance; while others yield most when they are dry. 882

Prepara-tion.

3. There are two processes by which volatile oil may be obtained. When it exists in plants in great abundance, and in vesicles in a fluid state, it may be separated by mechanical means. Thus, by simple expression, the volatile oils are extracted from many plants, as, for instance, from the fruit of the orange and the lemon. From the outer rind of these fruits, when they are fresh, the volatile oil is obtained in the liquid form; but in general, the volatile oils of plants are neither so abundant, nor do they exist in that state of fluidity, by which they can be procured by so simple a process. In most cases they are subjected to the process of distillation; and for this purpose they are macerated for some hours in water. They are then introduced into a still along with the water; a moderate heat is applied and continued till the fluid boil, when a great quantity of vapour of water, mixed with the volatile oil, passes over, and is received in proper vessels. The oil collects on the surface of the water, from which it may be easily separated. The water itself is of a milky colour, on account of a small quantity of oil suspended in it; and even after the water becomes transparent by the particles of the oil separating from it, and rising to the top, it is still loaded with the peculiar odour of the plant. This was supposed to be a separate principle of vegetables, to which Boerhaave gave the name of *spiritus rector*, and which is still known by the name of *aroma*. This fragrance of the water is owing to the solution of a certain portion of oil in it. In the distillation of the volatile oils, different practices are followed, according to the nature of the plant, and the proportion of the oil existing in it. The roots, wood, bark, fruits, dried plants, after being cut in pieces, rasped down or bruised, are macerated for some hours, or for some days, according to the solidity or particular state of the vegetable matter. Fresh plants are distilled with the smallest quantity of water, have no need of previous maceration, and do not require so high a temperature. 88[3]

4. The volatile oils are particularly distinguished by their fragrance, which varies in the oils extracted from different plants. The consistence of the volatile oils also varies considerably. Sometimes they are as fluid as water, which is the case with those obtained by expression. Some are thick and viscid, as those generally are which are extracted from woods, roots, barks, and fruits of the warmer regions. Some congeal, or assume a granulated solid consistence at different temperatures. Of these last, some are always found to be in the concrete state. Several of the volatile oils are susceptible of crystallization, depositing in the remaining portion of the oil which continues liquid, transparent polyhedrons, more or less of a yellow colour, which are found to be pure oil. This last change, Vauquelin

Fragr[ance]. 88[4] Fluidi[ty]. 88[5] Cryst[allization].

Vauquelin thinks, is owing to an incipient oxidation; for it never takes place, unless oils have been kept for some time.

5. There is great variety of colour among volatile oils. Some are nearly colourless, as the oil of turpentine; some are yellow, as the oil of lavender; some are of a reddish yellow or brown, as the oil of cinnamon or of rhodium; some blue, as the oil of chamomile; and some green, as that of parsley. But the most prevailing colour among volatile oils is yellow or reddish.

6. Volatile oils have almost always an acrid, and even burning taste. Yet it is observed that the most acrid vegetable matters do not yield an oil possessed of this quality. The specific gravity of volatile oils is generally less than that of water. Some, however, as those of sassafras and canella, have a greater specific gravity. The specific gravity of oils varies from 0.8697 to 0.9910, in those which are lighter than water; but those which are heavier are from 0.0363 to 1.4049.

7. When volatile oils are exposed to the light, the colour becomes considerably deeper; they become thicker, and increase in specific gravity. In speaking of a similar change which takes place in the fixed oils, this change was ascribed to the absorption of oxygen; but, according to the experiments and observations of M. Tingry, it is effected merely by the action of light; for in his experiments oxygen gas was entirely excluded *.

8. Volatile oils, when exposed to heat, evaporate very readily. They are much more combustible than the fixed oils; and in burning give out a great quantity of smoke, a very bright white flame, and a good deal of heat. They require a greater proportion of oxygen than the fixed oils, and yield a greater quantity of water. This arises from a greater proportion of hydrogen, and a smaller quantity of carbon, which they contain.

9. When volatile oils are exposed to the open air, they undergo another change. They assume a deeper colour, and become viscid, exhaling at the same time a very strong odour. The air around is deprived of its oxygen; it combines with the hydrogen of the oil, and forms water, which is observed in drops on the surface. Many of the volatile oils when thus exposed pass into the resinous state, and are almost entirely deprived of their odour. This depends on the loss of part of their hydrogen, and the increase of the proportion of carbon.

10. The volatile oils are in some degree soluble in water. When agitated with this liquid, they combine with it, and communicate to it a very strong odour, and a slightly acrid taste.

11. Phosphorus and sulphur are soluble in volatile oils. With phosphorus the solution is luminous in the dark, is extremely fetid, and gives out, by the force of heat, phosphureted hydrogen gas. The combination with sulphur is known under the name of *balsam of sulphur*. This gives out sulphureted hydrogen gas on the application of heat.

12. The concentrated sulphuric acid produces a brown colour, increases the viscidity of the volatile oils, and disengages part of their hydrogen with effervescence and heat. Part of the oil is decomposed; charcoal is deposited, and it contains an acid. Nitrous acid, when brought into contact with the volatile oils, produces instantaneous deflagration; converts them in a great measure into water and carbonic acid; and a voluminous mass of charcoal remains behind. Muriatic acid has scarcely any action; but oxymuriatic acid renders them colourless, concrete in part, or viscid, and brings them more nearly to the state of resins.

Inflammable Substances.

594 Uses.

13. Some of these oils are employed in medicine. They are used also for the solution of those substances which are to be employed as varnishes; and many of them are used in perfumery.

595 Tests of purity.

14. Many of the volatile oils being produced in small quantity, are high priced. There is therefore some temptation to adulterate them with fixed oils, with cheaper volatile oils, or with other substances, to increase the quantity. Hence it is of some importance to be able to detect such frauds. When a volatile oil is adulterated with a fixed oil, there is a very easy test to discover it. Let a single drop of the oil that is suspected fall on clean paper, and expose it to a gentle heat. If the oil is pure, the whole will be evaporated, and no trace will remain on the paper; but if it has been mixed with a fixed oil, a greasy spot remains behind. Volatile oils are frequently adulterated with oil of turpentine; but this can only be detected by its peculiar odour, which continues for a longer time than most of the other volatile oils. When they are adulterated with alcohol, it is easily detected by mixing a little of the oil with water, which immediately produces a milkiness, by the abstraction of the alcohol from the oil, and its combination with the water.

596 Empyreumatic oils.

15. There is another class of oils known under the name of *empyreumatic oils*, which have different properties from those which have been described. These oils are acrid and stimulating, with a strong fetid and disagreeable odour. It would appear that these properties are owing to a partial decomposition of other oils. These oils are produced, as the name imports, by the action of fire. They are obtained when oils are forced to rise in vapour, and pass over in common distillation, with a greater degree of heat than that of boiling water, or by the application of a strong heat to substances from which no oil was previously extracted. These empyreumatic oils agree in some of their properties with the volatile oils. They combine in small proportion with water, and they are soluble in alcohol; and probably any difference that exists between them is owing to a partial decomposition; for when they are distilled, the oil is restored to a state of purity, and the carbonaceous matter which had been separated, remains behind.

Chap. XII. Of ALKALIES.

597 Origin of the name.

The word *alkali* is derived from the Arabian name of a plant, *kali*, which affords the substance now distinguished by that term. When other substances were discovered, possessed of similar properties, the meaning of the term was extended, and applied to such matters as had several common properties. Three substances have been generally ranked under the head of alkalies. These are potash, soda, and ammonia; to to which has lately been added lithina. Some other substances, also, of vegetable origin, are now considered as alkalies. But these will be more advantageously introduced in a different place. The alkalies are characterised by the following properties.

898 Characters.

1. They have a peculiar taste, which is disagreeably caustic, even when they are diluted with water.

2. They change vegetable blue colours to a green.

3. They have a strong attraction for water, and combine with it in all proportions.

4. They have a strong affinity for acids.

5. They melt in a moderate heat, but with a stronger heat they are volatilized.

899 Natural division.

The alkalies have been divided into two kinds, namely, the *fixed* and *volatile*. Potash and soda, and lithina, are denominated *fixed alkalies*, because they require a great degree of heat to dissipate or volatilize them. Ammonia has been called the *volatile alkali*, because a very moderate degree of heat is sufficient to volatilize it.

Fourcroy has classed two of the earths, namely, barytes and strontites, under the head of alkalies. In some of their properties, these earths, no doubt, are analogous to the alkalies; but in other properties they are more closely allied to the earths. There seems, therefore, to be no inconveniency or ambiguity in classing them, as usual, among earthy substances.

It may perhaps be considered as one of the general characters of the alkalies which we have now enumerated, that they have no action on oxygen, azotic, or hydrogen gases; nor is there any action between the alkalies and carbon.

Sect. I. *Of Potash and its Combinations.*

900 Names.

1. This substance has been long known in commerce, under many different names, derived from the substances from which it is extracted, or from the processes by which it is prepared. The name of *ash* or *ashes* has been given to this substance, because it is procured from the burnt ashes of vegetables; and it has received the epithet of pot-ashes, because it is prepared in iron pots. It got the name of vegetable alkali, because it was supposed that it only existed in vegetables. Being prepared from nitre and tartar, it was called the *alkali of nitre* or *tartar*, and the *salt of tartar*, a name which it still retains in the shops. It has been proposed also to distinguish it by the term *kali*, the name of the plant from which it was originally procured.

901 Preparation.

2. Potash is generally prepared by burning wood or other vegetable matters, and thus reducing them to ashes. The ashes are then to be washed repeatedly with water, till the liquid comes off perfectly tasteless. If the liquid thus obtained be purified by filtration, and evaporated to dryness, a salt is obtained, which is the potash. In this state it is contaminated with much extraneous matter; but if it be exposed to a red heat, many of the foreign substances with which it is mixed, are dissipated; it becomes whiter, and from its colour is then sold under the name of *pearl-ash*. This salt is prepared in great abundance in those countries where wood abounds, as in North America and the north of Europe; and hence it is known in commerce under the name of *Russian* or *American pearl-ash*.

3. Potash, in this state, is considered as sufficiently pure for the ordinary purposes of life to which it is applied; but it is still mixed with much foreign matter, which renders it unfit for the purposes of the chemist. It has therefore always been considered as an object of great importance, to obtain it in a state of purity.

902 In this state is impure.

But even when it is seemingly pure, by being deprived of all extraneous substances, it is found to possess very different properties, after being subjected to certain processes. In one state it is comparatively mild and inactive; in another, extremely acrid and corrosive. Various opinions were entertained of the cause of this remarkable difference. The true cause was discovered and demonstrated by Dr Black in the year 1756. This ingenious philosopher, by a few simple and satisfactory experiments, clearly proved, that the different states of the alkalies, lime, and magnesia, are owing to their combination with a peculiar substance, to which he gave the name of *fixed air*, because it is fixed in these bodies. This fixed air, it has been already observed, is now known by the name of *carbonic acid*. When the alkalies are in combination with carbonic acid, they are in the mild state; but, when they are deprived of this acid, their effects being more powerful and corrosive, they are said to be in the caustic state.

903 Black's discovery.

When sulphuric acid is poured upon a quantity of potash in its ordinary state, an effervescence takes place. This, Dr Black proved, is owing to the escape of the carbonic acid in the state of gas; for when the alkali is in its pure or caustic state, no effervescence takes place. He also proved, that the alkalies and lime in their mild state, that is, when combined with carbonic acid, are heavier than in the caustic state, and that this difference of weight is exactly equal to the quantity of carbonic acid which escapes. Since, then, these substances exhibit such different properties in these two states, it is necessary to procure them in a state of purity, to examine their properties and effects. This is not without difficulty, on account of the strong affinity which exists between the alkalies and carbonic acid; for although previously pure, as soon as they are exposed to the air, they begin to attract the carbonic acid, and return to their former mild state.

904 Purification.

4. As this, therefore, is an object of importance, various processes have been proposed, to procure them as pure as possible. In these processes the principle is to separate the carbonic acid by the superior affinity of quicklime, and to dissolve it in alcohol, which leaves other substances behind.

905 Berthollet's process.

a. The following process for the purification of potash is recommended by Berthollet. It is to be mixed with double its weight of quicklime, with eight or ten times the weight of the whole mixture, of pure or rain water. Boil it for two or three hours in an iron vessel; then let it remain in a close vessel for 48 hours, taking care to agitate it occasionally. Let it afterwards be filtered, and boiled in a silver vessel with a strong heat, till it assume the consistence of honey. Pour a quantity of alcohol upon it, equal in weight to one-third of the alkali which has been employed; then put it on the fire, and let it boil for some minutes. Pour it afterwards into a bottle and allow it to cool. The matter in the bottle separates into three different strata:

Potash, &c.

strata: at the bottom are deposited solid bodies; in the middle there is an aqueous solution, or carbonate of potash; and on the top a liquor of a reddish brown colour, mixed with alcohol. Let this be carefully decanted off by means of a syphon. This is a solution of pure potash in alcohol. Put it into a bason of silver, or of tinned copper; evaporate it rapidly, till a dry, black and charry crust forms on the surface, and the liquor below, which has an oily appearance, becomes solid by cooling. Let the crust be removed, and pour the solution into porcelain vessels. When it cools, it becomes solid. It is then to be broken in pieces, and put into close vessels. This is the potash in a state of purity, not only freed from foreign matters, but also deprived of the carbonic acid.

Lime has a stronger affinity for carbonic acid than potash. When, therefore, lime deprived of its carbonic acid, as it is in the state of quicklime, is brought into contact in sufficient quantity with the potash, it deprives it of the carbonic acid. It is with this view that the lime is employed in this process. The alcohol has the property of dissolving potash, but has no action on the other substances with which it is combined. This is the reason why the alcohol, holding in solution the pure potash by its less specific gravity, forms the upper stratum in the bottle. By the evaporation, the last step of the process, the alcohol and water are driven off, and the pure potash remains behind in the solid state.

906 Lowitz.

b. A more economical process has been proposed by Professor Lowitz of Petersburgh. He boils together the potash and quicklime, as in the former process; filters the liquor, and evaporates, till a thick pellicle is formed on the surface. It is then set by to cool, till crystals are formed in it, which are crystals of extraneous salts, and are to be removed. He then continues the evaporation, and removes the pellicle as it forms on the surface during the process. When the fluid ceases to boil and no more pellicle is formed, he removes it from the fire, and keeps constantly stirring it while it cools. He then dissolves it in double the quantity of cold water, filters the solution, and evaporates in a glass retort, till regular crystals begin to be deposited. If the mass should consolidate ever so little by cooling, a small quantity of water is to be added, and it must be heated again, to render it fluid. When a sufficient quantity of regular crystals has been formed, he decants the liquid, which has a brown colour, and re-dissolves the salt after it is suffered to drain, in the same quantity of water. The decanted liquor is preserved in a well-closed bottle for several days, till it subside and become clear. He then decants it, evaporates, and crystallizes a second time, and repeats this process as long as the crystals afford, with the least possible quantity of water, solutions that are perfectly limpid. These solutions are to be preserved in well-closed bottles, to defend them from the access of air *.

907 Klaproth.

c. The method of preparing pure potash by the indefatigable and accurate Klaproth, is somewhat different from this. We shall detail it in his own words. "As many persons think that the preparation of a perfectly pure caustic ley is subject to more difficulties than it really is, I will here briefly state my method of preparing it. I boil equal parts of purified salt of tartar, (carbonate of potash, or vegetable alkali prepared from tartar) and Carrara marble, burnt to lime, with a sufficient quantity of water, in a polished iron kettle; I strain the ley through clean linen, and though yet turbid, reduce it by boiling, till it contain about one half of its weight of caustic alkali; after which I pass it once more through a linen cloth, and set it by in a glass bottle. After some days, when the ley has become clear of itself, by standing, I carefully pour it off from the sediment into another bottle. To convince myself of its purity, I saturated part of it with muriatic or nitric acid, evaporate it to dryness, and re-dissolve it in water. If it be pure, no turbidness will take place in the solution. The quantity of caustic alkali which this ley contains, I ascertain by evaporating a certain weighed portion of the ley to dryness, in an evaporating dish of a known weight. I also take care, in the preparation of this caustic ley, that the alkali be not entirely deprived of carbonic acid; because, in that case, I can with greater certainty depend on the total absence of dissolved calcareous earth. By employing burnt marble, or in its stead burnt oyster-shells, I avoid the usual contamination of the caustic ley by aluminous earth; because lime, prepared from the common species of lime-stone, is seldom entirely free from argil" †.

† Analyt. Essays, Pref. p. 8. Transl.

908 Properties.

5. Potash, thus obtained, is a white solid substance, which is susceptible of crystallization, in long, compressed, quadrangular prisms, terminating in sharp-pointed pyramids. These crystals, which are only obtained from very concentrated solutions, are soft and deliquescent, i. e. they attract moisture from the atmosphere. The taste is extremely acrid; and it is so corrosive, that it destroys the texture of the skin, the moment it touches it. It is from this property that it has derived the name of caustic, or the *potential cautery*, because it is employed for the purpose of destroying excrescences. According to Hassenfratz, the specific gravity of potash is 1.7085. It converts vegetable blues into a green colour.

909 Action of heat.

6. Light has no action on potash. When it is heated in close vessels, it becomes soft and liquid, and is afterwards converted into a white, opaque, and granulated mass, when it cools. If the heat be increased to redness, it swells up, and rises in vapour. If the vessel be opened, a white smoke arises, which is extremely acrid, and condenses on cold bodies with which it comes in contact. But though it is thus sublimed, it undergoes no other change than assuming a slight green colour.

7. There is no action between potash and oxygen or azotic gases, nor is there any direct action between it and carbon. Phosphorus and sulphur enter into combination with potash, and form peculiar compounds, the nature of which we shall consider, after having detailed the general properties of potash.

910 Of water.

8. Potash has a very strong affinity for water. Water, at the ordinary temperature, dissolves double its weight. The solution, when the potash is pure, is colourless and transparent, and nearly of the consistence of oil.

911 Acids.

9. Potash combines readily with the acids, and forms compounds with them, having different properties, according to the nature of the acid employed. Its affinities for the acids are in the following order: 912 Affinities.

Sulphuric,

Sulphuric,
Nitric,
Muriatic,
Phosphoric,
Phosphorous,
Fluoric,
Oxalic,
Tartaric,
Arsenic,
Succinic,
Citric,
Lactic,
Benzoic,
Sulphurous,
Acetic,
Saclactic,
Boracic,
Carbonic,
Prussic.

913 Uses.

10. Potash is employed for a great variety of purposes; it enters into combination with many substances, and forms with them valuable and important compounds. It is employed in medicine as a useful and powerful remedy; and in many arts and manufactures, as in bleaching, dyeing, and glass-making.

914 Composition.

This substance, though the subject of various conjectures as to its composition, was never analyzed till the year 1807, when Sir H. Davy effected this object by the application of a powerful galvanic apparatus. A piece of potash, slightly moistened, is laid on a plate of platinum, which is connected with the one end of the battery. The potash is, at the same time, touched with a wire of platinum, connected with the opposite end of the series. Fusion takes place at the two points of contact; oxygen is given out at the positive end, and at the negative, globules of metallic lustre make their appearance. These globules, with the oxygen, form the constituents of potash. The metalloid thus discovered has received the name of potassium. It is remarkably light, more so than alcohol, ether, or any known liquid. Potassium has a strong attraction for oxygen, and decomposes water with great readiness, combining with the oxygen to form potash, and setting hydrogen gas at liberty. When burnt in oxygen gas, it combines with a larger proportion of oxygen; the compound is called a peroxide; and when this compound is thrown into water, its superabundant oxygen is given off in the gaseous form, and the proportion just requisite to constitute potash is established.

Potash may also be decomposed by means of iron filings, under an intense white heat, in an iron tube; the due provision being made for preserving the potassium, which is distilled over in union with hydrogen, from the contact of air or water.

The strong affinity of potassium for oxygen, renders it a convenient instrument for analysing those bodies containing oxygen, which retain that principle by an affinity too strong to yield to other agents. Thus, by means of potassium, several other simple bodies have been detected; and the discovery of it forms on that account one of the most memorable eras in the history of chemistry.

I. Action of Phosphorus on Potash.

1. There is no direct combination between potash and phosphorus; but although these two bodies have little tendency to unite, they have a very powerful effect upon each other when they are heated together with water. It was in this way that Gengembre first obtained the singular gas, which has been already described, when treating of phosphorus, under the name of *phosphureted hydrogen gas*.

91[5] Phosphe[re]ted hy[dro]gen g[as].

2. If one part of phosphorus and ten parts of concentrated solution of pure potash be introduced into a small retort, and exposed to heat till it boils, phosphorated hydrogen gas will pass over, which may be received in jars over water: or if the beak of the retort be kept under the surface of water, the bubbles of the gas, as they rise to the surface, explode, and form the beautiful coronet of white smoke, formerly mentioned. In making this experiment, the retort should not be larger than to hold the solution, or it should be filled with hydrogen or azotic gases, in which the phosphorated hydrogen gas will not inflame and explode, with the risk of breaking the vessel; for the inflammation can only take place when it comes in contact with the oxygen of the atmosphere.

91[6] Proces[s of] obtaini[ng] it.

3. In this process, the water which holds the potash in solution, is decomposed. The oxygen combines with part of the phosphorus, and forms phosphoric acid, while another part of the phosphorus unites with the hydrogen, and passes over in the form of phosphorated hydrogen gas. Thus, without any perceptible action between the phosphorus and the potash, the decomposition of the water is aided by means of the potash, in consequence of its attraction for the phosphorus, combined with the oxygen in the state of phosphoric acid. For it is found, that a quantity of phosphorus of potash is formed, corresponding to that of the phosphorated hydrogen gas which is obtained. The decomposition is also assisted by the affinity of the phosphorus for the oxygen and hydrogen of the water. The whole of the phosphorated hydrogen gas which is formed, being disengaged, shows that no combination takes place between it and the potash *.

91[7] Natur[e of] the pr[ocess].

*Four[croy], Conna[issances], tom. ii p. 202.

II. Action of Sulphur on Potash.

1. Sulphur and potash very readily combine together. If one part of potash and three of sulphur be triturated together in a glass or porcelain mortar, the mixture becomes hot, the sulphur loses its yellow colour, and acquires a greenish tinge. There is disengaged a fetid smell of garlic; the mixture attracts moisture from the air, becomes soft, and is almost entirely soluble in water.

91[8] Sulph[uret] of pot[ash].

If two parts of potash and one of sulphur be well mixed together, and heated in a crucible, the mixture fuses; and by this process is obtained *sulphuret of potash* in the dry state. This was formerly called *hepar sulphuris*, or *liver of sulphur*, from its resemblance to the liver of animals. The same substance may be obtained by treating sulphur with the potash of commerce, with this precaution, not to apply too strong a heat, to occasion a sublimation of the sulphur, and the too rapid evolution of the carbonic acid from the potash. When the fusion is completed, it is poured out on a marble slab; it is covered up from the air, allowed to cool, and broken into small pieces, to be instantly put up in well-closed glass vessels.

2[?] Prope[rties].

2. The solid sulphuret of potash, thus prepared, is of a

ash, &c. a shining brown colour like that of the liver of animals, from which it derived its former name. Exposed to the air, it becomes green, then passes to grey, and even to white. It is dense, smooth, and has a vitreous fracture. It has no other smell than that of heated or sublimed sulphur; is acrid, caustic, and bitter to the taste, and leaves a brown spot on the skin. With a strong heat, in a porcelain retort, the sulphur is sublimed, and the potash remains in a state of purity at the bottom of the vessel. The sulphuret of potash converts vegetable blue colours to green, and afterwards destroys them.

920 ro-sulret. 3. But the sulphuret of potash possesses these properties, only while it is recently prepared, and very pure. When exposed to the air, it is readily decomposed, and more so, as the air is loaded with moisture. It absorbs water with avidity, acquires a green colour, and exhales the fetid odour of sulphurated hydrogen gas. This change is owing to the decomposition of the water which has been absorbed. Part of the sulphur combines with the hydrogen, and forms sulphurated hydrogen gas, which combines with the sulphuret, and forms hydrogenated sulphuret of potash.

921 ined nother ess. 4. This may also be formed by passing the sulphurated hydrogen gas into a solution of potash. The gas is absorbed and condensed, till the potash is fully saturated. To this substance Berthollet, who particularly investigated the nature of these compounds, gave the name of *hydro-sulphuret of potash*.

922 erties. This componnd crystallizes, and is more permanent than the sulphuret. The crystals are transparent and colourless, while those of the sulphuret are brown and opaque. The crystals are large and in the form of four-sided prisms, terminating in four-sided pyramids. It is decomposed by heat, and by the action of the acids. Sulphurated hydrogen gas is disengaged, but there is no deposition of sulphur. The oxymuriatic acid decomposes the sulphurated hydrogen, and then sulphur is precipitated. The pure hydro-sulphuret has no smell, when it has no addition of sulphur beyond the saturation of the hydrogen. The alkali seems to have a stronger affinity for the sulphureted hydrogen than for the sulphur, so that when it is saturated with the first, that is, in the state of hydro-sulphuret of potash, which is in the form of crystals, and without smell or inodorous, it combines with no more sulphur; but when sulphureted hydrogen gas is made to pass into a solution of the sulphuret of potash, already hydrogenated by its solution in water to a certain degree of saturation, the sulphureted hydrogen acts in the manner of acids, precipitates the sulphur like them, renders the liquid colourless, and leaves behind nothing but the hydro-sulphuret of potash *.

* urcroy, aiss. . tom. 206.

923 ogureul- et. 5. Sulphur combines with the latter compound, and forms a new compound, which may be obtained by pouring a liquid hydro-sulphuret upon sulphur. The sulphur is dissolved without the assistance of heat; the liquid assumes a darker colour, and then it is converted into the *hydrogureted sulphuret*. Hydrogureted sulphuret of potash is prepared by boiling together a mixture of pure potash and sulphur in water. This solution is of a deep greenish yellow colour, has a very acrid bitter taste, and a powerful action on many substances. It readily absorbs oxygen when exposed to the air. When it is kept in close vessels, sulphur is deposited; the liquid becomes transparent, and the smell is dissipated. Thus, there are three different compounds of sulphur with potash; namely, sulphuret of potash, hydro-sulphuret of potash, and hydrogureted sulphuret, which are all distinguished by peculiar properties. Potash, &c.

III. Compounds of Potash with Acids, or Neutral Salts.

1. Sulphate of Potash (U).

1. This salt, which was one of the most early known, is a compound of sulphuric acid and potash. It has been distinguished by a great variety of names, as *sal de duobus*, *sal polychrestus*, or salt of many virtues, *arcanum duplicatum*, and more lately *vitriolated tartar*, till in the new nomenclature it received the name of *sulphate of potash*. 924 Names.

2. It is prepared by different processes, either by directly combining the sulphuric acid with the potash, and evaporating and crystallizing it; or by decomposing other salts which have potash for their base, by means of the sulphuric acid, which, having a stronger affinity for the potash, combines with it and forms the new compound. 925 Preparation.

3. The sulphate of potash crystallizes in hexaëdral prisms, terminated by six-sided pyramids; but this form is susceptible of several varieties. It has a disagreeable bitter taste; it is not very hard, and may be easily reduced to powder. The specific gravity is 2.4073. At the temperature of 60°, it is soluble in 16 times its weight of water; boiling water dissolves about one-fifth part; on cooling, it crystallizes in a confused mass; and it is only by slow spontaneous evaporation that regular crystals can be obtained. 926 Properties.

4. It suffers no change by the action of the air. When placed upon burning coals, it decrepitates, and loses its water of crystallization. At a greater heat it melts, and is converted into a kind of enamel as it cools. 927 Action of air and heat.

5. When this salt is exposed to a red heat, along with hydrogen gas or carbon, it is decomposed, and converted into a hydrogenated or carbonated sulphuret of potash.

6. The sulphuric acid, with the assistance of heat, combines with the salt, and forms another with excess of acid. It undergoes a partial decomposition by the action of nitric acid. The nitric acid combines with nearly $\frac{1}{7}$ of potash, which is owing to the action of double affinity. The nitric acid combines with one part of the potash, while the sulphuric acid unites with the sulphate of potash, and forms a salt with excess of acid. A similar decomposition takes place by means of the muriatic acid.

7.

(U) In the present chemical nomenclature the compounds of acids with any base are known by names analogous to this; and when the acid has its greatest proportion of oxygen, as in this case the sulphuric acid, the name of the compound terminates in the syllable *ate*, as sulphate of potash, nitrate of potash; but when the acid has its smaller proportion of oxygen, the name of the compound terminates in *ite*, as sulphite and nitrite of potash.

928 Composition. 7. The component parts of sulphate of potash are, according to

	Bergman.		Kirwan.
Acid	40	-	45.2
Potash	52	-	54.8
Water	8	-	00.0
	100	-	100

929 Names. *Acidulous sulphate*, or *super-sulphate of potash*.—1. This salt was formerly called *vitriolated tartar with excess of acid*. It is prepared by heating together, in a retort, three parts of the sulphate of potash, with one part of its weight of concentrated sulphuric acid.

930 Properties. 2. It crystallizes in long flexible, shining crystals, and sometimes it exhibits the form of six-sided prisms. It has a sharp, acrid, and hot taste. It reddens vegetable
931 Action of water. blues. Exposed to the air, it becomes a little more opaque, but without any other change. It is more soluble in water than the sulphate of potash, requiring
932 Of heat. only 2 parts of water at 60°, and dissolves in less than its own weight of boiling water. It melts very readily, and has the appearance of a thick oil. When it cools, it becomes a white, opaque mass, exhibiting on its surface shining silky crystals. When exposed to a great heat, the excess of acid is driven off, and it is converted into the sulphate of potash.

933 Hydrogen. 3. It is readily decomposed by the action of hydrogen and of red-hot charcoal, which deprive it of a great portion of the sulphur; and by sulphur itself, which carries off the excess of sulphuric acid in the form of sulphurous acid.

4. The first of these salts, the sulphate of potash, is employed in medicine as a purgative; the last has been applied to no use whatever.

2. Sulphite of Potash.

934 Names and preparation. 1. This salt was long known under the name of the *sulphurous salt of Stahl*. It is a compound of the sulphurous acid and potash. Its nature and properties have been particularly investigated by Berthollet, Fourcroy, and Vauquelin. It may be formed by passing a current of sulphurous acid gas into a solution of carbonate of potash in three times its weight of distilled water, till the effervescence ceases. The liquor becomes transparent and hot, and, as it cools, the sulphite of potash is deposited in crystals.

935 Properties. 2. This salt is in the form of long, small needles, diverging from a centre, or in rhomboidal plates, or in dodecahedrons formed by two tetrahedral pyramids, united and truncated very near the base. The crystals are white and transparent, but sometimes of a slight
936 Action of the air. yellow colour. The taste is acrid and sulphureous. The specific gravity is 1.586. The sulphite of potash, exposed to the air, very readily effloresces (x); becomes white and opaque, and is converted into sulphate of potash. This is owing to the sulphurous acid abstracting oxygen from the air, and becoming sulphuric acid. It is very soluble in water, at the temperature of the atmosphere, and much more so in boiling water. When this solution is exposed to the air, it is soon covered with a thick pellicle, which falls to the bottom, and is afterwards replaced by another. This is sulphate of potash, which is formed in contact with the air. The oxymuriatic acid gas combined with this solution, forms almost immediately shining crystals of the sulphate of potash.

3. Charcoal heated with this salt in a retort, yields sulphurated hydrogen gas, and carbonic acid; and there remains in the retort, a hydrogenated sulphuret of potash. 937 Of charc[oal].

3. Nitrate of Potash.

1. This salt is composed of nitric acid and potash, and is well known under the names of *saltpetre* and *nitre*. It has also been denominated *salt of nitre*, *nitre of potash*, or *nitrated potash*. It is one of the most important of the salts, not only on account of the attention which it has excited, in tracing its formation, and studying its nature and composition, but also on account of its numerous and valuable applications in domestic economy and in the arts. 938 Constitu[ent] parts an[d] names.

2. The nitrate of potash exists ready formed in many plants, as in tobacco, borage, bugloss, pellitory. It has been observed crystallized in needles in their dried stalks. According to some, it has been absorbed by the vegetable from the soil in which it grows, while others suppose that it is formed within the plant, from the elementary principles. 939 Found i[n] many plants.

Nitre exists in great abundance on the surface of the earth in different parts of the world, especially in the warmer regions, as in India, Egypt, and South America. But the production of nitre is not limited to these countries. It is produced artificially in Germany and France, by means of what are called *nitre beds*. These are formed by collecting together the refuse of animal and vegetable matters, in which the putrefactive process is going on. They are mixed with earthy substances, but chiefly with calcareous earth, such as the rubbish from buildings, or collections of the soil in which lime abounds. All that is necessary to favour the formation of the nitre, is to moisten occasionally with water, the mixture of the animal, vegetable, and earthy matters; to expose it to a moderate temperature, and to defend it from rains, which would carry off the salt as it is formed. This artificial production of nitre was greatly improved and extended by the French during the late war, when they were precluded from the usual supply of this salt from India. It is now produced, it is said, in great abundance in France. 940 Prepare[d] artificia[lly].

The nature of the process, and the change which takes place in this artificial production of nitre, will be understood by considering its component parts. The constituent parts of the nitric acid are azote and oxygen.

(x) A salt is said to effloresce, when deprived of its water of crystallization in the ordinary temperature of the atmosphere. A powdery crust is first formed on the surface; and as the process goes on, the whole falls down into powder. The term *efflorescence* is opposed to *deliquescence*, by which the deliquescent substance attracts moisture from the air.

ash, &c. gen. The oxygen is furnished by the air: and unless there is a supply of air, no change takes place. A great quantity of azotic gas is given out by animal matters during the putrefactive process. But although these substances, when brought into contact with each other, do not combine to form nitric acid, it has been found by experiment, that azote, in its nascent state, or in the moment of evolution, enters into union with oxygen, and forms nitric acid, while the nitric acid thus formed combines with the potash which is furnished by the soil, or the vegetable matters.

941 ifica-n.

3. After the nitre is formed, it is mixed with water, which is evaporated, and a salt is obtained of a brown colour, which is called *crude nitre.* This is a mixture of several salts, and from these the pure nitre is separated by other processes. When it is sufficiently purified, it is obtained in crystals of six-sided prisms, terminating in six-sided pyramids. The primitive form of its crystals is a rectangular octahedron, in which two faces of a pyramid are inclined to the other pyramid at an angle of 120°, and the two others at an angle of 111°. The form of the integrant molecule is the tetrahedron; but there are considerable varieties in the crystals of this salt, according as it is slowly or more rapidly evaporated.

942 perties.

4. This salt is distinguished by a cool, sharp, and bitterish taste. It is very brittle. When nitre in large crystals is reduced to powder, it is found to be a little humid; but that which is in the form of a white, opaque, irregular mass, yields a dry powder, on which account it is generally preferred for many purposes, particularly in the manufacture of gunpowder. The specific gravity of nitre is 1.9369. It is not altered by exposure to the air. At the temperature of 60° it dissolves in seven times its weight of water, and during the solution, a great degree of cold is produced. Boiling water dissolves twice its weight of this salt.

943 tion of t.

5. When the nitre of potash is exposed to heat, it fuses before it becomes red, and is converted into a liquid of an oily consistence. It loses but very little of its water of crystallization, and if it be allowed to cool, it congeals into an opaque mass with a vitreous fracture, which is known by the name of *mineral crystal.* While it is melted, it undergoes no change; but when the temperature necessary for simple fusion is increased, it gives out oxygen gas to the amount of about $\frac{1}{8}$ of its weight. Towards the end of the process, azotic gas is evolved, and the potash remains behind pure, so that the salt has been completely decomposed. But to effect this decomposition, a very strong heat is necessary. When only part of the gas is extracted, the nitrate of potash is converted into the *nitrite.*

944 char-l.

6. When nitre is mixed with charcoal in the proportion of three parts of the former to one of the latter, a violent inflammation takes place, either by exposing the mixture to a red heat, or by bringing it into contact with a burning body. Or the mixture may be projected into a red-hot crucible, when a deflagration or detonation takes place, and when the residuum in the crucible is examined, it is found to be potash partly united with carbonic acid, or the carbonate of potash. This was formerly called *nitre fixed by charcoal* or an *extemporaneous alkali of nitre.* The deflagration in this case is owing to the combustible matter, the charcoal coming in contact with the oxygen which is evolved by the nitre, exposed to a high temperature. In another process, this experiment was performed in close vessels, to collect the elastic fluids which are disengaged; and besides the carbonic acid gas which is formed by the union of the carbon and oxygen, and the azotic gas disengaged by the decomposition of the nitre, a small quantity of water was found in the vessels. To this product the alchemists gave the name of *clyssus,* and ascribed to it very wonderful properties in the preparation of the philosopher's stone. Potash, &c.

945 Of phosphorus.

7. A violent deflagration also takes place when phosphorus and nitre are treated in the same way. But this experiment should be performed with very small quantities, and with great caution. A mixture of nitre and phosphorus struck smartly with a hammer, produces a very violent detonation.

946 Of sulphur.

8. When sulphur is combined with three times its weight of nitre, it burns with great rapidity. This preparation was formerly made by detonating the two substances in a red-hot crucible. The product is sulphate of potash, known by the name of *sal polychrest of Glaser.* The sulphur combines with the oxygen of the nitric acid, and forms sulphuric acid, which enters into combination with potash.

947 Gunpowder.

9. But one of the most important combinations of nitre is with charcoal and sulphur, in the formation of gunpowder. This substance was first known in Europe in the 14th century. It is said that it was known to the Chinese much earlier. The proportions of the materials which enter into the composition of gunpowder are,

Nitre	76
Charcoal	15
Sulphur	9
	100

948 Preparation.

The materials are first reduced to a fine powder separately. They are then carefully mixed together, and formed into a paste with a little water. When the paste has dried a little, it is forced through a sieve, by which means it is reduced to grains of such a size as may be wanted. The powder is then dried in the air, or in the sun; and after being dried, it is put into barrels which turn round by means of machinery, and thus by the friction of the grains of powder against the sides of the barrel and against each other, it is polished. This is called *glazing* the powder.

949 Nature of its action.

10. The theory of the combustion, and terrible effects of gunpowder is thus explained. The sulphur and the charcoal burn with great rapidity by the addition of the nitre with which they are intimately mixed. During the combustion carbonic acid gas, azotic gas, sulphurous acid gas, and according to some, sulphurated hydrogen gas, are formed. Water and ammonia also are said to be produced*. But according to Mr Cruickshank, the quantity of water formed is not perceptible. The substances which remain after the deflagration are, carbonate of potash, sulphate and sulphuret of potash, and some charcoal. It is obvious, that the irresistible effects of gunpowder are owing to the sudden evolution and expansive force of the elastic fluids which are formed and disengaged.

* *Fourcroy Connaiss. Chim.* iii. 122.

950 Fulminating powder.

11. Another combination of nitre produces effects still more terrible. When three parts of nitre, two parts of potash, and one of sulphur, are previously well dried and mixed

Potash, &c. mixed together by trituration, they form a compound which is known by the name of *fulminating powder*. A few grains of this mixture exposed to heat in an iron ladle first melt, assuming a darker colour; and when the whole is in fusion, there is a violent explosion. The heat should be applied slowly and gradually, till it is completely fluid, and then by bringing it nearer the heat, the full effect of the explosion is obtained. This combustion and explosion are also owing to the instantaneous evolution of elastic fluids. The potash unites with the sulphur, and forms a sulphuret, which, with the assistance of the nitre, is converted into sulphurated hydrogen. At a certain temperature the sulphurated hydrogen gas is disengaged, along with the oxygen gas of the nitre, and suddenly taking fire, strikes the air by the explosion which accompanies the evolution of the gases. When the mixture is made with equal parts

951 Powder of fusion. of nitre and solid sulphuret of potash, the detonation is more rapid, but the explosion is less violent. With three parts of nitre, one of sulphur, and one of sawdust, well mixed together, what is called *powder of fusion* is formed. If a little of this powder is put into a walnut shell, with a thin plate of copper rolled up, and the mixture set fire to, it detonates rapidly, and reduces the metal to a sulphuret, without any injury to the shell.

952 Fluxes. 12. A mixture of equal parts of nitre and tartar detonated in a crucible, gives a product which is much employed in metallurgy. This compound, called *white flux*, is a mixture of pure potash with the carbonate. When one part of nitre and two of tartar are treated in the same manner, the product obtained is a mixture of potash and charcoal. From its black colour, it is known under the name of *black flux*. This also is employed for a similar purpose.

953 Composition. 13. Nitrate of potash, according to Bergman, is composed of

31 acid,
61 potash,
8 water.

100

According to Kirwan, it is composed of

44 acid,
51.8 potash,
4.2 water.

100.0

954 Uses. 14. Nitre is not only employed for the purposes already mentioned, but it is used in medicine as a cooling remedy in feverish disorders, and as a diuretic in urinary affections. It is employed also in many arts, as in dyeing, and in domestic economy, for the preservation of animal matters, which are to be used as food. To these substances it imparts a red colour. From nitre, nitric acid is obtained, by decomposing it by means of sulphuric acid. Nitre is also employed to burn along with sulphur in the formation of sulphuric acid.

4. Nitrite of Potash.

This salt cannot be formed by direct combination of the nitrous acid with potash; but if a quantity of nitre be exposed for some time in a crucible or retort, to a strong heat, it becomes deliquescent and acid. It changes the blue colours of vegetables into green, attracts moisture from the air, detonates feebly with combustible substances, and gives red thick vapours by the action of sulphuric, nitric, muriatic, phosphoric, and fluoric acids. This is the nitrite of potash, which is decomposed by these acids, and gives out the red fumes of nitrous acid. Little more is known of the nature of this salt, with regard to its form, solubility, affinities, or the proportions of its constituent parts. Potash, &c.

5. Muriate of Potash.

1. This salt was formerly known by the name *febrifuge salt of Sylvius*. It was afterwards called *digestive salt*, *regenerated sea salt*, and by Bergman *salited vegetable alkali*. 955 Names.

2. It is prepared by the direct combination of muriatic acid and potash. The solution is evaporated till a pellicle appears, when it is set by to crystallize.—It is a curious effect of the new opinions already adverted to respecting muriatic acid and chlorine, that when the muriate of potash is deprived of water, it must be considered as a substance of totally different composition, as now containing neither muriatic acid nor potass, but consisting entirely of chlorine and potassium, and therefore called a chloride of potassium, or in the French nomenclature, a chloruret. It becomes necessary to maintain this, because, when potassium is introduced into dry chlorine gas, a combination is effected, and the compound thus formed cannot be considered as muriate of potash, since there is no oxygen present to form potash, and no hydrogen to form muriatic acid. Both these elements are afforded when water is presented, and muriate of potash is established. 956 Preparation and properties.

3. The crystals are in the form of regular cubes, or rectangular parallelopipeds. It has a disagreeable bitter taste, and by this is easily distinguished from muriate of soda or common salt. The specific gravity of this salt is 1.836. When the air is moist, it deliquesces; but when the air is dry, it parts with its moisture. Three parts of cold water are sufficient for its solution. Boiling water dissolves a little more, but regular crystals cannot be obtained by cooling. The solution must be left to slow spontaneous evaporation.

4. When the muriate of potash is exposed to heat, it decrepitates, loses its crystalline form, and falls into powder by the separation of .08 parts of its weight of water. When it acquires a red heat, it melts; if the temperature be elevated, it is sublimed in the form of white vapour, unchanged. After complete fusion, if it is allowed to cool suddenly, it becomes solid, and divides on the surface, into many small plates of a square form. 957 Action of heat.

5. This salt is decomposed by means of the sulphuric and nitric acids. The first disengages the muriatic acid with effervescence in the gaseous form. By the action of the nitric acid the muriatic acid is converted into the oxymuriatic by combining with the oxygen of the nitric acid. With one part of nitric acid and two parts of muriate of potash, a compound of the two acids is formed, which was formerly employed in the solution of gold. This is a *nitro-muriatic acid*, or *aqua regia*.

6. This salt is no longer employed in medicine. It is recommended to be used for the decomposition of nitrate of lime in the mother waters of nitre, to obtain the 958 Uses.

ash, &c. the nitrate of potash, and also for procuring the crystallization of alum.

6. Hyper-oxymuriate or Chlorate of Potash.

959 covery history. 1. This singular salt was the first known of all the combinations of this kind. Fourcroy mentions, that Dr Higgins prepared this salt, which he calls *nitre*, by passing the oxymuriatic acid gas into a solution of potash; but he seems to have paid no farther attention to it, except observing, that it detonated on red-hot coals (X). It was by Berthollet that it was first formed with any thing approaching to an intelligent view of its composition. And since its discovery, it has been particularly examined by Lavoisier, Dolfuz, Vanmons, Fourcroy, and Vauquelin, on the continent, and in England by Hoyle and Chenevix. It is prepared by introducing chlorine into a solution of the alkali. Two different salts are formed. One portion of the chlorine combines with the hydrogen of the water to form muriatic acid, and this acid combines with the alkali, forming a muriate of potash, which remains in solution. Another portion of the chlorine combines with the oxygen of the water to form chloric or hyper-oxymuriatic acid, and this combines with another portion of the potash to form the salt now under consideration, which makes its appearance in the form of crystals at the bottom of the liquid. The old mode of explaining these phenomena was, that one part of the oxymuriatic acid (or chlorine) gave oxygen to the other part, so that the portion which lost oxygen was converted into muriatic acid, and that which gained oxygen into hyper-oxymuriatic acid. The decomposition of water, however, is a more probable theory, whatever view we entertain of the nature of chlorine. After the salt has been removed from the solution in which it crystallizes, it may be purified by dissolving it in boiling water. The solution may be filtered, and allowed to cool, when the crystals are deposited.

960 perties. 2. The crystals of this salt are most commonly in the form of square plates or of parallelopipeds, of a shining silvery white colour. The primitive form of the crystals is an obtuse, rhomboidal prism; they are very transparent and brittle; the taste is cool, pungent, and disagreeable, very different from that of nitrate of potash. When it is rubbed smartly, it phosphoresces, and gives out a great quantity of sparks or luminous traces.

3. It becomes yellow after long exposure to the air, but is otherwise not changed. It is soluble in about 20 parts of water at the ordinary temperature of the atmosphere; but boiling water dissolves about one-third of its weight, so that the whole is nearly crystallized by cooling.

961 n of 4. When this salt is exposed to heat, although it contains a considerable proportion of water of crystallization, it fuses quietly; and when the heat is increased, it gives out a quantity of oxygen gas nearly equal to one-third of its weight. This is the purest oxygen gas that can be obtained. Potash, &c.

5. But the most extraordinary effects of this salt are those produced by its action on combustible substances.

a. If a small quantity of charcoal reduced to powder and this salt be rubbed together in a mortar, there is a slight explosion, and the charcoal is inflamed. 962 Of charcoal.

b. Three parts of the salt with one of sulphur, rubbed together in a mortar, produce a violent detonation. Or, if the same mixture is struck with a hammer on an anvil, there is an explosion like the report of a pistol (Y). 963 Of sulphur.

c. The same effect is produced by employing phosphorus, and treating it in the same way with this salt. One or $1\frac{1}{2}$ grains of the salt should first be reduced to powder, and brought together to one place in the bottom of the mortar, and then introducing the phosphorus, and rubbing it strongly on the salt, a violent explosion will instantly take place. A similar detonation may be produced with the same substances by percussion. 964 Of phosphorus.

d. Three parts of the salt, one-half part of sulphur, and one-half charcoal, give more rapid and stronger detonations, with the evolution of a very bright flame. Detonations are also produced, by treating this salt with sugar, gums, oils, and some metallic substances.

6. When concentrated sulphuric acid is poured upon this salt, there is a considerable detonation; it is thrown about to a great distance, sometimes with a red flame; and there is exhaled a brown vapour, accompanied with a strong odour of oxymuriatic acid. Even when a lighted taper is brought into contact with the gas which is disengaged, it explodes more violently than when the acid first came in contact with the salt. In some cases, the explosion was so sudden and so violent, that it broke the vessels in which the mixture was made. This happened to Mr Hoyle of Manchester, and afterwards to Mr Chenevix; so that experiments with sulphuric acid and this salt should be conducted with small quantities, and with great caution. If concentrated sulphuric acid be poured on any of the mixtures of this salt with sulphur, charcoal, the metals, or with sugar, there is an instantaneous inflammation, the most brilliant that can be conceived. There is no detonation, but the combustion is extremely rapid, and the odour of oxymuriatic acid is perceptible. Concentrated nitric acid poured upon this salt, causes it to crackle and effervesce, but without explosion, and without flame; oxymuriatic acid gas is disengaged. With the muriatic acid, this last produces effervescence, with the evolution of a considerable quantity of 965 Of acids.

(X) "The acid elastic fluid (says Dr Higgins), which issues when two pounds of manganese are mixed and distilled with two or three of ordinary spirit of sea salt (muriatic acid), may all, except a small portion of phlogistic air, be condensed in a solution of fixed vegetable alkali; and the solution, thus impregnated, yields a considerable quantity of nitre, which crystallizes in the ordinary form, and detonates on red-hot coals. The solution at the same time yields regenerated sea-salt (muriate of potash)." *Higgins, Exper.* p. 181.

(Y) In experiments with this salt, the quantity employed should never exceed one or two grains, at least by those who have not been previously acquainted with its terrible effects.

Potash, &c. of gas, similar in colour and smell to oxymuriatic acid gas; but in some of its properties considerably different. This gas is more rapidly absorbed by water. If a small jar or bottle be filled with this gas, and a slip of paper moistened with ether be introduced into it, and the mouth of the jar be slightly covered to prevent the contact of air, an explosion takes place, with a deposition of charcoal. A similar experiment may be made, by moistening a feather with oil of turpentine, and introducing it into the jar filled with this gas. It instantly takes fire with a red flame, and a great quantity of black smoke.

966 Composition.

7. According to the analysis of this salt, as given by Fourcroy, it consists of

Muriate of potash,	67
Oxygen,	33
	100*.

But according to the experiments of Mr Chenevix, its constituent parts are,

Acid,	58.3
Potash,	39.2
Water,	2.5
	100.0 †.

967 Uses.

8. This salt has been employed in bleaching; but other substances, particularly lime, have been substituted for the potash; so that at present it is more rarely used. It was proposed by M. Berthollet, when he first observed its effects, to employ it as a substitute for nitre in the manufacture of gunpowder; and when it was tried in the way of experiment, it seemed to be more powerful than the usual component parts of powder; but when it was attempted to be made in the large way, at Essone, in the year 1788, a dreadful accident, which happened by the spontaneous explosion of the mixture, in the death of M. le Tors, and Mademoiselle Chevraud, prevented its effects from being fairly proved. The danger which attends the trituration of the proper materials with this salt, has precluded any future attempt.

* *Fourcroy Connaiss. Chim.* iii. p. 226.

† *Philos. Trans.* 1802.

7. Fluate of Potash.

968 Little known.

This salt has only been examined by Scheele and Bergman. It is the combination of fluoric acid with potash. When the acid is saturated, there is formed a gelatinous mass, which does not crystallize, and which has a slightly acrid saline taste. When it is evaporated to dryness, and exposed to the air, it attracts moisture. If it be strongly heated in a crucible, it fuses without effervescence. It then becomes caustic, is very soluble in water, and is decomposed by the sulphuric and nitric acids.

8. Borate of Potash.

This is a compound of the boracic acid and potash; but very little is known of its nature and properties. It is prepared by decomposing nitre by means of the boracic acid with the assistance of heat. The heat drives off the nitric acid, and there remains behind a white, half-fused porous mass, which is soluble in water, and yields, by evaporation and cooling, small crystals. The same salt may be formed by direct combination of the boracic acid and potash. This salt seems to be analogous in many of its properties to borax. Potash, &c.

9. Phosphate of Potash.

This combination of phosphoric acid with potash was announced and described by Lavoisier in the year 1774. Its properties have been more carefully investigated by Vauquelin; but from the investigation of other chemists it appears, that there are two salts formed from the same acid and base; the one in which they are neutralized, and the other in which there is an excess of acid.

a. Superphosphate of Potash, is formed by the direct combination of phosphoric acid and potash. This salt does not crystallize, but exists in a gelatinous form, and has a sweetish saline taste. Its specific gravity when dry, is 2.8516. It is very soluble in water; it attracts the moisture from the air, and becomes thick and viscid. 969 Properties.

1. When heated, it undergoes the watery fusion, then froths up, and becomes dry. When the temperature is raised, it melts into a transparent glass. The sulphuric, nitric, and muriatic acids decompose this salt. It has been applied to no use. 970 Action of heat.

b. Phosphate of Potash.—This salt may be formed by exposing pure potash and the former variety to a strong heat. The alkali combines with the excess of acid, and neutralizes the whole. By the action of heat, a white-coloured substance is obtained, which is the phosphate of potash. It is scarcely soluble in cold water, but soluble in hot water; and as the solution cools, there is deposited a shining gritty powder. This salt is very fusible. Before the blow-pipe it melts into a transparent bead, which becomes opaque on cooling. 971 Action of heat.

2. This salt is soluble in nitric, muriatic, and phosphoric acids, and forms with them thick glutinous solutions. It has not yet been applied to any use. 972 Of acids.

10. Phosphite of Potash.

This salt is prepared by dissolving carbonate of potash in phosphorous acid. The solution is evaporated, and it deposits crystals of the *phosphite of potash.* It has a sharp saline taste. It is crystallized in four-sided rectangular prisms with dihedral summits. It is very soluble in water, requiring only three parts of it for solution. It is not altered by exposure to the air.

11. Carbonate of Potash.

1. This salt, which is a compound of carbonic acid and potash, has been known under a great variety of names, in some measure descriptive of its properties, before its composition was discovered by Dr Black.

2. This salt is obtained from vegetable matters by burning, and washing out the salt and evaporating it; but the potash obtained in this way is not fully saturated with carbonic acid. After it has been purified from foreign ingredients, the saturated carbonate of potash may be prepared by exposing a pure solution of potash to carbonic acid gas, as it is disengaged from fermenting liquors. The carbonate of potash, as it is formed, crystallizes in the solution. The crystals may be taken out and dried upon unsized paper, and put up in well-closed bottles. Or it may be prepared by passing a current of carbonic acid gas, disengaged from the 973 Preparation.

ash, &c. the carbonate of lime by an acid, into a solution of potash, in tall narrow bottles. The carbonate crystallizes at the surface of the liquid. It may also be obtained by the process of Berthollet, which is to distil with an unsaturated solution of potash, solid carbonate of ammonia, from which the potash carries off the carbonic acid, while the ammonia is disengaged in the state of gas.

974 perties. 3. The carbonate of potash crystallizes in quadrangular prisms, terminated by quadrangular pyramids. It has a sweet alkaline taste, and changes vegetable blues to a green colour. The carbonate of potash requires very near four times its weight of water to dissolve it. At the boiling temperature it dissolves five-sixths of its weight. It does not crystallize by cooling, but only by slow evaporation. Pelletier has observed, that carbonate of potash dissolved in boiling water, gives out bubbles of carbonic acid gas, which shews that this salt loses a portion of its acid at this temperature. Its specific gravity is 2.012. When it is exposed to the air, it soon effloresces. When it is deliquescent, it is owing to part of the potash being unsaturated with carbonic acid.

975 ion of t. 4. When it is exposed to a slight degree of heat, it loses its water of crystallization. Part of its carbonic acid also separates from it, but the whole cannot be driven off by this process. The last portions adhere with a very strong affinity.

976 compo- by sulphur. 5. When the carbonate of potash is heated with sulphur at a high temperature, the acid escapes in the state of gas; and there is formed a sulphuret, at the moment of the effervescence produced by the extrication of the acid.

977 all s. 6. All the acids hitherto discovered, have the property of separating the carbonic acid from potash, and of forming with its base particular salts. This salt loses more than a third of its weight, by being deprived of its carbonic acid. The component parts of carbonate of potash are, according to Potash, &c.

	Bergman,	Pelletier,	Kirwan.
Carbonic acid,	20	43	43
Potash,	48	40	41
Water,	32	17	16
	100	100	100

7. Potash of commerce is never saturated with carbonic acid. It is in this state that the carbonate of potash is generally employed. It has a stronger alkaline taste, and is more acrid and corrosive. It soon deliquesces when exposed to the air. It does not combine with a greater proportion of carbonic acid, merely by exposure to the atmosphere. For the purposes of the manufacturer it is of great importance to be able to ascertain, by a simple test, the quantity of pure potash in the different kinds which are brought to market. Mr Kirwan has proposed to discover the proportion of the salt, by determining the quantity of the earth of alum which is precipitated by the potash. A different method has been proposed by Vauquelin with the same view. His method is to saturate a given weight of the salt with nitric acid of known density. He has also made a number of experiments to discover the quantity of foreign ingredients in different kinds of potash. The following table shews the kinds of matter and the proportions in six species of potash *. 978 Potash of commerce. 979 Tests of its purity.

12. Arseniate of Potash.

980 para- 1. The compound of arsenic acid and potash forms a salt which does not crystallize. When evaporated to dryness, this salt deliquesces in the air, gives a green colour to syrup of violets without changing the tincture of turnsole.

981 perties. 2. When strongly heated it fuses into a white glass; and by the contact of silica and alumina in the crucible it passes to the acidulous state, having been deprived of part of the potash. Exposed to a red heat, in close vessels with charcoal, the arsenic is sublimed. It is decomposed by the sulphuric acid. It decomposes salts which have bases of lime and magnesia; forming in the solution arseniates of lime and magnesia *.

* Fourcroy Connaiss. v. 85.

Superarseniate of Potash.—If the arsenic acid be added to the arseniate of potash till it no longer change the colour of violets, but reddens that of turnsole, it yields regular transparent crystals in quadrangular prisms, terminated by tetrahedral pyramids. This salt is the *arsenical neutral salt* of Macquer. He obtained it by decomposing the nitrate of potash, by means of the white oxide of arsenic, employing equal parts 982 With more acid crystallizes.

Potash, &c. parts of each. It is different from the former, because it crystallizes, reddens vegetable blues, and does not decompose salts with a base of lime or magnesia.

13. Tungstate of Potash.

983 Preparation. 1. This compound of tungstic acid and potash, is formed by dissolving the oxide of the metal in a solution of pure potash, or its carbonate. The alkali is not fully neutralized. The salt precipitates from the solution by evaporation, in the state of a white powder.

984 Properties. 2. It is distinguished by a caustic metallic taste, deliquesces in the air, and is soluble in water. This solution in water is decomposed by all the acids which produce a white precipitate. This precipitate is a triple salt, differing according to the nature of the acid which is employed †.

† *Jour. de Mines*, No. xix. p. 21.

14. Molybdate of Potash.

985 Preparation. 1. The compound of molybdic acid and potash is formed by detonating three parts of nitre and one of sulphuret of molybdena in a crucible; or by combining directly the molybdic acid with potash. The salt affords small irregular crystals, from its saturated solution in boiling water. According to Klaproth, the crystals are in the form of small rhomboidal plates, of a shining appearance, and heaped together.

986 Properties. 2. The taste is metallic. When exposed to the blow-pipe on charcoal, they fuse rapidly, without swelling up, and are converted into small globules, which are absorbed by the charcoal. In a silver spoon they are melted by the blow-pipe into small gray particles, which shrink on cooling, and deposite, during the process, a whitish powder. This salt is completely soluble in distilled water with the assistance of heat. It has an excess of acid, and is therefore an acidulous molybdate of potash, or supermolybdate of potash. It is decomposed by the nitric acid, which unites with the alkali, and precipitates the molybdic acid in the form of small crystals ‖.

‖ *Annal. de Chim.* viii. p. 106.

15. Chromate of Potash.

Nothing farther is known of the nature of this salt, than that it is easily formed by the combination of the chromic acid with potash, and that the crystals are of an orange colour, which sufficiently distinguishes them from the crystals of all other salts.

16. Columbate of Potash.

Columbic acid, digested for an hour with a solution of potash, affords this salt by evaporation and cooling, in the form of white glittering scales, resembling the concrete boracic acid. It is not changed by exposnre to the air, has a disagreeable acrid taste, and is not very soluble in cold water; but after it is dissolved, the solution is perfect and permanent. It is decomposed by nitric acid, and precipitates in the form of white powder §.

§ *Phil. Trans.* 1802, p. 58.

17. Acetate of Potash.

1. This salt, which is a compound of acetic acid and potash, has been long known under a variety of names, which were derived from the substances from

987 Names. which it was obtained; or from its properties and effects. It was called *regenerated tartar*, *secret foliated earth of tartar*, *essential salt of wine*, *digestive salt of Sylvius*, *diuretic salt*. It may be formed by saturating carbonate of potash with distilled vinegar, and by evaporating the solution slowly to dryness. When the heat is too great, the acid is decomposed, and the salt assumes a brown colour. 988 Preparation.

2. This salt has a pungent, and somewhat alkaline taste. Exposed to the air, it becomes moist. It is very soluble in water, and if the solution be diluted, it is spontaneously decomposed in close vessels. Thick, mucous flakes are deposited. 989 Properties.

3. When it is heated, it melts and froths up, and is then decomposed and charred. When distilled in a retort, it yields an acid liquid, an empyreumatic oil, and a great deal of carbonic acid gas, and carbonated hydrogen gas. In this process the acid is completely decomposed; what remains in the retort is potash mixed with charcoal. According to Proust, this acid liquid contains ammonia and the prussic acid, and the carbonate and prussiate of potash are found in the retort ‡. 990 Action of heat.

‡ *Ann. de Chim.* xli p. 13?.

4. This salt is decomposed by the strong acids. Distilled with sulphuric acid, it yields an acetic acid which is very acrid. The component parts of the acetate of potash are, according to Dr Higgins, 991 Composition.

38.5	Acid and water,
61.5	Potash.
100.0	

18. Oxalate of Potash.

The compound of oxalic acid and potash may be formed by direct combination of the acid and the alkali. The oxalic acid combines in two proportions with potash, either in a small quantity, or in sufficient quantity to saturate the potash. When the acid is in excess, it is called the *acidulous oxalate*, or *superoxalate of potash*.

1. The oxalate of potash is formed by completely saturating the oxalic acid with potash; and by adding an excess of the alkali, crystals are obtained. 992 Preparation.

2. Without this excess of acid, the salt does not crystallize, but assumes a gelatinous form.

3. When this salt crystallizes, it is in the form of six-sided prisms, with two-sided summits. It is decomposed by heat, and also by the strong acids, which deprive it of a portion of the potash, and convert it into the acidulous oxalate. With an addition of oxalic acid the acidulous oxalate is also formed. 993 Properties.

Superoxalate of Potash.—1. This salt exists ready formed in the *rumex acetosa*, and the *oxalis acetosella*; hence it has been distinguished by the name of *salt of sorrel*, because it is extracted from this plant. 994 Exists in plants.

2. This salt may be formed by gradually combining potash with a saturated solution of oxalic acid. When a sufficient quantity of the alkali has been added, the salt is precipitated in crystals. Scheele discovered that the salt which is extracted from these plants, is in this state of combination. He proved the existence of the acid, and he shewed that the natural salt might be imitated by this process. 995 Preparation.

3. The crystals of this salt are in the form of small opaque parallelopipeds. The taste is acid, pungent, and bitter. It is not very soluble in cold water, but soluble 996 Properties.

soluble in about ten times its weight of boiling water. Exposed to the air, it undergoes no change. It is decomposed by heat.

19. Tartrate of Potash.

997 Prepara-tion. 1. This is a compound of tartaric acid and potash. It has been long known under the name of *soluble tartrate*, and *vegetable salt*. It is formed by adding tartar or cream of tartar to a hot solution of carbonate of potash. The additions of the tartar are to be continued as long as there is any effervescence. The solution is then boiled for half an hour, filtered and evaporated, till a pellicle appears on the surface, and when it is allowed to cool slowly, it deposits crystals.

998 Properties. 2. The crystals of this salt are in the form of long, rectangular prisms, terminated by two-sided summits. This salt has a bitter taste. The specific gravity is 2.5567. Exposed to the air, it is deliquescent. Four parts of cold water dissolve one of the salt; hot water dissolves a greater quantity. When heated, it swells up and blackens. By distillation it yields an acid liquid, some oil, and a great quantity of gas. It leaves behind a considerable portion of alkali, mixed with charcoal. It is decomposed by the stronger acids, which deprive it of a portion of its potash, and reduce it to the acidulous tartrate, which is precipitated in the solution. By the addition of tartaric acid to the solution of this salt, it is also converted into the acidulous tartrate.

999 Tartar. *Supertartrate of Potash.*—1. This is a compound of tartaric acid with potash, but with an excess of acid. The substance which is well known under the name of *tartar*, and which is found encrusted on the bottom and sides of vessels in which wine has been kept, is the supertartrate or the acidulous tartrate of potash; 1000. Purifica-tion. but in this state it is very impure. It is purified by solution in boiling water, and by filtration while it is hot. When it cools, there is a copious deposition of the pure salt in crystals. These are the crystals or cream of tartar.

1001 Contains alkali. 2. It had been long known to chemists, that potash could be obtained from tartar, by exposing it to a strong heat, which produced a controversy whether the alkali existed ready formed in the tartar, or whether it was not, in some way or other, produced by the action of heat during the process. This point was not fully settled till Scheele discovered the method of extracting the acid, the other component part of tartar.

1002 Properties. 3. The crystals of tartar are in the form of small irregular crystals, but chiefly of six-sided prisms. This salt has an unpleasant acid taste, is very brittle, and its specific gravity is 1.953. It requires for its solution 30 parts of boiling water, and 60 of cold water. It undergoes no change when exposed to the air, but in the solution in water the salt is decomposed, depositing a mucous matter, and leaving behind an impure carbonate of the alkali.

1003 Action of heat. 4. Exposed to heat, it melts, swells up, blackens, and the acid is totally decomposed. When it is distilled, an oily matter, and an acid liquid, which is an impure acetic acid, with a great quantity of carbonic acid, are obtained. This acid was formerly called *pyrotartarous acid* (z).

1004 Composition. 5. The component parts of tartar, according to Bergman, are,

Acid	77
Potash	23
	100

Or of the saturated salt,

Tartrate of potash	56
Acid	44
	100

By the analysis of Thenard, it is composed of

Acid	57
Potash	33
Water	7
	97 *

* Annal. de Chim. xxxviii. p. 39.

20. Citrate of Potash.

1005 Properties and composition. This compound of citric acid with potash may be formed by combining together 36 parts of the acid with 61 parts of the carbonate of the alkali. This salt is very soluble in water, but little disposed to crystallize. It is very deliquescent. According to the analysis of Vauquelin, it consists of

Acid	55.55
Potash	44.45
	100.00

21. Malate of Potash.

This salt, which is a compound of malic acid and potash, is deliquescent, and very soluble in water, but its properties are little known.

22. Gallate of Potash.

The compound of gallic acid and potash has little solubility in water, but its other properties are unknown.

23. Benzoate of Potash.

This salt, composed of benzoic acid and potash, crystallizes on cooling, into small needles. A drop of the solution spread on the side of the vessel, as it evaporates, exhibits an arborescent crystallization. It has a sharp saline taste, is deliquescent in the air, and very soluble in water.

24. Succinate of Potash.

This compound of succinic acid and potash, forms crystals in three-sided prisms; the taste is bitter and saline; it deliquesces in the air, and is very soluble in water.

25.

(z) The pyrotartarous acid, the pyromucous, and the pyroligneous acids, were discovered by Fourcroy and Vauquelin to be nothing else than the acetic acid impregnated with extraneous substances, particularly with what is called an empyreumatic oil. See *Annales de Chimie*, xxxv. p. 161.

25. Saccolate of Potash.

This is the compound of saclactic acid and potash. It forms small crystals, which are soluble in eight times their weight of boiling water.

26. Camphorate of Potash.

1006 Preparation. 1. This salt, which is a combination of camphoric acid and potash, may be formed by saturating a solution of carbonate of potash with camphoric acid. When the effervescence has ceased, the solution is to be evaporated with a gentle heat, when it affords crystals by cooling.

1007 Properties. 2. The camphorate of potash is in the form of regular hexagonal crystals, which are white and transparent; the taste is bitterish and slightly aromatic. Exposed to the air, when it is moist, the salt loses its transparency; but if the air is dry, there is no change. It is soluble in four parts of boiling water; but in water at the temperature of 60° requires 100 parts.

1008 Action of heat. 3. Exposed to heat before the blow-pipe, it burns with a blue flame, and the potash remains behind pure. When the heat is stronger, it froths up, the acid is sublimed, and it gives out a thick smoke, which is slightly aromatic.

1009 Of acids. 4. It is decomposed by the mineral acids. If the solution be much diluted with water, the decomposition is not perceptible; but if brought to the consistence of a thick syrup, the camphoric acid crystallizes in cooling. A new salt also is partially crystallized. By solution in cold water the acid may be separated.

1010 Of alcohol. 5. The camphorate of potash is soluble in alcohol, and it burns with a deep blue flame.

1011 Decomposition. 6. It is decomposed by, 1. Nitrate of barytes and of silver; 2. By all the salts whose base is lime; 3. Sulphate of iron; 4. Muriate of tin and of lead *.

* *Annal. de Chim.* xxvii. p 24.

27. Suberate of Potash.

1012 Preparation. 1. This salt, which is a compound of suberic acid with potash, is formed by saturating the acid with the crystallized carbonate of the alkali.

1013 Properties. 2. It crystallizes in four-sided prisms, which have unequal sides. The taste is bitter and saline. It reddens vegetable blues, and is very soluble in water.

1014 Action of heat. 3. Exposed to heat, it swells up and melts; the acid is dissipated, and the potash remains behind. It is decomposed by the mineral acids, which, combined with the potash, precipitate the suberic acid. It is decomposed also by barytes, by all the metallic salts, by sulphate and phosphate of alumina, by the nitrates and muriates of lime and of alumina †.

† *Ann. de Chim.* xxiii. p. 52.

28. Mellate of Potash.

The mellitic acid combines with potash, and forms this salt, which is fully saturated with the acid, and in this state it crystallizes in long prisms; but with an additional portion of acid, an acidulous mellate, or supermellate, is formed. This salt, as Vauquelin observes, also crystallizes; but the properties of these salts have not been much examined ‡.

‡ *Ibid.* xxxvi. p. 208.

29. Lactate of Potash.

This salt is only known as being deliquescent, and soluble in alcohol.

30. Prussiate of Potash.

The compound of prussic acid and potash, is formed by dissolving the alkali in the acid. The salt is very soluble in water, produces a green colour on vegetable blues, and with the application of a moderate heat, it is decomposed.

31. Sebate of Potash.

This salt has been little examined. According to the experiments of Thenard, it has little taste, is not affected by exposure to the air, and is decomposed by the sulphuric, nitric, and muriatic acids: the solution, if it be concentrated, becoming solid on the addition of the acid from the crystallization of the sebacic acid ||.

|| *Ibid.* xxxix. p. 193.

32. Urate of Potash.

This compound of the uric acid with potash, is formed by triturating the acid with the alkali. The mixture assumes the form of a saponaceous paste, which is very soluble in water, when there is an excess of the alkali, but less so when the acid is saturated. This salt has little taste; when neutralized is not very soluble in water, and seems little disposed to crystallize. It is decomposed by the muriatic acid *.

* *Fourc. Connais. Chim.* x. p. 221.

IV. Compounds of Potash with Inflammable Substances.

101 Alcohol. 1. Potash is very soluble in alcohol. The solution assumes a red colour, and becomes acrid. It is by a solution of potash in alcohol, that the former is obtained in a state of purity; for the alcohol dissolves the potash, while other substances are deposited. By the application of heat to this solution, there is a partial decomposition of the alcohol.

2. Ether has no perceptible action on potash.

101 Fixed oils. 3. Potash readily enters into combination with the fixed oils, but particularly with that class of them denominated *fat oils;* and forms with them very important compounds, namely, soaps. The compound with potash and the fat oils is a *soft* soap.

101 Volatile. 4. Potash also enters into combination with the volatile oils, but in very small proportion, which likewise forms a species of soap.

Sect. II. *Of Soda and its Combinations.*

101 Names. 1. Soda, the other fixed alkali, has been distinguished by a great number of different names. It was called *fossil* or *mineral alkali*, because it was supposed that it only existed in the mineral kingdom. It is the substance which is mentioned in Scripture as a detergent, under the name of *nitre*.

101 Found in the soil. 2. This alkali exists in great abundance in different parts of the earth, and particularly on the surface of the soil in Egypt, where it is distinguished by the name of *natron*. It is also found on the walls of caves and places under ground, and old edifices.

102 Obtained from plants. But the soda of commerce is generally obtained from different species of plants which grow on the sea-shore; and as it is prepared from them, it has received different names in different countries. The *salsola soda* yields this alkali in greatest abundance. This plant is called *barilla* in the Spanish language, and from this the

the soda which is prepared on the shores of that country, has been called *barilla ashes*. For the purposes of commerce also, soda is prepared in great quantities from the ashes of another tribe of marine plants, namely the *algæ*, and particularly from the *fuci*, all of which yield it in greater or less proportion. As it is prepared from these plants, it is known in France by the name of *varec*, and in Britain by the name of *kelp*. Soda exists in great abundance in the waters of the ocean. There it is in combination with the muriatic acid, forming the well-known compound of *common salt*.

021 3. In many of their properties soda and potash approach very near to each other. They were accordingly considered as the same alkali, till, towards the middle of the 18th century, by the experiments of Duhamel, Pott, and Margraff, they were distinctly characterised, and the properties of each fully ascertained.

022 4. The soda of commerce is in very different degrees of purity, according to the care and attention with which it is prepared, and the purposes for which it is intended. To have it perfectly pure, it must be subjected to a similar process with those which have been already detailed for the purification of potash; and by means of these processes it may be procured in a solid and crystalline form.

023 5. When soda is in a state of purity, it is usually in the form of solid plates, of a grayish white colour, and the taste exactly similar to that of potash. It is also extremely caustic and corrosive. By slow evoporation from a solution in alcohol, it assumes the form of prismatic crystals; but these, when exposed to the air, very soon effloresce, and fall to powder. Soda changes the blue colour of vegetables to green. Its specific gravity is 1.336. When it is exposed to heat, it softens, and readily melts. It liquefies by the action of heat like an oily matter, and when it becomes red-hot, boils, and is reduced to vapour, which is the soda unchanged, extremely acrid, and corroding the skin when it comes in contact with it.

025 6. When exposed to the air, it first becomes moist and soft, by absorbing water and carbonic acid; but when the air becomes dry, it effloresces and falls into a powder; and in this respect is sufficiently distinguished from potash. Soda has a very great affinity for water. When the dry alkali is moistened with water, it is absorbed, and becomes solid, with the extrication of caloric. When more water is added, it dissolves, and also gives out heat, and a peculiar odour, which is no doubt owing to a portion of the alkali raised in the state of vapour along with the water.

026 7. Soda is a similar compound to potash, and the decomposition is effected by the same process, though somewhat more difficult. It is an oxide of sodium.

027 Sodium is a soft metalloid, less fusible than potassium, its melting point being about 180°. It attracts oxygen slowly from the air. It rapidly decomposes water by combining with its oxygen. Its different chemical habitudes are closely analogous to those of potassium.

8. The affinities of soda are the same with those of potash.

9. Soda is employed for many similar purposes as potash. On account of some of its qualities, it is preferred to potash, in many manufactures, because it is less acrid and corrosive, and is therefore less apt to destroy the texture of animal and vegetable matters to which it is applied.

I. Action of Phosphorus on Soda.

Soda scarcely enters into combination with phosphorus. There is no phosphuret formed either by the dry or humid way; but when phosphorus is boiled with a pure solution of soda, phosphorated hydrogen gas is evolved in the same way as when it is treated with potash. 1028 Phosphorus.

II. Action of Sulphur on Soda.

Soda readily combines with sulphur by simple trituration, by fusion, and by the humid way. In the two first cases, there is formed a sulphuret of soda, which may be decomposed by heat, and by the acids, and which decomposes water in the same way as the sulphuret of potash. By the humid way there is formed a hydrogenated sulphuret of soda, which has an extremely fetid odour, and emits, by the action of the acids which decompose it, sulphurated hydrogen gas. 1029 Sulphur.

Hydrosulphuret of Soda.

This may be prepared in the same way as the hydrosulphuret of potash. It forms a crystallized salt in the shape of four-sided prisms, terminated by quadrangular pyramids. The crystals are colourless, inodorous, and very soluble in water. When this salt is exposed to the air, it deliquesces, and becomes of a green colour. It is decomposed by the action of acids. Soda, it would appear, has less affinity for sulphur and sulphurated hydrogen than potash.

III. Compounds of Soda with the Acids.

1. Sulphate of Soda.

1. This salt, which is a compound of sulphuric acid and soda, is well known under the name of *Glauber's salt*, from the name of Glauber, a German chemist, who discovered it, in examining the residuum of the decomposition of common salt by means of sulphuric acid. It has also been called the *admirable salt of Glauber*, *vitriolated mineral alkali*, and *vitriol of soda*. 1030 Names.

2. This salt may be obtained by the direct combination of sulphuric acid and soda. But it is more commonly prepared by the decomposition of muriate of soda or sea salt, by means of sulphuric acid. The solution is then to be filtered, purified, and crystallized in the usual way. 1031 Preparation.

3. It crystallizes by slow evaporation, in transparent six-sided prisms, terminated by two-sided summits; but the crystals are seldom regular, and the sides of the prisms are furrowed. The taste is cool, bitter, and nauseous. The specific gravity is 1.4457 *. 1032 Properties.

4. When it is exposed to the air, especially when the air is dry, it effloresces, which is owing to the escape of the water of crystallization. It loses about 0.3 of its weight. It is very soluble in cold water, and it requires only $\frac{3}{4}$ths of its weight of boiling water. 1033 Action of air.

5. When it is exposed to heat, it melts, on account of the great quantity of water of crystallization which it contains; and this is called the *aqueous fusion*. Afterwards it dries when the water is evaporated. It loses about .58 of its weight. To melt it afterwards, it 1034 Of heat.

* Manches. Mem. vol. xxviii. p. 12.

Soda, &c. it must be exposed to a red heat long continued, which is called the *igneous fusion*. After it is cooled, it is found to have suffered no change. When water is added, it returns to its former state.

6. It is decomposed by means of charcoal, which at a red heat converts it into sulphuret of soda, by depriving the acid of its oxygen. The component parts

1035 Composition. of this salt, according to Bergman, are

Acid	27
Soda	15
Water	58
	100

But according to Mr Kirwan, it is composed of

	Crystallized.		Dried at 700°.
Acid	23.52	-	56
Soda	18.48	-	44
Water	58.	-	0
	100.00		100 *

* Nichol. Journ. iii. p. 215.

It is decomposed by barytes; and by potash, but less powerfully. Lime and strontites are also capable of producing a partial decomposition in the humid way, and in contact with the air.

7. This salt is a good deal employed in medicine, as a purgative; in chemistry, for the purpose of decomposing other substances; and in the arts, for the extraction of soda.

2. Sulphite of Soda.

1036 Discovery. 1. This salt, which is a compound of sulphurous acid and soda, was first taken notice of by Berthollet. It is prepared by passing sulphurous acid gas into a saturated solution of carbonate of soda. The sulphite of soda is precipitated at first, in a confused mass of very small crystals, which are re-dissolved in warm water, and crystallize again on cooling.

1037 Properties. 2. The crystals of sulphite of soda are in four-sided prisms, two broad, and two narrow, terminated by two-sided summits. They are perfectly transparent. The taste is cool and sulphureous. The specific gravity is 2.9566.

1038 Action of the air. 3. Exposed to the air, it effloresces, and the powder formed on the surface is converted into a sulphate. It

1039 Of water. is extremely soluble in water. Boiling water takes up more than its own weight. It crystallizes again on cooling, but sometimes the solution is formed into a single mass when it is exposed to the air; and if quickly cooled with agitation, it affords nothing but needle-formed crystals. This solution exposed to the air is converted into the sulphate.

1040 Of heat. 4. This salt readily undergoes the aqueous fusion; if the heat be increased, a portion of sulphur is driven off, and it is converted into a sulphate.

5. It is decomposed by means of the acids, which disengage the sulphurous acid in the state of gas. The oxymuriatic acid gas, brought into contact with a solution of this salt in water, instantly converts it into sulphate. It is decomposed by barytes, lime, and potash; by the sulphates of lime, of ammonia, and of magnesia.

6. The component parts of this salt have been found by analysis to be, Soda, &

1041 Composition.

Sulphurous acid,		31
Soda,	-	18
Water.	-	51
		100

It has not been applied to any use.

3. Nitrate of Soda.

1. This compound of nitric acid and soda was formerly known by the name of *cubic nitre*, and *rhomboidal nitre*. It is prepared by the direct combination of the acid with the alkali; or by decomposing the muriate or carbonate of soda by nitric acid. 104 Names.

2. It crystallizes in the form of rhomboids and prisms. The taste is cooling, but more bitter than that of the nitrate of potash. 1043 Propert

3. The specific gravity is 2.0964. Exposed to the air, it attracts moisture in a slight degree. It is soluble in three parts of cold water, and in less than its own weight of boiling water.

4. When it is thrown on red-hot coals, it decrepitates slightly; it is not so fusible as nitre, but it is also decomposed, and gives out oxygen gas mixed with azotic gas. 1044 Heat.

5. In its decomposition it is similar to the nitrate of potash. It detonates, however, less powerfully with combustible bodies, and burns them with less facility. It is decomposed by barytes and potash.

6. The proportions of its constituent parts are, according to Bergman, 104 Compos tion.

Acid,	43
Soda,	32
Water,	25
	100

According to Mr Kirwan,

	Dried in a heat of 400°.		After being ignited.

Soda,	40.58	-	42.34
Water,	6.21	-	00.00
	100.00		99.89 †.

† Nich Jour. ii p. 215.

4. Nitrite of Soda.

Chemists are not acquainted with the properties of this salt, although it is known to be formed after the partial decomposition of nitrate of soda by means of heat.

5. Muriate of Soda.

1. The muriate of soda, which is a compound of muriatic acid and soda, of all the other salts, from its great abundance in nature, and its valuable uses, was the earliest known under the name of *salt*. It has been distinguished by the names of *common salt*, *kitchen salt*, *sea-salt*, and sometimes *sal gem*, *rock salt*. 104 Commo salt. 104 Names

2. This salt, which is found in such abundance in nature, 104 Abund in nat

nature, is never formed by art. In some parts of the world it exists in the bowels of the earth in large masses, from whence it is dug out, and simply reduced to powder, to be applied to use. But to obtain it from the waters of the ocean, in which it exists in different proportion, according to the temperature, the climate, and other circumstances, it must be extracted by evaporation, which is effected by different processes, according to the strength of the solution, and the art of the manufacturer. In some parts of the world, all that is done is to collect the salt as it forms on the shores of the sea, or on the rocks, by the evaporation of the water; but, in general, some art is necessary, even when the salt is obtained by spontaneous evaporation. On the coasts of France, Spain, Portugal, and the shores of the Mediterranean, the sea water is admitted into ponds during the flowing of the tide, and its return is prevented by sluices which are shut. It is then evaporated by the heat of the sun; and, as this evaporation is gradual and slow, the salt crystallizes in large cubes, and it is known in commerce by the name of *bay salt*, from the circumstance of its having been formed in creeks and bays of the sea.

1049 By [...]t.

3. But as this process can only be followed in those climates where there is a sufficient degree of temperature to promote the evaporation speedily, artificial heat is generally employed in the manufacture of salt. Sometimes the water is received in large ponds or flat vessels, where it is allowed to evaporate for some time in the open air. It is afterwards boiled in flat iron pans; and, during the boiling, the impurities which rise to the surface are removed. When the water is sufficiently concentrated by the evaporation, a pellicle forms on the surface, which is the crystallization of the salt. This falls to the bottom, and another pellicle forms, till the whole of the salt is crystallized. The purity of the salt and the size of the crystals depend on the slow evaporation; and hence it is, that the purest salt, as it is manufactured in Britain, is that which is called *Sunday salt*. This is obtained from the last quantity of water which is boiled on the Saturday night; and as it has time to cool slowly, the evaporation is more gradual, and the crystals are purer and larger.

1050 Purification.

4. But in this state the muriate of soda is far from being pure. A very ingenious method has been proposed for the purification of sea-salt by Lord Dundonald. The salts with which common salt is impregnated, are more soluble in water than the salt itself, and they dissolve in much greater proportion in hot than in cold water. But common salt is nearly equally soluble in both. On this principle, therefore, the process proceeds. A quantity of salt to be purified is put into a conical vessel or basket, which is slightly stopped at the apex, so that the water may pass through. A saturated solution of common salt is then prepared. This solution of salt is poured boiling hot over the salt in the basket. It can dissolve none of the common salt in the basket, because it is already saturated; but, as it passes through, it dissolves the other salts, and carries them along with it. It was found by experiment, that a saturated solution of 1 lb. of common salt poured upon 10lbs. removes about $\frac{4}{5}$ths of all the foreign salts with which it is impregnated.

1051 By other processes.

5. But, even after this process, the salt is not perfectly pure for the purposes of chemistry. For this purpose it may be dissolved in four parts of cold water. Filter the solution, to separate any substances with which it is mixed. Pour into it some drops of a solution of soda, till no farther precipitate is observed. The fluid is then to be evaporated, and the salt, as it forms on the surface in small cubical crystals, may be extracted; or it may be obtained in larger crystals by slow evaporation.

It may also be purified, by dropping into a solution of common salt a solution of muriate of barytes, and then of carbonate of soda, as long as any precipitate is formed. The liquid may then be filtered and evaporated, till the solution crystallizes.

6. The muriate of soda crystallizes in perfect cubes; 1052 Properties.
but from these there are several deviations in the form of its crystals. Sometimes the angles of the cubes are truncated; sometimes they are in the form of octahedrons; which is the case when common salt is dissolved in human urine, and allowed to evaporate spontaneously. But the primitive form of the crystal, as well as of the integrant particle, according to Hauy, is the cube. The taste is sweetish and agreeable, and is that which is properly called *salt*, with which all similar tastes are compared. The specific gravity is 2.120. When all the water that can be driven off is expelled, it is considered as a chloride of sodium, in the same way as has been mentioned of muriate of potash. See N° 956.

7. It undergoes no change by exposure to the air. 1053 Action of air,
Common salt attracts moisture from the atmosphere; but this is owing to an impregnation of other salts which are deliquescent. These salts are muriate of magnesia, sulphate of magnesia, and sulphate of lime. It is from these that it is to be purified by the processes which have been described above. 1054 and water.
It is soluble in little more than $2\frac{1}{2}$ times its weight of water; and it is almost equally soluble in hot and cold water.

8. When it is exposed to a strong heat, it decrepitates and gives out its water of crystallization. It melts in a red heat, and rises in the air in the state of white vapour; but it is unchanged; for if this vapour be collected by condensing it in the cold, it is found to possess all the properties of common salt.

9. The muriate of soda is decomposed readily by 1055 Decomposition.
sulphuric acid, as well as by several other acids which have a stronger attraction for its base than the muriatic acid; or by the aid of double affinity, when an acid is in combination with a base, which at the same time acts on the muriatic acid. It is by means of the sulphuric acid that the chemist procures muriatic acid 1056 By sulphuric acid.
from the muriate of soda. Sometimes the salt is decomposed by the same acid to obtain the soda. The sulphuric acid combines with the soda, and forms sulphate of soda, while the muriatic acid is disengaged, and that it may not be lost, it is conveyed into a leaden chamber, which contains a solution of ammoniac, where it forms sal ammoniac. The sulphate of soda is exposed to strong heat in a furnace, to drain off any portion of sulphuric acid that it may contain. It is then mixed with its own weight of chalk, and half its weight of charcoal in powder. The mixture is strongly heated in a reverberatory furnace, and occasionally stirred to permit the escape of gas and sulphur, which fly off. When the mass cools, it becomes solid and black.

black. The charcoal, in decomposing the sulphuric acid of the sulphate of soda, sets the sulphur free, which combines with the lime of the carbonate of lime, and is partly sublimated; while a part of the carbonic acid combines with the soda, so that the product is a mixture of carbonate of soda, of lime and charcoal, analogous to the soda of commerce. In this way 0.58 of crude soda may be extracted. Other acids, as well as the sulphuric, such as the acetic, the phosphoric, and boracic, have been proposed to be employed with the same view; or indeed, any acid which has a stronger affinity for the soda than the muriatic acid, and is not decomposed with much difficulty.

10. But these processes are not sufficiently economical to answer the purposes of the manufacturer: Other processes have, therefore, been proposed and tried with the same view; but scarcely any has succeeded. This salt is very readily decomposed by barytes or potash, which combines with the muriatic acid, and sets the soda free; but the expence of preparing these substances far exceeds the price of the soda in the market, so that they cannot be employed to advantage.

1057 By lime.

It has been proposed to decompose sea salt by means of lime, for obtaining the soda. Soda is separated from the acid by mixing the common salt with lime, in the form of paste, and by exposing it to moisture. In a short time the soda appears on the surface in the state of efflorescence. Scheele, it is observed by Berthollet, was the first who noticed the decomposition of the muriate of soda by means of lime. He explains this decomposition by showing, that lime acts on salts with fixed alkaline bases. It decomposes a small part of the muriate of soda, with which it is in contact, and the soda, eliminated by this means, combines with the carbonic acid of the atmosphere. The carbonate of soda effloresces, so that it opposes all resistance to the action of the lime, and the decomposition of the muriate of soda continues until it is impeded by the quantity of muriate of lime formed. It is in this way that the same philosopher accounts for the formation of soda in the soil of Egypt. The circumstances necessary for this are, 1st, A sand containing a great quantity of carbonate of lime; 2d, moisture; and 3d, muriate of soda; and these circumstances are found to exist in those places where there is an abundant production of soda *. A manufactory for the purpose of extracting soda from sea salt, by means of lime, was established in France by Guyton.

* *Research.* p. 59, and 112.

1058 By lead.

11. Common salt is decomposed for the purpose of obtaining the soda, by means of litharge. In a mixture of four parts of litharge, and one of sea salt, with a little water, in the course of a few hours, a decomposition of the salt is effected. The muriatic acid of the salt combines with the lead, and is precipitated; while the soda remains in the solution, from which it may be separated by filtration and evaporation.

1059 By iron.

It has been found too, that sea salt may be decomposed by other metallic substances. Scheele observed, that iron produced this effect. By dipping a plate of iron in a solution of salt, and exposing it in a moist place, it was incrusted with soda. From other experiments it appears, that this decomposition may be effected by means of copper and zinc.

1060 Composition.

12. Muriate of soda, according to Bergman, is composed of

Acid	52
Soda	42
Water	6
	100

According to Kirwan, when dried in the temperature of 80°, it is composed of

Acid	38.88
Soda	53.00
Water	8.12
	100.00

13. Common salt may be regarded almost as a necessary of life. It is the most useful of all substances for the preservation of animal matters which are intended for food. It is probable that it is highly useful, not merely as a seasoning for food, of which it is one of the most agreeable, but also to promote its digestion. It is also employed in many arts, as in metallurgy, in dyeing, and in the enamelling of stoneware. 1061 Uses.

6. Hyperoxymuriate, or Chlorate of Soda.

1. This salt is prepared in the same manner as the combination of this acid with potash. It is, however, difficult to obtain it pure, as it has nearly the same degree of solubility in water as the muriate of soda. It is soluble in three parts of cold and less of warm water. It is also soluble in alcohol, and it seems to communicate a greater degree of solubility to the muriate of soda. 1062 Preparation.

2. The crystals of this salt are in the form of cubes, or in rhomboids. It produces the sensation of cold in the mouth, and its taste is easily distinguished from muriate of soda. It is decomposed by heat, by combustible bodies, and by acids, in the same manner as the hyperoxymuriate of potash. 1063 Properties.

3. This salt is composed of 1064 Composition.

Hyperoxymuriatic acid	66.2
Soda	29.6
Water	4.2
	100.0 *

* *Philos. Trans.* 1802. p. 144.

7. Fluate of Soda.

1. This salt, which is a compound of fluoric acid and soda, is formed by saturating the acid with the alkali. If the solution be evaporated till a pellicle appears, crystals of fluate of soda are obtained. 1065 Preparation.

2. These crystals are in the form of small cubes, have a bitter and astringent taste, are not deliquescent, and not very soluble in water. They decrepitate on hot charcoal, and melt before the blow-pipe into a semitransparent globule. 1066 Properties.

3. The concentrated acids disengage the fluoric acid with effervescence. This salt is also decomposed by lime-water, barytes, and magnesia.

8. Borate of Soda.

This salt, a compound of the boracic acid and soda, is formed by saturating the acid with the alkali; but nothing is known of its nature and properties. The specific

specific gravity is 1.1351. But the combination of soda with this acid, which is a natural production, has been particularly examined.

Sub-borate of Soda, or Borax.

1067 tory. 1. This substance has been long known. Indeed it is supposed, that the ancients were acquainted with it, and that they employed it for several purposes, under the name of *chrysocolla*, which is mentioned by Pliny. It received this name from them, it is supposed, from knowing its property of soldering gold and the other metals. The name borax is derived from some of the oriental languages. Although borax was the subject of research among the alchemists and earlier chemists, yet nothing was known of its nature and composition till the beginning of the 18th century. It was then decomposed by Homberg, by exposing it to heat with sulphate of iron. The acid was separated by sublimation, and long after known by the name of the *sedative salt of Homberg*. In 1732 its real composition was discovered by Geoffroy. He obtained the acid crystallized in the humid way. In 1748 Baron decomposed borax by means of the vegetable acids, and he completed the knowledge of its composition, by forming it with the acid and the alkali. Bergman afterwards shewed, that borax is a salt with excess of soda; and to be neutralized, it requires one half of its weight of boracic acid.

2. Borax is a natural production of the earth in many parts of the world. It is formed at the bottom of some lakes in Persia, the Mogul territory, in Thibet, in China and Japan. It has been also found in some lakes in Tuscany. In the East Indies it is known under the name of *tincal*, and in commerce under that of *crude borax*. In this state the borax is in the form of small, semitransparent, greenish crystals, intermixed with a greasy matter, of a dirty gray colour, and of a sweetish alkaline taste.

068 fica. 3. The purification of borax was originally in the hands of the Venetians; but it has since been practised, and now almost exclusively, by the Dutch. Their process is not exactly known. Valmont-Bomare, who visited one of these places in Holland, says, that 80 parts of purified borax are obtained from 100 of the crude materials; and to extract the salt completely, from eight to twelve solutions and crystallizations are necessary; that all the vessels employed in the purification of this salt, are either of lead, or covered with lead; but he adds, that one part of the process was concealed from him, and he suspects that lime-water may have been employed in this part of the process.

069 perties. 4. Borax, after being thus purified, is in the form of compressed six-sided prisms with three-sided summits. The taste is sweetish, and perceptibly alkaline. It changes the vegetable blues to a green colour. The specific gravity is 1.742. It effloresces slightly in the air, and is soluble in water. Twelve parts of water of the temperature of 60° dissolve one of borax. Six parts are only necessary at the boiling temperature.

070 on of 5. When borax is exposed to heat, it readily melts. As the water of crystallization flies off, it swells up and acquires a greater bulk, and assumes the form of a porous mass. By this process it loses more than one-third of its weight, and in this state it is called *calcined borax*. When it is exposed to a red heat, it is converted into a transparent glass, which is soluble in water.

6. Borax is decomposed by all the acids which have a stronger affinity for the soda. It is by means of the sulphuric and the nitric acids, that boracic acid is obtained from borax. 1071 Of acids.

7. The component parts of borax, according to Kirwan, are 1072 Composition.

Boracic acid	36
Soda	17
Water	47
	100

It is supposed that only five parts of the soda are saturated with the acid, and that the other twelve parts form the excess of alkali which is contained in the salt.

8. Borax is much employed in the arts, as a flux for metals, and to promote the soldering of the more precious metals. It is also employed by the mineralogist, as a flux for treating minerals by the blow-pipe. Calcined borax is employed in medicine as an absorbent *. 1073 Uses.

* Fourcroy Connaiss. Chim. iii. p. 325.

9. Phosphate of Soda.

1. This compound of phosphoric acid and soda was the first discovered of the combinations of phosphoric acid. Margraaf was the first who extracted it from human urine, then in combination with ammonia, forming a triple salt, which was known by the name of *fusible* or *microscomic salt*. Haupt afterwards obtained it separate, and distinguished it by the name of *sal mirabile perlatum*, or wonderful perlated salt, on account of its pearl-like colour. At last the younger Rouelle discovered that soda was one of its constituent parts. By some it was supposed, that the acid was different from the phosphoric, because no phosphorus could be obtained from it. To this acid Bergman gave the name of perlated acid; but by the analysis of Klaproth, it was proved that this salt consists of phosphoric acid and soda, with an excess of acid. 1074 History.

2. This salt is prepared by saturating the liquid acid phosphate, which is obtained from burnt bones by means of the sulphuric acid, with carbonate of soda, which must be added in excess. The carbonate and a little phosphate of lime are precipitated in the solution, which must be filtered and evaporated till a thin pellicle appears on the surface. The phosphate of soda is crystallized by cooling. Or it may be obtained by the direct combination of phosphoric acid and soda, which must also be added in excess. 1075 Preparation.

3. The phosphate of soda crystallizes in lengthened rhomboids, whose angles are often truncated, and sometimes it affords rhomboidal prisms, and several other varieties. The excess of soda is necessary, to make it assume a regular form, and thus it changes vegetable blues to a green. The specific gravity is 1.33. It has a sweetish, saline taste, similar to that of common salt. 1076 Properties.

4. It effloresces in the air, and is very soluble in water. Four parts of water at the temperature of 60°, and one half its weight of boiling water, are sufficient to dissolve it. 1077 Action of water.

5. The phosphate of soda, exposed to heat, undergoes the watery fusion. In a red heat it melts, and is converted, 1078 Of heat.

Soda, &c. converted, on cooling, into a milky white glass. By the action of the blow-pipe on charcoal, it melts into a globule, which is transparent while it is hot, but becomes opaque on cooling, and assumes the polyhedral form when it becomes solid.

1079 Of acids. 6. The sulphuric, nitric, and muriatic acids decompose it partially, and convert it into the acidulous phosphate of soda.

1080 Uses. 7. Since the properties of this salt was discovered, it has become an object of considerable importance, on account of the various uses to which it has been applied. It was introduced into medicine by Dr Pearson, and is found to be a mild laxative, particularly agreeable on account of its taste, as it may be taken in broth, as a substitute for common salt. It is employed by mineralogists as a test for the fusion of mineral substances by the blow-pipe, and in soldering, as a cheap substitute for borax.

10. Phosphite of Soda.

1081 Preparation. 1. This compound of phosphorous acid and soda, may be formed by the direct union of the acid and alkali in solution; and by evaporation crystals may be obtained.

1082 Properties. 2. This salt crystallizes sometimes in four-sided prisms with unequal faces; sometimes in long rhomboids, or in the form of feathers. The taste is cool and sweetish. It effloresces in the air, and is soluble in two parts of cold water, and little more soluble in warm water; so that it crystallizes by evaporation rather than in cooling.

1083 Action of heat. 3. It melts readily under the blow-pipe, gives out fine phosphoric light, and is converted into a glass which continues transparent while it is hot, but becomes opaque when it cools.

1084 Composition. 4. The component parts of this salt are,

Phosphorous acid	16.3
Soda -	23.7
Water -	60.0
	100.0

5. This salt is easily decomposed by lime, barytes, and magnesia. It decomposes the sulphates, nitrates, and muriates of lime, of barytes, strontites, and magnesia. It has not yet been applied to any use.

11. Carbonate of Soda.

1085 History. 1. This salt, which is a compound of carbonic acid and soda, was long applied to various uses, before its nature and composition were known; nor was it perfectly understood till the discovery of Dr Black, which shewed the two states in which the alkali exists; in the caustic or pure state, and in the mild state, when it is combined with fixed air, or carbonic acid. The different names under which it is known, have been already mentioned in treating of soda. It is found in great abundance in Egypt, where it effloresces on the soil, and is distinguished by the name of *natron*. In a similar state of efflorescence, the carbonate of soda is found in subterraneous places, and on the walls of buildings; but it is chiefly extracted, as has been already observed, from sea-plants, especially from those which belong to the genus of *fuci*.

1086 Preparation. 2. Carbonate of soda may be obtained by dissolving a quantity of the soda of commerce with three or four times its weight of pure cold water, and then by filtering the liquor, and evaporating till a slight pellicle is formed. This pellicle, which consists of small cubes of common salt, is to be removed. The heat is to be continued as long as any pellicle is formed, after which the liquid is set by to cool, and the carbonate of soda crystallizes.

1087 Properties. 3. The form of the crystals of carbonate of soda are irregular or rhomboidal octahedrons, formed by two quadrangular pyramids, truncated near the base, which exhibits dicahedral solids, with two acute and two obtuse angles. The taste is slightly acrid; it converts vegetable blues to a green colour, and its specific gravity is 1.3591.

1088 Action of water. 4. The carbonate of soda effloresces very rapidly in the air. It is soluble in two parts of cold, and little more than its weight of boiling water. It crystallizes on cooling; but to obtain regular crystals, the evaporation must be slow and spontaneous.

1089 Of heat. 5. When exposed to heat, it undergoes the watery fusion, and if the heat be continued, it passes into the igneous fusion. It is somewhat more fusible than the carbonate of potash, which renders it preferable in the manufacture of glass.

6. In its decomposition by other substances, it is exactly similar to the carbonate of potash.

1090 Composition. 7. The component parts of carbonate of soda are, according to

		Kirwan.	
	Bergman.	In crystals.	Dry.
Carbonic acid	16	14.42	40.05
Soda	20	21.58	59.86
Water	64	64.00	00.00
	100	100.00	99.91

12. Arseniate of Soda.

1. This is the compound of the arsenic acid with soda; and when the acid is saturated with the alkali, the salt crystallizes.

2. According to Scheele the form of the crystals of this salt is like those of the acidulous arseniate of potash. Pelletier observes that the arseniate of soda crystallizes in six-sided prisms, terminated by planes perpendicular to their axis. In other respects it is similar to the arseniate of potash, being decomposed by charcoal, by the acids and the earths. With an excess of acid, it does not crystallize, but becomes deliquescent.

13. Tungstate of Soda.

1091 Preparation. 1. This salt, which is the compound of tungstic acid and soda, may be formed by dissolving the oxide of tungsten in a solution of pure soda, or carbonate of soda. By evaporating the solution, crystals of tungstate of soda are obtained.

1092 Properties. 2. The crystals of this salt are in the form of elongated, six-sided plates. The taste is acrid and metallic. It is soluble in four times its weight of cold water; and boiling water dissolves one half of its weight. It restores the colour of turnsole which has been reddened by an acid.

1093 Action of acids. 3. This salt is decomposed by the sulphuric, nitric, muriatic, acetic, and oxalic acids. They form a white triple

triple salt, which is also produced by lime-water. The phosphoric acid produces no change, and if the sulphuric acid be afterwards added, it no longer causes a precipitate. The tungstate of soda is not decomposed by the sulphate of potash or of magnesia. The muriates of lime and barytes occasion a white precipitate. The solution of tin, and all other metallic solutions, also decompose it *.

* Jour. de M[ine]s, N. 19. p.

14. Molybdate of Soda.

15. Chromate of Soda.

The chromic acid combines with soda, and forms a salt, the crystals of which are of an orange colour, but its other properties are unknown.

16. Columbate of Soda.

Columbic acid enters into combination mith soda, but little is known of its properties.

17. Acetate of Soda.

194 Prepara-tion and properties.

1. The combination of the acetic acid with soda was formerly known by the name of *crystallized foliated earth.* This salt is prepared by saturating the acetic acid with carbonate of soda. The solution is then filtered, and evaporated till a slight pellicle appear on the surface; and when it is set by to cool, crystals are deposited.

2. The crystals of acetate of soda are in the form of striated prisms, like those of sulphate of soda. It has a bitter, pungent taste, is not deliquescent in the air, and is soluble in about three parts of cold water. The specific gravity is 2.1. When exposed to heat it is decomposed, being first deprived of its water of crystallization. After distillation, the residuum has the property of phosphorus. It is decomposed by barytes and potash †.

† Fourcroy Conn. iss. Chim. tom. vii. 198.

18. Oxalate of Soda.

The oxalic acid is capable of forming an acidulous salt with soda; but when it is fully saturated, the oxalate of soda thus formed is difficult of crystallization. If two parts of crystallized carbonate of soda are dissolved in one part of oxalic acid, part of the oxalate of soda is precipitated, and what remains in the solution, being evaporated, affords crystals in the form of small grains. This salt is more soluble in warm than in cold water, and gives a green colour to the syrup of violets. It is decomposed by potash. In other respects it resembles the oxalate of potash.

19. Tartrate of Soda.

This compound of tartaric acid and soda is formed by saturating the acid with the alkali. The form of the crystals of this salt is that of fine needles. The specific gravity is 1.7437. This salt combines with another portion of acid, and forms an acidulous tartrate or supertartrate of soda, which is not more soluble in water than the acidulous tartrate of potash.

20. Citrate of Soda.

1. This salt, which is a compound of citric acid and soda, is formed by directly combining the acid and alkali.

2. It crystallizes in six-sided prisms, which are not terminated by a pyramid. It has a saline taste, effloresces in the air, and is soluble in two parts of water. When heated, it boils up, swells, and is charred. It is decomposed by barytes and lime water. It is composed of

Acid	60.7
Soda	39.3
	100.0

21. Malate of Soda.

This salt, formed of malic acid and soda, is deliquescent in the air, and very soluble in water. Its other properties are unknown.

22. Gallate of Soda.

The nature of the compound of gallic acid with soda has not yet been ascertained. A green colour is produced, when the alkali is dropt into the acid.

23. Benzoate of Soda.

The compound of benzoic acid with soda forms a salt which readily crystallizes. It is deliquescent in the air, and very soluble in water. The taste is sharp and saline. This salt exists ready formed in the urine of graminivorous animals.

24. Succinate of Soda.

The combination of succinic acid with soda, forms beautiful transparent crystals by spontaneous evaporation. The crystals are in the form of four-sided prisms with two-sided summits. The taste of the salt is bitter. It is not deliquescent in the air, and it requires about three times its weight of water to dissolve it. It is decomposed when it is exposed to heat in close vessels.

25. Saccolate of Soda.

All that is known of this salt is, that it crystallizes in small crystals, and is soluble in five times its weight of boiling water.

26. Camphorate of Soda.

1. This compound of camphoric acid with soda is formed by saturating a solution of carbonate of soda in water with the acid; and by evaporation with a gentle heat, the crystals are obtained, when the solution cools.

2. The crystals of camphorate of soda are irregular. They are white and transparent. The taste is bitter. Exposed to the air, this salt effloresces. It is soluble in eight parts of boiling water.

3. Exposed to heat, it melts and swells, and the acid is dissipated in thick vapours of an aromatic odour. With the blow-pipe it burns with a blue flame, and is decomposed. The acid is sublimed, and the alkali remains behind. It is decomposed by potash, and by the strong acids *.

* *Ann. de Chim.* xxvii. p. 28.

27. Suberate of Soda.

The compound of suberic acid with soda forms a salt which does not crystallize. It has a slightly bitter taste, and reddens the tincture of turnsole. It deliquesces in the air, and is very soluble in water. Exposed

posed to heat, it swells and melts; the acid is sublimed, and the alkali remains behind. The mineral acids decompose it, and it is also decomposed by the calcareous, aluminous, and magnesian salts †.

† Ibid. xxiii. p. 33.

28. Mellate of Soda.

The compound of mellitic acid with soda, when it is saturated, forms crystals in cubes or three-sided tables. Sometimes they are formed in groups, and sometimes they are insulated.

29. Lactate of Soda.

All that is known of this salt is, that it does not crystallize, but is soluble in alcohol.

30. Prussiate of Soda.

This salt, which is a compound of prussic acid and soda, is very soluble in water, converts vegetable blues to green, and when it is exposed to a very moderate heat, it is partially decomposed.

31. Sebate of Soda.

Nothing farther is known of the compound of sebacic acid with soda, than that it is soluble in water.

IV. Compounds of Soda with Inflammable Substances.

1. Soda enters into combination with alcohol, and forms a reddish-coloured acrid solution; but when heat is applied to this solution, it appears that the alcohol is partially decomposed.

2. There is no action between ether and soda.

3. Soda readily combines with the fixed oils, and especially that class of them called *fat oils*, and forms with them compounds called soaps.

4. Soda combines in very small quantity with the volatile oils, and the compounds thus formed have some of the properties of soap.

Sect. III. *Of Lithina and its Combinations.*

This alkali was discovered by M. Arfvredson, a pupil of Berzelius, in 1818, in a mineral called *petalite*. It is also contained in spodumene and in crystallized lepidolite. It is distinguished from potash and soda, chiefly by neutralizing a much larger quantity of the different acids than either of those alkalies, surpassing in this respect even magnesia.

1095 History and properties.

Like the two preceding alkalies, it is a compound of oxygen with a metalloid called *lithium*, which in properties greatly resembles sodium.

With the acids, lithina forms salts similar to those of soda, but differing from them in some slight particulars. Their crystalline forms are not exactly the same, and they are generally more deliquescent.

Sect. IV. *Of Ammonia and its Combinations.*

1096 History.

1. This substance has been long known under the names of *volatile alkali*, *volatile spirit of sal ammoniac*, *caustic volatile alkali*, *hartshorn*, *spirit of hartshorn* and *of urine*, because it was obtained from these substances. It has received the name *ammonia*, from *sal ammoniac*, a salt which was extracted from the urine and dung of camels, collected near the temple of Jupiter Ammon in Africa. This salt was first known to the ancients. It is first mentioned by Basil Valentine, who lived in the 15th century, as being prepared from certain substances, with an account of some of its properties. But the difference between the pure salt and its compound with the carbonic acid, was not known till the discovery of Dr Black. It was supposed to be in the state of greatest purity in the solid and crystalline form; and in its pure, caustic, and liquid state, it was supposed to be changed, and contaminated with the lime or the different matters which had been employed in extracting it from sal ammoniac. It was afterwards examined by Dr Priestley in the state of gas, and he decomposed it by electricity, but without discovering its constituent parts. This was at last effected by the researches and experiments of Scheele and Bergman, and finally confirmed by those of Berthollet.

109 Preparation.

2. Ammonia may be obtained by the following process. Three parts of quick lime, and one part of sal-ammoniac reduced to powder, are to be put into a retort, and the beak of the retort immersed under mercury in the mercurial apparatus. A jar filled with mercury is inverted above it. Heat is applied to the retort, and a gas comes over in great abundance. This gas is *ammonia*, or *ammoniacal gas*. Sal-ammoniac consists of the muriatic acid and ammonia. The affinity of lime for muriatic acid is stronger than that of ammonia, and therefore the ammonia is disengaged in the state of gas, while the lime combines with the acid. The gas must be received over mercury, because it is readily absorbed by water.

109 Propert

3. Ammonia in the state of gas resembles common air. It is transparent and colourless, and may be indefinitely compressed and dilated. The smell is extremely pungent and acrid, particularly irritating the eyes and nostrils. It has an acrid and caustic taste, but is much less corrosive than the other alkalies. It changes vegetable blues to a green colour. It is lighter than common air. Its specific gravity is 0.000732; so that it is nearly one half lighter. According to Mr Kirwan, a cubic inch of this gas weighs only .27 of a grain.

It is totally unfit for respiration. No animal can breathe it without instant death. It is also unfit for the support of combustion; but although it extinguishes burning bodies, the flame of a candle let down into this gas is considerably enlarged in volume by the addition of another flame, which is of a pale yellow colour.

109 Action heat.

4. This gas is unaltered by the action of light. When it is exposed to a strong heat, as when it is passed through a red-hot porcelain tube, it is decomposed and converted into azotic and hydrogen gases. It is also decomposed by the electric spark. When it is exposed to the temperature of —45°, it is condensed, and assumes a liquid form; but it returns to the gaseous state by an elevation of temperature.

11 Of oxy

5. There is no action between oxygen gas and this gas in the cold; but if the two gases mixed together are made to pass through a red-hot porcelain tube, the ammonia is decomposed; a detonation takes place, the hydrogen combines with the oxygen and forms water. The azote passes off in the state of gas.

11 Comm air.

6. There is no action between this gas and azotic gas, nor is there any action between common air and ammoniacal gas in the cold; but if the mixture be made

made to pass through a red-hot porcelain tube, water is formed, and the gas which escapes is a combination of the azotic gas of the atmosphere, and of that which entered into the composition of ammonia. But if the same experiment be made with a greater proportion of oxygen gas, the product is nitric acid, which is formed by the combination of part of the oxygen and the azote *.

* urcroy ıiss. . ii. 6.

102 osi-

7. It has been already mentioned, that the constituent parts of ammonia were discovered by Scheele and Bergman, and Priestley and Berthollet. According to the experiments of the latter, ammonia is composed of 121 parts of azote, and 29 of hydrogen. This result was obtained by decomposing the ammonia by means of electricity. One hundred parts of ammonia, therefore, are composed of

Azote	80
Hydrogen	20
	100

03 ıter.

8. Ammoniacal gas combines very rapidly with water. If a bit of ice be brought into contact with this gas, it absorbs and condenses it, and instantly becomes liquid. There is at the same time a production of cold; but water in the liquid state, as it absorbs this gas, becomes warm, because the gas is deprived of that quantity of caloric which is necessary to retain it in the gaseous form. The water, as it absorbs the gas, becomes specifically lighter. When water is saturated with this gas, it is known under the name of liquid ammonia. The specific gravity of a saturated solution is 0.9054. When this solution is exposed to the temperature of 130° the ammonia is driven off, and assumes the gaseous form; and when it is slowly and gradually cooled to the temperature of from —35 to —42°, it crystallizes; but when the temperature is rapidly diminished to —58° it assumes the form of jelly. At that temperature it has no smell †.

† . de xxxi.

By Sir H. Davy's experiments, a saturated solution of ammonia contains, in 100 parts,

Water	74.63
Ammonia	25.37
	100.00

He has also ascertained the different proportions of water and ammonia which are contained in 100 parts of liquid ammonia of different specific gravities ‡. These are exhibited in the following table.

‡ y's rches,

Table of the quantities of Ammonia, such as exists in the aëriform state, saturated with water at 52°, in Aqueous ammoniacal Solutions of different specific gravities.

9713		7,17	92,83

9. The order of affinities of ammonia is the same as that of the fixed alkalies. 1104 Affinities.

I. Action of Phosphorus on Ammonia.

1. There is no action between ammonia and phosphorus in the cold; but when the two gases are passed through a red-hot porcelain tube, the ammonia is decomposed, and its constituent parts enter into combination with the phosphorus. There is formed phosphorated hydrogen gas, and phosphorated azotic gas. In this case there is a double action of the phosphorus, one part combining with the hydrogen, and another with the azote. 1105 With heat.

2. Ammonia is also decomposed by red-hot charcoal, when it passes over in the state of gas at this temperature. Part of the carbone of the charcoal combines with the ammonia, and forms prussic acid.

II. Action of Sulphur on Ammonia.

1. Ammonia combines with sulphur in the state of vapour. This combination constitutes a sulphuret of ammonia, which has the property of decomposing water, and is then converted into a hydrogenated sulphuret of ammonia. This may be prepared by distilling, in a retort, a mixture of muriate of ammonia, lime, and sulphur. By this process a liquid of a deep orange colour, which exhales extremely fetid vapours, on account of the excess of ammonia which it contains, is produced. This was known under the name of the *fuming liquor of Boyle*. This sulphuret is decomposed by heat, by the acids and sulphurated hydrogen gas.

2. When ammonia absorbs sulphurated hydrogen gas, either by agitating the gas in a vessel with liquid ammonia, or by passing a current of the gas through it, there is an evolution of caloric and the formation of vapour, and the liquid is converted into an orange colour. This is the hydrosulphuret of ammonia. It has no longer the fetid odour of the hydrogenated sulphurate,

phuret, and it may be crystallized. It is decomposed by the action of heat, by the acids, and by the metallic oxides.

III. Compounds of Ammonia with the Acids.

1. Sulphate of Ammonia.

1106 History. 1. The compound of sulphuric acid with ammonia was formerly called *secret sal ammoniac of Glauber*, because it was discovered by that chemist. It was also called *vitriolated ammonia*, and *vitriolated volatile alkali*. It was discovered by Glauber in examining the residuum of the decomposition of ammonia by means of sulphuric acid.

1107 Preparation. 2. This salt may be formed by saturating the acid with the alkali, and afterwards crystallizing it.

1108 Properties. 3. The crystals of sulphate of ammonia are six-sided prisms with unequal sides, terminated by six-sided pyramids. The sulphate of ammonia undergoes little change in the air. It slowly attracts moisture in a humid atmosphere. It is soluble in two parts of cold water, and in a similar quantity of boiling water.

1109 Action of heat. 4. When exposed to heat, it melts; and if the heat be continued, it loses a part of its base, and is converted into the acidulous sulphate of ammonia. This differs from the sulphate by its sharp taste, and its property of reddening vegetable blues, greater solubility, and a different action on several compounds.

5. This salt is not decomposed like the other sulphates, on account of its greater volatility. The component parts of this salt, according to Mr Kirwan, are,

Acid	54.66
Ammonia	14.24
Water	31.10
	100.00

2. Sulphite of Ammonia.

1110 Preparation. 1. The compound of sulphurous acid with ammonia is prepared by passing a stream of sulphurous acid gas into a vessel with liquid ammonia. The gaseous acid is readily absorbed, much heat is produced, and the sulphite of ammonia crystallizes on the cooling of the saturated solution.

1111 Properties. 2. This salt is in the form of six-sided prisms terminating in six-sided pyramids, or in that of four-sided rhomboidal prisms, with three-sided summits. The taste is at first cool and pungent, and afterwards sulphurous. It is deliquescent in the air, from which it absorbs oxygen, and is converted into the sulphate. It is soluble in its own weight of cold water. The solution produces a great degree of cold. Boiling water dissolves still more. Water saturated with sulphite of ammonia, and agitated in the open air, presents this salt in a few hours converted into the sulphate, without any crust on the surface, or muddiness in the liquid, because it is very soluble in water.

3. It decrepitates slightly on red-hot coals; when it is gradually heated in a close vessel, it gives out at first water and ammonia, and then sublimes totally in the state of acidulous sulphite.

4. The constituent parts of this salt are,

111[2] Composition.

Sulphurous acid	60
Ammonia	29
Water	11
	100

3. Nitrate of Ammonia.

1. This compound of nitric acid and ammonia was formerly called *nitrous sal ammoniac*, *inflammable nitre*. This salt has been particularly examined by Berthollet, and more lately by Sir H. Davy. 1113 History.

2. Nitrate of ammonia is prepared by directly combining the acid and the alkali, and it may be obtained in crystals by careful evaporation and slow cooling. 1114 Preparation.

3. This salt crystallizes in six-sided prisms, terminating in long six-sided pyramids; but the appearance of the crystals varies with the temperature in which the evaporation goes on. Sometimes they are in long silky threads, soft and elastic; the taste is very acrid, bitter, and penetrating; and the specific gravity is 1.5785. 1115 Propert.

4. When the nitrate of ammonia is exposed to the air, it attracts moisture, and deliquesces. It is soluble in two parts of cold water. Boiling water dissolves double of its own weight. 1116 Action water.

5. Nitrate of ammonia very readily undergoes the watery fusion. If the heat be continued, it is entirely deprived of its water of crystallization; and when the temperature is increased, it explodes spontaneously, giving out at the same time a white brilliant flame, with considerable noise; it is then entirely dissipated into vapour. This detonation instantaneously takes place, when the nitrate of ammonia is thrown on a red-hot iron. It was from this property that the salt derived its name of *inflammable nitre*. The nature of this rapid combustion will be understood by considering the component parts of the salt. The hydrogen of the ammonia enters into combination with the oxygen of the acid; water is formed, and azotic gas is disengaged from each of the component parts of the salt. In the different states of crystallization, this salt requires different temperatures for its fusion and decomposition. The following are the conclusions from Sir H. Davy's experiments. 1117 Of heat

" *a.* Compact or dry nitrate of ammonia undergoes little or no change at temperatures below 260°.

" *b.* At temperatures between 275° and 300°, it slowly sublimes without decomposition, or without becoming fluid.

" *c.* At 320° it becomes fluid, decomposes, and still slowly sublimes; it neither assuming nor continuing in the fluid state, without decomposition.

" *d.* At temperatures between 340° and 480°, it decomposes rapidly.

" *e.* The prismatic and fibrous nitrates of ammonia become fluid at temperatures below 300°, and undergo ebullition at temperatures between 360° and 400°, without decomposition.

" *f.* They are capable of being heated to 430° without decomposition or sublimation, till a certain quantity of their water is evaporated.

" *g.* At temperatures above 450°, they undergo decomposition, monia, &c. composition, without previously losing their water of crystallization *."

119 7. This salt has been applied to no use but for the purposes of chemical experiment, and especially for the preparation of the nitrous oxide or gaseous oxide of azote, which has been already described in treating of the compounds of azote.

4. Nitrate of Ammonia.

If this salt be formed by depriving the nitrate of ammonia of part of its acid, it must be extremely difficult, Fourcroy observes, to obtain it in this way, before the salt is totally decomposed ‡.

urcroy, aiss. t. iii. o.

5. Muriate of Ammonia.

120 ory. 1. The compound of muriatic acid and ammonia has been known, from time immemorial, by the name of *sal ammoniac*. It derives this name from Ammonia, a country of Libya, which name is descriptive of the sandy soil of that region (A). Hence too is the origin of the epithet *Ammon* given to Jupiter, to whom a temple was erected in that country. This salt was originally collected in great quantities near this temple, where it was formed in the sand, from the excrementitious matters of different animals, particularly camels. It was well known to the Greeks and Romans, and was employed by them in several arts. Before the nature of this salt was known, it was chiefly brought from Egypt; but it is now found to exist, ready formed, in different countries, particularly in the vicinity of volcanoes, where it seems to be sublimed. It is found also in the mountains of Tartary and Thibet, in grottoes in the neighbourhood of Puzzuoli, and dissolved in the waters of some lakes in Tuscany. The nature of the muriate of ammonia was first discovered by Geoffroy; it was afterwards more accurately examined by Duhamel; and, at last, its properties were fully developed by Black, Bergman, and Scheele, Berthollet and Fourcroy.

21 ca- 2. The muriate of ammonia, which is found ready prepared in nature, is extremely impure. It must therefore be subjected to several processes, to separate the foreign matters with which it is impregnated. The salt which is found sublimed in the crater of volcanoes, is generally mixed with arsenic and sulphur. In Egypt it is prepared by collecting together the excrements of animals which feed on saline plants. These substances are dried and burnt in furnaces which are constructed on purpose, or used as the common materials of fuel. The soot which is thus formed, is collected, and put into large glass bottles, and exposed to a strong heat, which is gradually increased for 72 hours. Towards the second day the salt is sublimed, and attaches itself to the upper part of the bottles. When the apparatus has cooled, the bottles are broken, and the salt in form of a cake is taken out, which amounts to little less than one-third of the soot which was employed. This manufacture is carried on at Grand Cairo; and the French consul then resident there, communicated an account of it to the Academy of Sciences, in the year 1719. But it was not till 40 years after this period that it was manufactured in Europe. The first manufactory was established in Germany in 1759; others afterwards commenced in France, and in different parts of Britain.

In the European manufactories it is prepared by different processes. Sometimes the calcareous muriate is precipitated by a carbonate of ammonia extracted from animal matters. After the lime is deposited, the liquor is evaporated, and the muriate of ammonia is sublimed. Sometimes too it is prepared by forming a sulphate of ammonia; and by mixing the salt with a muriate of soda, and exposing the mixture to heat, a double decomposition is effected, and the muriate of ammonia is sublimed. It is also prepared by the direct combination of muriatic acid and ammonia.

3. Prepared in this way by sublimation, it is in the form of a solid mass, which has some degree of elasticity. 1122 Properties. It yields to the pressure of the finger, may be compressed into smaller bulk, and is with difficulty reduced to powder. The specific gravity is 1.42. The taste is pungent, acrid, and cooling. By solution in water and slow evaporation, it crystallizes in the form of long four-sided pyramids. The primitive form of the crystal is the regular octahedron; and that of the integrant particle, the regular tetrahedron. Sometimes it crystallizes in cubes, and sometimes the prisms are very small, and grouped together, exhibiting a feathery appearance.

4. The muriate of ammonia is not altered by exposure to the air. 1123 Action of water. It is soluble in three or four times its weight of cold water. Great cold is produced during the solution; and on this account it is employed with snow and ice in the production of artificial cold. Boiling water dissolves nearly its own weight of this salt.

5. The muriate of ammonia is fusible and volatile. 1124 Of heat. When it is thrown on red-heat coals, it is entirely dissipated in white vapour. Exposed to a high temperature, it is decomposed.

6. This salt is readily decomposed by the sulphuric 1125 Of acids. acid, which disengages the muriatic acid with violent effervescence. It is also decomposed by the nitric acid, which oxygenates the muriatic acid. In this way a nitro-muriatic

(A) From the Greek word αμμος, which signifies *sand*.

Ammonia, &c. nitro-muriatic acid is prepared, which is employed for the solution of gold. Barytes, potash, soda, and lime, decompose the muriate of ammonia, and disengage the ammonia in the state of gas, merely by trituration; but if heat be applied, the decomposition is more rapid and complete.

1126 Composition. 7. According to the analysis of Mr Kirwan, the component parts of the muriate of ammonia are,

Acid,	42.75
Ammonia,	25.00
Water,	32.25
	100.00 *

* Nichol. Journ. iii. 216.

1127 Uses. 8. No salt is more generally employed than muriate of ammonia. In chemistry it is used for the extraction of ammonia, and the carbonate of ammonia; for the production of cold, and as an instrument of analysis. It is also employed in medicine; in the art of dyeing, for the preparation of colours; in metallurgy, for the indication and separation of some metallic substances, and in the arts, for covering the surface of copper and other vessels, to prevent oxydation in the process of tinning; and for the same purpose in soldering.

6. Hyperoxymuriate, or Chlorate of Ammonia.

1128 Preparation. The compound of hyperoxymuriatic acid and ammonia is formed by pouring carbonate of ammonia into a solution of any of the earthy hyperoxymuriates. A double decomposition takes place, and a hyperoxymuriate of ammonia is formed.

1129 Properties. This salt is very soluble in water and in alcohol. It is decomposed at a low temperature, and gives out a quantity of gas together with a smell of hyperoxymuriatic acid. Such a smell, Mr Chenevix observes, is doubtless owing to the great quantity of oxygen contained in the acid, which is more than what is necessary to combine with the hydrogen contained in the alkali. Some part, therefore, is disengaged without decomposition. Mr Chenevix who formed this salt, could not succeed in ascertaining the proportion of its constituent parts †.

† Phil. Trans. 1802, p. 148.

7. Fluate of Ammonia.

1130 Preparation and properties. 1. This compound of fluoric acid and ammonia is prepared by saturating the acid with the alkali. By evaporation it crystallizes in small needles or prisms, which have a pungent taste analogous to that of sulphate of ammonia.

2. When it is heated, this salt gives out ammonia, and is sublimed in the state of an acidulous fluate. This salt decomposes the nitrate and muriate of lime, and the sulphate of magnesia.

8. Borate of Ammonia.

The compound of boracic acid and ammonia is little known. It is formed by the direct union of the acid with the alkali. It has so little permanency, that the solution being evaporated, the whole of the ammonia is volatilized, while the boracic acid crystallizes. The base of every other salt decomposes it *.

* Fourcroy Connaiss. Chim. iii. p. 336.

9. Phosphate of Ammonia.

1. This salt, the compound of phosphoric acid and ammonia, was long confounded with the phosphate of soda, as it exists with it in urine, under the names of *fusible salt*, *native salt of urine*, *microcosmic salt*. It was first accurately distinguished by Schlosser, De Chaulnes, and Rouelle, about the year 1770; soon after by Lavoisier, and more lately by Vauquelin. 1131 Names and history.

2. At first it was extracted from the salt of urine; and many processes were adopted to obtain it pure, and separate from the muriate and phosphate of soda, with which it is always accompanied. It is now prepared artificially by directly combining phosphoric acid with ammonia; and by slow evaporation of the solution to a certain consistence crystals are obtained on cooling. 1132 Preparation.

3. The phosphate of ammonia crystallizes in regular four-sided prisms, terminated by four equal-sided pyramids, and sometimes in the form of small needles closely interwoven with each other. It has a cooling, saline, pungent taste, and changes the syrup of violets to a green colour. Its specific gravity is 1.8051. 1133 Properties.

4. In a moist air, it is slightly deliquescent, but otherwise it is unchanged. It is soluble in four parts of cold water, and still more so in boiling water. 1134 Action of water.

5. Exposed to heat, it undergoes the watery fusion, swells up, and melts into a transparent glass, which is acid, part of the base being driven off. Hence it derived the name of *fusible salt*. 1135 Of heat.

6. It is readily decomposed by charcoal, by the sulphuric, nitric, and muriatic acids, and by the two fixed alkalies. 1136 Acids.

7. The phosphate of ammonia is employed as a flux in essaying mineral substances with the blow-pipe. It is greatly used also in the fabrication of coloured glasses and artificial precious stones. 1137 Uses.

10. Phosphite of Ammonia.

1. This is a compound of phosphorous acid and ammonia. It is prepared by the direct combination of the acid with ammonia or the carbonate of ammonia, and by slow evaporation it may be obtained in crystals. 1138 Preparation.

2. It sometimes crystallizes in long transparent needles, and sometimes in four-sided prisms, terminated by four-sided pyramids. It has a strong pungent taste. 1139 Properties.

3. This salt is slightly deliquescent in the air, is soluble in twice its weight of cold water, and being more soluble in boiling water, it crystallizes on cooling. 1140 Action of water.

4. When it is heated on charcoal with the blow-pipe, it boils up, and loses its water of crystallization. When this has escaped, it is surrounded with a fine phosphoric light; and as the salt begins to vitrify, there are evolved bubbles of gas, which burn as they come in contact with the air, with a vivid flame, and form with the atmosphere a ring of white vapour of phosphoric acid. What remains is phosphoric acid in the vitreous state. The same effect may be produced by heating six or seven grains of the salt in a small glass globe to which a tube is adapted, and immersed under jars over mercury. The salt melts, swells, and gives out bubbles of phosphorated hydrogen gas, which spontaneously inflame as they come in contact with the air, and exhibit the white coronet of vapour which is the characteristic property of the combustion of this gas. During this decomposition, the base of the salt, the ammonia, is also volatilized, and pure phosphoric acid 1141 Of heat.

monia, &c. acid remains behind. This salt is decomposed by charcoal, the acids, and by potash and soda.

142 posi- 5. The constituent parts of this salt are the following,

Phosphorous acid,	26
Ammonia,	51
Water,	23
	100

6. It has not hitherto been applied to any use,

11. Carbonate of Ammonia.

143 ies. 1. The compound of carbonic acid with ammonia has been distinguished by different names, as *concrete volatile alkali*, *aërated volatile alkali*, and *cretaceous sal ammoniac*. Its peculiar nature and properties were not clearly understood, till, by the discovery of Dr Black, it was demonstrated to be a compound salt. This salt is obtained by a great many different processes. Formerly it was procured by distilling animal matters, and particularly horns, as the horns of the hart, whence it derived the name of volatile salt of hartshorn.

144 ara- 2. Carbonate of ammonia may be prepared by directly combining carbonic acid and ammonia in the state of gas over mercury; or it may be obtained by mixing together two parts of chalk, and one part of muriate of ammonia, well dried and reduced to powder, and exposing them to heat in a porcelain retort. The gas, as it comes over, is collected in a receiver, which is to be cooled with cloths moistened with water. This is the carbonate of ammonia, which is sublimed and attaches itself to the sides of the receiver. In this process there is a double decomposition. The carbonic acid of the lime combines with the ammonia, and forms carbonate of ammonia, which is driven off by heat; and the muriatic acid of the muriate of ammonia combines with the lime and forms muriate of lime, which remains in the retort.

145 erties. 3. The carbonate of ammonia is crystallized; but the crystals are so irregular, that their form has not been accurately ascertained. Bergman describes them as octahedrons, whose four angles are truncated; while according to Romè de Lisle, they are compressed four-sided prisms, terminated by a two-sided summit. The taste of this salt is slightly acrid, and the smell is perceptibly that of ammonia, though more feeble. It converts vegetable blues to green. Its specific gravity is 0.966.

146 on of r. 4. When this salt is pure, it is not sensibly changed by exposure to the air. It is very soluble in water, and, during its solution, produces cold. Two parts of cold water dissolve more than one of the salt. Water, at the temperature of about 120°, dissolves more than its own weight, &c. When it is rapidly cooled, the salt crystallizes in the most regular form which it assumes. Boiling water cannot be employed for its solution, because at this temperature the salt is driven

147 eat. off in the state of vapour. When this salt is thrown upon hot iron, it melts, boils, and is converted into vapour.

148 cids. 5. It is decomposed by all the acids with effervescence; and the effervescence with this salt is more violent than with the carbonate of the two fixed alkalies, because the proportion of carbonic acid is greater. Ammonia, &c

6. The constituent parts of this salt, according to Bergman, are, 1149 Composition.

Carbonic acid,	45
Ammonia,	43
Water,	12
	100

But Mr Davy has found, that the proportion of acid and water in this salt depends on the temperature at which it is formed. It is greater when the temperature is low, and diminishes as the temperature is increased.

7. This salt is employed in medicine, and also in the manufacture of muriate of ammonia, for which purpose it is produced by distillation from animal matters. The use of it, when it is mixed with volatile oils, as a perfume, or as a stimulant in smelling bottles, is well known. 1150 Uses.

12. Arseniate of Ammonia.

1. This salt, the compound of arsenic acid and ammonia, is formed by combining the acid with the alkali. When the solution is evaporated, it affords crystals of arseniate of ammonia. 1151 Preparation.

2. It crystallizes in the form of rhomboidal prisms; or, with an excess of acid, in the form of needles. The crystals of the first convert the syrup of violets into green, and those of the second are deliquescent in the air. 1152 Properties.

3. When this salt is gently heated, the ammonia is disengaged, and the arsenic acid remains behind; but when the heat is violent and sudden, part of the alkali and of the acid are decomposed, water is formed, azotic gas is disengaged, and the arsenic is sublimed in the metallic state. 1153 Action of heat.

13. Arsenite of Ammonia.

This is a compound of the white oxide of arsenic, or arsenious acid, with ammonia; but nothing is known of its properties.

14. Tungstate of Ammonia.

1. This compound of tungstic acid and ammonia is formed by dissolving the oxide of tungsten in the solution of ammonia or carbonate of ammonia; and by evaporating the solution, the salt is obtained in the form of crystals. 1154 Preparation.

2. It crystallizes in small scales, which have some resemblance to boracic acid; or in small needles, which are four-sided. This salt has a metallic taste. It is not deliquescent in the air, but is soluble in water. When it is exposed to heat, it is decomposed. 1155 Properties.

3. The component parts of this salt are,

Tungstic acid,	78
Ammonia and water,	22
	100

15. Molybdate of Ammonia.

16. Chromate of Ammonia.

 17. Acetate

Ammonia, &c.

17. Acetate of Ammonia.

1156 Preparation. 1. This compound of acetic acid and ammonia has been long known by the name of *spiritus mindereri.* In this state it is combined with an excess of acid. It may be obtained, but with some difficulty, on account of its volatility, by slow evaporation. It then crystallizes in the form of needles. Crystals are also obtained by very slow sublimation of this salt.

1157 Properties. 2. The crystals of acetate of ammonia are long, slender, flat, and pointed, of a pearly white colour *. The taste is cooling, with a mixture of sweet. Exposed to air, it is deliquescent, and is very soluble in water. When it is heated to the temperature of 170°, it melts; and when the temperature is raised to 25°, it is sublimed. By distillation of the salt in solution, with a strong heat, it is partly decomposed. The ammonia is first driven off, then the acid, and, towards the end of the process, part of the neutral salt.

* *Higgins's Experiments*, p. 188.

18. Oxalate of Ammonia.

1158 Preparation. 1. The compound of oxalic acid and ammonia may be prepared by directly combining the acid with the alkali. By evaporating the solution, the salt crystallizes.

2. When the acid is saturated with the alkali, the crystals are in the form of four-sided prisms, terminated by two-sided summits; one of which is larger, and includes three sides of the prism. These salts are soluble in water.

1159 Action of heat. 3. When this salt is exposed to heat, carbonate of ammonia is driven off, and nothing remains behind but a little charcoal. From this it appears, that the acid is decomposed, the carbon and oxygen combining together to form carbonic acid, which enters into combination with ammonia. It is decomposed by the mineral acids. The oxalic acid combines with it, and forms an acidulous oxalate of ammonia. The oxalates of potash and soda form compounds with this salt, which are known by the name of *triple salts.*

1160 Uses. 4. This is one of the most useful salts to be employed as a reagent in detecting lime in liquid solutions, and for ascertaining the nature and proportions of calcareous salts.

19. Tartrate of Ammonia.

The compound of tartaric acid and ammonia forms a salt which very readily crystallizes. This salt has a cooling bitter taste, is very soluble in water, and easily decomposed by heat. It is subject also to spontaneous decomposition. By the action of the stronger acids, part of the base is separated, and it is converted into an acidulous tartrate of ammonia.

20. Citrate of Ammonia.

1. This salt, which is a compound of citric acid and ammonia, is formed by the direct combination of the acid and alkali, and it crystallizes when the solution is evaporated to the consistence of a thick syrup.

2. The crystals are in the form of an elongated prism. They are very soluble in water, and have a saline cooling taste. This salt is decomposed by heat, the ammonia being driven off.

3. It is composed of

Acid	62
Ammonia	38
	100

21. Malate of Ammonia.

This salt, which is a compound of malic acid and ammonia, is a very soluble and deliquescent salt. Its other properties are unknown.

22. Benzoate of Ammonia.

The compound of benzoic acid and ammonia forms a very soluble salt, which readily crystallizes, and the crystals arrange themselves in an arborescent or plumose form. This salt is volatile, and is decomposed by all other acids *.

* *Fourcr. Connaiss. Chim.* vii 193.

23. Succinate of Ammonia.

The compound of succinic acid and ammonia forms a salt, which affords needle-shaped crystals that are deliquescent, and are sublimed by heat, without being decomposed.

24. Saccolate of Ammonia.

Nothing farther is known of this salt, than that it has an acid taste, and is readily decomposed by heat.

25. Camphorate of Ammonia.

1. This salt, which is a compound of camphoric acid and ammonia, is prepared by adding the acid to a solution of carbonate of ammonia, and hot water, till effervescence ceases. The evaporation must be conducted with a very gentle heat, on account of the volatility of the ammonia. 1161 Preparation.

2. It is difficult to obtain this salt crystallized. When the solution is too much evaporated, it affords a crystalline mass, in which appear small needles; but if it be evaporated to dryness there remains a solid opaque mass, which has a slightly bitter and pungent taste. 1162 Properti[es].

3. This salt is slightly deliquescent in the air; it is not very soluble in cold water, but may be dissolved in three parts of boiling water. In these salts, it would appear that the acid resists the action of the water; for when there is an excess of base, they become more soluble.

4. Exposed to heat on red-hot coals, it swells and melts, and then rises in vapour. With the blow-pipe, it gives a blue and red flame, and is entirely dissipated. 1163 Action of heat.

5. This salt is decomposed by the sulphuric, nitric, and muriatic acids, and if the solution be sufficiently concentrated, the camphoric acid is deposited. It is also decomposed by potash and soda, and more rapidly with the assistance of heat. This salt is completely soluble in alcohol †. 1164 Of acid[s].

† *Ann. Chim.* x. p. 31.

26. Suberate of Ammonia.

This compound of suberic acid with ammonia affords crystals in the form of parallelopipeds. It has a slight saltish taste, leaving an impression of bitterness. It reddens vegetable blues, and is deliquescent in the air. It is very soluble in water. When it is thrown on on burning coals, it swells up, and is deprived of its water of crystallization. It is entirely dissipated by the action of the blow-pipe. It is decomposed by the sulphuric, nitric, muriatic, and oxalic acids, by the fixed alkalies, and the aluminous and magnesian salts*.

* [illegible]nal. de C[illegible] tom. [illegible] p. 55.

27. Mellate of Ammonia.

This salt, which is a compound of mellitic acid and ammonia, is formed by saturating the acid with the alkali. By evaporation it affords transparent, six-sided crystals. This salt, when exposed to the air, becomes opaque, and of a silvery white colour.

28. Lactate of Ammonia.

This compound of lactic acid and ammonia forms a salt which crystallizes. It is deliquescent in the air, and is decomposed by heat, great part of the ammonia being driven off.

29. Prussiate of Ammonia.

The compound of prussic acid and ammonia affords a salt which has the odour of ammonia. When this salt is exposed to heat, it is entirely dissipated.

30. Sebate of Ammonia.

31. Urate of Ammonia.

The compound of uric acid and ammonia forms a salt which is not very soluble in water, and in many of its properties resembles the acid itself.

IV. Compounds of Ammonia with Inflammable Substances.

1. Ammonia enters into combination with alcohol, with the assistance of a moderate heat; but the ammonia is separated when the mixture is exposed to a temperature below the boiling point of alcohol.

2. Ammonia readily mixes with ether; but the nature of the compound, or whether it be a chemical combination, is not known.

3. Ammonia forms a compound with the fixed oils, which is well known under the name of *soap* or *liniment*.

4. With the volatile oils it forms compounds, which have somewhat similar properties.

Chap. XIII. Of EARTHS.

1. The word *earth* is taken in different significations. Sometimes it signifies the globe, and sometimes it is used to denote the soil on the surface of the globe. In chemistry it is employed to signify certain elementary substances, of which a great proportion of the solid parts of the globe is composed; and these substances are found to possess many peculiar, and some common properties.

[illegible]65 Pr[illegible]rties. 2. The general properties of the earths are the following.

a. They have neither taste nor smell.

b. They are incombustible.

c. They are nearly soluble in water.

d. They have a specific gravity which is under 5.

[illegible]66 En[illegible]eration. The number of the earths which are at present known, is ten, and we shall treat of them in the following order.

1. Lime,
2. Barytes,
3. Strontites,
4. Magnesia,
5. Alumina,
6. Silica,
7. Yttria,
8. Glucina,
9. Zirconia.
10. Thorina.

Sect. I. *Of Lime.*

1. Lime has been known from the remotest antiquity. The great abundance in which it is found in nature, and the important uses to which it may be applied, led men to employ it for many purposes from the earliest ages of the world. It was well known to the ancients as mortar, and as a manure, and they were not unacquainted with some of its medicinal virtues. But it was long before the nature and properties of lime were fully known; and particularly those changes which quicklime undergoes when it is exposed to the air, or limestone to the action of heat. It was not till Dr Black made his brilliant discoveries, that the nature of these changes was fully developed, and the fanciful theories which had been proposed to account for them were entirely rejected. 1167 Early known.

2. Lime is seldom found perfectly pure in nature; but it is universally diffused, and exists in some places in the greatest abundance, in combination with other substances, and particularly with carbonic acid. To obtain it pure, a quantity of chalk, or marble, or limestone, is exposed to a strong heat, by which means the carbonic acid with which it is in combination, is driven off. When the limestone, or marble, or chalk, which has been employed, is sufficiently burnt or calcined, and removed from the fire, and water poured upon it, it swells up, and at last falls down into a powder. This powder is called *quicklime*. In this process of slaking lime, as it is called, a great quantity of water is quickly absorbed, and the water being fixed in the lime in the solid state, gives out that caloric which is necessary to retain it in the state of liquidity, so that a great quantity of heat is evolved. Part of the water, also, rises in vapour in consequence of the great heat, before it is consolidated with the lime. The heat produced is so great, that water may be boiled, and combustible bodies may be inflamed. Accidents have happened to carriages and vessels loaded with lime, to which water had been admitted. So much heat was produced, that they have been set fire to, and burnt. Light is also emitted when lime is slaked. This, it is said, is seen when the process is conducted in a dark place, and the quantity of lime is considerable. 1168 Preparation of pure lime. 1169 Slaking.

3. The purity of lime, thus obtained, is in proportion to the purity of the substance which was calcined. The lime which is obtained by burning pure white marble, or what is called *calcareous spar*, is tolerably

Lime, &c. lerably pure. But there are other processes by which those substances with which it may happen to be mixed may be separated. If a quantity of chalk be washed in pure water, dissolved in distilled acetic acid, and afterwards precipitated by carbonate of ammonia, the precipitate being washed and calcined, pure lime is the product. The lime which is obtained from oyster-shells, may be rendered pure by the following process. First wash the shells in different quantities of water, and boil them, to separate any mucilaginous substance. Introduce them into a furnace, and calcine them to whiteness. After the first calcination, put them into a porcelain retort, and expose it to a red heat. By this process pure lime is obtained. To preserve it in this state of purity, it must be kept in close vessels.

1170 Properties and composition.

4. Pure lime is of a white colour, has a hot, sharp, caustic taste, and destroys the texture of animal substances, to which it is for some time applied. It converts the syrup of violets and other vegetable blues to a green colour. The specific gravity of lime is 2.3. This earth may be decomposed by the galvanic battery, in contact with mercury, a substance, the affinities of which materially promote the object. The metallic base or calcium forms an amalgam with the mercury, which may be afterwards expelled by heat, and the calcium is obtained pure. It is a white metal, and when gently heated, burns and resumes the state of lime.

1171 Action of water.

5. After the lime has been prepared and slaked; if more water be added to dilute it, and reduce it to the consistence of thick cream, this is what was formerly called *milk* or *cream of lime*. But if a greater quantity of water be added, and the solution be filtered, a transparent liquid is thus obtained, which is known by the name of lime-water. Four hundred and fifty parts of water are required, it is said, to dissolve one of lime. This water is clear and limpid, has a sharp acrid taste, and renders the syrup of violets green. When this water is evaporated, and the whole driven off, the lime remains pure. If the solution of lime-water be exposed to the air, the surface is soon covered with a pellicle, which gradually acquires solidity and thickness. The pellicle is owing to the attraction of the lime for the carbonic acid of the atmosphere, forming a carbonate of lime, which being insoluble in water, is precipitated.

1172 Crystallizes.

6. Lime, according to Trommsdorf, crystallizes. This was first discovered by Scheele. The method by which Mr Trommsdorf obtained the crystals lime is the following. Boil any quantity at pleasure of muriate of lime, with one-fourth or less of caustic lime, and evaporate the solution till a drop of it let fall on a cold stone assume the consistence of a syrup. It is then to be filtered, and put into a close vessel, that the solution may cool as slowly as possible. Crystals of lime are thus obtained, which must be washed in alcohol, to separate any part of the muriate of lime which may adhere. For the complete success of this experiment, some pounds of the muriate of lime must be employed *.

* *Phil. Mag.* xii. 53.

1173 Action of heat.

7. Lime undergoes no change by the action of light, and it remains unaltered when it is exposed to the greatest heat.

8. Lime is one of the most important of the earthy bodies. It is applied to a great many valuable purposes, and fortunately it can be obtained in the greatest abundance. It is employed in medicine, both as an internal remedy, and an external application. As a manure, it is of the most extensive utility; nor is it of less importance, as it is employed for a cement in building. When quicklime is mixed with sand and water, and reduced to the form of a thick paste, it is in the state of mortar. It is an object of the utmost importance that the mortar which is employed as a cement in building, should be durable. To obtain this object, a good deal of attention has been paid by different philosophers in ascertaining the proportions which seem to answer best, or the additions which may be made to the usual materials in the formation of good and durable mortar. The proportions which have been proposed by Dr Higgins are, 1174 Mortar.

Coarse sand,	4 parts,
Fine sand,	3
Quicklime,	1

The lime should be recently slaked, and the quantity of water should be just sufficient to bring it to a proper consistency.

Dr Higgins found that burnt bones, if they did not exceed one-fourth of the lime, added to the mortar, improved its tenacity, and prevented it from cracking in drying.

It has been proposed to add a certain proportion of unslaked lime to the mortar, with the view of giving it greater solidity. Mortar acquires its hardness from the lime absorbing carbonic acid, and returning to the state of lime-stone, and also from the combination of part of the water with the lime. According to Guyton's experiments, the following proportions compose a good, durable mortar,

Fine sand,	3 parts
Cement of well-baked bricks,	3
Slaked lime,	2
Unslaked,	2

It is sometimes necessary to use mortar as a cement under water, but common mortar is unfit for this purpose. It has been found by experiment, that manganese added to mortar gives it the property of consolidating under water. To prepare a mortar for this purpose, Guyton recommends the following process. Mix together 90 parts of limestone, six parts of black oxide of manganese, and four parts of blue clay in the state of powder. Let the mixture be calcined, to drive off the carbonic acid; then add 60 parts of sand, and mix it together with a sufficient quantity of water, to bring it to the consistency of mortar.

9. The order of the affinities of lime is the following: 117[illegible] Affiniti[es]

Oxalic acid,
Sulphuric,
Tartaric,
Succinic,
Phosphoric,
Saclactic,
Nitric,
Muriatic,
Suberic,

Fluoric,

Fluoric,
Arsenic,
Lactic,
Citric,
Benzoic,
Sulphurous,
Acetic,
Boracic,
Carbonic,
Prussic.

I. Phosphuret of Lime.

76 Pr ra- tio 1. Lime combines with phosphorus, and forms a compound which is called *phosphuret of lime*. To prepare this compound, introduce into the bottom of a glass tube, closed at one end, one part of phosphorus, and afterwards place a little above it four or five times its weight of quicklime in powder. Expose to a heat that part of the tube which contains the lime, so that it may become red hot. In this state raise the tube and draw it along the coals, till that part of it containing the phosphorus be also exposed to the heat. The phosphorus is raised in the state of vapour through the lime, and combines with it, so that the whole mass forms a compound of a brown colour. This is the phosphuret of lime.

77 Pr ties. 2. It has a deep brown colour, no smell, and when it is exposed to the air it falls to pieces. It is insoluble in water, but it decomposes that liquid at the moment it comes in contact with it. An effervescence takes place, and phosphorated hydrogen gas is emitted, which is spontaneously inflamed when it comes to the surface of the water. It is owing to this gas that phosphuret of lime, when it is moistened, gives out the fetid smell of garlic; and as this gas is formed by the decomposition of the water, part of it combines with the phosphuret of lime, and forms a hydrogenated phosphuret, so that the phosphuret when it is taken from the water and dried, gives out flame, when concentrated muriatic acid, which disengages the phosphorated hydrogen gas, is poured upon it.

II. Sulphuret of Lime.

8 Pre a- tion 1. This compound of sulphur and lime may be formed by exposing to heat in a crucible, sulphur and lime reduced to powder. They fuse slightly, or rather combine into an acrid, reddish mass, which is the sulphuret of lime, formerly called *calcareous liver of sulphur*.

9 Hy ate zen- il- phu 2. When it attracts moisture from the air, or if a little water be thrown upon it, it changes colour, and passes to a greenish yellow, emitting at the same time an extremely fetid odour, and forming sulphurated hydrogen gas, becomes a hydrogenated sulphuret.

3. When sulphur and lime are combined together by means of water, the result is not a simple sulphuret, but always a hydrogenated sulphuret, on account of the water which is decomposed. This may be prepared, either by throwing water on quicklime, covered with sulphur in powder; the heat which is emitted by the slaking of the lime effecting the combination: or it may be prepared by heating in a matrass, sulphur and lime in powder with ten times their weight of water, or by heating lime water on sulphur. By the two first processes, a liquid is obtained of a red, orange, or yellow colour, of an extremely fetid odour, and a pungent acrid taste. This hydrogenated sulphuret of lime exposed to the air, is deprived of its colour, gradually decomposed, and the sulphur combining with the oxygen of the air, is first converted into sulphurous, and afterwards into sulphuric acid. It is decomposed by the acids, sulphur is precipitated, and sulphurated hydrogen gas is disengaged.

1180 Hydrosulphuret.

4. Lime combines readily with sulphurated hydrogen. When sulphurated hydrogen gas is passed into a bottle of lime-water, the gas is absorbed and fixed by combining with the lime, it renders it more soluble, and forms the hydrosulphuret of lime. This hydrosulphuret, as Berthollet observes, performs the part of an acid, by saturating the lime, and gives it the property of crystallizing. This hydrosulphuret has no colour, and, exposed to the air, emits a strong fetid odour. It is extremely soluble in water, and is decomposed by the acids with effervescence, while sulphurated hydrogen gas is given out. Thus, lime enters into three different combinations with sulphur, namely, into the sulphuret of lime, the hydrosulphuret, and the hydrogenated sulphuret.

III. Compounds of Lime with acids.

1. Sulphate of Lime.

1. The compound of sulphuric acid and lime has been known under a great variety of names, as *selenite*, *gypsum*, *plaster of Paris*, *alabaster*, *vitriol of lime*. The sulphate of lime is found in great abundance in nature; and it is found sufficiently pure, so that artificial preparation is not required. 1181 Names. 1182 Found native.

2. When sulphate of lime is pure, it is frequently found crystallized. The primitive form of its crystals is a quadrangular prism, whose bases are rhomboidal, and the angles 113° and 67°. The integrant particle has the same form. The specific gravity is from 2.1679 to 2.3114. It is not changed by exposure to the air. It is little soluble in water. Five hundred parts of cold water, and 450 of boiling water, are required to dissolve it. When it is exposed to heat, it loses its water of crystallization, decrepitates, becomes very friable, and falls down into a very white opaque powder. When this powder is reduced to a paste with water, it absorbs it very rapidly, and becomes in a very short time solid. From this peculiar property, it is employed for forming *casts*, under the name of plaster of Paris. When it is strongly heated for a long time, it becomes phosphorescent, and then melts; and before the blow-pipe it gives an opaque, vitreous globule. 1183 Properties. 2184 Action of heat.

3. This salt becomes more soluble by the action of sulphuric acid, without being converted into an acidulous sulphate of lime. The nitric and muriatic acids increase its solubility without decomposing it. It is partly decomposed by the phosphoric acid in the cold. 1185 Of acids.

4. The component parts of sulphate of lime, according to Bergman, are, 1186 Composition.

Acid	46
Lime	32
Water	22
	100

After

After being dried in different temperatures, according to Mr Kirwan, the component parts are,

	Dried in 270°	In a red heat.	In a white heat.
Acid	50.39	55.84	56
Lime	35.23	38.81	41
Water	14.38	5.35	00
	100.00	100.00	100

Anhydrous Sulphate of Lime.

This is a variety of the sulphate of lime found native in different places, which, as the name imports, contains no water of crystallization. It is found crystallized. The primitive form of the crystal is a rectangular prism, having two of its bases broader than the other two. The specific gravity is 2.950. It has a pearly lustre, considerable hardness, phosphoresces when it is heated, is transparent, and insoluble in water. The component parts are, according to the analysis of Mr Chenevix,

Acid	44.88
Lime	55.12
	100.00

2. Sulphate of Lime.

1187 Preparation.

1. This salt may be prepared by passing a current of sulphurous acid gas into a bottle of distilled water, in which is suspended pure carbonate of lime in powder. A brisk effervescence takes place; the sulphite, as it forms, falls to the bottom in the state of powder; and if the gas be continued to be added after the effervescence has ceased, the sulphite of lime in the state of powder is completely re-dissolved; the liquid becomes warm; and as it cools, it affords crystals.

1188 Properties.

2. This salt is either in the state of white powder, or in the form of six-sided prisms, terminated by long, six-sided pyramids. At first it has no taste, but when it is kept in the mouth for some time, it becomes sulphureous. It effloresces slowly when exposed to the air, and is converted into sulphate of lime on the surface. It is less soluble in water than the sulphate of lime, requiring 800 parts of water to dissolve it.

1189 Action of heat.

3. When it is exposed to heat, it is deprived of some water, becomes white, and is reduced to powder. A strong heat separates some sulphur, and it is then converted into sulphate of lime.

1190 Composition.

4. The component parts of this salt are,

Sulphurous acid	48
Lime	47
Water	5
	100

3. Nitrate of Lime.

1191 History.

1. This salt, which is the compound of nitric acid and lime, has been long known under the names of *calcareous nitre*, *mother water of nitre*, Baldwin's phosphorus. It always accompanies nitre, and as one of its names imports, remains in the solution from which nitre has been obtained.

1192 Preparation.

2. This salt may be prepared by dissolving carbonate of lime in nitric acid, evaporating to the consistence of syrup, and allowing the solution to cool slowly. It is thus obtained in the state of crystals.

119[illegible] Propert[illegible]

3. The crystals of nitrate of lime are in the form of six-sided prisms, terminated by long pyramids. Sometimes they are in the form of long striated needles, grouped together, of a silvery whiteness. The taste is acrid, hot, and bitter. The specific gravity is 1.6207.

119[illegible] Action [of] water.

4. This is one of the most deliquescent salts. Exposed to the air for a few hours, it is totally melted. It is sometimes employed in chemistry on account of this property of attracting moisture, to deprive gases of the vapour of water with which they may be combined. For this purpose, the gases are made to pass through tubes which contain dried nitrate of lime. It is owing to a mixture of this salt, that nitre is sometimes deliquescent in the air. The nitrate of lime is extremely soluble in water. One part of cold water dissolves four of this salt. Boiling water dissolves still more.

119[illegible] Of hea[t].

5. When heated, this salt is very fusible. It melts like oil, and after it becomes dry, it often acquires, during calcination, the property of becoming luminous in the dark. Hence the origin of one of its names. More strongly heated, it is decomposed; gives out red vapours of nitrous gas, oxygen and azotic gases, and there remains behind pure lime.

11[illegible] Of aci[ds].

6. This salt is decomposed by the sulphuric acid, partially by the phosphoric, and by potash and soda. By double affinity it is decomposed by the sulphates of potash, of soda, and ammonia. Sulphate of lime, which is an insoluble salt, is always precipitated.

11[illegible] Composition.

7. By the analysis of Bergman, the constituent parts of nitrate of lime are the following,

Acid,	43
Lime,	32
Water.	25
	100

By the analysis of Mr Kirwan, when it is well dried in the air,

Acid,	57.44
Lime,	32.00
Water,	10.56
	100.00

This salt has not been applied to any use. It is recommended by Fourcroy as a substitute for nitre in the extraction of nitric acid *.

4. Nitrite of Lime.

When the nitrite of lime is exposed to heat, till it give out some bubbles of oxygen gas, there remains behind a calcareous nitrite, which converts vegetable blues to green, and gives out a great quantity of red vapour by the action of acids. It seems to be in the state of nitrite of lime, that this compound possesses the phosphorescent property †.

5. Muriate of Lime.

11[illegible] Name.

1. The compound of muriatic acid and lime has been known by the names of *calcareous marine salt*, *fixed sal ammoniac*, and *Homberg's phosphorus*. This salt

* Fou[rcroy] Conn[aissances] Chim. p. 135.

† Ibid. p. 159.

salt is frequently found in solution in some mineral waters.

199 2. It is prepared by saturating muriatic acid with carbonate of lime, and evaporating the solution to the consistence of syrup. It crystallizes on cooling.

200 3. The muriate of lime crystallizes in six-sided prisms, terminated by six-sided pyramids. The taste is acrid, bitter, and disagreeable. It is extremely deliquescent in the air. Cold water dissolves nearly double its weight. In a perfectly dry state, it is chloride of calcium. See N° 956. Its specific gravity is 1.76.

201 4. Exposed to heat, it becomes soft, melts, and swells up, and then is deprived of its water of crystallization. At a very high temperature it is also deprived of part of its acid. In this state, with an excess of lime, it acquires the property of shining in the dark, from which it has been called *the phosphorus of Homberg*.

202 5. This salt is decomposed by the sulphuric acid, by the nitric acid, which converts it into the oxymuriatic, and partly by the phosphoric and fluoric acids.

203 6. According to the analysis of Bergman, the constituent parts of this salt are,

Muriatic acid,	31
Lime,	44
Water,	25
	100

But, according to Mr Kirwan, when it is dried in a red heat, it is composed of

Acid,	42
Lime,	50
Water,	8
	100

204 7. This salt is only employed for chemical experiments, and particularly for the production of artificial cold, by mixing it with snow or pounded ice. Of all the salts employed for this purpose, it seems to have the greatest effect, in consequence of the rapid transition from the solid to the liquid state. To prepare the salt for this purpose, it is most convenient to evaporate it to the consistence of a pretty thick syrup; and then by stirring it constantly as it cools, it is obtained in a dry granulated state, which should be reduced to powder in the cold, and put up in bottles secured with ground stoppers.

6. Hyperoxymuriate or Chlorate of Lime.

205 This salt, which is the compound of hyperoxymuriatic acid and lime, is prepared by putting a quantity of pure white marble, reduced to powder, into one of the bottles of Woulfe's apparatus, half filled with water, and by passing a current of oxymuriatic acid gas into the liquid, till the effervescence ceases, and the powder has nearly disappeared. It acquires a pungent styptic taste, with a reddish colour. It exhales the odour of oxymuriatic acid, and not of the hyperoxymuriatic acid. When ammonia is added to this solution, it is decomposed, and there remains ordinary muriate of lime, from which circumstance it seems doubtful whether there is at all formed a hyperoxymuriate of lime. According to Mr Chenevix this salt is extremely deliquescent, melts at a low heat, in its water of crystallization, and is very soluble in alcohol. The component parts of this salt are, 1206 Composition.

Acid,	55.2
Lime,	28.3
Water,	16.5
	100.0†

This salt has been successfully employed in the process of bleaching. 1207 Uses.

7. Fluate of Lime.

1. The compound of fluoric acid and lime has been long known under the names of *fluor spar*, *cubic spar*, and *phosphoric spar*, from the figure of its crystals, or from some of its properties. This salt exists in great abundance in nature, and in a state of considerable purity. 1208 History.

2. It may be artificially prepared, by combining fluoric acid with lime in solution in water. The salt is deposited in the form of powder in the bottom of the vessel; and when it is taken out, it is to be well washed and dried. 1209 Preparation.

3. When the fluate of lime is found native, it is generally crystallized in the form of cubes, the angles of which, and sometimes the edges, are truncated. The primitive form of the crystal is the regular octahedron. The form of its integrant particle is the regular tetrahedron. It has frequently a considerable degree of transparency, and exhibits a great variety of colours. The specific gravity is 3.15. It has no taste, is not altered by exposure to the air, and it is insoluble in water. 1210 Properties.

4. When it is exposed to heat, it decrepitates and becomes luminous in the dark; but when it has once given out this light, it cannot be restored, either by exposing it to the sun's rays, or by calcination with charcoal or any other combustible substance. From this circumstance it appears, that this phosphorescent property is owing to some volatile principle which has been a constituent part of the salt. The artificial fluate of lime also possesses the same property, and even, according to Scheele, in a higher degree. When it is strongly heated, it melts into a transparent glass. 1211 Action of heat.

5. This salt is decomposed by the sulphuric, nitric, and muriatic acids, by the carbonates of potash and soda, and by most of the phosphates. It is by decomposing it by means of the sulphuric acid, that the fluoric acid is obtained. 1212 Of acids.

6. The fluate of lime is much employed in small pieces of sculpture, and for ornamental purposes in the formation of cups, vases, and pyramids. It is employed also as a flux for mineral substances. 1213 Uses

8. Borate of Lime.

This salt, which is a compound of boracic acid and lime, is prepared by pouring a solution of boracic acid into lime water, or by decomposing the soluble alkaline borates by means of lime water. A precipitate is thus formed, of a salt nearly insoluble, which is insipid, and in the form of a white powder. Little is known of the properties of this salt.

9. Phosphate of Lime.

1. The compound of phosphoric acid and lime, known

† Philos. Trans. 1802, p. 147.

known under the name of *calcareous phosphoric salt*, is one of the most interesting discoveries of modern
1214 History and preparation. chemistry. This was made by Scheele and Gahn in 1774, when they proved that it formed the basis of bones. To obtain this salt in a state of purity, a quantity of bones is calcined to whiteness, reduced to powder, and well washed with water to separate the carbonate of soda and other soluble salts which are generally combined with it. The phosphate of lime is thus procured in the form of an insipid white powder. In this state it is generally mixed with a little carbonate of lime, which may be separated by diluted acetic acid, and afterwards washing it with water.

1215 Properties. 2. By this process the phosphate of lime is procured in a state of purity from the solid matter of bones. It has no taste, and does not change the colour of vegetable blues. When it is prepared artificially, it is in the form of white powder, but as it exists in nature, it is found regularly crystallized. This is known to mineralogists under the name of *apatite*, of which there are several varieties. The primitive form of its crystal is the regular six-sided prism; the primitive form of the integrant molecule is a three-sided prism, whose bases are equilateral triangles. It remains unaltered by exposure to the air, and it is soluble in water.

1216 Action of heat. 3. When this salt is exposed to heat, it scarcely undergoes any change; but when it is exposed to the strong heat of a glasshouse furnace, it is converted into a semitransparent porcelain.

1217 Of acids. 4. The phosphate of lime is decomposed by the sulphuric, nitric, muriatic, and other acids; but this decomposition is only partial. Part of the lime only is abstracted, and the salt is converted into an acidulous phosphate of lime.

1218 Composition. 5. The component parts of phosphate of lime, according to Fourcroy and Vauquelin, are,

Acid,	41
Lime,	59
	100

1219 Uses. 6. The phosphate of lime is of great importance in chemistry, for the purpose of extracting phosphoric acid, to be decomposed to obtain phosphorus. It is also employed for making cupels, for polishing metals and precious stones, and for removing spots of grease from linen, paper, and silk. It is used in medicine as a remedy for rickets, to correct the supposed effects of acids in softening the bones.

Superphosphate of Lime.

1220 History. 1. This salt, with an excess of acid, was discovered by Fourcroy and Vauquelin in 1795. Scheele had remarked, that the phosphate of lime was dissolved by an acid in human urine; but he had not ascertained that this combination between the phosphoric acid and the phosphate of lime constituted a permanent salt.

1221 Preparation. 2. It may be obtained artificially by the partial decomposition of the phosphate of lime by means of any acid, or by dissolving this salt in phosphoric acid. This last process, Fourcroy observes, is the most certain; and when the phosphoric acid has dissolved as much as it can take up of the phosphate of lime, the salt is in the state of acidulous phosphate, or superphosphate.

3. This salt crystallizes in small silky threads, or in brilliant plates of a pearly lustre, which are attached to each other, and seem to have the consistence of honey 1222 Properties. or glue. It has a strong acid taste. Exposed to the air, it is slightly deliquescent. It is soluble in water, and the solution produces cold. It is more soluble in boiling water, and crystallizes by cooling.

4. When this salt is exposed to heat, it first melts, 1223 Action of heat. and then swells up and dries. If the temperature be increased, it undergoes the igneous fusion, and is converted into a transparent glass. The phosphoric acid in this salt is more readily decomposed by charcoal than in the neutral phosphate of lime. It is not decomposed by any of the acids, excepting the oxalic. The proportions of its constituent parts are the following: 1224 Composition.

Acid,	54
Lime,	46
	100 *

10. Phosphite of Lime.

1. This salt, composed of phosphorous acid and lime, 1225 Preparation. is formed by the direct combination of the acid with the earth, and when they are saturated, it falls to the bottom in the form of white powder. This powder is re-dissolved with an excess of acid, and in this state of acidulous phosphite of lime, crystallizes by evaporating the solution.

2. When thus obtained, it is in the form of a white 1226 Properties. powder, if it is just neutralized; but with an excess of acid, it forms small prisms or needles. This salt has no taste; it is not changed by exposure to the air; and it is insoluble in water.

3. When it is exposed to heat, it gives out a phosphoric light, yields a small quantity of phosphorus, and 1227 Action of heat. is converted into a phosphate. By the action of the blow-pipe it melts into a transparent globule.

4. The neutral phosphite of lime is soluble in acids, 1228 Of acids. without being decomposed. The proportions of its constituent parts are, 1229 Composition.

Phosphorous acid,	34
Lime,	51
Water,	15
	100

11. Carbonate of Lime.

1. This salt exists in great abundance in nature; 1230 Names. and it is known by great variety of names, as *limestone*, 1231 Preparation. *marble*, *chalk*. It may be prepared artificially, by directly combining carbonic acid with lime; but in this process the proportions of the acid and earth must be accurately adjusted; for, if there is too little acid, the first precipitate which is formed is re-dissolved in the water, and seems to form carbonate with excess of lime. If there be too much acid, the carbonate first precipitated is also re-dissolved, and disappears in this excess of carbonic acid.

2. The carbonate of lime is perfectly tasteless. The 1232 Properties. specific gravity is 2.7. It is frequently found crystallized, and exhibits a great variety of forms. When it is transparent and in the rhomboidal form, it has the property

* Fourc. Connaiss. Chim. ii. p. 247.

ne, &c. property of double refraction. The primitive form of its crystals is an obtuse rhomboid, whose angles are about 101½° and 78½°. The integrant molecule has the same form.

3. When it is exposed to the air it undergoes no
1233 tion of t. change. It is insoluble in water.

4. Exposed to a strong heat, it decrepitates, and is deprived of its water of crystallization. It becomes white, opaque, and friable. If the heat be increased and continued, the whole of the carbonic acid is driven off in the state of gas.

1234 acids. 5. The carbonate of lime is readily decomposed by all the acids with effervescence, owing to the disengagement of the carbonic acid in the state of gas.

1235 nbina-. 6. The component parts of carbonate of lime, as they have been ascertained by the analyses of Bergman and Kirwan, are the following.

	Bergman.	Kirwan.
Acid,	34	45
Lime,	55	55
Water,	11	00
	100	100

12. Arseniate of Lime.

1236 para-. This salt, which is a compound of arsenic acid and lime, is prepared by dropping the acid into lime water. A precipitate is formed, which is soluble either with an excess of the base, or the acid. Or it may be formed by dissolving carbonate of lime in arsenic acid. The
1237 ion of t. acidulous arseniate of lime, when it is evaporated, affords small crystals. When this salt is heated, it melts, but is not decomposed *.

* *ourcroy naiss. m. x.* 3.

13. Tungstate of Lime.

1238 nd na-. The compound formed by tungstic acid and lime is found native. It is from the mineral called tungsten,
1239 ara-. that the metallic substance is obtained which bears this name. When the solution of tungstic acid is added to lime water, a precipitate of tungstate of lime is formed, similar to the native compound tungsten. This mineral is found crystallized. The primitive form of the crystal is the octahedron, which is composed of two four-sided pyramids, applied base to base. It is of a yellowish colour, with some degree of transparency and considerable hardness. It is insoluble in water, and
1240 posi-. is scarcely altered by the action of heat. The specific gravity is about six. The component parts of this salt are,

Tungstic acid,	70
Lime,	30
	100

14. Molybdate of Lime.

15. Acetate of Lime.

1241 ara-. 1. The compound of acetic acid and lime is formed by dissolving the carbonate of lime in the acid, till it is saturated. By evaporating the solution till a pellicle
1242 perties. forms on the surface, it crystallizes on cooling.

2. The crystals of acetate of lime are in the form of small prisms, with a shining silky lustre. The taste is bitter and sour. It is not changed by exposure to the air, but is soluble in water. The specific gravity is 1.005. Lime, &c.

3. When it is exposed to heat, it is decomposed, 1243 Action of heat.
partly by the separation of the acid, and partly by its decomposition. The component parts of this salt, according to Dr Higgins, are, 1244 Composition.

Acetic acid and water,	64.3
Lime,	35.7
	100.0 †.

† *Experiments*, p. 47.

16. Oxalate of Lime.

The oxalic acid saturated with lime forms an insoluble salt, which may be formed by dropping oxalic acid into any of the acid solutions of lime. The oxalate of lime, thus formed, is a white powder, which converts the syrup of violets to a green. This salt cannot be decomposed by any other acid, the affinity of oxalic acid for lime is so strong. It is on this account that oxalic acid is employed as a test for lime, whether it is in a state of combination or uncombined. This salt may be decomposed by exposing it to heat. The acid itself is driven off, and undergoes decomposition.

The component parts of this salt, according to Bergman, are,

Acid,	48
Lime	46
Water	6
	100

17. Tartrate of Lime.

The compound of tartaric acid and lime may be formed, by dissolving lime in the acid; or by adding a solution of lime in powder to a solution of tartar in boiling water, till it ceases to effervesce, and to redden vegetable blues. The salt precipitates in the form of a white powder, which is insoluble, excepting with an excess of acid. This salt is decomposed by the sulphuric, nitric, and muriatic acids. 1245 Preparation.

18. Citrate of Lime.

This salt, which is a compound of citric acid and lime, may be formed by the direct combination of the acid and the earth. Small crystals are formed, which are precipitated, and are scarcely fusible in water, excepting with an excess of acid, and from this solution it may be obtained crystallized. The component parts of this salt are, 1246 Preparation. 1247 Composition.

Citric acid	62.66
Lime.	37.34
	100.00 ‡.

‡ *Fourcroy* vii. p. 207.

19. Malate of Lime.

1. The compound of malic acid and lime may be formed by combining the acid with the earth, and neutralizing them. Small irregular crystals are thus obtained, which are scarcely soluble in boiling water, but become very soluble with an excess of acid. In this state it is the supermalate of lime. This salt is found ready 1248 Preparation. 1249 Exists in plants.

Lime, &c. ready formed in some vegetables, as in house-leek and similar succulent plants.

1250 Properties. 2. This acidulous malate of lime has an acid taste. When it is evaporated, it forms a solid, shining substance, analogous to varnish. It is decomposed by the sulphuric and oxalic acids, and also by the alkalies. Lime water added to a solution of this salt, combines with excess of acid, and precipitates the malate of lime.

20. Gallate of Lime.

The gallic acid combined with lime forms a yellowish coloured, insoluble salt, which, with an excess of base, becomes soluble.

21. Benzoate of Lime.

The compound of benzoic acid and lime forms a salt which is very soluble in water. This salt crystallizes in an arborescent form on the sides of the vessel which contains the solution. It is decomposed by the sulphuric, nitric, and muriatic acids. It exists in great abundance in the urine of graminivorous quadrupeds.

22. Succinate of Lime.

The compound of succinic acid and lime forms salts which are not very soluble in water, and are not altered by exposure to the air.

23. Saccolate of Lime.

Saclactic acid and lime form an insoluble salt.

24. Camphorate of Lime.

1251 Preparation. 1. This salt, which is a compound of camphoric acid and lime, is formed by adding lime-water to crystallized camphoric acid. The solution is then to be boiled, filtered, and evaporated to three-fourths of its quantity. As it cools, the salt is deposited.

1252. Properties. 2. The camphorate of lime has no regular shape, unless the evaporation has been properly managed, when it is found in the form of plates lying on each other. It is of a white colour, and has a slightly bitter taste.

1253 Action of water and heat. 3. It effloresces in the air, and falls down into powder. It is scarcely soluble in cold, and requires about 200 parts of boiling water for its solution. When it is exposed to heat, if it be moderate, it melts and swells, but if thrown on red-hot coals, or heated in close vessels, the acid is decomposed and sublimed, and the lime remains pure.

4. It is decomposed by the sulphuric, nitric, and muriatic acid. With the sulphuric acids there is formed an insoluble precipitate. The nitric and muriatic acids precipitate the camphoric acid. This salt is also decomposed by the carbonate of potash, and the phosphate of soda.

5. The component parts of this salt are,

Camphoric acid	50
Lime	43
Water	7
	100 *

* Ann. de Chim. xxvii. 23.

25. Suberate of Lime.

1254 Properties. This salt, which is a compound of suberic acid and lime, does not crystallize, is perfectly white, has a slight saline taste, and does not redden the tincture of turnsole. It is scarcely soluble in cold water. Boiling water dissolves it more abundantly, but as it cools, a part of it is precipitated. When it is placed upon burning coals, it swells up, the acid is decomposed, and the lime remains in the state of powder. This salt is decomposed by the sulphuric, nitric, and muriatic acids, by potash and soda, and their carbonates, and by the phosphate and borate of soda †. — Barytes, &c. — 1255 Action of heat.

† Ibid. xxiii. p.

26. Mellate of Lime.

The mellitic acid dropt into lime-water forms a precipitate which is re-dissolved by adding nitric acid. Or when the mellitic acid is mixed with a solution of sulphate of lime, a precipitate is formed of small, gritty crystals, which do not affect the transparency of the water.

27. Lactate of Lime.

The compound of lactic acid and lime forms a deliquescent salt, which is soluble in alcohol.

28. Prussiate of Lime.

The compound of prussic acid and lime is formed by dissolving the lime in the acid. The solution is then to be filtered, and the lime which has not combined with the acid is to be separated by adding carbonic acid in water, in the proportion necessary to precipitate the lime from the same bulk of lime-water. The solution, after a second filtration, must be preserved in close vessels. By distillation the prussic acid is driven off, and the pure lime remains behind. This salt is decomposed by all the other acids, and also by the alkalies.

29. Sebate of Lime.

When sebacic acid is dropped into lime-water the transparency of the water is not disturbed, so that the compound of this acid with lime is soluble in water.

IV. Compounds of Lime with Inflammable Substances.

Lime does not enter into combination with alcohol or ether; but it forms compounds with the fixed oils, which are known by the name of soaps. Lime combines also in small quantity with the volatile oils, forming a similar compound.

Sect. II. *Of Barytes and its Combinations.*

1. For the knowledge of this earth we are indebted to modern chemistry. It was discovered by Scheele in 1774; and its properties were investigated by him, and in the following year by Gahn, who analyzed a mineral which had been distinguished by the name of *ponderous spar*, on account of its weight, and found that it was composed of sulphuric acid and the new earth. It received the name of *terra ponderosa* from Bergman, who also examined its properties, and confirmed the experiments of Scheele and Gahn. Mr Kirwan gave it the name of *barytes*, from the Greek word βαρυς, which signifies heavy. Its properties were farther investigated by Dr Hope, in 1793 *, and by Pelletier, Fourcroy, and Vauquelin, in 1797 †. — 1256 History.

* Edin. Trans. iv. 36.

† Annal. Chim. xxi. 113.

2. This earth may be obtained in a state of purity

[Ba]rytes, &c. rity by the following process: A quantity of sulphate of barytes, a mineral found in considerable abundance in nature, is first reduced to a fine powder. [12]57 Prepara[tion]. Mix it with $\frac{1}{8}$th of its weight of charcoal powder, and expose the mixture in a crucible to a strong heat, for several hours. The sulphuric acid, by this process, is decomposed, by being deprived of its oxygen, which combines with the carbon of the charcoal, and forms carbonic acid, which is driven off. The sulphur remains in combination with the earth, forming a sulphuret of barytes. This sulphuret is to be dissolved in water, and nitric acid poured into the solution. The nitric acid combines with the barytes, and forms nitrate of barytes, while the sulphur is precipitated. The solution is to be filtered, and slowly evaporated till it crystallize. The crystals thus formed are then put into a crucible, and exposed to a strong heat. The nitric acid is decomposed, and driven off, and the earth remains behind in a state of purity.

Dr Hope has recommended another process, which is more economical. By this process the sulphate of barytes is decomposed as in the former. The sulphuret which is obtained is thrown into water, that all soluble matters may be dissolved. To the solution, after filtration, a solution of carbonate of soda is to be added. A precipitate takes place in the form of a white powder. This powder is to be washed with water, made up into balls with charcoal, and exposed to a strong heat in a crucible. The balls are afterwards to be thrown into boiling water, when part of the barytes is found dissolved, and, as the water cools, it crystallizes.

[12]58 Properties and composition. 3. Barytes, as it is obtained by decomposing the nitrate in the first process, is in the form of small, gray, porous masses, which are easily reduced to powder. It has a hot, burning taste; and when introduced into the stomach, is a deadly poison. Its specific gravity is 4.00. It destroys the texture of all animal substances. It converts vegetable blues to a green colour. In many of its properties it is perfectly analogous to the fixed alkalies. It is decomposed by the same process as lime. Its base is called barium. It is a dark grey metal, more than twice the weight of water. Barium is susceptible of a higher degree of oxidation by simply heating barytes in contact with oxygen.

[12]59 Action of water. 4. When it is exposed to the air, especially if the atmosphere be loaded with moisture, it swells up in a few minutes, becomes hot, and at last falls into a white powder. It is then deprived of part of its acrimony, and is increased in weight 0.22. This is owing to the absorption of water from the atmosphere. If a small quantity of water be thrown upon barytes, it boils up, is strongly heated, is enlarged in volume, and gives out a great quantity of heat. After being slaked in this manner, it is diluted with water, the earth crystallizes, and assumes the appearance of needle-formed crystals, which, at the end of some time, if exposed to the air, spontaneously fall to powder. With a greater quantity of water the barytes is completely dissolved. Cold water takes up about $\frac{1}{20}$ of its weight. This solution changes the syrup of violets to green, and at last destroys the colour. When this liquid is exposed to the air, a thick pellicle is formed on the surface, which is owing to the absorption of carbonic acid from the atmosphere. Boiling water dissolves $\frac{1}{2}$ its weight of pure barytes. The solution affords crystals as it cools. They are in the form of long, four-sided prisms, transparent and white, which effloresce in the air; but the form of the crystals varies according to the rapidity of the evaporation and crystallization.

5. Light has no action on barytes. Heated on charcoal with the blowpipe, it melts into an opaque, gray globule, which soon penetrates the charcoal. Exposed to heat in a crucible, it melts, and attaches itself to the sides of the vessel, to which it adheres strongly, forming a kind of greenish covering. Less strongly heated, it hardens, and internally assumes a bluish green shade. There is no action between barytes and oxygen, azote, hydrogen, or carbon. 1260 Of heat.

I. Phosphuret of Barytes.

1. Barytes enters into combination with phosphorus, forming the compound called *phosphuret of barytes*. 1261 Preparation. This is prepared by introducing a mixture of barytes and phosphorus into a glass tube closed at one end, and exposing the mixture to the heat of burning coals. The two substances rapidly combine together.

2. The phosphuret of barytes, thus obtained, is of a dark or shining brown colour, having a metallic appearance, very fusible, and exhaling, when it is moistened, a strong fetid odour: in the dark it is luminous. When it is thrown into water, it is decomposed, giving out phosphorated hydrogen gas, and is gradually converted, by the action of the air and the water, into *phosphate of barytes* *. 1262 Properties.

II. Sulphuret of Barytes.

1. A similar combination also takes place between barytes and sulphur. The combination may be formed by introducing barytes and sulphur well mixed together, into a crucible, and exposing them to a red heat. At that temperature the mixture melts, and the compound which is formed is the sulphuret of barytes. 1263 Preparation.

2. This substance is very soluble in water, which it instantly decomposes; and, when it is saturated with the sulphurated hydrogen which is formed, it is converted into a hydrogenated sulphuret of barytes, which deposits by cooling, crystals of different forms, sometimes in that of small needles, sometimes in that of large six-sided prisms, sometimes in the form of octahedrons, and often in that of small, brilliant, hexagonal plates, which are crystals of sulphurated hydrogen and barytes, denominated by Berthollet, *hydrosulphuret of barytes*. When the sulphuret of barytes is dissolved in water, it instantly exhales the fetid odour of sulphurated hydrogen gas. The liquid which has deposited crystals of hydrosulphuret of barytes, retains a hydrogenated sulphuret in solution. When it is exposed to the air, this solution becomes of an orange yellow. Crystals of hydrosulphuret of barytes, with spots or yellowish plates, are often observed in the midst of the white masses. 1264 Properties. 1265 Hydrogenated sulphuret.

3. The sulphuret of barytes is most remarkable for the great rapidity with which it decomposes water, and the great quantity of the sulphurated hydrogen with which it combines, forming the hydrosulphuret of barytes; which latter is slowly, and with difficulty, decomposed by the air, and the great proportion of sulphurated hydrogen gas which is disengaged by the action of acids, without any precipitation of sulphur.

4.

* Fourcroy Connaiss. Chim. ii. p. 191.

Barytes, &c.

1266 Three compounds. 4. Thus there are three different combinations of sulphur with barytes. In the first, the sulphur is directly combined with the barytes, as when they are exposed to heat in the state of dryness, which is the simple sulphuret of barytes. In the other, the sulphur combined with the hydrogen, is in the state of hydrosulphuret of barytes. This compound is prepared by passing sulphurated hydrogen gas into water holding barytes in solution, which, as it combines with the gas, becomes more soluble, and is condensed and absorbed by the water. The distinctive character between the latter combination and that of the sulphuret of barytes is, that the first, by the action of acids, only gives out sulphurated hydrogen gas, without any deposition of sulphur; and the second, exposed to heat, is deprived of its sulphur, which is sublimed, without affording sulphurated hydrogen gas. Between these two states, there is an intermediate combination, in which the sulphuret of barytes holds in solution more or less sulphurated hydrogen; so that, by the action of acids, it affords sulphurated hydrogen gas, with a deposition of sulphur at the same time. To this intermediate compound, Berthollet has given the name of *hydrogenated sulphuret of barytes* *.

* Fourcroy *Connaiss. Chim.* ii. p. 191.

III. Compounds of Barytes with the Acids.

1267 Affinities. Barytes enters into combination with the acids, and forms with them compounds, which are distinguished by the name of *salts*. The order of the affinities of barytes for the acids, according to Bergman, is the following:

Sulphuric acid,
Oxalic,
Succinic,
Fluoric,
Phosphoric,
Saclactic,
Nitric,
Muriatic,
Suberic,
Citric,
Tartaric,
Arsenic,
Lactic,
Benzoic,
Acetic,
Boracic,
Sulphurous,
Carbonic,
Prussic.

1. Sulphate of Barytes.

1268 Found native. 1. This salt, which is a compound of sulphuric acid and barytes, was formerly distinguished by the name of *heavy spar*, *phosphoric spar*, or *Bolognian stone*. It exists in great abundance in nature, particularly accompanying metallic veins; from which circumstance, probably, and from its great weight, it was supposed to contain a metallic substance. It is rarely formed artificially, as that found in nature is sufficiently pure.

1269 Properties. 2. The sulphate of barytes is the heaviest of all the salts, the specific gravity being 4.4. It has neither taste nor smell. Sometimes it is found crystallized, and sometimes compact. There is a considerable variety among the forms of its crystals. The primitive form of sulphate of barytes is a rhomboid, with right angles at the bases, whose angles are $101\frac{1}{2}°$ and $78\frac{1}{2}°$ The integrant molecule is the same.

3. This salt remains unchanged in the air, and it is insoluble in water. When it is suddenly heated, it decrepitates. By the action of a strong heat, it melts with difficulty; and before the blow-pipe it fuses, and is converted into a white opaque globule. It is decomposed at a red heat by hydrogen and charcoal, and is converted into a sulphuret which is phosphoric. This was formerly called, from an accident, *Bolognian phosphorus*. A piece of the sulphate of barytes was found in the neighbourhood of Bologna, by a shoemaker of that city, who, suspecting that it contained silver, put it into the fire to separate the metal. He found no metal, but he observed that by heating it acquired the property of shining in the dark, and thence it obtained the name of Bolognian stone or phosphorus. 1270 Action of heat.

This salt is decomposed by the carbonates of potash and soda, either by exposing them to a strong heat in a crucible, or by boiling them together in solution.

According to the different analyses which have been made to ascertain the constituents of this salt, it appears that there is a considerable difference between the natural and artificial sulphate of barytes, as in the following table: 1271 Composition.

	Native.	Artificial.
Acid	13	33
Barytes	84	64
Water	3	3
	100	100*.

* Fourcroy *Connaiss. Chim.* ii. p. 25.

By another analysis, when the artificial sulphate was heated to redness, the component parts were found, according to

2. Sulphite of Barytes.

1. This compound of sulphurous acid and barytes is formed by passing sulphurous acid gas into water, in which is mixed, or suspended, carbonate of barytes in the state of fine powder; or by the direct combination of sulphurous acid and barytes, either solid or in solution. In whatever way it is prepared, the salt is deposited in the form of powder, or crystallized. 127[illegible] Preparation.

2. The crystals of sulphite of barytes are sometimes in the form of small, brilliant, and opaque needles, or very hard transparent crystals in the form of tetrahedrons, with truncated angles. It has little taste. The specific gravity is 1.6938. It is scarcely altered when exposed to the air, and is insoluble in water. When it is exposed to heat, sulphur is driven off, and there remains a sulphate of barytes. It is decomposed by the sulphuric and muriatic acids, with the disengagement of sulphurous acid. 127[illegible] Properties.

3. This salt has been applied to no use, excepting for 127[illegible] Uses.

rytes, &c. for the chemical purpose of ascertaining the purity of sulphurous acid. It is employed in this way by Fourcroy. If there be any mixture of sulphurous acid with the sulphuric, it may be detected by this salt; for as there is a stronger affinity between sulphuric acid and barytes than between sulphurous acid and the same earth, the sulphuric acid, if any be present, combines with the barytes, and forms with it an insoluble salt, which is precipitated.

1275 posi- 4. The following are the proportions of the constituent parts of this salt.

Sulphurous acid	39
Barytes	59
Water	2
	100 *.

ourcroy naiss. n. iii. 5.

3. Nitrate of Barytes.

276 ara- This compound of nitric acid and barytes is prepared by saturating the acid with native carbonate of barytes; or, by the decomposition of sulphuret of barytes, by nitric acid. By filtration and evaporation this salt crystallizes.

277 erties. 2. The crystals of nitrate of barytes are in the form of regular octahedrons, or in small brilliant plates. The specific gravity is 2.9149. It has a hot, acrid, and austere taste, and is little changed by being exposed to the air. It is soluble in 12 parts of cold, and in about three or four parts of boiling water. When placed upon burning coals, it decrepitates, boils up, and becomes dry, and gives out sparks round the points where it comes in contact with the burning coal. When it is heated in a retort, it gives out a little water, oxygen gas, and azotic gas; and there remains behind, the barytes in the form of a solid, gray, porous mass.

278 posi- The constituent parts of this salt, according to Fourcroy, Vauquelin, and Kirwan, are the following:

	Fourcroy and Vauquelin †.	Kirwan ‡.
Nitric acid	38	32
Barytes	50	57
Water	12	11
	100	100

d. iii. 6. chol. . iii. 5.

This salt is only employed for detecting sulphuric acid in nitric acid, and to be decomposed for the purpose of obtaining pure barytes.

4 Nitrite of Barytes.

Nothing farther is known of this salt, than that it is formed when the nitrate of barytes is decomposed in a retort by means of heat. If the operation be stopped at the time that a third part of the oxygen gas has been disengaged, the nitrite of barytes remains.

5. Muriate of Barytes.

279 ory. 1. This salt, which is a compound of muriatic acid and barytes, was first investigated by Scheele and Bergman, and little more has been since added by the experiments and researches of other chemists.

280 ara- 2. It is prepared by the direct combination of muriatic acid with the carbonate of barytes; or, by decomposing the sulphuret of barytes by the muriatic acid, filtering the solution, and evaporating till a pellicle appear on the surface. If it be allowed to cool slowly, crystals of muriate of barytes are formed. But the sulphate of barytes, which is employed, sometimes contains iron: so that a muriate of this metal is formed along with the muriate of barytes. To separate the iron, the mixture is to be calcined, by which the acid is driven off, and the iron remains behind in the state of oxide, which is insoluble in water. Barytes, &c.

3. The primitive form of the crystals of this salt is a four-sided prism with square bases. The form of the integrant particles is the same. It crystallizes in tables, or in eight-sided pyramids. The taste is acrid, astringent, and metallic. The specific gravity is 2.8257. When dried, it is converted into a chloride of barium. 1281 Properties.

4. It undergoes no change by exposure to the air. It is soluble in five or six parts of cold water, but boiling water dissolves more; and, on cooling, the salt crystallizes. 1282 Action of water.

5. When exposed to heat, it decrepitates, loses its water of crystallization, dries, falls down to powder, and at last melts; but no heat that can be applied decomposes it. 1283 Of heat.

6. This salt is decomposed by the sulphuric and nitric acids, and a precipitation of nitrate or of sulphate of barytes is formed. 1284 Of acids.

7. The constituent parts of this salt, according to Mr Kirwan, are, 1285 Composition.

		When dried.
Acid,	20	23.8
Barytes,	64	76.2
Water,	16	00.0
	100	100.0

8. This is one of the most delicate tests for detecting sulphuric acid in any solution. Water, which holds 0.0002 parts of sulphuric acid, exhibits a visible precipitate by a single drop of the solution of muriate of barytes. Nay, there is a slight cloud in a few minutes produced by the addition of a solution of this salt to water which holds 0.00009 parts of sulphuric acid in solution. The muriate of barytes has been proposed and recommended as a cure for scrophula; and it is said, in some cases in which it has been used, with good effect; but it ought to be administered with the utmost caution. The carbonate of barytes is one of the most active poisons, and probably all the salts of this earth are possessed of similar properties. The dose should not exceed five or six drops of the solution at first *. 1286 Uses.

* *Fourcroy Connaiss. Chim.* iii. p. 267.

6. Hyperoxymuriate, or Chlorate of Barytes.

1. The compound of hyperoxymuriatic acid and barytes was formed by Mr Chenevix. The process which he followed was, to cause a current of oxymuriatic acid gas to pass through a solution of a large quantity of barytic earth in warm water. This salt he found soluble in four parts of cold, and less of warm water; but as it crystallizes like the muriate of this earth, and has the same degree of solubility, he could not separate the hyperoxymuriate from the muriate, which was formed at the same time. He therefore thought of obtaining it by double affinity, as in the following process. 1287 Preparation.

2.

Barytes, &c.

2. When phosphate of silver is boiled with muriate of barytes, a double decomposition takes place; muriate of silver and phosphate of barytes are formed, both of which being insoluble, are precipitated. But the phosphate of silver does not decompose the hyperoxymuriate of barytes. When therefore the muriate and hyperoxymuriate of barytes are boiled with phosphate of silver, the muriate of barytes only is decomposed. The muriate of silver and the phosphate of barytes are precipitated, and the hyperoxymuriate of barytes remains in solution. When this salt is decomposed by the stronger acids, it is accompanied with a flash of light, which Mr Chenevix conjectures, is owing to the relative proportionate affinities, and consequently the greater rapidity of the disengagement.

1288 Composition. The proportions of this salt are,

Hyperoxymuriatic acid,	47.0
Barytes,	42.2
Water,	10.8
	100.0 *

* Phil. Trans. 1802. p. 147.

7. Fluate of Barytes.

This compound of fluoric acid and barytes may be formed, by pouring fluoric acid into a solution of nitrate or muriate of barytes. A precipitate is formed, which is the fluate of barytes. This salt is decomposed with effervescence by the sulphuric acid, and it is precipitated by lime water. Of the proportions of its constituent parts and other properties, nothing is known.

8. Borate of Barytes.

The compound of boracic acid and barytes is formed by pouring a solution of boracic acid into a solution of barytes. An insoluble white powder is precipitated, which, according to Bergman, may be decomposed, even by the weak vegetable acids.

9. Phosphate of Barytes.

1289 Preparation. 1. The compound of phosphoric acid and barytes has been only examined by Vauquelin. It is prepared, either by the direct combination of phosphoric acid with barytes, or the carbonate of barytes; or by precipitating a solution of nitrate or muriate of barytes, by means of an alkaline phosphate. The phosphate of barytes is precipitated in the form of powder.

1290 Properties. 2. This salt is in the form of white powder, without any appearance of crystallization. It is not altered by exposure to the air, and is insoluble in water. The specific gravity is 1.2867.

1291 Action of heat. 3. This salt at a high temperature is fusible. It is converted into a vitreous matter or gray enamel. Before the blow-pipe, on charcoal, it gives out a yellow phosphoric light. The vitreous globules become opaque on cooling. It is decomposed by the sulphuric acid. The phosphoric and phosphorous acids, when added in excess, have the property of re-dissolving the salts which they form with barytes.

10. Phosphite of Barytes.

1292 Preparation. 1. This compound of phosphorous acid and barytes, is formed by the direct combination of the acid with the earth; or by precipitating the soluble phosphites by a solution of barytes. By the last process the salt is obtained in the greatest purity.

2. The phosphate of barytes is in the form of a white powder, which is insipid, not altered by exposure to the air, not very soluble in water without an excess of acid, by which means it is converted into the acidulous phosphite. 1293 Properties.

3. The phosphite of barytes melts under the blow-pipe into a globule, which is surrounded with a most brilliant light. The vitreous globule becomes, on cooling, white and opaque. 1294 Action of heat.

4. This salt is decomposed by most of the acids; by lime and lime water. The other alkaline and earthy bases combine with the excess of phosphorous acid, when it is in the state of acidulous phosphate, and there remains behind a neutral phosphite. 1295 Of acids.

5. The component parts of this salt are, 1296 Composition.

Phosphorous acid,	41.7
Barytes,	51.3
Water,	7.0
	100.0 *

*Fourc. Connais. Chim. ii. p. 251.

11. Carbonate of Barytes.

1. This compound of carbonic acid and barytes has been known by the names of *aërated heavy spar*, *aërated baroselenite*, and *witherite* from the name of Dr Withering, who first discovered that it is a natural production. Its nature and properties were first investigated by Scheele and Bergman, about the year 1776, and since that time by Kirwan, Hope, Klaproth, Pelletier, Fourcroy and Vauquelin. 1297 Names.

2. The carbonate of barytes is found native in striated, lamellated, semitransparent masses. The primitive form of its crystals is the six-sided prism. The specific gravity is 4.331. 1298 Native.

3. The carbonate of barytes may be prepared artificially, by exposing a solution of pure barytes to the air, or by passing carbonic acid gas into the solution. It may be prepared also in the dry way, by mixing together sulphate of barytes and carbonate of potash or soda, and exposing the mixture to strong heat; or by decomposing, by means of carbonate of potash, soda, or ammonia, the nitrate or muriate of barytes in solution in water. By whatever processes the carbonate of barytes is obtained, it is in the form of a white tasteless powder. When thus prepared, the specific gravity is 3.763. 1299 Prepared by art.

4. It undergoes no change by exposure to the air. Cold water dissolves $\frac{1}{4304}$; boiling water $\frac{1}{2304}$ part.

5. The carbonate of barytes undergoes little change when it is exposed even to the strongest heat. The artificial carbonate loses about 0.28 of its weight by calcination, while the native carbonate becomes white and opaque, and is converted into a bluish green colour, without any perceptible loss of weight; but if it be heated in a black lead crucible, or if it be formed into a paste, with 100 parts of the salt to 10 of charcoal, the carbonic acid is separated. 1300 Action of heat.

6. The component parts of the carbonate of barytes are the following: 1301 Composition.

Native

arytes, &c.

Native Carbonate.

	Withering.	Fourcroy.
Acid	20	10
Barytes	80	90
	100	100

Artificial Carbonate.

	Bergman.	Pelletier.
Acid	7	22
Barytes	65	62
Water	28	16
	100	100

When both the natural and artificial are exposed to a red heat, the component parts, as ascertained by Mr Kirwan, are,

Acid	22
Barytes	78
	100

302 7. This salt has been found native only in small quantity, otherwise it is supposed, that it might be of great use for the preparation of barytic salts, which promise great service in several arts and manufactures. It has been proposed to employ it in medicine; but in experiments on animals, it has been found to act as a most deadly poison. Great caution, therefore, should be observed in employing it as an internal remedy*.

* urcroy).

12. Arseniate of Barytes.

The compound of arsenic acid and barytes is formed by dissolving the earth in the acid. It is an insoluble, uncrystallized salt; but with an excess of acid it becomes soluble, and is decomposed by sulphuric acid. It melts when exposed to a strong heat, but is not decomposed.

13. Tungstate of Barytes.

With the tungstic acid, barytes forms an insoluble salt.

14. Molybdate of Barytes.

Barytes with the molybdic acid forms a salt which has very little solubility.

15. Chromate of Barytes.

It is little known, but said to be insoluble in water.

16. Columbate of Barytes.

17. Acetate of Barytes.

03 ra- 1. This salt, which is a compound of acetic acid and barytes, may be prepared by directly combining the acid with the earth; or by decomposing sulphuret of barytes by means of acetic acid. By evaporating the solution, it may be obtained crystallized.

04 rties. 2. The crystals of the acetate of barytes are in the form of fine transparent prisms. The specific gravity is 1.828. This salt has an acid bitter taste, effloresces in the air, is very soluble in water, is decomposed by the carbonates of the alkalies, but not by the alkalies themselves, or the pure earths. Barytes, &c.

3. This salt may be employed to detect the presence and quantity of sulphuric acid in solutions, particularly in vinegar, which may be adulterated with the addition of this acid †. 1305 Uses.

† Fourcroy viii. 196.

18. Oxalate of Barytes.

1. The compound of oxalic acid and barytes is formed by adding the acid to a solution of barytes in water. A white powder precipitates, which is oxalate of barytes; it is insoluble in water. With an excess of oxalic acid, this precipitate is dissolved, and small angular crystals are formed. 1306 Preparation.

2. If these crystals are dissolved in boiling water, they become opaque, and fall down in the form of an insoluble powder, for the water combines with the excess of acid, which held them in solution. 1307 Action of heat.

19. Tartrate of Barytes.

The compound of tartaric acid and barytes forms a salt in the state of white powder, which has little solubility, excepting with an excess of acid. It is decomposed by the sulphuric, nitric, muriatic, and oxalic acids.

20. Citrate of Barytes.

1. The compound of citric acid and barytes forms a salt, by adding the earth to a solution of the acid. A flocculent precipitate at first appears, which is dissolved by agitation. The precipitate afterwards becomes permanent when the acid is saturated. 1308 Preparation.

2. This salt, which is at first deposited in the form of powder, shoots out afterwards into a kind of vegetation, of a silvery whiteness, with great brilliancy and beauty. It is soluble in a great proportion of water. This salt is composed of

Acid	50
Barytes	50
	100

21. Malate of Barytes.

The compound of malic acid and barytes is formed by adding the acid to a solution of the earth in water. A crystallized, soluble salt is precipitated.

22. Gallate of Barytes.

The compound of gallic acid and barytes is formed by the direct combination of the acid with the earth. A salt is thus formed, which is not very soluble, but with an excess of the base.

23. Benzoate of Barytes.

Benzoic acid combines with barytes, and forms a salt which is soluble in water, crystallizes, undergoes no change by exposure to the air, and is decomposed by heat and the stronger acids.

24. Succinate of Barytes.

Barytes forms, with succinic acid, a salt which has little solubility.

Strontites, &c.

25. Saccolate of Barytes.

This salt is insoluble in water.

26. Camphorate of Barytes.

1309 Preparation. 1. The compound of camphoric acid and barytes is formed by adding the crystallized acid to the solution of the earth, and then boiling the mixture. It is afterwards to be filtered and evaporated to dryness. What remains is camphorate of barytes.

1310 Properties. 2. This salt does not crystallize; but when it is slowly evaporated, small plates are deposited, which seem transparent in the liquid, but become opaque when exposed to the air. It has scarcely any taste; but an impression remains on the tongue, which is slightly acid and bitter.

3. This salt undergoes no change by exposure to the air. It is only soluble in 600 parts of water at the boiling temperature.

1311 Action of heat. 4. When exposed to the action of the blow-pipe, the acid is volatilized, and the earth is converted into a vitreous substance. The camphoric acid, as it burns, first exhibits a blue, then a red, and at last a white flame.

5. This salt is decomposed by the sulphuric, nitric, and muriatic acids, and by the oxalic, tartaric, and citric *.

* *Ann. de Chim.* xxvii. p. 28.

27. Suberate of Barytes.

This salt does not crystallize, and is only soluble in water with an excess of acid; when exposed to heat, it swells up and melts, and is decomposed by the sulphuric, nitric, muriatic, and oxalic acids †.

† *Ibid.* xxiii. 52.

28. Mellate of Barytes.

By adding mellitic acid to a solution of acetate of barytes, there is formed a flaky precipitate, which is re-dissolved with the addition of more acid. When the acid is poured into a solution of muriate of barytes no precipitate is formed; but a short time afterwards a group of transparent needle-formed crystals is deposited.

29. Lactate of Barytes.

Barytes forms with lactic acid, a deliquescent salt.

30. Prussiate of Barytes.

Prussic acid and barytes form a salt which is very little soluble in water, and is decomposed, not only by the sulphuric acid, but even by carbonic.

31. Sebate of Barytes.

Sebacic acid, added to a solution of barytes in water, forms no precipitate; from which it is inferred that the sebate of barytes is insoluble in water.

Sect. III. *Of Strontites and its Combinations.*

1312 History. 1. This earth was not discovered till about the year 1791 or 1792. Dr Crawford, indeed, previous to this period, in making some experiments on what he supposed was a carbonate of barytes, and observing a striking difference between this mineral and the carbonate of barytes which he had been accustomed to employ, conjectured that it might contain a new earth; and he sent a specimen to Mr Kirwan for the purpose of analyzing it. This conjecture was fully verified by the experiments of Dr Hope ‡, Mr Kirwan, and M. Klaproth, who were all engaged in the same analysis nearly about the same time. Strontites is found native in combination with carbonic and sulphuric acids. With the former it is found in considerable quantity in the lead mines of Strontian in Argyleshire, from which it has derived its name *strontites*, or *strontian* as it is called by others. The nature and properties of this earth have been still farther investigated by Pelletier, Fourcroy, and Vauquelin.

‡ *Edin. Trans.* iv. 3.

2. This earth may be obtained in a state of purity, either by exposing the carbonate of strontites, mixed with charcoal powder, to a strong heat, by which the carbonic acid is driven off; or, by dissolving the native salt in nitric acid, and decomposing the nitrate of strontites thus formed, by heat. Strontites obtained by either of these processes, is in small porous fragments of a greenish white colour. It has an acrid, hot, alkaline taste, and converts vegetable blues to green. The specific gravity is 1.647. It is decomposed by the same process as lime. Strontium, its base, bears a very near resemblance to barium. 131[illegible] Preparation. 131[illegible] Proper[ties].

3. Light has no perceptible action upon this earth. When it is exposed to heat, it may be kept a long time, even in a red heat without undergoing any change, or even the appearance of fusion. By the action of the blow-pipe it is not melted, but is surrounded with a very brilliant white flame. 13[illegible] Action [of] heat.

4. When a little water is thrown on strontites, it exhibits the same appearance as barytes. It is slaked, gives out heat, and then falls to powder. If a greater quantity of water be added, it is dissolved. According to Klaproth it requires 200 parts of water at the ordinary temperature of the atmosphere for its solution. Boiling water dissolves it in greater quantity, and when the solution cools, it affords transparent crystals. These crystals are in the form of rhomboidal plates, or in that of flattened silky needles, or compressed prisms. The specific gravity is 1.46. These crystals effloresce in the air, and have an acrid hot taste. The solution of this earth in water is acrid and alkaline, and converts vegetable blues to green. It is soon covered with a pellicle, by absorbing carbonic acid from the atmosphere. 13[illegible] Of wa[ter].

5. Strontites has the property of communicating a purple colour to flame.

6. The order of the affinities of strontites is the following: 1[illegible] Affini[ties].

Sulphuric acid,
Phosphoric,
Oxalic,
Tartaric,
Fluoric,
Nitric,
Muriatic,
Succinic,
Acetic,
Arsenic,
Boracic,
Carbonic.

I.

Strontites, &c.

I. Phosphuret of Strontites.

The phosphuret of strontites is prepared in the same way as the phosphuret of barytes.

II. Sulphuret of Strontites.

1318 The sulphuret of strontites is formed by exposing sulphur and the earth in a crucible, to heat. This sulphuret is soluble in water, by means of sulphurated hydrogen, which is disengaged by the decomposition of the water. The strontites thus combined with sulphurated hydrogen, forms a hydrosulphuret of strontites; and if this solution be evaporated, the hydrosulphuret of strontites may be obtained in crystals, and the hydrogenated sulphuret remains, as in similar compounds, in solution. When the hydrogenated sulphuret is decomposed by means of an acid, the sulphurated hydrogen gas which is disengaged, burns with a beautiful purple flame, on account of holding in solution a small quantity of the earth, which communicates this property.

III. Compounds of Strontites with the Acids.

1. Sulphate of Strontites.

1. The compound of sulphuric acid with strontites may be formed by adding sulphuric acid to a solution of strontites in water, and it is obtained in the state of a white powder. It is found native in different places, crystallized in fine needle-formed prisms. It has no taste, and is scarcely soluble in water. It suffers no change in the air. By the action of the blow-pipe it gives out a yellowish purple light. It is not decomposed by any of the acids; but it is decomposed by the carbonate of potash and soda, by the barytic salts, by the sulphates of potash and of soda, the phosphates of potash, soda, and ammonia, and by the borate of ammonia.

2. The component parts of this salt, according to Vauquelin, are,

Acid	46
Strontites	54
	100

But according to Klaproth, Kirwan, and others,

Acid	42
Strontites	58
	100

2. Sulphite of Strontites.

This salt is yet unknown.

3. Nitrate of Strontites.

1. The compound of nitric acid and strontites, is formed by precipitating, by means of nitric acid, the sulphuret of strontites, obtained from the decomposed sulphate, or by dissolving the carbonate of strontites in the acid. By evaporation it may be obtained in crystals.

2. The crystals of nitrate of strontites are in the form of octahedrons. The taste of this salt is cool and pungent. It is not altered by exposure to the air. The specific gravity is 3.0061. It is soluble in 15 parts of cold water, and much more soluble in boiling water, in which it crystallizes on cooling. Exposed to sudden heat it decrepitates. When it is subjected to heat in a crucible, it swells up, gives out oxygen and nitrous gas, and there remains behind pure earth. This salt has the property of communicating a purple flame to combustible substances with which it is mixed; as when a little of the salt in powder is thrown on the wick of a candle.

3. The component parts of this salt are, according to

	Vauquelin.	Kirwan.
Acid	48.8	31.7
Strontites	47.6	36.21
Water,	4.0	32.72
	100.0	100.00

4. Nitrite of Strontites.

The properties of this salt have not been examined.

5. Muriate of Strontites and Chloride of Strontium.

1. The compound of muriatic acid and strontites is prepared by dissolving carbonate of strontites in the acid. By evaporating the solution, the salt is obtained crystallized. When perfectly dry, it becomes a chloride of strontium. 1319 Preparation.

2. This salt crystallizes, in long, slender, hexagonal prisms. The taste is cooling and pungent. The specific gravity is 1.4402. It is not altered by exposure to the air. It is very soluble in water. Three parts of the salt are dissolved in two parts of cold water. These crystals, which are soluble in alcohol, communicate a purple colour, which is the distinguishing characteristic of this salt. When heated, it melts, and parts with its water of crystallization, without being decomposed, and there remains behind a semitransparent enamel. This salt is decomposed by a very strong heat. It is decomposed also by the sulphuric, nitric, and phosphoric acids; and by potash, soda, and barytes. 1320 Properties.

3. The constituent parts of this salt are, according to 1321 Composition.

	Vauquelin.	Kirwan.
Acid	23.6	18
Strontites	36.4	40
Water	40.0	42
	100.0	100

6. Hyperoxymuriate, or Chlorate of Strontites.

1. This combination of hyperoxymuriatic acid and strontites was prepared by Mr Chenevix, by a similar process to that which he employed in the formation of barytes with the same acid: and in many of its properties it is analogous. 1322 Preparation.

2. The crystals of this salt are in the form of needles. They melt in the mouth, and give the sensation of cold. It is composed of 1323 Composition.

Acid	46
Strontites	26
Water	28
	100 *

* Phil. Trans. 1802.

7.

Strontites, &c.

7. Fluate of Strontites.

The properties of this salt have not yet been investigated.

8. Borate of Strontites.

This compound of boracic acid and strontites is in the form of a white powder, and requires 130 parts of water for its solution. It converts the syrup of violets to a green colour, from which it is inferred, that it contains an excess of the earth.

9. Phosphate of Strontites.

1324 Preparation. 1. The compound of phosphoric acid and strontites, is formed by dissolving the carbonate of the earth in acid; or by mixing together the solutions of muriate of strontites with those of the alkaline phosphates.

1325 Properties. 2. It is thus obtained in the form of white powder, which is perfectly tasteless. It is not altered by exposure to the air. It is insoluble in water, without an excess of acid. It melts under the blow-pipe into a white enamel, and gives out a purple, phosphorescent light.

3. The constituent parts of this salt are,

Acid	41.24
Strontites	58.76
	100.00

10. Phosphite of Strontites.

The name of this salt is unknown.

11. Carbonate of Strontites.

1326 Found native. 1. This salt is found native; and, as we have already mentioned, was pointed out by Dr Crawford as different from the carbonate of barytes, with which it had been formerly confounded.

1327 Preparation. 2. It may be prepared artificially, by saturating a solution of strontites in water with carbonic acid; or, by precipitating soluble salts with a base of this earth, by means of alkaline carbonates. The carbonate of barytes crystallizes in needles, or in six-sided prisms. It has no taste. The specific gravity is 3.6750. It is

1328 Properties. not changed by exposure to the air, and it is nearly insoluble in water. When it is strongly heated in a crucible, to produce fusion, it is deprived of part of its carbonic acid. When heated under the blow-pipe, it melts into an opaque, vitreous globule, and gives out a purple flame.

1329 Composition. 3. The component parts of this salt, according to different chemists, are,

	Hope.	Klaproth and Kirwan.	Pelletier.
Acid	30.2	30.	30
Strontites	61.2	69.5	62
Water	8.6	0.5	8
	100.0	10.00	100

12. Arseniate of Strontites.

When arsenic acid is dropped into a solution of strontites in water, a copious precipitate is formed, which is redissolved when there is an excess of acid. When the arseniate of strontites is neutralized, it is only in a slight degree soluble in water *.

* Edin. Trans. iv. 17.

13. Tungstate of Strontites.
14. Molybdate of Strontites.
15. Cromate of Strontites.
16. Columbate of Strontites.
} Unknown.

17. Acetate of Strontites.

1. This compound of acetic acid and strontites is formed by dissolving the carbonate in the acid. By evaporation the salt may be obtained crystallized. 1330 Preparation.

2. The crystals remain unaltered by exposure to the air. They change vegetable blues to green, and are equally soluble in hot and cold water †. 1331 Properties.

† Edin. Trans. iv. p. 14.

18. Oxalate of Strontites.

The compound of oxalic acid and strontites is formed by the direct combination of the acid with the earth in solution. A precipitate appears in the form of a white powder, which is nearly insoluble in water. It is decomposed by heat.

The component parts of this salt are,

Acid	40.5
Strontites	59.0
	100.0

19. Tartrate of Strontites.

1. This salt is formed by dissolving the earth in the acid. The crystals are in the form of small triangular tables; they are not altered by the air, are insipid to the taste, and soluble in 320 parts of boiling water.

2. The constituent parts of this salt are,

Acid and water	47.12
Strontites	52.88
	100.00

20. Citrate of Strontites.

1. This combination of citric acid with strontites may be formed by mixing together a solution of nitrate of strontites and citrate of ammonia. A double decomposition takes place, but no precipitate is formed. By slow evaporation, crystals of citrate of strontites may be obtained.

2. This salt is soluble in water.

21. Malate of Strontites.

This salt is scarcely known.

22. Gallate of Strontites.

Little known also.

23. Benzoate of Strontites.

Unknown.

24. Succinate of Strontites.

Succinic acid combines with strontites, and forms crystals, which may be obtained by slow evaporation.

12.

nesia, &c. 25. Camphorate, suberate, mellate, lactate, prussiate, and sebate of strontites. Unknown.

Sect. IV. *Of Magnesia and its Combinations.*

332 History. 1. Magnesia was first known about the beginning of the 18th century, when it was sold by a Roman canon, under the name of *magnesia alba* or *white magnesia*, and *the powder of the count of Palma*, as a cure for diseases; and like many new remedies, it was considered as universal. In the year 1707, Valentini discovered that this boasted *panacea* was the produce of the calcined ley which remains after the preparation of nitre. He gave it the pompous name of *the laxative powder of many virtues*. In the year 1709, Slevogt described the method of obtaining it by precipitation, from the mother ley of nitre. Lancisi and Hoffmann examined some of its properties in 1717 and 1722; and although the latter discovered that it formed different combinations with acids from those of lime, it was generally confounded with this latter substance.

But the nature of magnesia was not fully known, till Dr Black, in 1755, entered upon his celebrated investigations of the different properties of this substance, lime and the alkalies, in the mild and caustic state. Margraaf published the result of his experiments and researches on it in 1759, in which he gave many distinctive characters of this earth, and of its combinations; and, at last, by the observations of Bergman, published in 1775, and those of Butini of Geneva in 1779, the nature and properties of magnesia were fully demonstrated.

33 Preparation. 2. Magnesia, although it exists in great abundance in combination with other substances, has never been found perfectly pure in nature. The process by which it may be obtained in greatest purity, is the following. A quantity of Epsom salt, which is a compound of sulphuric acid and magnesia, is to be dissolved in water, and then precipitated by potash. The precipitate which is formed is to be well washed and dried, both with cold and hot water, to separate any saline matters with which it may be mixed. The nature of this process is obvious. The potash has a stronger affinity for sulphuric acid than magnesia. It therefore combines with the acid, and the magnesia is precipitated.

34 Properties and analysis. 3. Magnesia, when it is obtained pure, is in the form of a fine white powder, or in white friable cakes resembling starch. It has no smell, and no sensible taste; but becomes dry, and leaves on the tongue a slight sensation of bitterness. Its specific gravity, according to Kirwan, is 2.330. It gives a slight tinge of green to syrup of violets, or other delicate vegetable blues. It is decomposed by the same process as lime; and an amalgam of magnium, its base, is obtained. This base itself, however, has never been procured in a separate state.

35 Action of heat. 4. Magnesia is not acted upon by light. It is not melted when exposed to the greatest heat. By strong calcination it becomes finer, whiter, and more friable. When it is exposed to heat in the form of paste with water, it contracts its dimensions, and acquires a phosphoresent property; for when it is strongly rubbed on a hot iron plate, it becomes luminous in the dark. It is not altered by the action of the blow-pipe on charcoal, but gives out a flame of a slight yellow colour. Magnesia, &c.

5. There is no action between magnesia and oxygen or azote. When exposed to the air, it attracts a little moisture from the atmosphere, but this goes on very slowly. 1336 Of air.

Butini exposed a quantity of magnesia for the space of two years in a porcelain cup slightly covered with paper, and he found that it had acquired only $\frac{1}{144}$ part of its weight in addition, during that time.

6. There is no action between magnesia and hydrogen or carbon, and very little between it and phosphorus.

7. Magnesia is very little soluble in water. According to Mr Kirwan it requires near 8000 times its weight of cold water to dissolve it. Butini found, that water boiled with this substance, and left in contact with it for three months, had scarcely acquired $\frac{1}{10000}$ part of its weight; but water combines with magnesia in the solid state. One hundred parts of magnesia, according to Bergman, thrown into water, and taken out and dried, acquired 18 parts of additional weight. 1337 Of water.

8. Magnesia enters into combination with the acids, and forms with them peculiar salts. The order of its affinities is the following, according to Bergman. 1338 Affinities.

Oxalic acid,
Phosphoric,
Sulphuric,
Fluoric,
Arsenic,
Saclactic,
Succinic,
Nitric,
Muriatic,
Tartaric,
Citric,
Lactic,
Benzoic,
Acetic,
Boracic,
Sulphurous,
Carbonic,
Prussic.

9. Magnesia does not enter into combination with the fixed alkalies; but in combination with some of the earths, it becomes fusible by means of a strong heat. With lime in certain proportions, it forms a greenish yellow glass. 1339 Of earths.

10. Magnesia is much employed in medicine as a gentle laxative, and as an absorbent to destroy the acidity in the stomach. It is used in pharmacy to suspend or aid the solution of resinous and gummy substances, such as camphor and opium, in water, which are otherwise little soluble. 1340 Uses.

I. Of Sulphuret of Magnesia.

1. Magnesia enters into combination with sulphur, either in the dry or humid way. Two parts of magnesia and one of sulphur, put into a crucible, and exposed to heat, form an orange yellow mass, which is not very soluble in water, but emits the odour of sulphurated hydrogen gas, when it comes in contact with that liquid, and which is very readily decomposed by means 1341 Preparation.

Magnesia, &c. means of heat. The heat that is applied to obtain this sulphuret, must be very moderate, otherwise the sulphur is driven off.

2. The sulphuret of magnesia is formed with more difficulty in the humid way. When two parts of magnesia and one of sulphur in powder, with 20 parts of water, are exposed to heat on a sand bath, the liquid becomes of a pale yellow colour, which is slightly fetid, but has nothing of the strong odour of the other sulphurets. There is formed very little of the sulphuret of magnesia; for the greatest part of the sulphur and magnesian earth remains uncombined. There is very little sulphureted hydrogen produced, the water scarcely exhaling the odour of this gas.

1342 Properties. 3. The solid sulphuret of magnesia decomposes rapidly when exposed to the air. It seems to absorb very little sulphureted hydrogen gas; so that the properties of the hydrosulphuret of magnesia are yet unknown *.

* *Fourcroy Connaiss. Chim.* iii. 160—167.

II. Compounds of Magnesia with Acids.

1. Sulphate of Magnesia.

1343 History. 1. The compound of sulphuric acid and magnesia was formerly known under the name of *Epsom* and *Seidlitz salts*, because it exists in the water of these springs, and *sal catharticus amarus, bitter purging salt*, on account of its properties. It was long confounded with sulphate of soda, till its properties were investigated by Black, Macquer, and Bergman, and its nature and composition fully ascertained.

1344 Preparation. 2. This salt exists abundantly in nature. It is found in many mineral springs, and it forms a considerable proportion of the saline ingredients of sea water. The bittern or mother water of common salt, that is, the water which remains after the crystallization, consists chiefly of sulphate of magnesia. It is therefore rarely prepared by art, by the direct combination of its constituent parts. It is easily purified by dissolving the salt in water, and by evaporation and crystallization.

1345 Properties. 3. The sulphate of magnesia, thus prepared, is crystallized in four-sided prisms, terminated by four-sided pyramids. There is, however, some deviation from this form. The primitive form of the crystal is a quadrangular prism with square bases. The integrant molecule is a triangular prism, whose bases are right-angled isosceles triangles. It has a cool, bitter taste. The specific gravity is 1.66.

1346 Action of water and heat. 4. Exposed to the air it effloresces. It is soluble in its own weight of cold water: boiling water dissolves more than two-thirds of its weight. Exposed to heat, it undergoes the watery fusion, and being deprived of its water of crystallization, it does not melt, nor is it decomposed by the strongest heat. By the action of the blow-pipe it melts with difficulty into an opaque, vitreous globule.

1347 Of alkalies. 5. The sulphate of magnesia is decomposed by the fixed alkalies, but with ammonia it forms a triple salt.

1348 Composition. The component parts of this salt are, according to

	Bergman.	Kirwan. In crystals.	Kirwan. Dry.
Sulphuric acid	33	29.35	63.32
Magnesia	19	17.00	36.68
Water	48	53.65	00.00
	100	100.00	100.00 *.

* *Nichol. Journ.* iii. p. 215.

6. The sulphate of magnesia is employed in medicine as a purgative. From this salt, too, the earth of magnesia is usually extracted. 1349 Uses.

2. Sulphate of Ammonia and Magnesia.

1. This is a triple combination of sulphuric acid with ammonia and magnesia. It is prepared by the partial decomposition of the sulphate of magnesia by means of ammonia. By evaporating the solution, the triple salt is obtained in crystals. 1350 Preparation.

2. This salt crystallizes in octahedrons. It has a bitter acrid taste, does not effloresce in the air, is less soluble in water than either of the salts of which it is composed, but it is more soluble in hot than in cold water, and it crystallizes on cooling. By heat it undergoes the watery fusion. It then dries and is decomposed. The component parts of this salt are, 1351 Properties.

Sulphate of magnesia	64
of ammonia	32
	100 †.

† *Fourcr. Connaiss. Chim.* iii. 49.

3. Sulphite of Magnesia.

1. The compound of sulphurous acid and magnesia is formed by passing sulphurous acid gas into two parts of water, with one of carbonate of magnesia. A violent effervescence takes place, with the evolution of heat. The sulphite of magnesia is formed, and precipitated to the bottom in the state of powder; but with an excess of acid it is re-dissolved, and crystallizes. 1352 Preparation.

2. The crystals of sulphite of magnesia are in the form of depressed transparent tetrahedrons. It has a mild earthy taste, which soon becomes sensibly sulphureous; it has no smell. Its specific gravity is 1.3802. 1353 Properties.

3. It effloresces in the air, and is slowly converted into sulphate of magnesia. It is soluble in 20 parts of cold water. Boiling water dissolves a greater proportion, and from this it crystallizes on cooling. Exposed to heat, this salt becomes viscid, and by calcination it loses 0.45 of its weight. If the heat be increased, it is decomposed; the acid is driven off, and the pure earth remains behind. 1354 Action of air, &c.

The component parts of this salt are,

Sulphurous acid	39
Magnesia	16
Water	45
	100

4. Sulphite of Ammonia and Magnesia.

1. This triple salt is formed by decomposing the sulphite of ammonia by magnesia, or the sulphite of magnesia by ammonia, in solution in the cold; or, by mixing together the solutions of the two salts. 1355 Preparation.

2. This salt is in transparent crystals, the form of which has not been determined. When it is exposed to the air, it is converted into sulphate of ammonia and magnesia. It is less soluble in water than either of the two sulphites of which it is formed. By the action of heat, sulphurous acid is given out, acidulous sulphite of ammonia is sublimed, and there remains behind pure magnesia †. 1356 Properties. 1357 Action of heat.

† *Ibid.* p. 89.

5. Nitrate of Magnesia.

1. This compound of nitric acid and magnesia was formerly

gnesia, &c. formerly called *nitre with base of magnesia*, and magnesian *saltpetre*. It is formed by the direct combination of the acid with the earth. By evaporation it is crystallized.

1359 perties. 2. This salt crystallizes in four-sided rhomboidal prisms, whose summits are oblique or truncated. Sometimes it is in the form of small needles combined in groups. The taste is penetrating and bitter. The specific gravity is 1.736.

1360 ion of er. 3. It is deliquescent in the air, and is soluble in its own weight of cold water. It is more soluble in boiling water, in which it crystallizes on cooling; but it can only be obtained in regular crystals by slow evaporation from its solution in cold water.

1361 heat. 4. By the action of heat it undergoes the watery fusion; the water is driven off, and it becomes dry. It is decomposed in a strong heat, gives out a little oxygen gas, then nitrous gas, and at last the nitric acid.—The pure earth remains behind.

1362 posi-t The component parts of this salt are, according to

	Bergman.	Kirwan.
Acid	43	46
Magnesia	27	22
Water	30	32
	100	100

6. Nitrate of Ammonia and Magnesia.

1363 para-t. 1. This triple salt is formed, either by the direct combination of the solutions of nitrate of ammonia, and nitrate of magnesia, by which the salt is obtained pure and crystallized; or, by partially decomposing the nitrate of ammonia by magnesia, or the nitrate of magnesia by ammonia.

1364 perties. 2. The crystals of this salt are in the form of fine prisms. It has a bitter, acrid, and ammoniacal taste. It is less deliquescent in the air than either of the constituent salts, and less soluble in water. It requires 11 parts of cold water to dissolve it, but less of boiling water. It crystallizes on cooling.

1365 on of h. When it is rapidly heated, it inflames spontaneously. When slowly heated in close vessels, it gives out oxygen gas, azotic gas, a greater proportion of water than it contains, nitrous gas, and nitric acid, without the smallest trace of ammonia; which shows that it is decomposed, that the hydrogen combines with the oxygen of the acid, and forms water.

1366 posi-t. The component parts of this salt are,

Nitrate of magnesia	78
———— ammonia	22
	100*.

ourcroy naiss. n. iii. 44.

7. Nitrite of Magnesia.

Nothing is known of the properties of this salt.

8. Muriate of Magnesia.

1367 ud na- 1. This compound of muriatic acid and magnesia was formerly called *marine salt of magnesia*, and was confounded with the muriate of lime, with which it is frequently accompanied. The difference between these two salts was first pointed out by Dr Black, and Bergman afterwards examined the nature and properties of muriate of magnesia. The salt is obtained by dissolving magnesia in muriatic acid till they are saturated, and then evaporating the solution. Small irregular crystals are obtained. This salt exists in the waters of the ocean, and in mineral waters, along with the muriates of soda and lime. Magnesia, &c.

2. It is extremely difficult to obtain the muriate of magnesia in any regular form. It is either in the state of powder, or very small regular needles, or in a kind of jelly. It has a disagreeable bitter taste. The specific gravity is 1.601. 1368 Properties.

3. It is very deliquescent in the air. Cold water readily dissolves its own weight, and it is still more soluble in boiling water.

4. It is completely decomposed by heat; the acid is driven off, and the pure earth remains behind *. 1369 Action of heat.

1370 Composition.

	Bergman.	Kirwan.
Acid	34	34.59
Magnesia	41	31.07
Water	25	34.38
	100	100.04†.

* Fourcroy iii. 204.

† Nichol-son's Journ. iii. 215.

9. Muriate of Ammonia and Magnesia.

This triple salt is formed by mixing the solutions of muriate of magnesia and muriate of ammonia; and by evaporating the solution the salt crystallizes in the form of small polyhedrons. It has a bitter, ammoniacal taste. It is little altered by exposure to the air, and is soluble in six parts of cold water. It is decomposed by heat. The muriate of ammonia is sublimed, and the muriate of magnesia is deprived of its acid. 1371 Preparation. 1372 Properties.

The component parts of this salt are, 1373 Composition.

Muriate of magnesia	73
———— ammonia	27
	100

10. Hyperoxymuriate of Magnesia.

This is similar in its chemical and physical properties to the hyperoxymuriate of lime, and it is prepared in the same way. It is precipitated by lime and ammonia.

The component parts are, 1374 Composition.

Acid	60
Magnesia	25.7
Water	15.3
	100.0*.

* Phil. Trans. 1802, p. 149.

11. Fluate of Magnesia.

1. This salt is formed by combining together fluoric acid and magnesia. According to Scheele, it precipitates in the form of a gelatinous mass; but Bergman observes that great part of the salt is deposited as the saturation approaches. By evaporating the solution, crystals in the form of six-sided prisms, terminated by a low pyramid composed of three rhomboidal sides, are obtained. 1375 Preparation. 1376 Properties.

2. This salt is not decomposed by the strongest heat, or by any acid.

12. Fluate of Ammonia and Magnesia.

This triple salt is formed, by mixing the solutions of the fluate of ammonia and magnesia. A precipitation is formed, which is the triple salt in crystals. The properties of this salt are unknown †.

† Fourcroy, iii. 308.

13. Borate

Magnesia, &c.

13. Borate of Magnesia.

1377 Preparation. 1. This salt is formed by the direct combination of boracic acid with magnesia. The earth is slowly dissolved, and when the solution is evaporated, crystals are obtained.

1378 Properties. 2. The crystals of this salt are very small and irregular. It melts when exposed to heat, without being decomposed; but it may be decomposed, it is said, by alcohol ‡.

‡ Ibid 319.

14. Borate of Magnesia and Lime.

1379 Found native. 1. This salt, which has been lately discovered native, is called by mineralogists *cubic quartz*. It was analyzed by Westrumb in 1788. It is an insipid salt, and is regularly crystallized in polyhedrons of 22 faces. The specific gravity is 2.566.

1380 Properties. 2. It is not altered by exposure to the air, nor is it soluble even in boiling water. Exposed to a strong red heat, the crystals lose their lustre; and with a white heat they decrepitate, and at last melt into a yellow coloured glass.

1381 Composition. 3. The component parts of this salt are,

Acid	73.5
Magnesia	14.6
Lime	11.9
	100.0

15. Phosphate of Magnesia.

1382 Preparation. 1. This salt may be obtained by the direct combination of phosphoric acid and carbonate of magnesia; for, it may be prepared by mixing together phosphate of soda and sulphate of magnesia in solution. In a few hours, large, transparent crystals are formed in the solution.

1383 Properties. 2. This salt crystallizes in six-sided prisms with unequal sides, but it is frequently in the form of powder. It has a cooling, sweetish taste. The specific gravity is 1.5489.

1384 Action of water. 3. It effloresces in the air, is not very soluble in cold water, and requires about 50 parts of boiling water for its solution, and part of it crystallizes on cooling.

1385 Of heat. When it is heated, it is easily deprived of its water of crystallization, and if the heat be moderate, it melts and falls down into a white powder. With a stronger heat, it is melted into glass.

16. Phosphate of Ammonia and Magnesia.

1386 Found native. 1. This triple salt was discovered by Fourcroy in a calculous concretion, found in the colon of a horse. The results of his experiments on this substance have been confirmed by Berthollet and Vauquelin.

1387 Composition. 2. It may be prepared artificially, by mixing together a solution of phosphate of magnesia with a solution of phosphate of ammonia.

1388 Properties. 3. The crystals are in the prismatic form, but cannot be accurately ascertained. This salt has no taste. In the concrete form, it is found in the cavities of animal bodies, and sometimes it is crystallized, but most frequently lamellated and semitransparent.

1389 Action of heat. 4. It is not changed by the action of the air, and is scarcely soluble in water. When it is heated moderately, it falls to powder. With a strong heat it is deprived of the ammonia, and under the blow-pipe it melts into a transparent globule. It is decomposed by the sulphuric, nitric, and muriatic acids.

1390 Common salt. The component parts of this salt found in the intestine of the horse are,

Phosphate of ammonia	33.3
——— magnesia	33.3
——— water	33.3
	100.0

17. Phosphite of Magnesia.

1391 Preparation. 1. This salt may be prepared by directly combining phosphorous acid with magnesia. Or it may be obtained in a purer state, and crystallized, by mixing together solutions of phosphites of soda or of potash, and sulphate of magnesia, by which means it is obtained in brilliant milky flakes.

1392 Properties. 2. This salt, which has no sensible taste, sometimes crystallizes in the form of tetrahedrons. It effloresces in the air, and is soluble in 400 parts of cold water. When exposed to heat, it suddenly swells up, and melts into a glass. Under the blow-pipe it gives out a phosphoric light, and becomes opaque on cooling.

The component parts of this salt are,

Acid	44
Magnesia	20
Water	36
	100

18. Phosphite of Ammonia and Magnesia.

This salt is formed by the partial decomposition of phosphite of ammonia by means of magnesia, or by mixing together the solutions of the two phosphites. If the solutions be sufficiently concentrated, the triple phosphite is readily deposited. It forms crystals, and has little solubility in water. Its other properties are unknown.

19. Carbonate of Magnesia.

1393 Names, preparation. 1. This salt, which was first distinguished by Dr Black, has been called *mild magnesia*, *aërated magnesia*. It is formed by mixing together sulphate of magnesia and carbonate of potash in solution. Or it may be obtained by dissolving pure magnesia in water saturated with carbonic acid. The salt, as the solution is evaporated, crystallizes.

1394 Properties. 2. The magnesia of commerce, which is in the state of powder, or light friable cakes, is not fully saturated with the acid. But when it is crystallized by the above processes, it is in the form of transparent six-sided prisms, terminated by a hexagonal plane. This salt has little taste. The specific gravity is 0.2941.

1395 Action of water and heat. 3. When it is crystallized, it soon loses its transparency in the air. It is soluble in 48 parts of cold water. Exposed to heat in a crucible it slightly decrepitates, is deprived of its water and acid, and falls down into a powder. It is decomposed by all the acids. The component parts of this salt are, according to

1396 Composition.

	Bergman.	Butini.	Fourcroy.
Acid	30	36	50
Magnesia	45	43	25
Water	25	21	25
	100	100	100

The

Magnesia, &c.

The magnesia of commerce is composed of

	Fourcroy.	Kirwan.
Carbonic acid	48	34
Magnesia	40	45
Water	12	21
	100	100

20. Carbonate of Ammonia and Magnesia.

This triple salt is prepared by decomposing carbonate of ammonia by means of magnesia; or by precipitating a solution of carbonate of magnesia by means of pure ammonia. This salt, however, has not been particularly examined.

21. Arseniate of Magnesia.

When arsenic acid is saturated with magnesia, a thick matter forms towards the point of saturation, which is soluble in excess of acid; but when it is evaporated, it does not crystallize. It assumes the form of a jelly. It is decomposed by the alkaline arseniates.

22. Tungstate of Magnesia.

This acid, in combination with magnesia, forms a salt which appears in the form of brilliant scales. It is not altered by exposure to the air, and it is soluble in water. It is decomposed by acids, and a white powder is precipitated.

23. Molybdate of Magnesia.
24. Chromate of Magnesia.
25. Columbate of Magnesia.
} Unknown.

26. Acetate of Magnesia.

This salt is formed by the direct combination of magnesia with acetic acid. It does not crystallize, but a viscid mass remains when the solution is evaporated. It has a sweetish taste, leaving afterwards an impression of bitterness. The specific gravity is 1.378. It deliquesces in the air, is very soluble in water, and is decomposed by heat.

27. Oxalate of Magnesia.

This salt is formed by combining oxalic acid with magnesia, and evaporating the solution. A salt is obtained in the form of white powder, which is scarcely soluble in water. It is decomposed by heat. The component parts of this salt are,

Acid and water	65
Magnesia	35
	100

28. Tartrate of Magnesia.

This compound of tartaric acid and magnesia forms a salt which is insoluble in water, without an excess of acid. When this is the case, it crystallizes by evaporation. The crystals are in the form of hexangular truncated prisms. It is first melted, and then decomposed by heat.

29. Citrate of Magnesia.

This salt is obtained by dissolving carbonate of magnesia in citric acid. From the thick solution of this salt there is no crystallization; but after some days, by a slight agitation, it assumes the form of a white opaque mass, which remains soft, as it separates from the edges of the vessel. The component parts of this salt are,

Acid	66.66
Magnesia	33.34
	100.00 *

* Fourcroy, vii. 208.

30. Malate of Magnesia.

This is a deliquescent salt, and very soluble in water.

31. Gallate of Magnesia.

Magnesia boiled with an infusion of nut galls, affords a clear liquid, which assumes a green colour. By evaporation to dryness the green colour vanishes, and the acid is decomposed.

32. Benzoate of Magnesia.

The combination of benzoic acid with magnesia affords plumose crystals which are easily soluble in water. This salt has a bitter taste.

33. Succinate of Magnesia.

This salt, which is formed by the combination of succinic acid and magnesia, does not crystallize. It is a white glutinous mass, which is deliquescent in the air.

34. Saccolate of Magnesia.

This salt is insoluble in water.

35. Camphorate of Magnesia.

1397 Preparation.

1. This salt is formed by mixing carbonate of magnesia with water, and adding crystallized camphoric acid. A slight effervescence takes place. The temperature should be increased, to drive off the carbonic acid. The solution is filtered while it is hot, and evaporated to dryness. The mass is dissolved in distilled water, filtered and evaporated by a gentle heat, till a pellicle appears on the surface. By cooling, there are deposited small plates, which are heaped upon each other.

1398 Properties.

2. This salt, which does not crystallize, is white and opaque, and has a bitter taste. In the air it is slightly efflorescent. It is not very soluble in water. Boiling water dissolves a little, but it is precipitated in cooling. When it is thrown on red-hot coals, the acid is volatilized, and pure magnesia remains behind. By the action of the blow-pipe it gives out a bluish flame. It is decomposed by sulphuric, nitric, and muriatic acids *.

* *Ann. de Chim.* xxvii. p. 37.

36. Suberate of Magnesia.

The compound of suberic acid and magnesia is in the form of powder. It has a bitter taste, is deliquescent in the air, and soluble in water. It reddens the tincture of turnsole. Exposed to heat, it swells up and melts. By the action of the blow-pipe, the salt is decomposed, the acid is driven off, and pure magnesia remains behind. The sulphuric, nitric, and muriatic acids, decompose it. It is also decomposed by the alkalies, barytes, and lime †.

† *Ibid.* xxiii. p. 56.

37. Mellate of Magnesia.

Unknown.

38. Lactate of Magnesia.

A salt in small deliquescent crystals.

39. Prussiate of Magnesia.

This salt may be prepared by directly combining prussic acid with pure magnesia; but the magnesia is precipitated when the solution is exposed to the air. It is also decomposed by the alkalies and lime.

Sect. V. *Of Alumina and its Combinations.*

1399 History. 1. *Alumina*, which is now employed to signify one of the simple earths, is derived from the word *alum*, of which this earth forms a constituent part, and from which it is obtained in greatest purity. It was formerly denominated *argil* and *argillaceous earth*. Pott and Margraaf were the first who distinguished this earth from the calcareous earth or lime, and proved that this latter earth could not be obtained from it by calcination. In the year 1739, Hellot shewed, that the basis of alum, separated from this salt by an alkali, was pure argil, or alumina. In 1758 and 1762 Macquer examined this earth, and detailed its characteristic properties. These were afterwards farther elucidated and confirmed by the experiments and researches of Bergman and Scheele, so that the nature and characters of this earth were completely developed, and it was universally admitted as distinct from all others hitherto known.

1400 Preparation. 2. Although alumina exists in great abundance in nature, yet it is rarely found in a state of perfect purity. It may be obtained pure by the following process.

Dissolve a quantity of common alum in water, and add to the solution, a solution of potash or carbonate of potash, or, what is supposed to be still better, liquid ammonia. An abundant white precipitate is immediately formed. Continue the addition of the alkali as long as any precipitate appears. When the whole of the precipitate has collected at the bottom of the vessel, pour off the fluid part, and wash the precipitate repeatedly with large quantities of water, to free it from all saline matters which it may have retained. Dry the precipitate in a moderate heat, and the substance thus obtained is alumina in a state of tolerable purity. If this precipitate retain any portion of sulphuric acid, it may be separated by adding muriatic acid in small quantities at a time, till the whole is dissolved. Evaporate the solution till a drop of it, when suffered to cool on a plate of glass, yields minute crystals. Then set by the solution till it cool, and crystals will be deposited. Let these crystals be removed by pouring off the fluid, and continue the evaporation till no more crystals are formed. In this way the alum which the earth retained may be separated. The liquid which remains is to be mixed with ammonia as long as any precipitate appears. This precipitate, well washed and dried, is pure alumina.

3. The alumina obtained by this process, is either in the form of friable fragments, or of very fine white powder, soft to the touch, and insipid to the taste. It has a peculiar odour, which is distinguished by the name of *earthy smell*, and is only perceptible when it is breathed upon, or moistened (o). It adheres to the tongue in consequence of its rapidly absorbing moisture. The specific gravity is 2. It has never been decomposed, but is, from analogy, concluded to be a compound of a metallic base (alumium) with oxygen. 1401 Properties and composition.

4. Saussure has observed, that alumina exhibits two different appearances, according to the quantity of water which has been employed in the solution of the aluminous salt. If the quantity of water does not exceed what is necessary for the solution of the salt, we obtain a light friable white earth, which is very spongy, and adheres to the tongue. This he calls *spongy alumina*. But when the salt is dissolved in a large quantity of water, we obtain, after drying the precipitate in the same temperature, a yellowish brittle transparent mass, which splits into small fragments, when held in the hand, like solid sulphur. It has a smooth conchoidal fracture, no earthy appearance, does not adhere to the tongue, and does not swell up when put into water. It occupies 10 or 12 times less volume than in the spongy state, and has some resemblance to gum arabic, or a dried jelly. This he distinguishes by the name *gelatinous alumina* *. 1402 Spongy alumina. 1403 Gelatinous.

* Journ. Physique, lii. p. 1[illegible]

5. Alumina undergoes no change by being exposed to light. When it is exposed to heat, it is diminished in bulk, in consequence of being deprived of the water with which it is combined. Accordingly, Saussure has observed, that the spongy alumina, exposed to the same temperature, loses a greater quantity of moisture than the gelatinous alumina. The former, when exposed to a red heat, loses 0.58 part of its weight; but the latter only 0.43 part. When they are both exposed to a very strong heat, the spongy alumina is deprived of no more water than what it gives out with a red heat, while the gelatinous parts with only 0.4825. On this property of the contraction of bulk of alumina when exposed to heat, depends the principle of the thermometer, or pyrometer, of Wedgwood, of which we shall immediately give a short description. 1404 Action of water.

When alumina is exposed to a very strong heat suddenly applied, as by means of the blow-pipe, with a stream of oxygen gas, it is susceptible of a kind of fusion; and, when it is cooled, it appears under the form of an enamel, of a greenish colour, and so hard as to cut glass.

6. Alumina is not soluble in water, but it absorbs and retains that fluid in considerable quantity. With a greater quantity of water it is diffused in it, and may be 1405 Of water.

(o) This smell, however, as it has been justly observed by Saussure, is owing to the oxide of iron, with which the alumina, in its ordinary state of purification, is contaminated; for when it is perfectly pure, and no traces of oxide of iron can be detected, it has no perceptible smell. To alumina which was perfectly inodorous, he communicated this smell, by triturating it with oxide of iron. *Journal de Physique*, lii. p. 287.

uina, :c. be formed into a paste, in which state it is moulded with great facility into any form.

7. There is no action between alumina and oxygen, azote, hydrogen, or phosphorus; and very little between it and sulphur, except when they are in a state of minute division, or in combination with some other substances. Carbone combines with alumina, of which

106 rbone. there are many natural compounds, among the class of bituminous fossils; but even in these compounds, the carbon and alumina are mixed with other earths, and with the oxide of iron.

107 :id. 8. Alumina enters into combination with almost all the acids, and forms salts which are more or less soluble and susceptible of crystallization. Some are insoluble in water, and others require an excess of acid.

108 ties. 9. The order of its affinity for the acids is the following:

Sulphuric acid,
Nitric,
Muriatic,
Oxalic,
Arsenic,
Fluoric,
Tartaric,
Succinic,
Saclactic,
Citric,
Phosphoric,
Lactic,
Benzoic,
Acetic,
Boracic,
Sulphurous,
Carbonic,
Prussic.

.09 kalies. 10. Alumina combines with the fixed alkalies. When they are heated together, an opaque mass, which has little coherence, is formed. Fixed alkali dissolved in water, with the assistance of heat, has the property of dissolving alumina; but from this solution it may be precipitated by means of an acid, and then it is obtained in great purity. Liquid ammonia also holds a small quantity of alumina in solution, if it has been recently precipitated.

.10 rths. 11. Alumina enters into combination with many of the earths, and particularly with lime and silica. These compounds form the chief basis of all kinds of pottery and porcelain. Alumina combines with lime, and enters into fusion with it by means of heat. A compound is also formed with alumina and barytes, or strontites, by exposing them together in a crucible to a strong heat; or, by boiling them together in water. Magnesia and alumina alone do not enter into combination by means of the strongest heat; but a porcelain is obtained from a mixture of lime, magnesia, and alumina. But in the proportions that are employed, it is necessary that the alumina be greatest. The following table shews the results of experiments on these earths in different proportions †.

12. This is one of the most important of the earths, on account of the variety of purposes to which it is applied. It forms the bases of all kinds of earthen ware, from the coarsest brick to the finest china. It is also chiefly employed in the pots or crucibles which are exposed to very strong heat, as in glass manufactnre and cast iron. It is employed also in dyeing and calico-printing, and in the cleaning or scouring of woollen stuffs. It has been applied to a valuable use by the late Mr Wedgwood, in the construction of an instrument capable of ascertaining high degrees of temperature, to which the common thermometer cannot reach. 1411 Uses.

13. This instrument is constructed on the principle of the contraction of pure clay, when it is exposed to heat. Mr Wedgwood took a very pure clay, and formed it into small short cylinders, exactly of the same size. These are baked in a low red heat, to expel the whole of the air and moisture which adhere to the clay. The cylinders are thus prepared for the measurement of strong heats. For this purpose, one of the cylinders is introduced between two rulers, to which a scale is attached, and its bulk is exactly measured. It is then introduced into the furnace whose heat is to be tried, and the temperature is to be estimated according to the diminution of bulk which the cylinder has sustained. The quantity of contraction is measured by means of two metallic rulers, which are fixed upon a plate. These rulers are 24 inches in length, and are divided into 240 parts. The distance between the rulers at the upper extremity of the scale is 0.5 of an inch, and at the lower extremity 0.3 of an inch. The size of the clay cylinder, before it is introduced into the furnace, nearly fits the upper part of the scale; or at least the degree at which it stands, before it is introduced into the furnace, is marked. After being heated, the clay cylinder is again applied to the scale, and the diminution of bulk is measured by the distance at which it stands between the rulers from the top of the scale, or from the degree at which it stood before it was exposed to the heat. 1412 Wedgwood's pyrometer.

Mr Wedgwood connected the scale of his pyrometer with Fahrenheit's thermometer. The first degree of his scale which marks a red heat, corresponds to the 947° Fahrenheit; but to make this instrument better understood, we may state a few of the corresponding degrees of the two instruments. 1413 Scale of it.

† ...wan ...ral. I.

Alumina, &c.

	Wedgwood.	Fahrenheit.
Red heat	0 =	947

Welding heat of iron	95	13427
Cast iron melts	130	17977
Greatest heat in an air furnace eight inches square	160	21877
Extremity of the scale, or highest temperature observed	240	32277

This instrument has been of considerable importance in some arts and manufactures, and it is undoubtedly fitted to give some information concerning those intense heats which can be measured by no other instrument which has yet been contrived. But as the same kind of clay cannot always be obtained, and as it is probable that the contractions of the cylinders are not proportional to the temperatures, their estimation by this instrument can only be considered as an approximation to certainty.

I. Compounds of Alumina with Acids.

1. Sulphate of Alumina.

1414 Preparation. 1. This is a compound of sulphuric acid and alumina. It may be formed by the direct combination of the acid with the earth. But in the preparation of this salt, the earth and the acid must be in a state of purity, and must be saturated with each other. The solution is then evaporated to dryness; the salt is again dissolved in distilled water, and evaporated slowly till it crystallizes.

1415 Properties. 2. The crystals of this salt are in the form of thin plates, soft and pliant, with a brilliant pearly lustre, and of an astringent taste. It is not altered by exposure to the air; it is very soluble in water, but it does not crystallize readily. 1416 Action of heat, &c. When it is heated, it is infusible; but by long calcination, it dries and falls down to powder. At a high temperature it is decomposed, and the acid is driven off.

3. The sulphuric acid readily combines with this salt, and forms with it an acidulous sulphate of alumina. This salt has a more acid taste than the former; it crystallizes with more difficulty, and the crystals have more brilliancy. It reddens vegetable blues, and frequently assumes the form of a thick gelatinous mass.

4. All the alkaline and earthy bases, except silica and zirconia, decompose either of these two salts. The saturated sulphate of alumina, according to Bergman, is composed of

1417 Composition.

Sulphuric acid	50
Alumina	50
	100

2. Acidulous Sulphate of Alumina and Potash, or Alum.

1418 History. 1. The alum of commerce, now of such extensive utility in many of the arts and manufactures, was imported into Europe from Asia, previous to the 15th century, during which it was begun to be manufactured in Italy. Alum works were erected in Spain and Germany in the 16th century; and towards the end of it, a manufactory of this salt was established in Yorkshire in England. But the true nature of alum has been only of late understood. It is to the experiments and researches of Vauquelin that we are indebted for the knowledge of its component parts.

1419 Preparation. 2. Alum is generally obtained by exposing to the weather for some time aluminous schistus, or what are called *aluminous ores*, which are natural productions sometimes found in the neighbourhood of volcanoes, and sometimes, as in Britain, dug out of coal mines which abound with pyrites or sulphuret of iron. When these substances, which are also mixed with a considerable proportion of clay, are exposed to air and moisture, the sulphur combines with the oxygen of the air, or with that of the water, by decomposing it, and is thus converted into sulphuric acid. This combines with the alumina, and thus there is formed a sulphate of alumina. The salt, thus formed, is dissolved in water, and must be purified by repeated boilings and crystallizations. This aluminous schistus is generally mixed with a considerable proportion of sulphate of iron. From this it is to be separated during the process, and the potash or ammonia, which is necessary to constitute the triple salt, must be added. Even before the component parts of alum were discovered, the addition of potash or ammonia was found to be necessary to complete the process. This was well known to the manufacturers, who supposed that it was necessary to take up a quantity of acid, which being in excess, prevented the granulation, as it was called, or the crystallization of the alum.

1420 Properties. 3. Alum crystallizes in regular octahedrons; but this form is subject to considerable variety, according to the difference of proportion which is found to take place among its component parts. The primitive form of the crystal is the regular octahedron, and the integrant molecule the regular tetrahedron. It has a very astringent, styptic, and somewhat sweetish taste. It usually reddens vegetable blues. The specific gravity is 1.7109.

1421 Action of water and heat. 4. It is little changed by exposure to the air. By long contact there is a slight efflorescence on the surface. Alum is soluble in 16 or 20 parts of cold water. Boiling water dissolves a greater proportion. When exposed to heat, it melts in its water of crystallization. It then swells up, enlarges in volume, and there remains behind a light, porous, dry mass, which has a sharp acid taste, and reddens more strongly vegetable blues. In this state it is called *burnt* or *calcined alum*. When it is exposed to a stronger heat, the acid is driven off.

1422 Varieties. 5. According to the experiments of Vauquelin, there are three kinds or varieties of alum, which, although they possess nearly the same properties, have different constituent parts, or different proportions of the same constituents. The first is sulphate of alumina and potash with an excess of acid; which indeed is necessary to constitute alum. The second consists of alumina and ammonia, also with an excess of acid. The third variety, which is most frequently found among the alum of commerce, is a mixture of both. It contains

Alumina, &c.

tains both potash and ammonia. When an additional quantity of potash is added, the alum crystallizes, not in its usual form, but in the form of cubes, and hence it has been denominated *cubic alum.* If a still greater quantity of potash be added, the crystallization is nearly interrupted; and it then appears in the form of flakes.

23 Composition. The component parts of alum are, according to

	Vauquelin.		Kirwan.
Sulphate of alumina	49	Acid	17.66
——— potash	7	Base	12.00
Water	44	Water	70.34
	100		100.00

24 Action of charcoal. 6. The three varieties of alum are nearly decomposed in the same way, by combustible substances. If alum be exposed to a moderate heat with charcoal, it is converted into the state of neutral salt, because the charcoal acts on the excess of acid, before it can effect the decomposition of the salt; but when it is strongly heated, there is formed with the sulphate of alumina and potash a black substance, which spontaneously takes fire in the air. This substance has been distinguished by the name of *pyrophorus;* and it is called *Homberg's pyrophorus,* because it was discovered by that chemist.

25 Pyrophorus. Pyrophorus is prepared by mixing together three parts of alum, and one of flour or sugar, in an iron ladle, and exposing the mixture to heat till it ceases to swell, and becomes black. It is then to be reduced to powder, put into a glass phial, and again exposed to heat, till a blue flame proceeds from the mouth of the phial. After it burns for a minute, it is allowed to cool, and must be kept in a well-closed bottle.

26 Properties. 7. The pyrophorus thus formed, contains a hydrogenated sulphuret of potash and alumina, mixed with charcoal in a state of minute division. It kindles more readily in humid than in dry air. The oxygen gas of the atmospheric air is absorbed. Part is converted into carbonic acid, and part combines with the sulphur, and forms sulphuric acid; so that when the pyrophorus is burnt, it no longer contains the hydrogenated sulphuret as before, but sulphate of alumina and potash; not in the state of alum, because it has been deprived of the excess of acid, which gives alum its peculiar character.

8. Pyrophorus gives out a very fetid odour, when it is thrown into water, and leaves behind a sulphuret of potash, and of hydrogenated alumina. It is inflamed by nitrous gas, and by oxymuriatic acid gas *.

*Fourcroy, iii. 59.

27 Uses of alum. 9. The uses of alum are very numerous. It is employed in medicine as an astringent and styptic. It is also employed in the arts of bleaching, of tanning, dyeing, calico-printing, and others. It is sometimes used in preserving animal matters from putrefaction, and it might be employed for the purpose of securing wood from catching fire.

28 Preparation. *Sulphate of alumina and potash.*—1. If a solution of crystallized alum be boiled with a solution of pure alumina, the saturated sulphate of alumina and potash is formed. The excess of acid, it is obvious, in this process, enters into combination with the alumina. The alum, as the earth is added, is gradually precipitated in the solution, in the form of a white powder.

2. This salt, saturated with alumina, never assumes any regular form. It has no taste, is not changed by exposure to the air, is not soluble in water, and when it is exposed to heat, it is not altered, except at a very high temperature. This salt is less easily decomposed than any of the other varieties of sulphate of alumina. By the action of some of the acids it is converted into alum, which is owing to the acid combining with the additional portion of alumina that saturated the excess of acid existing in the alum. This salt has been applied to no use. 1429 Properties.

3. Sulphite of Alumina.

1. The compound of sulphurous acid and alumina is prepared by passing sulphurous acid gas into water in which pure alumina is mixed or suspended. 1430 Preparation.

2. The sulphite of alumina, thus formed, is in the state of a white, soft powder, which has at first an earthy taste, and becomes afterwards sulphureous. When it is exposed to the air for a long time, it is converted into the sulphate of alumina, and more rapidly if it be combined with an excess of sulphurous acid. It is insoluble in water. Exposed to heat, the acid is driven off, and partially decomposed, for there remains behind a small quantity of sulphur. The component parts of this salt are 1421 Properties. 1432 Composition.

Sulphurous acid	32
Alumina	44
Water	24
	100

4. Nitrate of Alumina.

1. This salt was formerly known under the names of *nitre of argil,* and *nitrous alum.* It is formed by the direct combination of the nitric acid with alumina. It has been found impossible to neutralize the acid; and it cannot be obtained crystallized, excepting in the form of thin plates, and often only in a gelatinous mass. 1433 Preparation.

2. This salt has an austere and acid taste. The specific gravity is 1.645. It is deliquescent in the air, and extremely soluble in water. When it is heated, the acid is driven off, and the pure earth remains behind. It is readily decomposed by the sulphuric acid, which disengages the nitric acid; and by the muriatic acid, which is converted into the oxymuriatic acid. 1434 Properties.

5. Nitrate of Alumina.

This salt is unknown.

6. Muriate of Alumina.

1. This salt, which is a compound of muriatic acid and alumina, is formed by the direct combination of the acid with the earth; but is never neutralized. The acid is always in excess. 1435 Purification.

2. This salt is rarely crystallized, but most frequently in the form of white powder, or in that of a gelatinous mass. It has an astringent, acid, and sharp taste. It reddens the tincture of turnsole and of violets. It is extremely deliquescent in the air, and very soluble in water. When it is exposed to heat it melts, and is decomposed. 1436 Properties.

Alumina, &c.

composed. The acid is separated, and the pure alumina remains behind. It is decomposed in the same way as the other muriates.

7. Hyperoxymuriate of Alumina.

1. This salt is prepared by passing oxymuriatic acid gas through water in which newly precipitated alumina is suspended. The alumina disappears, and when sulphuric acid is poured into the solution, a strong smell of hyperoxymuriatic acid gas is perceived.

2. This salt is deliquescent, and it is soluble in alcohol. Mr Chenevix could not ascertain the proportion of its principles*.

* Philos. Trans. 1802. p. 149.

8. Fluate of Alumina.

The combination of fluoric acid and alumina affords a salt which cannot be crystallized, but which is in the form of a jelly. It has always an excess of acid, and an astringent taste. It is decomposed by all the earthy and alkaline bases. With the latter it forms triple salts.

9. Borate of Alumina.

It is extremely difficult to form a compound of alumina and boracic acid by direct combination. This salt may be formed by mixing together a solution of borate of soda, with a solution of sulphate of alumina. Its properties have not been examined.

10. Phosphate of Alumina.

This salt is little known. By saturating phosphoric acid with alumina, a white powdery mass is obtained, which has little tate, except there be an excess of acid, and then it seems to form an acidulous salt. It melts under the blow-pipe into a transparent globule, without decomposition. It is decomposed by the alkalies, some of the earths, and the acids.

11. Phosphite of Alumina.

1. This salt is formed by the direct combination of phosphorous acid with alumina. The solution is to be evaporated to a proper consistence.

2. The phosphite of alumina does not crystallize, but forms a thick, viscid, gummy mass, which becomes dry and solid in the air. It has an astringent taste, is very soluble in water, swells up when it is heated, and gives out a phosphoric light. It is decomposed by all the alkaline and earthy bases.

12. Carbonate of Alumina.

1437 This compound little known. Little is known of the combination of carbonic acid and alumina. Bergman had observed, when alum was precipitated by an alkaline carbonate, that very little or no effervescence took place; he therefore concluded, that the carbonic acid, not being driven off, must have combined with the alumina which was precipitated. And besides, he found that the liquid contained a portion of carbonate of alumina, which is deposited some hours or some days afterwards by the evaporation of the carbonic acid, which held it in solution.

Common clay, which is a mixture of alumina and silica, contains a certain portion of carbonic acid, which is disengaged by the application of strong heat. He obtained from one species of clay several times its volume of this acid, mixed with a small portion of hydrogen gas. It is owing to the same combination of carbonic acid, that clays, treated with acids, effervesce, without containing any carbonate of lime.

According to Saussure, alumina is dissolved in water, which is saturated with carbonic acid; but when the solution is exposed to the air, it is decomposed. 1438 The acid combined with water.

13. Arsenic of Alumina.

This salt is formed by dissolving alumina in arsenic acid, and evaporating the solution to dryness. A thick mass is thus obtained, which is insoluble in water. It is decomposed by the sulphuric, nitric, and muriatic acids, as well as by the earthy and alkaline bases.

14. Tungstate of Alumina.

This salt has not been examined.

15. Molybdate, chromate, and columbate. Unknown.

18. Acetate of Alumina.

The acetic acid enters into combination with alumina, and forms with it small needle-shaped crystals, which are soft, deliquescent, and have an astringent taste. The specific gravity of this salt is 1.245. Its other properties are unknown.

19. Oxalate of Alumina.

Oxalic acid very readily combines with alumina. When the solution is evaporated, a yellowish, soft, transparent mass is obtained, but it does not crystallize. 1439
This salt has an astringent taste, is deliquescent, and reddens the tincture of turnsole. When it is heated, it swells up, is deprived of its acid, and the alumina remains behind, slightly coloured. It is decomposed by the stronger acids. Properties.

The component parts of this salt are, 1440 Composition.

Acid and water	56
Alumina	44
	100

20. Tartrate of Alumina.

Alumina enters into combination with tartaric acid, and forms an uncrystallized, gelatinous mass, which has an astringent taste, is not deliquescent in the air, but is soluble in water.

21. Citrate of Alumina.

The properties of this salt have not been examined.

22. Malate of Alumina.

When malic acid is added to a solution containing alumina, a precipitate is formed, which is scarcely soluble in water.

23. Gallate of Alumina.

If pure alumina be added to a solution of nut-galls, an insoluble compound is formed with the tannin and extract. The liquid remained clear and white, and it afforded by evaporation, small crystals, which are gallate of alumina with excess of acid *.

* Phil. Trans. 1803. p. 244.

24. Benzoate of Alumina.

The compound of benzoic acid and alumina affords a salt,

salt, which crystallizes in an arborescent form. It has a bitter taste, is deliquescent in the air, soluble in water, is decomposed by the action of heat, and even by most of the vegetable acids.

25. Succinate of Alumina.

The compound of succinic acid and alumina affords salts which crystallize in the form of prisms, and are easily decomposed by heat.

26. Saccolate of Alumina.

This compound of saclactic acid and alumina forms a salt which is insoluble in water.

27. Camphorate of Alumina.

441 Preparation. 1. The compound of camphoric acid and alumina is formed by precipitating alumina by means of ammonia, washing the precipitate, and diluting it with distilled water. Crystals of camphoric acid are then to be added. The mixture is to be heated, filtered, and evaporated.

442 Properties. 2. A white powder is then obtained, which has a bitter, acid, and astringent taste. It reddens vegetable blues. This salt is scarcely altered by exposure to the air. Water dissolves about $\frac{1}{100}$ part of its weight. Boiling water dissolves it more readily; but on cooling, a precipitate is formed. When it is exposed to heat, it swells up, and the acid is volatilized. By the action of the blow-pipe, a blue flame is produced, the salt is decomposed, and the pure alumina remains behind. This salt is decomposed by the mineral acids, and even by some of the vegetable acids. It is also decomposed by the nitrates of lime and barytes *.

* Annal. de Chim. t. xxvii. p.

28. Suberate of Alumina.

443 Properties. The compound of suberic acid and alumina may be formed by evaporating the solution with a very moderate heat, in a large open vessel. This salt does not crystallize; but the dried matter which is obtained is transparent, of a yellowish colour, and has a styptic, bitterish taste. When too much heat is employed, the salt melts and blackens. It reddens the tincture of turnsole, and is slightly deliquescent in the air. Exposed to the action of the blow-pipe, the acid is volatilized and decomposed, and the alumina remains behind. It is decomposed by the mineral acids, the earths, and the alkalies †.

† ... xxiii. p.

29. Mellate of Alumina.

The properties of this salt are unknown.

30. Lactate of Alumina.

This is a deliquescent salt.

Sect. VI. *Of Silica and its Combinations.*

44 History. 1. Silica has been distinguished by the names of *siliceous earth*, or *quartzy earth*, because it is obtained from *silex*, or flint, and from the stone called *quartz*. This earth exists in great abundance in nature, and it constitutes the bases of some of the hardest stones of which the nucleus of the globe consists; and, on account of its great abundance, it has been regarded as the primitive or elementary earth, the base of all the other earths. Silica forms one of the constituent parts of most stony bodies; but it exists in greatest abundance in agates, jasper, flints, quartz, and rock crystal; in the latter it is nearly in a state of purity.

2. But to obtain it perfectly pure, a quantity of quartz or rock crystal may be exposed to a red heat. When it is taken from the fire, and while it is yet hot, it is suddenly immersed in cold water. It is then to be reduced to powder; and, if transparent rock crystal has been employed, it is then in a state of tolerable purity. To have it perfectly pure, mix one part of the pounded stone with three parts of potash, and expose them in a crucible to heat which is sufficient for the fusion of the mixture. The mass thus obtained is soluble in water. Add a sufficient quantity of water for its solution, and drop in muriatic acid, as long as there is any precipitate. Let this be repeatedly washed with water, and dried. The substance thus obtained is pure silica. 1445 Preparation.

3. It is in the form of a very fine white powder, which has neither taste nor smell. The particles are rough and harsh to the feel, as when they are rubbed between the fingers, or touched with the tongue. The specific gravity is 2.66. Though never hitherto decomposed, it is assumed to be an oxide of silicium. It may now be observed, once for all, that the remaining earths are in the same situation, with respect to the present state of chemical knowledge. 1446 Properties and composition.

4. Light has no action on silica; and it is one of the peculiar characters of this earth, that it resists, unchanged, the greatest degree of heat. 1447 Action of heat, &c.

5. There is, no action between silica and oxygen, azote or hydrogen, nor is it changed by exposure to the air. It is not acted upon by carbon, phosphorus, or sulphur. It is insoluble in water; but in a state of minute division, it absorbs a considerable portion, and forms with this liquid a transparent jelly. When it is exposed to the air, the whole of the moisture is evaporated.

6. Silica is frequently found in nature in the crystallized form, and then it is distinguished by the name of *rock crystal*. It is most commonly in hexagonal prisms, terminated by hexagonal pyramids. Crystals of silica have also been formed artificially. In a solution of silica in fluoric acid which had remained at rest for two years, Bergman found crystals, some of which were cubes, and some had truncated angles, at the bottom of the vessel. Crystals of silica have also been formed, by diluting largely with water the combination of silica and potash, and allowing it to remain for a long time. Professor Seigling of Erfurt obtained crystals from a solution which had been kept eight years in a glass vessel. A crust was formed on the top, composed of carbonate of potash and crystallized silica. The crystals of the latter were in the form of tetrahedral pyramids, perfectly transparent, and so hard as to strike fire with steel. 1448 Crystals.

7. Silica is only acted on by a very few of the acids. These are, the phosphoric and boracic, which combine with it by fusion, and the fluoric, which dissolves silica either in the gaseous or liquid state. When silica is held in solution in water by means of an alkali, it is also dissolved by the muriatic acid. 1449 Action of acids.

8. The alkalies have a very powerful action on this earth. 1450 Of alkalies.

Silica, &c. earth. In the preparation of the pure earth, it was combined with potash by means of fusion. This compound is different in its nature and properties, according to the proportions of the silica and the alkali. Two or three parts of potash with one of silica form a compound which is deliquescent in the air, and soluble in water. This was formerly distinguished by the name *liquor silicum*, or *liquor of flints*. It is now called *silicated alkali*. When this solution is long exposed to the air, the earth is deposited in a flaky gelatinous form. It is decomposed by acids, which combine with the alkali, and the pure earth falls to the bottom in the state of fine powder. When the solution is largely diluted with water, and if a greater quantity of the acid be added than is sufficient to saturate the alkali, the silica remains in solution. This is particularly the case when muriatic acid is employed. When the silica is in greater proportion than the potash, a compound is formed which is possessed of very different
1451 Glass, properties. The substance thus obtained is glass.

9. This earth also enters into combination with some of the earths. If to a solution of the liquor of flints lime water be added, a precipitate is formed,
1452 Of earths. which is found to be a compound of silica and lime. Silica also combines with lime by means of heat, and in certain proportions a glass is formed.

The following table, drawn up by Mr Kirwan, exhibits the effects of heat on these earths in different proportions *.

* *Mineral.* i. p. 56.

Proportions.	Wedgw.	Effect.
50 Lime 50 Silica	150°	Melted into a mass between porcelain and enamel, of a white colour, semitransparent at the edges, and which gave feeble sparks with steel.
80 Silica 20 Lime	156°	Not melted, but formed a brittle mass.
80 Lime 20 Silica	156°	Formed a yellowish-white loose powder.

10. Silica enters into combination with barytes. The following table will shew the effect of different proportions of these earths, as they were ascertained by Mr Kirwan †.

† *Ibid.* 57.

Proportions.	Wedgw	Effect.
80 Silica 20 Barytes	155°	Formed a white brittle mass.
75 Silica 20 Barytes	150°	A brittle hard mass, semitransparent at the edges.
66 Silica 33 Barytes	150°	Melted into a hard, somewhat porous, porcelain mass.
50 Silica 50 Barytes	148°	A hard mass not melted.

Proportions.	Wedgw.	Effect.
80 Barytes 20 Silica	148°	The edges melted into a pale greenish mass, between a porcelain and an enamel.
75 Barytes 25 Silica	150°	Melted into a somewhat porous porcelain mass.
66 Barytes 33 Silica	150°	Melted into a yellowish, and partly greenish white, porous porcelain.

11. Silica also enters into combination with strontites. Three parts of strontites and one of silica, strongly heated in a silver crucible for an hour, afforded a gray, sonorous, vitreous mass, which has no taste, and is insoluble in water.

12. Siliceous earth enters with difficulty into combination with magnessia; but if equal parts of silica and magnesia be exposed to very strong heat, they melt into a white enamel.

13. But the most important compounds of all the earths are those of silica and alumina. These earths may be combined together, as appears from the experiments of Guyton, in the humid way. He mixed together equal parts of alumina dissolved by means of potash, and of silica held in solution by the same alkali. When the solutions came into contact, a brown zone was immediately formed, which spread by agitation through the whole mass, and communicated to it a yellowish colour. The mixture was no farther changed during the space of an hour, although it was occasionally stirred by a glass rod; but at the end of that time the whole mass assumed the appearance of a thick, opaque, white jelly *. When the silica and alumina are mixed together, and formed into a paste with water, and exposed to heat, they strongly cohere, and assume a considerable degree of hardness. This compound forms the basis of all kinds of pottery and porcelain. 145[illegible] Porcel[illegible]

* *Ann[illegible] Chim.* p. 248.

I. Compounds of Silica with Acids.

1. Muriate of Silica.

When muriatic acid is poured upon a solution of silicated potash, part of the silica remains in the solution combined with the acid. To this compound Fourcroy has given the name of *muriate of silica*. This solution, which is perfectly transparent, is always acid. When it is concentrated by slow evaporation, it assumes the form of a transparent jelly. But if the solution be boiled, it is decomposed, and the silica is precipitated in the form of small crystalline particles, so that it is totally separated from the water and the acid †. 145[illegible] Prepar[illegible]tion. 14[illegible] Proper[illegible]

† *Four[illegible]* iii. 21[illegible]

2. Fluate of Silica.

Fluoric acid combines with silica, either in the gaseous or liquid state. When it is disengaged from lime in the state of gas, by means of an acid, if the process be performed in glass vessels, they are corroded. The fluoric acid in the state of gas combines with the silica, 14[illegible] Prepa[illegible]tion.

silica, and retains it, even when it is condensed by water. This earth may be precipitated from the liquid solution by means of an alkali. When fluoric acid gas is condensed by water, part of the silica with which it was combined is precipitated; but this portion is at last dissolved by new additions of the acid, so that the salt is in the state of an acidulous fluate. If this solution be evaporated, a quantity of silica, corresponding to the portion of acid disengaged, is deposited, and the liquid which remains contains a portion in proportion to that of the acid which is left in the solution ‡.

3. Fluate of Potash and Silica.

This triple salt is formed, when a solution of fluate of potash is exposed to heat in glass vessels; or, when the fluoric acid which has been prepared in glass vessels is combined with potash. But the nature of this triple salt has not been examined.

4. Fluate of Soda and Silica.

This triple salt is formed in the same way as the former.

5. Borate of Silica.

Boracic acid and silica combine together by means of a strong heat, and form a transparent glass. To this Fourcroy has given the name of *borate of silica*. This compound has no taste, is not altered by the air, nor is it soluble in water.

6. Phosphate of Silica.

This compound of phosphoric acid and silica is formed by means of fusion; and the compound is a hard, dense, transparent glass. When it is exposed to strong heat, it combines with the alkalies, and forms a triple salt. It is not decomposed by any of the acids. This substance is employed in the fabrication of artificial gems.

SECT. VII. *Of Yttria and its Combinations.*

1. This earth was discovered by Gadolin in 1794; and the account of his analysis of the mineral from which it is obtained, was published in the memoirs of the Swedish academy, and in Crell's Annals for the year 1796. In 1797 Ekeberg analyzed the same mineral, and confirmed the results of Gadolin. To the new earth found in this mineral, Ekeberg gave the name of *yttria*, derived from *Ytterby*, a place in Sweden where the stone is found. The same mineral was afterwards analyzed by Vauquelin and Klaproth, about the year 1800. The mineral from which this earth is obtained has received the name of gadolinite, is of a black colour, has a vitreous fracture, and its specific gravity is 4.0497. It is magnetic. When it is heated with borax, it melts, and communicates to the salt a yellowish colour inclining to violet. The component parts of this mineral are,

Yttria	.47
Silica	.25
Oxide of iron	.18
Alumina	.04
	.94

Yttria, &c.

1458 Preparation.

2. Yttria is obtained from this mineral, by reducing it to powder, and adding a mixture of nitric and muriatic acids, till the whole is decomposed. The solution is then to be filtered and evaporated to dryness. If then it be diluted with water, the silica will remain behind. The liquid which passed through the filter is also to be evaporated to dryness, and what remains is to be exposed to a red heat in a close vessel. It is afterwards dissolved in water, and filtered. The liquid which passes through the filter is transparent and colourless. By adding a solution of ammonia, a precipitate is formed, which being collected, is pure yttria.

1459 Properties.

3. This earth is in the state of a white powder. It has neither taste nor smell. It is not fusible. It is not soluble in water, or in any of the caustic fixed alkalies; but it readily dissolves in carbonate of ammonia. The specific gravity of this earth is 4.842.

4. This earth undergoes no change by the action of light. It is not acted on by oxygen, azote, or hydrogen, nor does it combine with sulphur. It forms compounds with the acids. These salts have a sweetish, austere taste, and some of them have a red colour.

I. Compounds of Yttria with the Acids.

1. Sulphate of Yttria.

1460 Preparation.

1. Sulphuric acid combines readily with yttria, and during the combination there is an evolution of caloric; and as the union goes on, the salt which is formed crystallizes in small brilliant grains.

1461 Properties.

2. These crystals are sometimes irregular, but often have the form of six-sided prisms, terminated by four-sided summits, and are of an amethyst red colour. This salt has a sweetish astringent taste, something like the salt of lead. The specific gravity is 2.791. It undergoes no change by exposure to the air. It is soluble in about 50 parts of cold water, but less so where there is not an excess of acid. This salt is partially decomposed when exposed to a red heat.

2. Sulphite of Yttria.

Unknown.

3. Nitrate of Yttria.

1462 Preparation.

Nitric acid combines with yttria by dissolving the earth in the acid. This salt crystallizes with difficulty. When it is evaporated by heat, if too much be applied, in place of becoming solid as other salts, it becomes soft, and assumes the appearance of a thick, transparent honey. When it cools, it becomes hard and brittle. It deliquesces in the air. When sulphuric acid is poured into a solution of nitrate of yttria, a precipitate is formed which crystallizes. These are crystals of sulphate of yttria *.

* *Ann. de Chim.* xxxvi. 143.

4. Muriate of Yttria.

This salt, which is a compound of muriatic acid and yttria, resembles the nitrate in many of its properties. It dries with difficulty, is fusible with a moderate heat, and is deliquescent in the air. This salt is decomposed by ammonia.

Yttria, &c.

5. Fluate of Yttria.
6. Borate of Yttria. } Unknown.

7. Phosphate of Yttria.

1463 Preparation. Phosphoric acid does not precipitate yttria from its combination with the other acids; but the phosphate of soda decomposes the salts of yttria, and forms a phosphate of yttria, which is precipitated in white, gelatinous flakes †.

† *Ibid*, 158.

8. Phosphite of Yttria.

Unknown.

9. Carbonate of Yttria.

1464 Preparation. This compound of carbonic acid and yttria was formed by Klaproth, by precipitating the earth by means of an alkaline carbonate, from its solution in acids. The carbonate of yttria is in the form of an insipid white powder. It is insoluble in water.

The component parts of this salt are,

Acid	18
Yttria	55
Water	27
	100

10. Arseniate of Yttria.

This salt is formed by boiling the earth in the acid. A white powder is precipitated, which is arseniate of yttria.

11. Tungstate, Molybdate, Chromate, and Columbate of Yttria. Unknown.

15. Acetate of Yttria.

This salt is formed by the direct combination of the earth with the acid. By evaporating the solution, a salt is obtained in crystals. These crystals, which are of a red colour, are in the form of six-sided plates obliquely truncated. This salt undergoes no change by exposure to the air.

16. Oxalate of Yttria.

This salt is formed by adding oxalic acid to the solution of yttria in acids. A precipitate is formed in the state of a white powder, which is insoluble in water. It may be obtained also by employing the oxalate of ammonia.

17. Tartrate of Yttria.

This compound is formed by precipitating yttria from its solution in acids by means of tartrate of potash. This salt is soluble in water.

18. Citrate, Malate, Gallate, and Benzoate of Yttria. Unknown.

22. Succinate of Yttria.

If the succinate of soda be added to a concentrated solution of muriate or acetate of yttria, a precipitate is formed, which is the succinate of yttria in the state of cubic crystals.

23. Saccolate, Camphorate, Suberate, Mellate, and Lactate of Yttria. Unknown.

28. Prussiate of Yttria.

The prussiate of potash crystallized and re-dissolved in water, causes a precipitate in the solution of yttria in acids. This is in the form of a white, gritty matter *.

* Ann Chim. x[...] p. 158.

Gluci[na], &c.

SECT. VIII. *Of* Glucina *and its Combinations.*

1. This earth was discovered by Vauquelin in the year 1789. He was requested by Haüy to analyze the beryl, to ascertain whether its constituent parts were the same with those of the emerald, which the latter had conjectured in observing a perfect correspondence in structure, hardness, and specific gravity. In the course of this analysis, Vauquelin discovered the new earth, to which, from its properties, he gave the name of *glucina*, from the Greek word γλυκος, which signifies sweet. The same experiments were repeated by Klaproth and Bindheim, and the results obtained by Vauquelin were confirmed. 146[5] History.

2. This earth is obtained by the following process. One hundred parts of the beryl or emerald, reduced to a fine powder, are fused with 300 parts of caustic potash. The fused mass is then diluted with distilled water, and dissolved in muriatic acid. The solution is to be evaporated to dryness, taking care to stir it towards the end of the evaporation. Dilute the residuum with a large quantity of water, and filter it. The silica is thus separated by means of the first process. The filtered solution, which contains the muriates of alumina and glucina, is precipitated by carbonate of potash. The precipitate is to be well washed, and dissolved in sulphuric acid. Add to this solution, a quantity of sulphate of potash, and evaporate to obtain crystallized alum. When by a new addition of sulphate of potash, and by a new evaporation, the solution yields no more alum, add to it a solution of carbonate of ammonia in excess, and agitate it well. The glucina, after being deposited, is dissolved by means of the excess of this salt, and the small quantity of alumina which may remain is precipitated without being dissolved. After some hours, when the aluminous precipitate is not diminished in volume by a new addition of carbonate of ammonia and agitation, the solution is to be filtered, and boiled in a glass matrass, and as the carbonate evaporates, there is precipitated a white, gritty powder, which is carbonate of glucina. The carbonic acid may be driven off, by exposing the powder in a crucible to a red heat †. 14[66] Prepa[ra]tion.

† Fo[urcroy] ii p. [...]

3. Glucina prepared by this process is in the form of a soft powder, or light white fragments, which are insipid to the taste, and adhere to the tongue. The specific gravity is 2.967 ‡. It is altogether infusible in the fire, and it neither contracts nor becomes harder, like alumina. It has no effect on vegetable colours. 1[467] Prop[erti]es.

‡ An[n. de] Chim. [...] 277.

4. There is no action between glucina and oxygen, azotic, or hydrogen gases. It is not changed by exposure to the air, nor is it acted on by carbon, phosphorus, or sulphur. It combines with sulphurated hydrogen. When sulphurated hydrogen gas is made to pass into water in which this earth is suspended, it combines 1[468] Hyd[rosul]phur[et].

conia, &c.

combines with it, and forms a hydrosulphuret, whose properties are similar to those of the other hydrosulphurets.

469 on of r. 5. Glucina is insoluble in water; but it forms with this liquid, in small quantity, a paste which is slightly ductile, but has less tenacity than that of alumina.

470 cids. 6. Glucina combines readily with all the acids, and forms with most of them soluble salts, which are distinguished by a sweet and slightly astringent taste. Its affinities are in the following order.

Sulphuric acid,
Nitric,
Muriatic,
Phosphoric,
Fluoric,
Boracic,
Carbonic.

471 kalies. 7. This earth is soluble in solutions of the fixed alkalies. It is also soluble in carbonate of ammonia, but it is insoluble in pure ammonia.

472 acte- pro- es. 8. The characteristic properties of this earth are, according to Vauquelin, the following.

a. It forms with acids sweetish and slightly astringent salts.

b. It is soluble in sulphuric acid when a little in excess.

c. It decomposes aluminous salts, by separating the earth when it is boiled in their solutions.

d. The salts of glucina are completely precipitated by ammonia.

e. It is soluble in the liquid carbonate of ammonia.

f. The affinity of this earth for the acids is between that of magnesia and alumina ‡.

‡ *urcroy* ii 161.

I. Compounds of Glucina with Acids.

1. Sulphate of Glucina.

473 ara- 1. This salt, which was first discovered by Vauquelin, is prepared by the direct combination of sulphuric acid with the earth, either in the pure state or in that of carbonate. The solution is to be evaporated to the consistence of syrup, and crystals are obtained on cooling.

474 erties. 2. This salt crystallizes with difficulty in the form of small needles; but their form has not been accurately ascertained. It has a sweet, and somewhat astringent taste. It is not perceptibly altered by exposure to the air, and is very soluble in water.

475 on of 3. When it is exposed to heat, it melts, swells up, and then dries. With a red heat it is entirely decomposed, the acid is driven off in the state of vapour, and the pure earth remains behind.

476 cids, 4. This salt is not decomposed by any of the acids, but it is decomposed by the alkaline and most of the earthy bases. The infusion of nut-galls added to a solution of this salt produces a yellowish white precipitate, which is characteristic of the salt *.

* *urcroy* *uaiss.* *. iii.*

2. Sulphite of Glucina.

This salt is yet unknown.

3. Nitrate of Glucina.

477 ara- 1. The compound of nitric acid and glucina is formed by the direct combination of the acid and earth in a state of purity. The solution is evaporated by a moderate heat to dryness, and then the salt is obtained in the state of powder.

Zirconia, &c.

2. The nitrate of glucina does not crystallize. It is either in the form of powder, or in that of a soft ductile mass. The taste is sweetish and astringent. 1478 Properties.

3. It is extremely deliquescent in the air, and is very soluble in water. It readily melts when exposed to heat, and if the heat be increased it is decomposed; the acid is driven off in the gaseous form, and the earth remains behind. It is only decomposed by sulphuric acid †. 1479 Action of heat.

† *Ibid.* 146.

4. Nitrite of Glucina.

Unknown.

5. Muriate of Glucina.

This salt, according to Vauquelin, by whom only it has been described, comes very near the nitrate of glucina in its properties. It seems to crystallize with more facility, but the crystals are so small that the form cannot be determined. It does not deliquesce in the air. When it is dissolved in alcohol, and diluted with water, it affords a very agreeable sweet liquor.

It is decomposed by heat, by the sulphuric acid, the nitric, and by the phosphoric, by the assistance of heat.

6. Fluate of Glucina. } Unknown.
7. Borate of Glucina. }

8. Phosphate of Glucina.

1. Vauquelin procured this salt by adding the phosphate of soda to the solution of the nitrate, the sulphate, or muriate of glucina. A copious mucilaginous matter is instantly precipitated. Or it may be obtained by heating together the muriate of glucina and phosphoric acid in the state of glass. 1480 Preparation.

2. This salt does not crystallize, but is in the form of mucilage or of white powder. It has no perceptible taste. It is not altered by exposure to the air, and it is insoluble in water without an excess of acid. It is not decomposed by strong heat. It melts under the blow-pipe into a transparent vitreous globule. It is decomposed by the sulphuric, nitric, and muriatic acids. 1481 Properties.

9. Phosphite of Glucina.

Unknown.

10. Carbonate of Glucina.

1. The compound of carbonic acid and glucina, which was discovered by Vauquelin, and only examined by him, is prepared by exposing the earth to the air, from which it attracts the acid, or by precipitating some of the soluble salts of glucina by means of an alkaline carbonate. The precipitate is to be washed with water, and dried in the air. 1482 Preparation.

2. This carbonate is in the state of a white powder, soft and greasy to the touch. It has not the sweet taste of the other salts of glucina. It is not changed by exposure to the air, and is insoluble in water. When exposed to heat, the acid is driven off, and the pure earth remains behind. It is decomposed by all the acids with a brisk effervescence. 1483 Properties.

Zirconia, &c.

11. Carbonate of Ammonia and Glucina.

This triple salt is formed by adding the earth of glucina to a solution of carbonate of ammonia. It is soluble in the same quantity of water which holds the carbonate of ammonia in solution. Its other properties are unknown.

12. Arseniate, tungstate, molybdate, chromate, and columbate of glucina. Unknown.

17. Acetate of Glucina.

Glucina readily dissolves in acetic acid. This salt does not crystallize; but by evaporation it is reduced to a gummy substance, which becomes slowly dry and brittle. For a long time it retains a kind of ductility. The taste is sweet and strongly astringent.

18. Oxalate, tartrate, citrate, malate, gallate, and benzoate of glucina. Unknown.

24. Succinate of Glucina.

This salt, according to Ekeberg, is formed by precipitating the earth from its solutions, by means of the succinates. It is therefore nearly insoluble.

25. Saccolate, camphorate, suberate, mellate, lactate, prussiate, and sebate of glucina. Unknown.

Sect. IX. *Of Zirconia and its Combinations.*

1484 History. 1. The name of this earth is derived from a stone, called *zircon* or *jargon*, which is found in the island of Ceylon. It was from this stone that Klaproth extracted the earth, some time before the year 1793. He soon after found the same earth in the oriental hyacinth. By this discovery, Guyton was led to analyze the hyacinths of France; and in those which were collected in the river of Expailly, he detected the same earth. The experiments of Klaproth and Guyton were repeated by Vauquelin, and their results were confirmed, so that the nature and properties of this earth have been fully developed.

1485 Preparation. 2. Zirconia is extracted from this mineral, in which alone it has been found, by the following process. A quantity of the mineral is to be reduced to fine powder, and fused with five or six times its weight of pure potash, in a silver crucible. The fused mass is then dissolved in water, by which means the alkali is separated. The residuum is then dissolved in muriatic acid, which is to be heated, to separate the silica; and when no farther precipitate appears by means of heat, add a caustic fixed alkali. Another precipitate is formed, which is to be well washed and dried. This is pure zirconia.

1486 Properties. 3. Zirconia, thus prepared, is in the state of fine white powder, which is nearly soft to the touch, and without taste or smell. When it retains water, it assumes the form of a jelly, and is semitransparent. The specific gravity is 4.3.

1487 Action of heat. 4. Light has no action on this earth. When it is exposed to the heat of the blow-pipe, it remains infusible, but gives out a yellowish, phosphoric light. Heated in a charcoal crucible, and surrounded with powdered charcoal, it undergoes a kind of fusion, but without becoming transparent, or assuming a vitreous form. It becomes extremely hard, strikes fire with steel, and scratches glass.

5. There is no action between zirconia and oxygen or azotic gases, nor is it changed by exposure to the air. It is not acted on by hydrogen, carbon, phosphorus, or sulphur.

6. This earth is insoluble in water; but it mixes with a considerable portion of this fluid, and forms with it a transparent jelly. If in this state it be slowly dried, it retains the water, and assumes a yellowish colour, and something of the transparency of gum arabic *. When it is dried in a very high temperature, it loses more than one-third of its weight. After having been exposed to a red heat, it becomes of a gray colour, harsh to the feel, and less soluble in acids. 1488 Of water

7. Zirconia combines with the acids, and forms with them peculiar salts. Many of these are insoluble in water, and are distinguished by an astringent taste. 1489 Of acids.

The order of the affinities of this earth is the following: 1490 Affinities.

Vegetable acids,
Sulphuric,
Muriatic,
Nitric.

8. Zirconia does not combine with the alkalies by fusion, and is insoluble in liquid alkalies. It may be dissolved, however, by the alkaline carbonates. 1491 Action of alkalies.

* Annal. Chim. xxi. 197.

I. Compounds of Zirconia with Acids.

1. Sulphate of Zirconia.

1. This salt is formed by the direct combination of the earth with sulphuric acid. The solution is to be evaporated to dryness. The salt thus obtained is in the form of a white powder, which is very friable. Sometimes it is in the form of crystals like small needles. It has no taste, is not changed by exposure to the air, and is insoluble in water. 1492 Preparation and properties.

2. This salt is readily decomposed by heat, the acid is driven off, and the earth remains behind. When it is boiled in water, the earth is precipitated, and the acid remains in the liquid. At a high temperature it is decomposed by charcoal, and converted into a sulphuret which is soluble in water, and the solution furnishes by evaporation crystals of hydrosulphuret of zirconia †. 1493 Action of heat.

† Ibid. 199.

2. Sulphite of Zirconia.

Unknown.

3. Nitrate of Zirconia.

1. This salt is formed by the direct combination of zirconia with concentrated nitric acid; and by evaporation it is obtained in the form of a yellow, transparent viscid mass, which dries with difficulty. 1494 Preparation.

2. This salt has a styptic and astringent taste, and leaves on the tongue a thick matter, which proceeds from a decomposition of the salt by means of the saliva. 1495 Properties.

3. When nitrate of zirconia, after being evaporated, is put into distilled water, a very small quantity only is dissolved. The greatest part remains under the form of 1496 Action of water and heat.

Zirconia, &c.

of gelatinous and transparent flakes. This salt is very readily decomposed by heat.

497 ...cids, 4. It is also decomposed by sulphuric acid, which forms in the solution a white precipitate soluble in excess of acid; by carbonate of ammonia, which produces a precipitate, soluble in an excess of this salt; and by an infusion of nut galls in alcohol, which affords a white precipitate, soluble in an excess of this infusion. But if the zirconia contains iron, the colour of the precipitate is bluish gray, of which a part remains in the solution, communicating to the liquor a pure blue colour. When this liquid is mixed with carbonate of ammonia, it affords a purple matter, by the refracted rays, but of a violet colour by reflected light. Crystallized gallic acid also precipitates the nitrate of zirconia, of a bluish gray colour. Most of the other vegetable acids also decompose this salt, and form combinations with the earth which are insoluble in water *.

* ...m. de C...t. xxii. p...9.

4. Nitrate of Zirconia.

Unknown.

5. Muriate of Zirconia.

498 ...ara-ti... 1. Of all the acids, the muriatic combines most readily with zirconia, when the latter is in the state of carbonate. This salt was first formed by Klaproth, and its properties were afterwards more particularly investigated by Vauquelin.

499 ...erties. 2. The muriate of zirconia has no colour, but possesses a very astringent taste, is very soluble in water, and also in alcohol. By slow evaporation, it affords small transparent needle-formed crystals, whose figure has not been determined. When muriate of zirconia contains any portion of silica, the crystals are cubical, have little consistence, and resemble a jelly. These crystals, exposed to the air, gradually lose their transparency, and are diminished in volume. There are formed, in the middle of the mass, white silky crystals in the shape of needles, which arise from the cubes.

500 ...n of ...acids, 3. Muriate of zirconia is decomposed by heat, which drives off the acid. It is even decomposed in the mouth by means of the saliva.

4. *a.* It is also decomposed by sulphuric acid, which forms a precipitate with the earth in heavy white flakes, while another part is retained in solution by the muriatic acid. But by the assistance of heat, the latter is dissipated, and the remaining part of the sulphate of zirconia is deposited. If the evaporation be stopped before it is brought to a state of dryness, it assumes the appearance of a jelly by cooling. The sulphate of zirconia is then soluble in muriatic acid.

b. This salt is also decomposed by the phosphoric, citric, tartaric, oxalic, and saclactic acids, which forming with its base insoluble compounds, precipitate in the form of white flakes.

c. The gallic acid precipitates the muriate of zirconia in the form of white matter, if the salt has been pure, but of a grayish green if it contain iron. In the latter case, the precipitate becomes, when dry, of a shining black colour, which has the same appearance as china ink. The liquid, in which are formed the gallates of zirconia and iron, preserves a green colour; and although new portions of gallic acid are added, no farther precipitation is produced. But the carbonate of ammonia throws down a copious flaky matter, which has a purple colour, and nearly resembles that of lees of wine. Thus it appears that the gallic acid has a greater affinity for zirconia than the muriatic, and that the gallates of zirconia and iron are soluble in muriatic acid.

d. The carbonate of potash, when fully saturated, decomposes the muriate of zirconia; and although this solution is attended with effervescence, the precipitate, washed and dried in the air, retains a large proportion of carbonic acid; for when this earth is afterwards dissolved in acids, it produces a brisk effervescence. The carbonate of ammonia at first forms a precipitate in the solution of muriate of zirconia. This precipitate is in great part redissolved by new additions of the ammoniacal salt, and there is produced a triple salt, which may be decomposed by heat.

e. A solution of sulphurated hydrogen gas in water, mixed with a solution of muriate of zirconia containing iron, becomes turbid, and produces a reddish colour; but there is no real precipitate. Hydrosulphuret of ammonia, instantly precipitates this earth of a fine green colour, which appears black when it is dry. When this precipitate is placed on burning coals, it emits the odour of sulphurated hydrogen gas, and becomes of a purple blue colour when reduced to powder.

f. Pure alumina decomposes the muriate of zirconia, with the aid of heat. The alumina is dissolved, the liquid becomes milky, and assumes the form of a jelly as it cools. It has been remarked, when the muriate of zirconia contains iron, it remains in solution with the alumina; and the zirconia, which has been precipitated in this way, contains no perceptible portion of this metal.

g. The prussiate of mercury produces in the solution of muriate of zirconia a copious white precipitate, which is soluble in muriatic acid.

h. A plate of zinc introduced into a solution of muriate of zirconia, produces a slight effervescence. The liquid becomes milky, and assumes the appearance of a white semitransparent jelly in a few days *.

* *Ann. de Chim.* xxxii. p. 201.

6. Fluate of zirconia, borate, phosphate, and phosphite of zirconia. Unknown.

10. Carbonate of Zirconia.

When an alkaline carbonate in solution is added to a solution of muriate of zirconia, the earth is precipitated without effervescence; and when this precipitate is exposed to heat in close vessels, it gives out carbonic acid gas. It also enters into combination with the alkaline carbonates, and forms with them triple salts. This, Vauquelin observes, is one of the remarkable characters of this salt.

The component parts of carbonate of zirconia, according to the same chemist, are, 501 Composition.

Acid and water	44.5
Zirconia	55.5
	100.0

11. Arseniate, tungstate, molybdate, chromate, and columbate of zirconia. Unknown.

16.

16. Acetate of Zirconia.

1502 Properties. Acetic acid combines with zirconia, and forms with it a salt which does not crystallize. When the solution is evaporated to dryness, the acetate of zirconia remains in the state of powder. This salt has an astringent taste, is not altered by exposure to the air, and is very soluble in water and in alcohol. This salt seems to have less tendency to be decomposed by heat than the nitrate of zirconia *.

* *Ann. de Chim* xxii. p. 206.

17. Oxalate, tartrate, citrate, and malate of zirconia. Unknown.

21. Gallate of Zirconia.

Gallic acid, added to a solution of muriate of zirconia, it has been already mentioned, produces a precipitate of a white matter, which is the gallate of zirconia. The properties of this compound have not been examined.

22. Benzoate, succinate, saccolate, camphorate, suberate, mellate, lactate, prussiate, and sebate of zirconia. Unknown.

Sect. X. *Of Thorina.*

1503 General account. This earth, which was found by Berzelius in gadolinite, and some other minerals found in the neighbourhood of Fahlun, differs from alumine and glucine by its insolubility in potash; from yttria, by its solutions being astringent to the taste and destitute of sweetness, and precipitated at a boiling heat; from zirconia, by remaining soluble in acids after being ignited, and by being precipitated by oxalate of ammonia.

Chap. XIV. Of METALS.

1504 Importance of metals. 1. The metals, on account of their importance and utility, have always greatly occupied the attention of mankind. Indeed such is their importance, that man could not take a single step in the improvement even of the simplest of the arts of life, without the assistance of some of the metals. In this view, the origin and improvement of many arts, and the knowledge of metallic substances, may be, in some measure, considered as coeval. The metals, therefore, became very early, and were probably the first objects of chemical investigation. In the extraordinary pursuits of the alchemists, they were the subjects of their eager researches, in the discovery of the means of converting the more abundant and baser metals, as they were called, into those which were more valued, on account of their durability and scarcity. They failed of their purposes; but their labours were not in vain. The facts which they discovered, in the progress of their investigations, were of no small importance to science.

1505 Characters. 2. The metals are distinguished from other substances by a number of characteristic properties. These are, brilliancy, colour, opacity, density, hardness, elasticity, ductility, malleability, tenacity, fusibility, power of conducting caloric and electricity.

1506 Brilliancy. 3. Lustre or brilliancy is one of the most striking characteristic properties of metallic substances, and hence it has been denominated *metallic lustre*. This is owing to the reflection of a great proportion of the rays of light by metallic surfaces. On account of this property, metals are employed in the construction of mirrors. Other substances, indeed, exhibit the appearance of this brilliancy, which is the case with the mineral called *mica*; but in this substance, as well as every other which is not metallic, it is merely superficial, and it entirely disappears when the surface is broken, or scratched with a sharp-pointed instrument. But the metal, treated in the same way, becomes more brilliant. The following is the order in which the metals possess this lustre:

Platinum,
Steel,
Silver,
Mercury,
Gold,
Copper,
Tin,
Zinc,
Antimony,
Bismuth,
Lead,
Arsenic,
Cobalt; and the other brittle metals.

4. Colour is one of the constant properties of metallic substances, while it is only accidental and variable in other minerals. And as the metals are the most opaque, and the densest bodies in nature, colour in them is very intense, or rather confounded with their brilliancy. The prevailing colour of metals is white; some however are yellow, and others reddish. Those of a white colour were formerly distinguished by the name of *lunar metals*, because silver, which was called *luna*, being placed at the head of these metals, has a white colour. Gold, which was distinguished by the name of *sol*, having a yellow colour, gave the name of solar metals to such as resembled it. The colour of metals is permanent, while they remain unaltered; but it is often totally lost when they enter into new combinations. 1507 Colour.

5. It is generally admitted, that all metallic substances are perfectly opaque. Newton indeed observed, that gold-leaf when reduced to $\frac{1}{280000}$ of an inch thick, appeared of a green colour, from which he concluded that it transmits the green rays; and he supposed that other metals might also transmit light, if they were sufficiently thin. But no metal has yet been found so malleable as to be reduced to that state of thinness to permit light to pass through it. Silver-leaf, so thin as to be only $\frac{1}{100000}$ part of an inch, is quite opaque. 1508 Opacity.

6. The metals are particularly distinguished from other substances by their density. Metallic substances have a greater specific gravity than any other bodies in nature; that is, the quantity of matter contained in a given bulk, is greater in the metals than in other substances. Even the lightest of the metals possess a greater density than the heaviest bodies known of any other kind of matter. The particles of which they are composed must therefore be in closer contact than in any other body. To this greater density is owing their superior lustre. 1509 Density.

7. The metals differ from each other greatly in degrees of hardness. In general, metallic substances are not 1510 Hardness.

etals. not so hard as many other natural bodies. The degree of hardness does not depend on the density, for the hardest metals are by no means the heaviest. This property, therefore, must be owing to the nature of the particles of which the metal is composed, or to some peculiar disposition or arrangement of these particles. It is found that some of the metals can be hardened by art, merely by hammering, or by sudden cooling after being heated. The hardness of metals, too, is greatly increased by being combined with each other, or with other substances; as, for instance, when copper and tin are combined together, or iron and carbon in the formation of steel, the utility of which latter, as it is applied for cutting instruments, depends on its hardness. Metallic substances, in comparing their different degrees of hardness, have been divided into eight classes, which are arranged in the following order.

1st, Iron and manganese.
2d, Platinum and nickel.
3d, Copper and bismuth.
4th, Silver.
5th, Gold, zinc, and tungsten.
6th, Tin and cobalt.
7th, Lead and antimony.
8th, Arsenic.

Mercury being always fluid at the ordinary temperature of the atmosphere, cannot be compared with regard to this property; and the degree of hardness which some of the other metals possess has not been
511 ascertained.

ticity. 8. The elasticity of metals seems to follow the same order in which they possess the property of hardness. The elasticity of some metals can be increased in the same way as their hardness, either by mechanical means, as by hammering, or by new combinations.

512 ility. 9. One of the most important physical properties of the metals is ductility. By this is meant that peculiar property which some metals possess, of being drawn out into wire, without destroying or diminishing the cohesive power of their particles. Some metals possess this property in a great degree, while others are entirely deprived of it; and some metals are extremely ductile, while they possess in a very small degree another property, namely, malleability. Iron is one of the most ductile metals, but is much less malleable than many others.

513 leabi-li 10. Malleability is also one of the most valuable properties of metallic substances. By this property they can be reduced to any form or shape which may be wanted, for those purposes to which they are to be applied. The property of malleability is supposed to depend on the form of the particles, or on the mode of their aggregation. Those metals which possess this property of malleability or laminability, seem to be composed of small plates, while the ductile metals seem to have their particles arranged in a fibrous form. When metallic substances are hammered, they become harder, denser, and more elastic, which is owing to their particles being brought into closer contact.

514 acity. 11. Tenacity is expressive of the power of cohesion between the particles of metallic substances. Different metals possess this property in very different degrees. The method which has been adopted to estimate the different degrees of tenacity, is by suspending wires of the same diameter of the different metals by one extremity, and attaching weights to the other, till the wires are broken. Iron, which has the greatest tenacity of all the metals, when formed into wire, $\frac{1}{10}$ of an inch in diameter, will support a weight of 500lb. without breaking, while a wire of lead of the same diameter, can only support about 29lbs. The following is the order of the ductile metals, according to the degree of their tenacity. Metals.

Iron,
Copper,
Platinum,
Silver,
Gold,
Tin,
Lead.

12. Another property of the metals is fusibility. 1515 Fusibility.
When they are exposed to a sufficient degree of heat, they melt, and are reduced to the state of liquidity. One of the metals, namely mercury, is always in the fluid state, at the ordinary temperature of the atmosphere. The different metals which are generally in the solid state, require very different temperatures for their fusion. Thus lead and tin require comparatively a lower temperature to be melted; while gold and platinum can only be brought to the state of fusion, by the greatest degree of heat that can be applied.

13. Metallic substances are the best conductors of caloric, but the comparative degrees of this property have not been ascertained. They are also found to be the best conductors of electricity. 1516 Conductors of caloric and electricity.

14. The metals possess some properties in common with other substances, as taste and smell, by which some of them are peculiarly distinguished; and in being susceptible of crystallization, which is the case with some, or of being volatilized, as happens to others.

15. But metallic substances are not only of vast importance in the arts of civilized life, on account of the properties which we have now detailed, which belong to them in the metallic state; but many of them are not less valuable in those changes which they undergo by new combinations, and the new properties they acquire, in consequence of these changes. One of the first and most ordinary changes to which metallic substances are subject, is their combination with oxygen. This is called in chemical language, *oxidation*. When a metal, as for instance, a piece of iron, is exposed to the air, when it is moist, it soon undergoes a remarkable change. It loses its metallic lustre, and the surface is covered with a brownish powder, well known by the name of *rust*. This change is owing to the combination of oxygen with the metal, and the rust of the metal in this state is known in chemistry by the name of *oxide*. The process by which this compound of oxygen and a metallic substance is formed, is called *oxidation*, and the product is denominated an *oxide*. 1517 Oxidation in the air.

16. But this process of oxidation is effected more rapidly when metals are exposed to the action of heat; and indeed many metals require a very high temperature to produce the combination, while it cannot be accomplished in others by the greatest degree of heat that 1518 By heat.

Metals.

that can be produced. This process was formerly called *calcination*, or calcining the metal; and the product, now denominated an *oxide*, was distinguished by the name of *calx* or *calces*, from its being reduced to the state of powder, in the same way as limestone, by burning.

1519 Are oxidated in different circumstances.

17. Metals differ very much from each other in the circumstances in which this oxidation takes place, in the temperature which is necessary, the facility of the combination, the proportions of oxygen which combine, and the force of affinity between the constituent parts of the oxide. Some metals are oxidated in the lowest temperature, as, for instance, iron and manganese; while others require the greatest degree of heat that can be applied. Such are silver, gold, and platinum.

1520 In the air.

18. The facility with which oxidation takes place in some metals is so great, such as iron, tin, lead, copper, and manganese, that they must be completely defended from the action of oxygen; but in gold and platinum, no perceptible change is observed, for whatever length of time they are exposed to the atmosphere.

1521 Proportion of oxygen determinate.

19. This oxidation and the quantity of oxygen absorbed is proportional to the temperature. There are, however, many metals which combine with a determinate proportion of oxygen at certain temperatures, and from this may be estimated the quantity of oxidation from the degree of heat which has been applied. The rapidity of the oxidation is almost always increased by the elevation of temperature. In this way actual combustion or inflammation is produced. Thus filings of metals thrown upon a body in the state of ignition, give out brilliant sparks; and steel, struck upon a flint, burns with a vivid flame in the air, in consequence of the great heat which is communicated to it by percussion.

20. Metallic substances combine with very different proportions of oxygen; and this quantity varies according to the manner in which the process has been conducted, or the temperature to which the metal has been exposed.

1522 Different phenomena of oxidation.

21. In these different states and conditions of oxidation, different phenomena are exhibited. Sometimes the metal becomes red-hot and is inflamed; sometimes the oxidation takes place without fusion, or does not combine with oxygen till after it has been melted; sometimes it is covered with a brittle crust, or with a substance in the form of powder. At other times a pellicle, exhibiting different colours, forms on the surface; but, in all cases, the metal is tarnished, loses its brilliancy and its colour, and assumes another, which announces the change that has taken place.

1523 Different affinities.

22. Another difference which takes place among metals, is the different degrees of force with which the oxygen adheres to the metal. The knowledge of this, and the different degrees of affinity between oxygen and metallic substances, is of great importance in many operations and chemical results.

1524 Caloric given out during oxidation.

23. During the fixation of oxygen in metallic substances, it is absorbed by some in its solid state, and gives out a great deal of caloric. In others it is combined, without giving out the same quantity. This proportion of caloric given out corresponds to the facility with which oxides part with their oxygen, or are reduced to the metallic state. Those which have combined with oxygen with the greater proportion of caloric, are most easily reduced; but those, on the contrary, in which the oyxgen has been deprived of its caloric, are reduced to the metallic state by a great addition of caloric, and the greatest number of oxides requires the addition of substances whose affinity for oxygen is greater than that of the metal.

1525 Different oxides.

24. Metallic oxides are extremely different in different metals, and even in the same metal, according to the proportion of oxygen. They are, however, possessed of some common properties. They are all in the form of powder or earthy substance, or so brittle as to be easily reduced to this state. They exhibit every shade of colour from pure white to brown and deep red, and they are heavier than the metals from which they have been obtained. Some oxides are revived, as it is called, or are reduced to the metallic state, merely by being in contact with light or caloric. Some require the addition of a combustible substance and a high temperature; while others have so strong an affinity for oxygen, that they cannot be deprived of it by the strongest heat, but become fusible in the fire, and afford a glassy matter more or less coloured, and even serve as a flux to the earths. Some oxides are volatile, but the greatest number are fixed. Some have an acrid and caustic taste, are more or less soluble in water, and even possess an acid quality; others are insoluble and insipid.

1526 Theory of Stahl.

25. Observing this remarkable change produced on metallic substances by the action of air or of heat, philosophers began early to account for it. According to Beccher and Stahl, the founders of chemical science, metals are composed of earths and phlogiston, and the process which takes place during the calcination of a metal, is merely depriving it of its phlogiston. This doctrine, which had undergone various modifications, from the difficulties which it presented in accounting for the phenomena of the calcination of metals, was finally overthrown by the celebrated experiments of Lavoisier. In one of these experiments he introduced eight ounces of tin into a glass retort, and having hermetically sealed it, after previous heating to expel some of the air, it was accurately weighed, and exposed to heat. The tin melted; and a pellicle appeared on its surface, which was soon converted into a gray powder. The heat was continued for three hours, but no farther change appeared upon the metal. When the retort was cooled, it was found to have the same weight as before the operation. The point of the retort was then broken off, and a quantity of air rushed in. This was equal to 10 grs. which was the 1527 Overturned.
additional weight required by the retort. The whole of the metallic substance in the retort was 10 grains heavier than when it was introduced, so that he concluded, that the 10 grains of air which had disappeared, had combined with the metal, and caused its increase of weight. The inference which he drew from this was, that the calcination of metals is not owing to their being deprived of any substance, but to their combination with air, and with the oxygen of the air; for it was found by future experiments, that the calcination or oxidation of metals could not be effected without

tals. without oxygen; and when it took place in a given quantity of common air, it was only the oxygen which was absorbed.

26. But as a still farther proof, that the calcination of metals is owing to the absorption of oxygen, they are reduced by those substances which have a greater affinity for oxygen. If charcoal in powder be mixed with a metallic calx or oxide, the oxygen combines with the carbon of the charcoal, forming carbonic acid, and the oxide is restored to the metallic state. If this process be performed in close vessels, the quantity of oxygen in the carbonic acid corresponds to the quantity which was absorbed by the metal during calcination.

27. From these observations, therefore, it appears that metallic substances combine with oxygen; and it has been observed, that not only different metals combine with it in different proportions, but the same
28 metal forms compounds of one, two, and sometimes three different portions. No combination takes place between azote or hydrogen and metallic substances; but some of them enter into combination with carbon, phosphorus, and sulphur, forming carburets, phosphurets, and sulphurets. The metals also combine with the acids, and form salts, some of which are of the utmost importance, not only in chemistry, but also in the arts of life. They also enter into combination with each other, forming a class of bodies which are distinguished by the name of *alloys*.

29 28. Metallic substances were formerly divided into *noble* or *perfect*, and *imperfect metals*. The noble or perfect metals were platinum, gold, silver, mercury; and the property on which this character was founded, was that of their being susceptible of being reduced by being exposed to heat. The other metals then known were called *imperfect metals*, because, to reduce them to the metallic state, the addition of some combustible substance was found to be necessary. They were also divided into *metals* and *semimetals*. Among the first were included those metals which were malleable and ductile; the semimetals comprehended those which possessed neither of these properties, and were therefore considered as less perfect. These distinctions, however, are now neglected, because they afford no well-founded or just marks of discrimination.

29. In the arrangement of the metals which we propose to follow, that of Fourcroy is adopted. He has divided them into five different classes, according to their ductility, and the proportions of oxygen with which they combine, or the facility with which that combination takes place. In the first class he includes those metals which are brittle, and in some of their combinations with oxygen have acid properties. These are,

Arsenic,
Tungsten,
Molybdena,
Chromium,
Columbium.

The second class comprehends those which are brittle, and simply susceptible of oxidation. These are the following:

Titanium,
Uranium,
Cobalt,
Nickel,
Manganese,
Bismuth,
Antimony,
Tellurium.

The third class comprehends those metals which have some degree of ductility, which are only two in number, viz.

Mercury,
Zinc.

The fourth class, which consists of three metals, includes such as are ductile, and easily oxidated. These are,

Lead,
Iron,
Copper.

The fifth class is composed of three metals, which are characterized by being very ductile, but oxidated with great difficulty. These are,

Silver,
Gold,
Platinum.

30. To these preliminary observations we have only to add, that metallic substances are found, either on the surface or in the interior of the globe, and either uncombined, or forming compounds with different substances. Some metals, as gold and platinum, are generally found in small grains, mixed with the soil. These, as well as the matters with which they are accompanied, have proceeded from the decomposition of the more solid parts of the globe. But metallic substances, which are met with in greater abundance, exist in the interior of the globe, in veins which traverse the other strata of the earth in different directions. The metals most commonly found in veins are, lead, copper, silver, zinc, mercury, and antimony. Some exist in detached masses. 1530 Natural history.

31. Metals, as they exist in the earth, are either in a state of purity, or the metallic state, when they are called *native* or *virgin metals*; or combined with each other, when they are said to be *alloyed*. They are found also combined with other substances, very frequently with sulphur; when they are said to be mineralized: or, they are combined with oxygen, when they come under the denomination of *oxides*; or they are combined with acids in the state of *salts*.

Sect. I. *Of Arsenic and its Combinations.*

1. It would appear that the ancients were acquainted with arsenic in its state of combination with sulphur, which is a reddish-coloured mineral, and was employed by them in painting; and although Theophrastus arranged it among metallic stones, probably on account of its weight, it was not known to possess a metallic substance 1531 History.

substance till the middle of the 17th century. Paracelsus, indeed, who lived at an earlier period, is said to have known it in the metallic state; but the process of obtaining it from orpiment and arsenic, was only first described by Schroeder in 1649. Lemery also published a process for extracting this metal in 1675. It was afterwards fully demonstrated by Brandt in 1733, and by Macquer in 1746, that arsenic possessed peculiar properties, and is totally distinct from all other metals. These facts were farther confirmed by Monnet in 1773, and by Bergman in 1777.

1532 Found native. 2. Arsenic is frequently found native, and is then in dark-coloured masses, which have little brilliancy, and exhibit no metallic lustre, except at the fracture. It is frequently found combined with other metals. In this state it is combined with iron, and is known by the name of *arsenical pyrites*, or *mispickel*. One of the most frequent combinations of arsenic is with sulphur, of which there are two principal varieties; the one is of a yellow colour, well known under the name of *orpiment*, and the other red, called *realgar*. It is also sometimes found in the state of white oxide, or arsenious acid; but this is a rare occurrence.

1533 Method of analyzing the ores. 3. In whatever state arsenic is found, it can easily be detected, by throwing a little of it on burning coals. The white fume which arises, and the garlic smell which is exhaled, are sufficiently characteristic of this metal. To obtain the metal from its oxide, it may be mixed with three times its weight of black flux. This mixture is put into a crucible, to which another crucible inverted is adapted. They are then to be luted together, to exclude the air. Apply heat to the lower crucible till it becomes red, defending the upper one as much as possible from the heat, by means of a plate of iron or copper, through which the lower crucible passes. When the apparatus has cooled, a crust of metallic arsenic is found in the upper crucible, in the form of crystals. This being detached and weighed, shows the quantity of pure metal in the mineral which has been tried.

In the humid way, Bergman recommends to treat native arsenic by dissolving it in four parts of nitro-muriatic acid, concentrating the solution by evaporation, and precipitating the muriate of arsenic which is formed, by means of water. If there is any silver, it is first precipitated in the form of an insoluble muriate, and iron is sometimes found in the solution precipitated by water.

The sulphurets of arsenic are to be treated by muriatic acid, adding a small quantity of nitric acid, to separate the sulphur. The oxide of arsenic may then be precipitated by water. The pure metal may be obtained by immersing a plate of zinc in the solution, having previously added a quantity of alcohol.

1534 Properties. 4. Arsenic is in the form of small plates of a blackish gray, brilliant, and metallic colour, with considerable lustre where there is a fresh fracture. The specific gravity is 8.31. It is extremely brittle, and is therefore easily reduced to powder. It has neither smell nor perceptible taste when it is cold; but when it is heated, and in the state of vapour, it is remarkable for a strong fetid odour of garlic. It sublimes before it melts, so that its fusing point is not known. It is the most volatile of all the metals. When slowly sublimed, it crystallizes in the form of regular tetrahedrons, and sometimes in that of octahedrons. The tetrahedron is the form of its integrant molecule.

5. When arsenic recently prepared is exposed to the air, it is soon tarnished, loses its lustre, becomes at first yellowish, and then passes to a black colour. It loses at the same time its hardness, and becomes extremely friable. When it is heated in contact with air, or if it be thrown into the state of powder on burning coals, it burns with a blue flame, and exhaling the strong odour of garlic, is sublimed in the form of a white, acrid, soluble mass, which has been called the *white oxide of arsenic*, or *white arsenic*. By this latter name it is well known in the shops. To this oxide of arsenic, because it possesses some acid properties, Fourcroy has given the name of *arsenious acid*. This acid bears the same relation to arsenic acid as the phosphorous and sulphurous acids do to phosphoric and sulphuric acids. 1535 Action of air.

6. This oxide or acid is extremely volatile. When it is heated in close vessels, it is sublimed in transparent, regular tetrahedrons. It is extremely acrid and caustic, corroding and destroying the organs of animals, so that it is the most violent poison known. The specific gravity is between 4 and 5. It reddens vegetable blues, and, when exposed to the air, it is covered with a slight efflorescence. 1536 Oxide or arsenious acid. 1537 Properties.

7. The arsenious acid is decomposed by hydrogen, carbon, phosphorus, and sulphur. At a red heat the, hydrogen and carbon combine with the oxygen, and reduce it to the metallic state. Phosphorus and sulphur are partly converted into phosphoric and sulphuric acids, and partly combine with the arsenic, forming a phosphuret or sulphuret of arsenic.

8. This acid is very soluble in water. It requires about 15 parts of boiling water for its solution, from which it may be obtained crystallized on cooling, or by slow evaporation. The crystals are in the form of regular tetrahedrons. The solution in water is extremely acrid, reddens vegetable blues, combines with earthy bases, decomposes the alkaline sulphurets, and affords with them a yellow precipitate in which the arsenic returns to the metallic state. The component parts of arsenious acid are,

Arsenic	75.2
Oxygen	24.8
	100.0

9. Arsenic combines with a greater proportion of oxygen; and in this compound it still exhibits acid properties, and is known by the name of *arsenic acid*. The method of preparing this acid, and its properties, have already been described, in the chapter on acids; and the compounds it forms with the alkalies and earths have been particularly detailed in the chapters which treat of these substances. 1538 Arsenic acid.

10. Arsenic does not decompose water. It may be kept for any length of time under water, without undergoing any change. There is no action between arsenic and carbon or azote. Arsenic, however, is soluble in hydrogen gas, to which it communicates a fetid odour and a poisonous property.

11. Arsenic enters into combination with phosphorus. When equal parts of phosphorus and arsenic are distilled together with a moderate heat, there is sublimed a dark-coloured brilliant substance, which burns on 1539 Phosphu[rus].

senic, &c. on red-hot coals, with a mixed odour of arsenic and phosphorus. This is the phosphuret of arsenic, which must be preserved under water. This compound may be formed under water at a boiling temperature in a matrass. As the phosphorus melts, it combines with the arsenic. The properties of this phosphuret of arsenic have not been examined.

540 S uret. 12. Arsenic combines readily with sulphur, either by fusion or by sublimation. The result of this combination is a yellow or red mass. This compound of sulphur and arsenic, which is a sulphuret of arsenic, is found native. The red is known by the name of *realgar*, and the yellow by that of *orpiment*.

541 S and a s. 13. Arsenic enters into combination with the acids, and forms with them peculiar salts. It also combines with the metals, forming *alloys*. The following is the order of the affinities of arsenic and of its oxide, as they have been arranged by Bergman.

542 A ities.

ARSENIC.	OXIDE of ARSENIC.
Nickel,	Lime,
Cobalt,	Muriatic acid,
Copper,	Oxalic,
Iron,	Sulphuric,
Silver,	Nitric,
Tin,	Tartaric,
Gold,	Phosphoric,
Platinum,	Fluoric,
Zinc,	Saclactic,
Antimony,	Succinic,
Sulphur,	Citric,
Phosphorus.	Lactic,
	Arsenic,
	Acetic,
	Prussic.

543 U 14. Arsenic, in the metallic state, is scarcely applied to any use, except for chemical purposes. It is sometimes alloyed with the metals, by which means they acquire new properties. In the state of white oxide, it is much employed in the arts. It has even been exhibited as an internal remedy in the diseases of cancer and intermittent fevers; but in all cases this terrible poison ought to be administered with the greatest caution. To counteract the effects of arsenic, when it has been accidentally taken into the stomach, one of the best antidotes is water impregnated with sulphurated hydrogen gas, or some of the alkaline sulphurets dissolved in water *.

* rcroy, v. 30.

I. Salts of Arsenic.

1. Sulphate of Arsenic.

544 E t of sul iric ac Concentrated sulphuric acid has no action on arsenic in the cold; but when they are boiled together, an effervescence takes place, sulphurous acid gas is disengaged, the arsenic is oxidated, and falls to the bottom in the state of white powder. According to Fourcroy, this powder retains but a small portion of sulphuric acid, the whole of which is nearly carried off by washing with water; nor are crystals obtained from the solution. By evaporation the white oxide of arsenic is precipitated, and sulphuric acid remains pure in the solution. There is no action between sulphurous acid and arsenic.

2. Nitrate of Arsenic.

Concentrated nitric acid produces a violent action with arsenic. Nitrous gas is disengaged, and towards the end of the process, azotic gas. The arsenic is converted at first into the white oxide, which, with a new addition of acid, passes to the state of arsenic acid; and when a great quantity of nitric acid is employed, with the aid of heat, the metal is instantly converted into arsenic acid. There remains no oxide in the solution, and there is no nitrate of arsenic formed. But, according to Bergman, when the nitric acid is diluted, it dissolves the oxide, and affords a crystallized salt like the white oxide. Arsenic, &c. 1545 Of nitric.

3. Muriate of Arsenic.

1. Muriatic acid has no action on arsenic in the cold; but when they are boiled together, the solution takes place, and there is disengaged a fetid gas, which seems to be arseniated hydrogen gas. From this it appears, that muriatic acid enables the arsenic to decompose water. A little nitric acid added, promotes the solution; and this solution, heated and concentrated at first in close vessels, is entirely sublimed in the form of a thick liquid, which was formerly called *butter of arsenic*. This salt is decomposed by water alone, which precipitates the metal. The muriate of arsenic, therefore, can scarcely be considered as a permanent salt *. 1546 Preparation.

*Fourcroy, v. p. 73.

2. When arsenic in the state of powder is thrown into oxymuriatic acid gas, it instantly catches fire, burns with a very brilliant white flame, and is converted into white oxide. If arsenic be added to liquid oxymuriatic acid, it is converted into arsenic acid, while the acid returns to the state of muriatic acid. 1547 Oxymuriatic acid.

4. Fluate of Arsenic.

Fluoric acid combines with the white oxide of arsenic, and affords small grains, which have a crystalline form; but their properties are unknown.

5. Borate of Arsenic.

Boracic acid also combines with the white oxide of arsenic, and affords a salt which is in the state of white powder, or in the form of small needles. Their properties are also unknown.

6. Acetate of Arsenic.

Acetic acid enters into combination with the white oxide of arsenic, and forms crystals, which are only known to be difficultly soluble in water.

7. Oxalate of Arsenic.

Oxalic acid, combined with arsenic, affords crystals in the form of prisms. Similar crystals are obtained by the combination of arsenic with the tartaric acid.

8. Benzoate of Arsenic.

Benzoic acid combines with the white oxide of arsenic, and by evaporating the solution, plumose crystals are obtained. This salt has an acid and acrid taste, is soluble in water, sublimes with a moderate heat, but with a stronger heat is decomposed, and is not precipitated from its solutions by alkalies.

Tungsten, &c.

Sect. II. *Of Tungsten and its Combinations.*

1548 History. 1. The name of tungsten is derived from a white, transparent mineral, which contains this metal in the state of acid united to lime. This mineral was analyzed by Scheele in 1781, and he found that one of its component parts is lime, and the other an earthy-like substance, to which he gave the name of *tungstic acid*. His discovery was confirmed about the same time by Bergman, who conjectured that the basis of the acid might be a metallic substance. This conjecture was verified by the experiments of Messieurs D'Elhuyart, two Spanish chemists, who discovered the same metal in the mineral called *wolfram*, and ascertained some of its metallic properties. It has since been farther examined by Vauquelin and Hecht, and by Allen and Aiken in London.

1549 Found native. 2. This metallic substance has been only found in the state of acid, in combination with lime, iron, manganese, and lead. When it is combined with lime, it is the tungsten of the Swedes, and in combination with iron it is called wolfram.

1550 Method of obtaining it. 3. To obtain this metal from the acid, it is mixed with charcoal in a crucible, and exposed to a very strong heat. By this process the metal was obtained in the form of a small button at the bottom of the crucible, in the first experiments which were made upon it by the German chemists. This crumbled to pieces between the fingers; and when it was examined with a magnifying glass, it was found to consist of a number of metallic globules, none of which were larger than a pin head.

1551 Properties. 4. The colour of the metal is a steel gray. The specific gravity is 17.6, or, according to others, 17.22. It is one of the hardest of the metals. It is also one of the most infusible, requiring a temperature of 170° Wedgwood. It crystallizes on cooling.

1552 Action of heat. 5. When it is heated in the open air, it is readily converted into a yellow oxide, which afterwards, by a stronger heat, becomes of a black colour, and then by combining with a greater proportion of oxygen, it assumes the character of an acid, namely the tungstic acid, whose properties and combinations with alkalies and earths have been already described.

1553 Of phosphorus, &c. 6. There is no action between tungsten and azote, hydrogen or carbon. Tungsten combines with phosphorus, forming a phosphuret, the properties of which are unknown. It also combines with sulphur, forming a sulphuret of a bluish black colour, and which may be crystallized. There is no action between this metal and sulphuric, nitric, or muriatic acids. It is only acted on by nitro-muriatic acid at a boiling temperature, and nitrous gas is disengaged. Nothing therefore is known of the combinations of tungsten with the other acids.

1554 Alloys. 7. This metal combines with the other metals, and forms alloys with them.

8. It is too little known, and has been produced in too small quantity, to be able to ascertain any thing of its uses or application.

Sect. III. *Of Molybdena and its Combinations.*

1555 History. 1. The mineral called *molybdena*, from which this metal is extracted, was analyzed by Scheele in 1778. He found that it contained sulphur, and a substance which he discovered to be possessed of acid properties. Previous to this time, this mineral had been confounded with plumbago or black lead, which it resembles in appearance. The acid which Scheele obtained from this substance, Bergman conjectured was a metallic oxide. These experiments were repeated by Pelletier; and he proved that molybdena was a peculiar metal combined with sulphur, and that in all the different processes the sulphur was separated, and the metal oxidated. The metal has since been called *molybdena*, and the mineral from which it is obtained *sulphuret of molybdena*. Molyb… &c.

2. Molybdena has never been found existing in any other but in the state of sulphuret, or in that of oxide. The sulphuret of molybdena, it has been observed, was long confounded with plumbago, or the carburet of iron. It has, however, a less greasy feel, more brilliancy, and inclining more to a blue colour. It stains the fingers less than carburet of iron, and leaves a bluish trace on paper. It is difficult to reduce it to powder, on account of the elasticity of the plates or scales of which it is composed. The sulphuret of molybdena too, becomes electric by friction. When the sulphuret of molybdena is treated with the blow-pipe, it exhales sulphur, which is detected by its odour, and a white vapour which is condensed on cold bodies in the form of plates or crystallized needles, of a yellowish colour, but which become blue by the contact of the interior flame. Molybdena has only been obtained in black, friable, agglutinated masses, which have some metallic brilliancy; and when broken, exhibit small round grains, of a grayish brilliant appearance. The specific gravity is about 7, and it is extremely infusible; but since the experiments of Dr Hielm, which were made in 1782, this metal has been procured in such small quantity, that its characteristic metallic properties have not been ascertained. 15… Chara… of the… 15… Prope… of the… tal.

3. When molybdena is exposed to a high temperature in contact with air, it is converted into a white oxide, which sublimes and crystallizes in the form of brilliant needles. This oxide has acid properties. When it is heated with combustible bodies, it assumes a bluish colour, with little brilliancy, as it approaches to the metallic state. According to Mr Hatchet, who made a set of experiments on the compound of this acid with lead, the molybdate of lead, molybdena, when it is not in the metallic state, appears to suffer four degrees of oxigenation. The first is the black oxide, which contains the smallest proportion of oxygen. This oxide is obtained by exposing to heat in a crucible a mixture of molybdic acid and charcoal in powder. A black mass remains, which is the oxide. The second is the blue oxide, which may be obtained by the same process, but it must not be continued so long. The third is the green oxide, which seems to be intermediate between an oxide and acid. Mr Hatchet proposes to call it *molybdous acid*. The fourth degree of oxidation is the molybdic acid itself, which has at first a white colour; but when it is fused and sublimed, is converted into a yellow colour. The properties of this acid and some of its combinations have been already described *. 15… Actio… heat. 15… Oxide… 15… Acids…

4. Molybdena combines with phosphorus; but the properties of this phosphuret are not known. It also combines

* Phil. Trans. 1796. p. 336.

combines readily with sulphur, and returns to the state of sulphuret of molybdena, in which it has only been found native.

1561 5. Molybdena enters into combination with the acids, forming with them peculiar salts.

1562 Acids. 6. The alkalies have the property of dissolving molybdena, and of promoting its oxidation. With the assistance of heat, the alkalies form with the sulphuret
1563 Alkalies. of molybdena an alkaline sulphuret, which holds the metal in solution.

7. Molybdena enters into combination with the metals, and forms alloys with them.

1564
I. Salts of Molybdena.

1. Sulphite of Molybdena.

Sulphuric acid, with the assistance of heat, dissolves molybdic acid, and affords a colourless solution; but when it is cold it becomes of a deep blue. But neither this nor any other of the salts of molybdena seem disposed to crystallize.

2. Nitrate of Molybdena.

Nitric acid converts the oxides of molybdena into molybdic acid, by giving up its oxygen.

3. Muriate of Molybdena.

Muriatic acid, when boiled with the oxide of molybdena, affords a solution of a deep blue colour, and there is formed a blue precipitate.

4. Fluate of Molybdena.

Fluoric acid forms a compound with the oxides of molybdena. The solution is of a greenish yellow colour when it is hot; but when it is evaporated to dryness, it becomes of a greenish blue.

5. Phosphate of Molybdena.

The oxide of molybdena is dissolved by phosphoric acid with the assistance of heat, and a solution of a blue colour is obtained.

6. Acetate of Molybdena.
7. Oxalate of Molybdena.
8. Tartrate of Molybdena.
9. Benzoate of Molybdena.

All these salts in solution are of a blue colour, and when evaporated to dryness, afford a blue powder. They are formed by digesting the several acids with the oxides of molybdena.

Sect. IV. *Of Chromium and its Combinations.*

1565 History. 1. This metal was discovered by Vauquelin in 1797, in a mineral called the *red lead ore of Siberia*. This ore had been formerly analyzed by several chemists, and even by Vauquelin himself; but their results of the nature of its composition only agreed, that lead was one of its constituent parts. Vauquelin by his last analysis found that it contained lead, combined with the new acid, of which the basis is a metal.

1566 2. The process which he followed was the following: He boiled one part of the red lead-ore of Siberia with two of carbonate of potash, in 200 parts of water. The potash combined with the new acid, while the carbonic acid united to the lead. The carbonate of lead precipitated to the bottom in the form of a white powder, and the new salt remained in solution. By adding nitric acid, the new salt was decomposed, the acid combining with the potash. This mineral is completely dissolved in muriatic acid. The solution assumes a deep green colour, and by evaporation affords muriate of lead. The fine green colour is owing to the oxide of the new metal having been deprived of part of its oxygen by the muriatic acid, and being thus converted from an orange red to a green.

3. The acid which is obtained by the first process, and the oxide by the second, being strongly heated with charcoal in a crucible, afforded a metal different from any other formerly known. To this metal the name of *chromium* was given, from the Greek word χρωμα, on account of the remarkable property which it possesses of communicating colour to all its saline combinations. 1567 Reason of the name of the metal.

4. The metal which was obtained, is of a grayish white colour, very hard and brittle, and extremely difficult of fusion; but the small quantity which has been hitherto obtained, precludes chemists from ascertaining its properties. 1568 Properties.

5. This substance has been found in four different minerals, existing in two states; in the state of green oxide, combined with the oxide of lead, and in the same state in the emerald; and in the state of acid, combined with the oxide of lead in the red lead-ore of Siberia, and also in the spinel ruby. It has also been discovered in the state of chromic acid, combined with iron, forming a chromate of iron. It has also been discovered in France. 1569 Found in different minerals.

6. Chromium, therefore, combines with oxygen in two different proportions; the green oxide, and the yellow, or the chromic acid. It is this acid which exists in the red lead-ore. When it is separated from the lead, it is in the form of powder, of an orange yellow colour, and is soluble in water. Its other properties have been already examined. The green oxide is prepared by exposing the latter to heat in close vessels. The chromic acid is partially decomposed; part of the oxygen is driven off, and the green oxide remains behind. Another oxide also, it is said, which is intermediate between chromic acid and the green oxide, has been obtained. 1570 Oxides.

7. Little is known of the action of acids on this metal; but in the few experiments which have been made, it appears, that it undergoes no change by means of sulphuric and muriatic acids. Nitric acid distilled upon it several times successively, changes it into green oxide, and at last into chromic acid. The same effect is produced more rapidly by means of the nitro-muriatic acid. 1571 Action of acids.

Sect. V. *Of Columbium and its Combinations.*

1. This metal was discovered by Mr Hatchet, in the year 1802, in a mineral which he found in the British Museum. This mineral had been sent along with specimens of iron ores from Massachusets in America, to Sir Hans Sloane, in whose catalogue it is described as a "very heavy black stone, with golden streaks." These streaks, Mr Hatchet observes, proved to be yellow 1572 History.

Columbium, &c.

1573 Characters of the ore. low mica. This mineral is externally of a dark-brownish gray colour; internally the same, inclining to iron gray. The longitudinal fracture is imperfectly lamellated; the cross fracture shews a fine grain. The lustre is vitreous, in some parts inclining to the metallic. It is moderately hard, but very brittle. The colour of the powder is dark chocolate brown. The particles are not attracted by the magnet. The specific gravity is 5.918.

1574 Analysis. 2. In the analysis of this mineral, Mr Hatchet discovered, that it consists of one part of oxide of iron, and three parts of a white-coloured substance, which exhibited the properties of an acid. The acid, under the name of *columbic acid*, with its combinations with the alkalies and earths, has been already described. Having found that it possessed properties different from all other acids, and also, that its base is metallic, he gave to the metal the name of *columbium*. In the attempts which Mr Hatchet made to reduce it to the metallic state, even when it was exposed to a very strong heat with charcoal, the oxide was only found in the state of powder, of a black colour. From these experiments it appeared, that this metal combines with oxygen in different proportions, and these oxides are distinguished by different colours.

3. When the white oxide of this metal was added to phosphoric acid in solution, and evaporated to dryness, the whole was put into a crucible, lined with charcoal, and exposed to a strong heat for half an hour. The inclosed matter had assumed a dark brown, spongy appearance, which had some resemblance to the phosphuret of titanium.

4. No sulphuret was obtained when it was mixed and distilled with sulphur.

5. Columbium combines with some of the acids, and forms salts, although few of these have been examined.

I. Salts of Columbium.

1. Sulphate of Columbium.

Boiling sulphuric acid forms a transparent colourless solution, with columbic acid. When water is added to this solution, it becomes turbid, assuming a milky appearance; and a white precipitate is gradually deposited, which cracks as it becomes dry upon the filter, and, from white, it changes to a lavender blue colour; and, when completely dry, to a brownish gray. It is then insoluble in water, is semitransparent, and breaks with a vitreous fracture. This precipitate obtained from the sulphuric solution, by the addition of water, is a sulphate of columbium.

Titanium, &c.

2. Nitrate of Columbium.

The oxide of columbium seems to be perfectly insoluble, and remains unchanged in colour, when digested in boiling concentrated nitric acid.

3. Muriate of Columbium.

Columbic acid, when recently separated from potash, is soluble in boiling muriatic acid. This solution may be considerably diluted with water, without any change being produced. When evaporated to dryness, it left a pale-yellow substance, insoluble in water, and which is dissolved with great difficulty, when it is again digested with muriatic acid.

4. Phosphate of Columbium.

A few drops of phosphoric acid being added to a part of the solution of columbium in concentrated sulphuric acid, at the end of about 12 hours converted the whole into a white, opaque, stiff jelly, which was insoluble in water. When a small quantity of phosphoric acid was added to the muriatic solution of columbium, in a few hours a white flocculent precipitate was formed * (A).

* Phil. Trans. 1802, p. 49.

Sect. VI. *Of Titanium and its Combinations.*

1. This metal was discovered in 1793 by Klaproth. He obtained it from a mineral called *red schorl*. In this mineral he found the oxide of a metal different from any other then known. Previous to this time, indeed, the same oxide had been discovered by Mr Gregor in a black sand, which is found in Menachan in Cornwall. To this, from the place, he gave the name 1575 History of its discovery.

(A) Another metal has been more lately announced by Ekeberg, which, in some of its properties, seems to resemble columbium. He obtained this metal from two minerals; to one of which he gave the name of *tantalite*, which is of a blackish gray colour, with some metallic lustre, and some appearance of crystallization. This mineral is very hard; the specific gravity is 7.953. When reduced to powder, it is of a brownish gray colour, and is not attracted by the magnet. To the other mineral he gave the name of *yttrotantalite*. It was found in small insulated masses, in veins of feldspar, and black mica. The fracture of this mineral is granular, of a gray metallic appearance, and may be scratched, although with difficulty, with a knife. It is not attracted by the magnet. The specific gravity is 5.13. From these minerals this chemist extracted a substance, which he concluded to be a peculiar metal in the state of oxide, having the appearance of a white powder. The following are the properties which he ascertained.

1. It is not soluble in any of the acids. 2. The alkalies attract and dissolve a considerable quantity of this substance, which may afterwards be precipitated by means of the acids. 3. The whole oxide of this metal undergoes no change of colour by the action of heat. 4. Its specific gravity when it has been exposed to a red heat is 6.5. 5. It fuses with phosphate of soda and borax, without communicating to them any colour. 6. The oxide of this metal, heated with charcoal powder, is reduced to the metallic state, exhibits a brilliant fracture, of a dark gray colour. 7. It is again converted into a white powder by the action of the acids. The other properties of this substance have not been detailed *. To this metal Ekeberg has given the name of *tantalium*.

* Ann. Chim. x. p. 276.

name of *menachine*, but he had not succeeded in reducing it to the metallic state. Klaproth afterwards analyzed the *menachanite* of Mr Gregor, and found that it was precisely the same as the oxide of the metal which he discovered in red schorl. To this metal he gave the name of *titanium*. The experiments of Klaproth were afterwards repeated by Vauquelin and Hecht in 1796. His results were confirmed, and they also succeeded in reducing a small quantity of the oxide to the metallic state.

1576 Natural history. 2. This metal has been found only in the state of oxide. Red schorl consists entirely of this oxide. It has been found in different countries, as in Spain, France, and Hungary. This oxide is disseminated in the fine specimens of rock crystal, which are brought from Madagascar, crystallized in long brilliant needles, the form of the primitive crystal being a six-sided prism, with two-sided summits; that of the molecule is a triangular prism, with right-angled isosceles bases. It is of a red colour of different shades. It is brittle, but the fragments are so hard as to scratch glass. The specific gravity is from 4.180 to 4.246. The other mineral, to which Klaproth has given the name of *titanite*, is composed of oxide of titanium, silica, and lime, nearly in equal proportions. Its specific gravity is 3.510.

1577 Analysis of it. 3. Titanium was obtained by Vauquelin, by reducing the native red oxide. He mixed together 100 parts of this oxide with 50 of calcined borax, and 50 of charcoal, formed into a paste with oil; and exposed the whole to the heat of a forge raised to 166° Wedgwood. By this process he obtained a dark-coloured, agglutinated mass, having a brilliant appearance on the surface.

1578 Properties. 4. Titanium obtained in this way is of a reddish yellow colour, shining and brilliant on the surface, and equally brilliant in some of its internal cavities. Its other properties, as it has been only procured in very small quantity, have not been determined.

1579 Action of heat. 5. Titanium seems to be one of the most infusible metals known. When the red oxide is exposed to heat in a crucible, it loses its lustre. By the action of the blow-pipe it is deprived of its transparence, and becomes of a grayish white colour. On charcoal it becomes still more opaque, and of a slate gray. The artificial carbonate of titanium, exposed to heat in a crucible, loses $\frac{25}{100}$ of its weight, becomes yellow, and, as it cools, resumes its white colour.

1580 Phosphuret. 6. Titanium enters into combination with phosphorus, and forms with it a phosphuret. This was prepared by Mr Chenevix, by exposing a mixture of phosphate of titanium, charcoal, and a little borax, in a crucible, to a very strong heat. The phosphuret which he obtained was in the form of a metallic button, of a pale white colour, brittle and granular, and infusible by the action of the blow-pipe. Titanium has not been combined with sulphur.

1581 Affinities. 7. This metal enters into combination with the acids, and forms salts with them. The affinities of the oxides of titanium, as they have been ascertained by Lampadius, are in the following order.

Gallic acid,
Phosphoric,
Arsenic,
Oxalic,
Sulphuric,
Muriatic,
Nitric,
Acetic †.

† *Ann. de Chim.* xxvi. p. 91.

1582 Alloys. 8. In the experiments which were made by Vauquelin and Hecht, to combine titanium with other metals, they did not succeed with silver, copper, lead, or arsenic; but they formed an infusible alloy with iron, of a gray colour, interspersed with yellow-coloured shining particles.

I. Salts of Titanium.

1. Sulphate of Titanium.

1583 Salts. According to the experiments of Klaproth, sulphuric acid has no action on the native red oxide of titanium from Hungary; but this acid is found to dissolve the carbonate of titanium with effervescence; and when this solution is evaporated, the red oxide is converted into a white, opaque, gelatinous mass. This was the result of Klaproth's experiment. In those of Vauquelin and Hecht, sulphuric acid being boiled with carbonate of titanium, assumed a milky appearance, and there were formed white, light flakes, which were dissolved by a stronger heat; the fluid became transparent, but did not afford crystals.

2. Nitrate of Titanium.

Nitric acid has scarcely any perceptible action on titanium, but it combines with the carbonate, and forms a transparent solution, which assumes an oily appearance in the air, and affords transparent crystals in the form of elongated rhombs, having the opposite angles truncated, so as to represent hexagonal tables. But according to Vauquelin and Hecht, when they heated a mixture of nitric acid with carbonate of titanium, nitrous gas was disengaged, and the liquid remained milky. Sugar added to the mixture causes a precipitate of the oxide, of a whiter colour than the carbonate; and if the nitric acid be employed diluted, the oxide of titanium is dissolved, but the solution becomes turbid by means of heat, and thus the addition of caloric opposes the combination of this oxide with nitric acid, by oxidating it in a higher degree than what is soluble in this acid.

3. Muriate of Titanium.

The carbonate of titanium is soluble in muriatic acid; and according to Klaproth, the solution affords a yellowish, transparent jelly, which contains numerous transparent, cubic crystals. Vauquelin and Hecht found, that the carbonate of titanium is dissolved with effervescence in concentrated muriatic acid; and the solution assumes a deep yellow colour, when it is made without the assistance of heat. When it was heated, it was reduced to a flaky mass, which was neither redissolved by water, nor by new additions of the acid. A similar solution which was not heated remained transparent; but when this solution was exposed to a temperature of about 170°, it was converted into a yellow, transparent jelly, of an acid and very astringent taste, which, by cooling, deposited a great number of small crystals which effloresced in the air. When

Titanium, &c. When this solution was boiled, oxymuriatic acid gas was disengaged, the oxide was precipitated, and is no longer soluble in muriatic acid, till it is boiled for a long time with nitric acid; from which it appears, that the oxide of titanium must have a great proportion of oxygen, to combine with muriatic acid, and in this state it can only combine with it in the cold, because when it is exposed to heat, the acid carries off a portion of its oxygen, which renders it insoluble. The oxide of titanium, separated from muriatic acid by the action of the blow-pipe, assumes a beautiful orange-yellow colour.

4. Carbonate of Titanium.

1584 Preparation. One part of the red oxide of titanium, and five parts of carbonate of potash, exposed to a red heat in a crucible, were soon fused, and formed a solid mass of a whitish gray colour, with small needle-form crystals on the surface. When this was reduced to powder, and washed with warm water, there was deposited a light white powder, which was found to be carbonate of titanium. The arsenic and phosphoric acids cause a white precipitate of the oxide of titanium from its solution in acids. A similar precipitate is produced by oxalic and tartaric acids; but it is instantly re-dissolved, and the solution recovers its transparency.

1585 Salts of titanium decomposed. The oxide of titanium is precipitated from its solution in acids; 1. By carbonate of potash, in the form of a white flaky matter, and by ammonia in the same way. 2. Prussiate of potash causes a copious precipitate of a mixed colour of green and brown. 3. Infusion of nut-galls produces a very voluminous precipitate, of a reddish brown colour; and if the solution be not too much diluted with water, it coagulates like blood. A rod of tin introduced into a small bottle, with a solution of this oxide in muriatic acid, caused in a few minutes a pale rose colour, in that part of the solution near the rod. This colour soon changed to a beautiful ruby. A rod of zinc first produced a violet colour, and afterwards that of indigo. 4. Sulphuret of ammonia combined with this solution, produced a pale green colour, and a precipitate of a bluish green.

Sect. VII. *Of Uranium and its Combinations.*

1586 Discovery. 1. This metal was discovered by Klaproth in the year 1789. It was then announced as a metal more difficult to be reduced than manganese, externally of a gray colour, and internally of a clear brown, of considerable lustre, and middling hardness; that it might be scratched and filed, and that its oxide gives a deep orange colour to porcelain.

1587 Natural history. 2. It has been obtained from three different minerals. The first is in the state of sulphuret, of a blackish colour, and of a shining fracture, and sometimes lamellated. This has been called *pitch blende*. The specific gravity is from 6.37 to 7.50. In this state it is sometimes combined with iron and sulphurated lead. The uranium is in the metallic state. The second ore from which this metal is obtained, is the native oxide of uranium. It is always in the state of yellow powder, on the surface of the sulphuret. The specific gravity is 3.24. When it is of a pure yellow colour, it is then a pure oxide. The third ore of the metal is the native carbonate of uranium. Of this there are two distinct varieties, the one of a pale green, and sometimes of a silvery white colour. This contains but a small quantity of the oxide of copper, and is very rare. The other is of a shining deep green, which is the green mica or *glimmer* of mineralogists. Klaproth supposed that it contained an oxide of uranium, mixed with the oxide of copper; but it has been since discovered to have carbonic acid in its composition. It is crystallized in small square plates, and sometimes, though rarely, in complete octahedrons.

3. The process by which Klaproth reduced this metal, is the following. He mixed the yellow oxide of uranium, precipitated from its solutions by an alkali, with linseed oil, in the form of a paste, and this being exposed to a strong heat, there remained a black powder, which had lost rather more than one-fourth of its weight. It was then exposed to the heat of a porcelain furnace, in a close crucible, and the oxide was afterwards found in a coherent mass, but friable under the fingers, and reduced to a black shining powder. It decomposed nitric acid with effervescence. This black powder, covered with calcined borax, was for the second time exposed to a still stronger heat, by which a metallic mass was obtained, consisting of very small globules adhering together. 1588 Analysis of the ore.

4. The colour of uranium is of a dark gray, and internally of a pale brown. It has little brilliancy, on account of the spongy mass, in which state it was obtained. It may be scratched with a knife, and is extremely infusible. The specific gravity is 6.440. 1589 Properties.

5. When uranium is exposed to a red heat in the open air, or when it is acted on by the blow-pipe, it undergoes no change. The yellow oxide of uranium does not melt. It acquires a brownish gray colour when it is long heated in the air, but it has not been ascertained whether it gains or loses oxygen.

6. The oxide of uranium is reduced by means of charcoal, when it is exposed to heat. Little is known of the combination of uranium with phosphorus; but when the oxide was treated with blood, and a strong heat applied, an acrid bitter mass was obtained, which was supposed to owe its fusibility to the phosphorus which it contained.

7. Uranium has not been artificially combined with sulphur, but it is not improbable that such a combination might take place, since it is found native in this state. Of the alloys of uranium with other metals nothing is yet known.

I. Salts of Uranium. 1590 Salts.

1. Sulphate of Uranium.

The yellow oxide of uranium is readily dissolved in diluted sulphuric acid; and the solution affords, by evaporation, a salt of a yellow colour, in the form of small prisms. The sulphate of uranium is different from all other metallic salts yet known, in colour, form, and other properties.

2. Nitrate of Uranium.

Nitric acid dissolves with equal facility the oxide of uranium. The solution being slowly evaporated, yields large crystals in regular hexagonal tables, of a yellowish

Cobalt, &c.

yellowish green colour. The crystals of nitrate of uranium are the most beautiful of all the metallic salts.

3. Muriate of Uranium.

Muriatic acid also dissolves the oxide of uranium, and furnishes small yellow crystals, which are deliquescent in the air.

4. Fluate of Uranium.

Fluoric acid combines with the oxide of uranium, and forms with it a crystallized salt, which is not altered by exposure to the air.

5. Phosphate of Uranium.

Phosphoric acid enters into combination with the oxide of uranium, and forms with it yellowish white flakes, which are very little soluble in water.

6. Arseniate of Uranium.

Arsenic acid may be combined with uranium, by decomposing the nitrate by means of an alkali. A precipitate is obtained of a yellowish powder, which is the arseniate of uranium.

7. Molybdate of Uranium.

In the same way molybdate of uranium may be obtained by adding a solution of molybdate of potash to the nitrate of uranium. It is obtained in the form of powder.

8. Acetate of Uranium.

The oxide of uranium is soluble in concentrated acetic acid, with the assistance of heat; and beautiful yellow crystals are obtained, in the form of long, slender, transparent, four-sided prisms, terminated by four-sided pyramids.

The solutions of the oxide of uranium in acids are precipitated by the alkaline sulphurets, of a brownish yellow, and their surface is covered at the same time with a gray metallic pellicle. The fixed alkalies precipitate from their solutions an oxide of uranium, of an orange yellow colour; ammonia occasions a precipitate of a bright yellow; and the alkaline carbonates throw down a carbonate of uranium of a whitish yellow, which is redissolved in an excess of alkali. The infusion of nut-galls thrown into one of these solutions, the excess of whose acid has been taken up by an alkali, produces a chocolate brown precipitate. Zinc, iron, and tin, introduced into these solutions, produce no change of colour, either in the cold or by heat.

Sect. VIII. *Of Cerium.*

Cerium was discovered by Berzelius and Hisinger in a Swedish mineral, formerly supposed to be an ore of tungsten. It is denominated cerium, from the planet Ceres, discovered about the same time; and the mineral containing it is named *cerite*. When this mineral is dissolved in nitro-muriatic acid, the solution, after being rendered neutral by potash, is precipitated with tartrite of potash or oxalic acid. This precipitate, when calcined, is the white oxide of cerium. The metal itself has very seldom been obtained pure, and only in very minute quantity. It is white, very hard, brittle, and volatile. It is capable of combining with another portion of oxygen by heat, and the peroxide thus obtained is red. The solutions of the oxides in the acids are either yellow or red, and give precipitates of different shades of these colours. 1592 History and combinations.

Sect. IX. *Of Cobalt and its Combinations.*

1. The mineral called *cobalt*, or *cobolt*, (B) seems to have been first employed to give a blue colour to glass after the middle of the 16th century; but it was not till about the year 1732, that cobalt was distinguished as a peculiar metal by Brandt, a Swedish chemist, who extracted it from its ore, and examined some of its properties. In 1761 Lehman gave a particular account of the nature and properties of this substance; but his researches were chiefly limited to the mineral in the state of ore. Bergman afterwards examined this metal, and pointed out the difference between it and nickel, manganese, and iron. The nature of it has been more lately investigated by Tassaert and Thenard, and some other French chemists. 1592 History.

2. Cobalt

(B) The following curious information is given by Beckman with regard to the discovery of this mineral. "About the end of the 15th century, cobalt appears to have been dug up in great quantity in the mines on the borders of Saxony and Bohemia, discovered not long before that period. As it was not known at first to what use it could be applied, it was thrown aside as a useless mineral. The miners had an aversion to it, not only because it gave them much fruitless labour, but because it often proved prejudicial to their health by the arsenical particles with which it was combined; and it appears even that the mineralogical name *cobalt* then first took its rise. At any rate, I have never met with it before the beginning of the sixteenth century; and Mathesius and Agricola seem to have first used it in their writings. Frisch derives it from the Bohemian word *kow*, which signifies metal; but the conjecture that it was formed from *cobalus*, which was the name of a spirit that, according to the superstitious notion of the times, haunted mines, destroyed the labours of the miners, and often gave them a great deal of unnecessary trouble, is probable; and there is reason to think that the latter is borrowed from the Greek. The miners, perhaps, gave this name to the mineral out of joke, because it thwarted them as much as the supposed spirit, by exciting false hopes, and rendering their labour often fruitless. It was once customary, therefore, to introduce into the church service a prayer that God would preserve miners and their works from *kobolts* and spirits."

"Mathesius, in his tenth sermon, p. 501, where he speaks of the *cadmia fossilis*, says: 'Ye miners call it *kobolt*; the Germans call the black devil and the old devil's whores and hags old and black *kobel*, which by their witchcraft do injury to people and to their cattle.'—Whether the devil, therefore, and his hags, gave this name to cobalt, or cobalt gave its name to witches, it is a poisonous and noxious metal."

1594 Ores. 2. Cobalt has never been found in nature in a state of purity. It is either alloyed with arsenic, both metals being in the metallic state, or it is combined with sulphur and arsenic, or in the state of oxide, or forming a salt with arsenic acid. 1. In the first state, when it is alloyed with arsenic, it is of a gray or whitish appearance, with some degree of brilliancy. The specific gravity is 7.72. It is sometimes crystallized in cubes, or octahedrons. When small fragments of this mineral are exposed to the action of the blow-pipe, or even to the flame of a candle, they give out a garlic smell. 2. The combination of sulphur and arsenic with cobalt is denominated *gray cobalt ore*. The specific gravity is from 6.33 to 6.45. The structure is lamellated, and when it is heated, it emits no garlic smell. It crystallizes in octahedrons, dodecahedrons, and some other forms resembling the sulphuret of iron, with which it is frequently combined. 3. The third species of cobalt ore is the oxide. It is found in black, friable masses, or in the state of a black efflorescence, which soils the fingers. This is a pure oxide of cobalt. 4. The fourth species is the arseniate of cobalt, which has been distinguished by the names of *flowers of cobalt*, *cobalt bloom*. It is of a peach-blossom colour, sometimes in the state of efflorescence, sometimes in the form of small needles of a deep colour, which remains even after they are reduced to powder, and sometimes in four-sided prisms terminated by two sided summits. When it is placed on hot coals, it gives out a strong garlic smell, loses its colour, and becomes black.

1595 Analysis of the ores. 3. To procure the pure metal from the ores of cobalt, the oxide in the state of black powder, after being roasted, is mixed with three times its own weight of black flux and a little common salt, put into a crucible lined with charcoal, and exposed to a forge heat. When the fusion is completed, the crucible is to be slightly agitated, to collect together the metallic globules into one mass. Sometimes two metallic buttons are found under the vitreous scoriæ. The cobalt occupies the upper part, and the bismuth being heaviest, is lowest. In this state the cobalt is almost always combined with a small portion of arsenic, nickel, or iron. But if the crystallized gray oxide of cobalt has been employed, the metal is obtained very pure, by the above process; and when the ore is rich, it yields from 60 to 80 per cent.

By a different process, cobalt may be obtained in the metallic state, which consists in treating the ore with nitric acid, which oxidates and dissolves both the cobalt and the iron. These oxides are precipitated by carbonate of soda, and well washed with water. They may be separated by means of nitric acid, which dissolves the oxide of cobalt, without touching that of the iron.

1596 Properties of cobalt. 4. Cobalt is of a gray colour, inclining to red, and of a very fine granulated texture. It is very brittle, so that it is easily reduced to a fine powder, which is of a gray colour, and with little brilliancy. The specific gravity, according to Bergman, is 7.700; according to others, it is from 7.811 to 8.5384.

1597 Action of heat. 5. Cobalt is one of the most infusible metals, requiring a temperature equal to 130° Wedgwood. It becomes red before it melts. When it is slowly cooled, and by pouring out a part of the fluid when it becomes solid at the edges, the cavity is found lined with prismatic crystals. The same crystallization may be effected by inclining the crucible at the moment the surface becomes solid.

6. When cobalt is exposed to a red-heat in an open vessel, it first loses its colour and its brilliancy, becomes of a deep gray colour, and then passes to a black, or an intense blue. With a still more violent heat, this last oxide melts into a bluish black glass. It appears, from the experiments of Thenard, that cobalt combines with different proportions of oxygen, forming different oxides. When a solution of cobalt in acids is precipitated by an alkali, the precipitate which is formed is first of a lilach colour; and with an excess of base it becomes successively blue and olive, and at last by drying it becomes entirely black. These different changes depend on the different proportions of oxygen with which it combines. 1598 Oxidation.

He precipitated a solution of cobalt by pure potash. The oxide collected on a filter was blue, and when exposed to the air it became of an olive colour; and when washed with oxymuriatic acid, it changed from green to brown, and from this shade to the deepest black. The black oxide dissolved with effervescence in muriatic acid; oxymuriatic acid gas was emitted in great abundance, and when the muriatic acid was concentrated, the solution was of a green colour, which in the space of 24 hours became purple. When the acid was diluted it became instantly red. The oxide is soluble in sulphuric and nitric acids, and the solution is of a red colour, accompanied with the evolution of bubbles, which seem to be oxygen gas.

The brown and coloured oxides produce with sulphuric, nitric, and muriatic acids, similar effects with the black oxide. With muriatic acid they both give out oxymuriatic acid, and form a solution of a green colour, which in time passes to a purple; or, if the acid be diluted with water, it becomes instantly red. The olive-coloured oxide is prepared by pouring potash into a solution of cobalt. There is formed a blue precipitate, which exposed to the air becomes green. If this oxide be treated with diluted muriatic acid, oxymuriatic acid is obtained with a slight degree of heat, and the solution becomes more and more red, as this acid is disengaged; so that the blue oxide combines with the oxygen of the air.

The blue oxide of cobalt, Thenard thinks, is most conveniently obtained by calcining the black oxide for half an hour in a cherry-red heat. It assumes a blue colour, by being deprived of part of its oxygen. This oxide dissolves in acids, without the disengagement of any gas. Its solution in concentrated muriatic acid is green, but if the acid be diluted with water, it is red. 1599
Thenard concludes from his experiments, that there are four different oxides of cobalt; the blue, the olive, the brown, and the black; although he supposes that the brown may be a mixture of the olive and black oxides*. Oxides, four.

7. There is no action between azote, hydrogen, or carbon, and cobalt.

8. Phosphorus enters into combination with cobalt, by projecting bits of phosphorus on small pieces of cobalt, red hot, in a crucible. The metal is instantly fused, and it absorbs about $\frac{1}{15}$ of its weight of phosphorus. A crust is formed at the same time on the surface, of a violet-red colour. This phosphuret of cobalt 1600 Phosphuret.

* *Annales de Chim.* x 210—2

balt has a metallic lustre, is of a whiter colour than the metal itself, and is more brittle. It loses its brilliancy in the air; and by the action of the blow-pipe, phosphorus is disengaged from the metallic globule, and inflames on the surface. There remains behind a vitreous globule of a deep blue colour.

601 Sulphuret. 9. Sulphur combines with difficulty with cobalt, but the compound may be formed by the aid of the alkalies. This metal is soluble in the alkaline sulphurets, and the result is a sulphuret of cobalt, of a yellowish white colour, which is only decomposed by means of the acids.

602 10. Cobalt enters into combination with the acids, and forms salts. It forms alloys also with most of the metals. The order of the affinities of cobalt and its oxides, according to Bergman, is the following:

COBALT.	OXIDE of COBALT.
Iron,	Oxalic acid,
Nickel,	Muriatic,
Arsenic,	Sulphuric,
Copper,	Tartaric,
Gold,	Nitric,
Platinum,	Phosphoric,
Tin,	Fluoric,
Antimony,	Saclactic,
Zinc,	Succinic,
Phosphorus,	Lactic,
Sulphur,	Acetic,
	Arsenic,
	Boracic,
	Prussic,
	Carbonic.

I. Salts of Cobalt.

1. Sulphate of Cobalt.

603 Preparation. 1. Concentrated and boiling sulphuric acid is decomposed by cobalt, with the evolution of sulphurous acid gas. A thick, grayish mass, inclining to red, is formed. Water dissolves the sulphate of cobalt, and affords a grayish coloured liquid.

604 Properties. 2. The sulphate of cobalt crystallizes in small needles, or four-sided rhomboidal prisms, terminated by two-sided summits. It is of a reddish colour, and is soluble in 24 parts of water. It is decomposed by heat, and there remains behind the black oxide of cobalt. By the action of the blow-pipe it swells up with effervescence. The alkalies also decompose it, by precipitating a reddish yellow oxide. One hundred parts of cobalt furnish 140 parts of this precipitate by pure alkalies; but when the precipitation is effected by means of the alkaline carbonates, 160 parts are obtained.

2. Nitrate of Cobalt.

605 Preparation. 1. Nitric acid combines with cobalt, with the assistance of a moderate heat. Nitrous gas is disengaged, the metal is oxidated, and is dissolved in the acid. The solution is of a flesh-red colour, but when it is concentrated, of a brown colour. By evaporation it affords small reddish-coloured prismatic crystals, which are deliquescent in the air, and which being placed on red-hot burning coals, swell up, and are decomposed, leaving behind a deep red oxide.

2. It is by the precipitation of this salt, that the oxide of cobalt is obtained for the purpose of enamels, and for giving a colour to porcelain. When the oxide is precipitated by means of an alkali, it is redissolved when the alkali is added in excess. Cobalt, &c. 1606 Enamels.

3. Nitrate of Ammonia and Cobalt.

This triple salt was formed by Thenard, by adding to a solution of cobalt in nitric acid, ammonia in excess. No precipitate is obtained. This solution being filtered and evaporated to dryness, and the residue being dissolved in water, and again evaporated, yielded, on cooling, regular cubic crystals of a red colour, and of a pungent taste. They were not changed by exposure to atmospheric air. Being calcined in a crucible, they burned like nitrate of ammonia, with a vivid, yellowish white flame. The residue was a black substance, which had all the properties of cobalt. The solution of this salt in water is not precipitated by any of the alkalies or earths. It is still more readily decomposed by sulphurated hydrogen, or the hydrosulphurets. When it is boiled with potash, ammonia is disengaged; the oxide of cobalt is precipitated, and a nitrate of potash is formed *.

* *Ann. de Chim.* xlii. 215.

4. Muriate of Cobalt.

1. Muriatic acid has no effect on cobalt in the cold; but a small quantity is dissolved with the assistance of heat. But the black oxide of cobalt is readily dissolved in muriatic acid. The solution is accompanied with effervescence, and the disengagement of oxymuriatic acid gas. When this solution is concentrated by evaporation, it becomes of a fine green colour, which changes to red when it is diluted with water. By farther evaporation it is crystallized, and affords small deliquescent crystals of muriate of cobalt in the form of needles. 1607 Preparation.

2. When these crystals are dissolved in water, and so diluted that the solution is nearly colourless, characters marked with it on paper disappear entirely; but when heated, assume a fine green colour. This solution was one of the first known sympathetic inks. In making experiments with this solution, the characters are written on paper, or, that the experiment may be more amusing, a landscape is drawn with a pencil, representing the verdure of summer on a winter scene. Those parts of the picture in which the sympathetic ink has been used, are invisible in the cold; but when it is moderately heated, they become of a fine green colour, changing from the winter to the summer scene. When it is removed to the cold, the colour again disappears, and if too much heat be not applied, the same change may be frequently repeated. When too much heated, the blue colour is converted to a brown, which becomes permanent. 1608 Sympathetic ink.

3. Various theories have been proposed to account for this remarkable change. According to some, it is owing to the moisture of the atmosphere being absorbed that the colour disappears; and when this is driven off by heat, it is restored. But to this opinion it has been objected, that the same effect is produced, when paper, on which characters have been written with this solution, is entirely excluded from the atmosphere, by being introduced into close vessels. According to others, the sympathetic effect of this solution depends on the iron which is combined with the cobalt. 1609 Theories.

Cobalt, &c. cobalt. Some suppose that the concentration of the solution, which takes place by the action of heat, is the cause of the appearance of the colour; and its dilution, by absorbing moisture from the atmosphere, the cause of its disappearance; while others are of opinion that it is partially deprived of its oxygen by being heated, and absorbs it again in the cold, when the colour vanishes.

1610 Another process. The sympathetic ink may be easily prepared, by dissolving the zaffre of commerce in nitro-muriatic acid.

5. Fluate of Cobalt.

Fluoric acid dissolves the oxide of cobalt, and forms with it a yellow-coloured gelatinous solution; or, by careful evaporation, it affords crystals, which are fluate of cobalt.

6. Borate of Cobalt.

Boracic acid has no action on cobalt; but it combines with the oxide, by mixing a solution of nitrate of cobalt with a solution of borax.

7. Phosphate of Cobalt.

Phosphoric acid dissolves the oxide of cobalt, and forms with it a reddish-coloured turbid solution, which affords a precipitate when the acid is saturated.

8. Carbonate of Cobalt.

This salt is formed by precipitating cobalt from its solutions in acids, by means of alkaline carbonates. One hundred parts of cobalt, which afford only 140 of precipitate by means of the pure alkalies, yield 160 parts, when the precipitate is effected by carbonate of soda.

9. Arseniate of Cobalt.

This salt is formed by combining the nitrate of cobalt with the arseniate of potash or of soda. It is sometimes found native, and it exhibits the deepest and most beautiful red of all the salts of cobalt.

10. Tungstate, molybdate, chromate, and columbate of Cobalt. Unknown.

14. Acetate of Cobalt.

This salt is readily formed, by dissolving the oxide of cobalt in acetic acid. It does not yield crystals by evaporating, but is deliquescent in the air. It assumes a blue colour when it is heated, but is red in the cold, so that it forms a sympathetic ink.

15. Oxalate of Cobalt.

This salt may be formed by precipitating the oxide of cobalt from its solution in acids, by means of oxalic acid. This precipitate, when it is dried, is in the form of a red powder, which is insoluble in water, but may be dissolved in excess of oxalic acid, and crystallized.

16. Tartrate of Cobalt.

The oxide of cobalt is soluble in tartaric acid, and forms a red-coloured solution, which affords crystals by evaporation.

II. Action of Alkalies, Earths, and Salts.

1611 Alkalies. 1. The alkalies have no action whatever on cobalt; but when the oxides are suspended in water, they separate them from other matters.

1612 Earths. 2. Some of the earths, but particularly silica, enter into combination with the oxide of cobalt and the fixed alkalies, and form a beautiful blue-coloured glass. The quantity of oxide must be small, otherwise the glass will appear nearly black and opaque, on account of the intensity of the colour.

161[illegible] Salts. 3. Some of the neutral salts exposed to a high temperature along with cobalt burn with a perceptible flame. It is by this means that the oxide is prepared for the purpose of enamels and colouring porcelain.

The hyperoxymuriate of potash, with one-third of its weight of cobalt in powder, detonates by percussion.

161[illegible] Uses. Cobalt is scarcely at all employed in the metallic state. *Zaffre* is used for coarse enamels and pottery ware. The purer oxides of cobalt are chosen for the purpose of colouring porcelain. *Azure* is a vitreous blue in the state of fine powder, which is prepared for similar purposes. Zaffre is fused along with silica and an alkali, and thus forms a deep blue glass, which is known by the name of *smalt*. This is reduced to a powder, and mixed with a great quantity of water. The first portion which precipitates is called *coarse azure*. Four different quantities are separated in this way. The last, which is the finest, is called azure of four fires.

SECT. X. *Of* NICKEL *and its Combinations*.

161[illegible] History. 1. The first mention which is made of this metal is by Hierne, a Swedish chemist, in a work entitled *The art of discovering metals*, published in 1694. He particularly describes the mineral from which nickel is extracted, and which was first called *kupfernickel*, or *false copper*, because it was taken for an ore of copper, and none could be obtained from it. This was the opinion of Henckel and Cramer, who supposed it to be copper combined with arsenic or cobalt. This mineral was generally arranged among copper ores, till it was examined and analyzed by the celebrated Swedish mineralogist Cronstedt, in 1751, and 1754. In these experiments, the account of which was published in the memoirs of the Swedish Academy, he proved that this mineral contains a new metal, different from all those which had been hitherto known, to which he gave the name of *nickel*. This opinion was generally adopted, and objected to only by Monet and Sage of France, who affirmed that this new metal was merely an alloy of cobalt, arsenic, iron, and copper. To remove these differences of opinion with regard to this substance, Bergman undertook an elaborate analysis of the ores of nickel, and an accurate examination of its peculiar properties in the metallic state. His experiments were detailed in a dissertation which was published in 1755. The object of his researches was, to ascertain if nickel was a peculiar metal; and from the result of his experiments it appeared, that it did not contain the smallest trace of copper, but that it is generally alloyed with cobalt, arsenic, and iron, from which indeed it can scarcely be completely separated; but that it possessed peculiar and distinct properties from the other metals; and these properties became more striking and characteristic in proportion to its purity.

2. Nickel

Nickel, &c.

1616 2. Nickel is found in the state of sulphuret, when it is called *kupfernickel*. It is of a reddish yellow colour, with little brilliancy, somewhat similar to tarnished copper, with which, from its appearance, it is frequently confounded. This mineral soon loses its brilliancy in the air, becomes of a brownish colour, and is covered at last with greenish spots. It is found forming veins in the earth, and is usually combined with arsenic, cobalt, and iron. Nickel has been found alloyed with iron, when it is of a laminated texture, and composed of rhomboidal plates. The fresh fracture is of a pale yellow, which becomes black by exposure to the air. Nickel is also found native in the state of oxide, when it is of a bright green colour. In this state it is generally on the surface of sulphuret of nickel. Native nickel has also been found, according to Bergman, or at least with a very small proportion of sulphur, but combined with iron, cobalt, and arsenic. He says, too, that it exists in combination with sulphuric acid.

1617 Separation of the metal. 3. To obtain nickel from its ores in the state of sulphuret, they are first roasted, by which means the sulphur and arsenic are driven off. In this process the mineral loses one-third or one-half of its weight; and in proportion to the quantity of pure metal, which exists in the ore, it assumes a richer green. The roasted ore is then mixed with two parts of black flux, put into a crucible covered with muriate of soda, and exposed to a forge heat, to bring it to fusion. When the apparatus has cooled, there is found under the brown, black, or blue scoriæ, a metallic button, which amounts to one-tenth, and sometimes to one-half, of the mineral employed.

1618 Properties. 4. Nickel, in the purest state in which it can be obtained, is of a yellowish white, or of a reddish white colour, with more or less lustre, and of a granulated texture. The specific gravity is 9 according to Bergman, but according to Guyton it is only 7.807. Bergman speaks of it as possessing some degree of ductility; but this, it is supposed, is owing to its alloy with iron, which latter constitutes $\frac{1}{7}$ of its weight. It is also magnetic, and this property has also been supposed to depend on the same alloy. Nickel is a very infusible metal, requiring a temperature equal to 150° Wedgwood. Its power of conducting caloric has not been ascertained, nor has its taste or its smell been recognized. It has never been obtained in crystals.

1619 Action of heat. 5. When nickel is exposed to heat in an open vessel, it combines with oxygen, and assumes a brown colour; but this requires a very high temperature. After long exposure to the air, when it is moist, and in the cold, 1620 Oxide. it becomes covered with an efflorescence of a bright green colour, of a peculiar and distinct shade. It is this efflorescence which is found on the surface of the native sulphurets of nickel, the shade of which is so remarkable, and so different from that of copper, that they can be easily distinguished. This oxide is composed of

Nickel	77
Oxygen	23
	100

6. There is no action between nickel and azote, hydrogen, or carbon; nor is it at all acted upon by water.

7. Nickel combines with phosphorus, and forms with it a phosphuret. This is prepared by decomposing phosphoric acid in the state of glass, which is done by mixing phosphoric glass, charcoal, and nickel, and fusing 1621 Phosphuret them together. Or it may be prepared, by projecting bits of phosphorus on the metal, while it is red hot, in a crucible. It acquires an addition of one-fifth part to its weight; but it parts with a small portion of phosphorus as it cools. The phosphuret of nickel is of a more brilliant and purer white than the metal itself. The texture resembles a collection of small needles heaped together. When it is heated under the blowpipe, the phosphorus burns on its surface, and the metal is oxidated. The component parts of this phosphuret, according to Pelletier, are, 1622 Composition.

Nickel	83.3
Phosphorus	16.6
	100.0 *.

* *Ann. de Chim.* xiii. 135.

8. Nickel combines readily with sulphur, and forms with it a sulphuret, which is somewhat different in its properties from the native sulphuret. It is hard, of a yellowish colour, and in small brilliant facets. When it is strongly heated in the open air, it gives out luminous sparks. 1623 Sulphuret.

9. Nickel enters into combination with several of the metals, and forms with them alloys; the properties of which are but little known. With cobalt and arsenic it forms native alloys. The alloy with the latter is of a reddish colour, has no magnetic property, is considerably hard, and its specific gravity is less than the mean specific gravity of the two metals. 1624 Alloys.

10. Nickel enters into combination with the acids, and forms with them salts, which are distinguished by peculiar properties. 1625 Salts.

11. The order of the affinities of nickel and its oxide, as they have been ascertained by Bergman, is the following: 1626 Affinities.

Nickel.	Oxide of Nickel.
Iron,	Oxalic acid,
Cobalt,	Muriatic,
Arsenic,	Sulphuric,
Copper,	Tartaric,
Gold,	Nitric,
Tin,	Phosphoric,
Antimony,	Fluoric,
Platinum,	Saclactic,
Bismuth,	Succinic,
Lead,	Citric,
Silver,	Lactic,
Zinc,	Acetic,
Sulphur,	Arsenic,
Phosphorus.	Boracic,
	Prussic,
	Carbonic.

I. Salts of Nickel.

1. Sulphate of Nickel.

1627 Preparation. Concentrated sulphuric acid, with the assistance of heat, is decomposed by nickel. Sulphurous acid gas is disengaged, and there remains behind a gray mass soluble in water, to which it communicates a beautiful green colour. By evaporating this solution, crystals of

a

Nickel, &c.

1628 Properties.

a pale emerald green are obtained, which are sulphate of nickel. The oxide of nickel is also readily dissolved by sulphuric acid, from which also crystals are obtained. It crystallizes in the form of square prisms, or in decahedrons, which are composed of two four-sided pyramids, truncated at the summits.

2. Nitrate of Nickel.

Nitric acid oxidates and dissolves nickel with the assistance of heat. The oxide is dissolved by this acid, without effervescence. The solution has a blackish green colour, which affords rhomboidal, deliquescent crystals, that are decomposed by heat, and leave, after being strongly calcined, and giving out oxygen gas, a black oxide. When the nitrate of nickel is exposed to a warm dry air, it is deprived of its water of crystallization, and even of its acid, so that there remains behind only an oxide of the metal.

3. Nitrate of Ammonia and Nickel.

This triple salt is formed, by adding ammonia in excess to the solution of nitrate of nickel. This salt is of a green colour. It is obtained in crystals by evaporation. The solution does not become turbid by the addition of alkalies, but the metal is precipitated by hydrosulphurets *.

* *Annal. de Chim.* xlii. 217.

4. Muriate of Nickel.

Muriatic acid dissolves nickel and its oxide slowly, except with the assistance of heat. The solution is of a green colour, and affords irregular crystals. The muriate of nickel is decomposed by heat, and by exposure to the air.

5. Fluate of Nickel.
