## T E L E G R A P H .

**T**ELEGRAPH, so named from two Greek words, *τέλος*, end or distance, and *γραφω*, to write, is a machine so constructed as to enable two persons to converse with each other at a distance, either by sentences, words, or letters, according to a convention previously agreed upon by the parties. Such a mode of communicating ideas beyond the reach of hearing is not, however, confined to any particular machine; the fingers of the human hand are quite sufficient, as every young boarding-school lady knows, for the purpose; and, when so applied, may be called a *Telegraph*. Thus also, the signal flags used on board ships to communicate with each other, by making them represent letters or numbers, or both, constitute a *Telegraph*; as may also the sending up of sky-rockets, blue-lights, the suspension of lanterns, the making of fires on beacons, high hills, &c. be considered as Telegraphic communications.

In imitation of the French, however, we have almost indiscriminately adopted the use of the word *Semaphore* for the Telegraph, which is perhaps of more extensive application, being derived from *σημα*, a sign, and *φέρω*, to bear; and may, consequently, be applied universally to whatever means may be used to communicate intelligence by signs or signals. Thus the firing of guns a certain number of times, at certain intervals,—the notes of a trumpet, bugle, French horn, or other wind instrument,—the strokes on a drum,—may be used to convey information to a limited extent. The troops and marines which landed on the coast of America in the last war, when scouring the woods in detached parties, were regulated by the notes of the bugle, which were so clearly understood, that no false movements were ever

made. The immense number of barges and boats which crowd the Imperial Canal of China are directed in their movements, both by night and day, by the sound of the *gong*. The Indians of America convey intelligence from hill to hill, by throwing out their arms with or without staves in them; by spreading their cloaks, holding up skins, &c.; and even the savage Hottentots, called *Bosjeismans*, the lowest probably in the scale of human beings, communicate with each other by arranging fires on the sides of the hills in certain positions.

It is rather surprising that an art so simple as that of conveying ideas by means of signals, so well understood in remote antiquity, and practised even by savages, should have made such little progress in its improvement, that it may be said to have remained in its original rude state nearly down to our own times, when it has almost at once been brought to that state of perfection, of which it appears to be capable.

One of the arguments usually adopted to prove that the art of conveying intelligence by signals was known in the very early ages of Greece, is deduced from the opening of the *Agamemnon* of *Æschylus*, where the man on the watch-tower, at the top of the palace, announces the fire-signals having communicated the fall of Troy, long before any of the Greeks had returned from the siege; and *Clytemnestra* afterwards relates the stations; but this event of the burning of Troy, supposed thus to have been known in Greece soon after it happened, proves nothing more than that the use of signals was known to the poet who wrote eight or nine hundred years after the event. Mention, however, is made by *Jeremiah* (Ch. vi. v. 1), who was at least 200 years before

Telegraph. Æschylus, of "setting up a sign of fire in Beth-hacerem;" and such signals are often alluded to by the prophets, as notices of the approach of an enemy.

The earliest decisive proof of telegraphic communications, except those by fires (*πυρροισιαι*), being in use among the Greeks, is found in the methods described by Polybius. (See *Ency. Brit.* under word TELEGRAPH.) The Romans had their *vexillarii*, and used flags and other contrivances for regulating the movements of their armies; and they had hollow tubes constructed in the walls of their cities, by which they could communicate with the several ports or works by sound, as is done in our times in some manufactories by means of pipes or trumpets. Wherever the Romans pitched their camp, an elevated spot was selected for the signal station, to convey intelligence to the foraging parties or detachments, but it is nowhere stated to what extent this was carried. Vegetius alludes to something like a beam in the air, on the same principle perhaps as our Semaphore.

In modern times, Kircher, who had more learning and less sense than any man of his day, and who has written on almost every subject, gives an idea of telegraphic communication; and so does the ingenious Marquis of Worcester, in his *Century of Inventions*; but so vague as to convey no notion of the means he was to employ, except the use of *colour*; for the "discourse" to be held, is stated to be "as far as eye can discover black from white." He also throws out a hint for a night telegraph, by which the same may be done, "though as dark as pitch is black." But almost every modern invention is supposed to exist in the mysterious "scantlings" of the Marquis of Worcester.

The first telegraph on record in modern times, applicable to universal purposes, is that of Dr Hooke, described in the *Philosophical Transactions* of the year 1684. He minutely details the mode in which the stations should be selected, their height and intermediate ground, so that the refraction of the air may not disturb the clear appearance of the object; the telescopes to be used; the characters to represent the alphabet, which, he says, may be varied ten thousand ways, and "none but the two extreme correspondents shall be able to discover the information conveyed:" and so convinced is he of the practical efficiency of his telegraph, as to leave no doubt on his mind, "that the same character may be seen at Paris within a minute after it hath been exposed in London." His method consisted in exposing in succession as many different shaped figures or signs, at least, as the alphabet consists of letters. If used in the day-time, they might be squares, circles, triangles, &c. made of deals; if at night, torches or other lights disposed in a certain order. These characters or signs were to be brought forth from behind a screen on rods, as they might be wanted, and exposed to view. The accompanying figure, where A is the screen, and □ one of the signs exhibited, will convey an idea of Dr Hooke's telegraph.

Monsieur Amantons, of the Royal Academy of Paris, made an experiment to convey intelligence, which

was highly approved of by the other members, and several persons of distinction belonging to the Court. By the description given of the machine, it seems to have differed very little from that of Hooke already published in the *Philosophical Transactions*; the signals being either large letters of the alphabet, or figures of various shapes to represent them; the latter being the more valuable, as, by a change of key, the nature of the communication might be kept a secret from those actually employed in making the signals.

It has been supposed that electricity might be the means of conveying intelligence, by passing given numbers of sparks through an insulated wire in given spaces of time. A gentleman of the name of Ronalds has written a small treatise on the subject; and several persons on the Continent and in England have made experiments on Galvanic or Voltaic telegraphs, by passing the stream at the two extremities or stations through phials of water; but there is reason to think that, ingenious as the experiments are, they are not likely ever to become practically useful.

Necessity is said to be the mother of invention; she is also frequently the foster-mother, who calls forth into action, and displays the utility of, inventions abandoned by their natural parent. Both Hooke's invention and Amantons' modification were published all over Europe, the former as early as 1684; yet they were not practically applied to any useful purpose till the year 1794, when Citizen Barrere, in a report made to the Convention, ascribed the invention then in use to Citizen Chappe.

Chappe's telegraph consists of a beam of wood, moveable on a pivot at the summit of an upright post; at each of the extremities of this beam is a moveable arm, as in the figure. The different positions in which both the beam and its two arms may be placed at angles of 45° give to this telegraph considerable powers; but it is a too complicated machine not to be liable to many mistakes, unless worked by long experienced operators.

In the year 1784, Mr Lovell Edgeworth produced his plan of a numerical telegraph, claiming, at the same time, the merit of having invented a mode of distant communication as far back as 1767, by employing a common windmill, and arranging the various positions of its arms and sails so as to represent a certain number of signals arranged in numerical order.

Mr Edgeworth's telegraph consisted of four wedges or cones, moveable on four upright posts, as under, which, by their different positions, might be used either numerically or alphabetically.

In the year 1795, when the advantages had been made evident which the French derived from M. Chappe's telegraph, the inventive faculties of our countrymen were called into action. Among other proposals, the Rev. J. Gamble produced two plans of a telegraph; the one consisting of five boards, one above the other, which, by opening and shutting singly, or according to all the combinations of which they were capable, gave

Telegraph. a certain number of distinct signals, representing either numbers or letters, as might be deemed most expedient. The arrangement of the shutters was as in this figure. The other plan was that of five beams of wood, turning on the summit of a post, so as to form five radii of a semicircle at equal angles of 45° with each other, as under.

Among other projects about this time was that of dividing a large circle into twenty-four parts, to represent the letters of the alphabet, round which a moveable radius was to traverse; then, by placing corresponding divisions, by means of wires, before the object-glass of the telescope, the coincidence of the two radii would mark out the letter meant to be designated. Of this kind, a plan by Mr Garnet approached nearest to efficiency; but, at best, could only be applied to very short distances.

In the same year (1795), Lord George Murray presented his plan of a six-shutter telegraph to the Admiralty, which was the one adopted and made use of during the whole war, and until the year 1816, when it was changed for a simplified Semaphore, which will be noticed hereafter. The annexed figure represents that of Lord George Murray.

On the same principle as the radiated telegraph of Mr Gamble, but differently arranged, the French, on the commencement of the second war in 1803, erected signal-posts along the coast, to which they gave the name of Semaphores, being two or three beams of wood on the same post, but turning on different pivots.

In 1807, Captain (now Colonel) Pasley published his *Polygrammatic Telegraph*, which differed only from the French Semaphore in having two beams turning on one pivot on the same post, and multiplying the number of posts; which he afterwards (in 1810) changed so far as to place three sets of beams or arms, two in each set, on one post, and thus approaching still nearer to the French Semaphore.

First Polygrammatic Telegraph.

Second Polygrammatic Telegraph.

In the year 1816, Sir Home Popham, who had already introduced a new code of signals into the navy, which was admitted on all hands as a great improvement on the old system, both as regarding the number, the arrangement, and the shape of the flags, now turned his attention to the land Semaphore, and proposed one on a construction of the same nature with those of M. Chappe and Colonel Pasley, but much simplified. It was, in fact, nothing more than two moveable arms on separate pivots on the same mast, as under.

This machine, on account of its simplicity, had obviously the advantage over all others that had been proposed; and being found of sufficient power and efficiency for all required purposes, it was adopted by the Admiralty, instead of the shutter telegraph, which had been in use since the year 1795.

Colonel Pasley, however, in 1822, still farther simplified this useful machine, at the expence of sacrificing a small portion of its powers, by making the two arms revolve on the same pivot, as under, to which he has given the name of the "Universal Telegraph."

The last, but by far the most persevering and voluminous writer on telegraphs, is Lieut.-Colonel Macdonald, who, in 1808, published what he deems improvements in the system of telegraphic communications, both as they regard the machine itself, and the dictionary to be used with it. He not only gives the preference, but is so much attached, to the shutter machine, that he is quite indignant at its being supplanted by the Semaphore; and so far from being satisfied with the powers of which a six-shutter telegraph is capable, he has extended his to no less than *thir-*

Telegraph. *teen* different boards, as under, by which he certainly gains power enough, but not without producing confusion and perplexity.

As the use of telegraphs is chiefly confined to public purposes, and more especially to convey speedy information respecting naval and military armaments and operations, the machine to be adopted, and the system of working it, ought to possess—*power—certainty—simplicity—celerity—and secrecy*. The power of the machine, or the number of distinct combinations of its moveable parts, should be equal to the conveyance of every possible order or information, either by numbers, representing the letters of the alphabet, or words, or sentences. To ensure *certainty*, the moveable parts or signs should be so well and clearly defined, so wholly within the field of the telescope, and so completely removed from all ambiguity, as not to be liable to the mistaking of one signal for another; hence, the advantage of the *simplicity* of the machine. And as one of the main uses of the telegraph is to convey instructions or intelligence in a speedier way than the intermediate distance can be travelled over, it is evident, that *celerity* is an important quality of telegraphic communication. It is equally obvious that, if such instructions or intelligence could not be conveyed in *secrecy* from him who sent it, to him who was to receive it, such a system would be highly defective and objectionable.

Bearing these observations in mind, we shall not have much difficulty in determining on the merits of the several telegraphic machines above mentioned. The choice, indeed, appears to lie between the six-shutter telegraph, so long used at the Admiralty, to communicate with the several ports,—the Semaphore of Sir Home Popham, which superseded it, and is now in use,—and the Universal Telegraph of Colonel Pasley. Colonel Macdonald, who conceives the shutter telegraph as the perfection of the art, boldly asserts, that “the Semaphore arm of proper dimensions is not to be seen in clear weather so well as the common sized boards, and in cloudy weather by no means so well;” and consequently that, “for this climate, the boarded telegraph is, in all respects, more advantageous.” This would be important if correct; but it is evident, that the Colonel is not aware of the discussion which took place on this very important part of the subject, on the first adoption of the boarded telegraph; had he read the clear and decisive observations of Mr Gamble, he would scarcely have ventured upon such an assertion.

“It is a theorem in optics,” says Mr Gamble, “that the apparent magnitude of an object varies nearly in the inverse ratio of its distance. Hence, it follows, that the larger its dimensions, to the greater

distance will it be visible. But the nature of our atmosphere, even in its most transparent state, is such as to render any calculation, grounded on this principle, extremely erroneous; and in general its density so obstructs, and its refracting powers cause such confusion in, the rays issuing from those surfaces which are not placed sufficiently distant to be distinct, that their image falling upon the retina is frequently so ill defined, as to render it difficult to determine either their figure or position; for which reasons, that which I shall term *insulation*, is generally a quality more requisite to give *distinctness* to an object, than magnitude of superficial dimensions.”

This is unquestionably true; but Mr Gamble illustrates his position thus: “An example of this distinctness arising from insulation cannot be more readily obtained than by taking a page of printed paper, and fixing the eye on some particular letter (as I); then retiring from it, the letter will be so confused with the surrounding ones, as not to be easily distinguished: but if the same letter (I) be printed on a plain sheet of paper, standing by itself (or *insulated*), the eye will then not only discern it at a much greater distance, but the image falling single and unencumbered upon the retina, we shall be able to determine whether it be inclined to the right or to the left, or whether it be placed horizontally on the paper.”

The shutter telegraph is the printed page, and the arm of the semaphore is the letter (I) on a plain sheet of paper.

But actual experiment has completely proved the fallacy of Colonel Macdonald's assertion, and the justice of Mr Gamble's theory. Every officer serving on the line of telegraphs has stated, that at all times, and more especially in cloudy weather, the arms of the semaphore are seen much better than the boards of the telegraph ever were. Lieutenant Pace, who for many years superintended the Admiralty station, declared that on the first day after the West Square semaphore was erected, he could clearly distinguish the positions of the arms *without a telescope*, and accurately take down any signals that could be made, which he had never been able to do under any circumstance whatever with the shutter telegraph. He also stated that he had frequently an open communication with the semaphore at West Square, whilst St Paul's was capt by a fog, which was at all times considered by him and his assistant as the conclusive sign that the boarded telegraph could not be worked. But in order to set the matter entirely at rest, the shutter telegraph on Nunhead, near Newcross, was left standing on the same hill with the new semaphore, in order to try their comparative distinctness, for a whole winter. The result was, that the semaphore was frequently distinctly visible when the boarded telegraph was so much enveloped in mist or fog, that the particular boards, shut or thrown open, could not be distinguished: and it appeared by a journal kept by this officer, that in the course of the winter, the days on which the semaphore was visible exceeded those on which the shutters could be seen by fully one-third. If, then, this be the case with a six-boarded telegraph, how much more objectionable must one of twelve

shutters be, which must necessarily be placed so near to each other as to make it at all times a matter of difficulty to discern at once how many, and which of them, are closed, and which open? Even in the six-shutter telegraph, one board has frequently been mistaken for the other: for it may be remarked, that such a mass of timber as is required for a shutter telegraph is seldom free from haze.

It will probably be urged, that the arms of the semaphore, having to describe a larger circle, must be slower in their operations; but this increased slowness is so amply compensated by the ease and certainty of reading off the signals as to render any such objection of little or no weight: it may make the difference of *one second* in each signal, whilst the machinery by which the semaphore is worked is as simple and as little liable to be out of order as that of the boarded telegraph.

The six-shutter telegraph, it is true, has greater powers than the two-armed semaphore, and much greater than the universal semaphore of Colonel Pasley; that is to say, the number of combinations of which it is capable of making without using the *stop-signal* (or signal which separates one word, or one sentence, from another), is much greater than in either of the other two; but *all* of them have sufficient powers, and a sufficient number of combinations, to convey with facility and dispatch any communication whatsoever; and in any language, either by letters, words, or sentences. Their respective powers may be seen by the following tables of their positions.

Admiralty Six-shutter Telegraph.

In all—62 separate and distinct signals; which may be made consecutively in any order, without requiring any *stop-signal*, when applied to spelling. The letters of the alphabet opposite to the signals, and the numbers from 1 to 0, may be changed in every possible way. When spelling is intended to be used, the number

of changes need not of course exceed that of the al- phabet; the rest, as in the table, may be applied to numbers; and what still remains may be made to represent *words* that are most commonly in use; as, for instance, *admiral, captain, ship of the line, frigate, arrived, sailed, harbour, &c.* in the navy; or, if military, *general, regiment, camp, &c.*

Admiralty Semaphore now in use.

Telegraph.

In all—28 separate and distinct signals; containing a sufficient number for expressing the letters of the alphabet, and, consequently, for spelling any message; but not a sufficient number left to express the numeral digits by single signs. The signal, No. 4, is besides, as Colonel Pasley is aware, liable to be mistaken, it being a mere elongation of the mast, which, at a great distance, and owing to the refractive power of the atmosphere, will always be ambiguous when exhibited as a single signal. But Colonel Pasley has added a short arm which he calls an *indicator*, as below at A; and which, when made moveable, more than compensates for this defect.

It was with a different view, however, that he has added this indicator. It was suggested to him by a Captain in the navy, who had experienced the greatest inconvenience, in using Sir Home Popham's ship Semaphores, from the signal men confounding the positions of the arms when seen in *reverse*.

We apprehend no experienced signal men could possibly make any mistake in merely changing the right hand for the left.

The respective powers of the three telegraphs, in making single, or, what may be called, primary signals, are, as appears from the tables, 62, 42, and 28. In making *two* changes, with a stop between them (that is, *three* signals) to represent a word or sentence, their powers will be as 3844, 1764, and 784. In making *three* changes (or, with the stop, *four* signals), as 238,328—74,088—21,952. Now, as the telegraphic dictionary of Sir Home Popham, which has been, and still is, used in the navy, does not exceed 13,000 words and sentences, and has never been found deficient in any of its divisions of subjects, it is evident that even the lowest power of the three is more than sufficient for all useful purposes; and that those compilers, who have swelled out their telegraphic dictionaries to upwards of 100,000 (one mentioned by Colonel Pasley has extended his labours to 140,000), have made them nearly useless, by the difficulty and loss of time, in finding the required phrase or sentence. We have actually seen in one telegraphic dictionary 126 pages, of 3 columns in each page, and 60 sentences in each column, containing upwards of 20,000 sentences (about one-third of the number of words in Johnson's *Dictionary*), and each of these sentences beginning with the personal pronoun HE; 20 pages with IF, &c. Compared with the use of such a dictionary, spelling the sentences is infinitely preferable as to certainty, and in many cases as to celerity. Indeed, we should say that the abbreviated nature of communications made by telegraph renders spelling by far the most eligible mode. In clear weather, the rapidity of working single signals, the short compass within which any message may be condensed, the impossibility of committing any mistake that cannot be immediately rectified, more than compensates for the difference of a few minutes, which the use of sentences may probably save. In cloudy or foggy weather, the latter method will al-

ways be liable to mistake. If experience may be assumed as a guide, the practice at the Admiralty, of spelling all sentences for the last thirty years, must decide in favour of that system.

In making use of the alphabetical table, much time may be saved, by condensing the message into the briefest form possible, leaving out of the sentences such words as may not alter the sense, and generally the vowels of words. For instance, "*Order the Agamemnon out of harbour, and direct her to proceed to Spithead.*" To convey this message alphabetically, it would be quite enough to say, "Agmemn to Spthead." If from *Spithead into harbour*, "Agmemn nto hrbr." In spelling, too, it is very desirable, especially in our foggy climate, that the intelligence to be conveyed should be compressed as much as possible into the early part of the message. By not observing this rule, a curious mistake is said to have been made in the course of the Peninsular war. The Admiral at Plymouth endeavoured to send up a message, but a fog coming on, part of it only on that day reached London. It began thus: "Wellington defeated"—and the rest was stopped by the fog: the anxiety for the remainder may readily be conceived; it came, however, complete towards the evening, and conveyed the intelligence, that "Wellington defeated the French," &c. Had the message been thus framed, "French defeated at," &c. (the word Wellington being quite superfluous), the anxiety for the particulars would have been of a very different kind. Much, therefore, depends, as far as celerity and certainty is concerned, on the construction of the sentence containing the intelligence to be conveyed.

The methods suggested for making use of telegraphic communications by night have not been less numerous than those for the day, though on land there are very few occasions on which they can be of the least possible use. A regiment might perhaps be ordered to move, at a moment's notice, in order to reach a particular point at a given time; or, as an extreme case, the enemy's fleet might be seen towards the close of the day in a particular quarter, which would make it desirable to have the intelligence conveyed in various directions; but no naval movement could take place during the night at any of the ports. So little useful, indeed, does a night telegraph, for the navy, appear to have been considered, that, with all the facility of applying lamps to the shutter-telegraph at the Admiralty, no attempt was ever made for carrying such a purpose into execution. Colonel Pasley's description of the application of his *Universal Telegraph* to night signals will suffice to show one method (as good as any other perhaps) of adopting the machine to this purpose.

"For night signals, one lantern, called the centre light, is fixed to the top of the post; and one lantern (I) as an indicator is fixed to a light crane or derrick, attached to the post, by night only, as under.

"These lanterns are stationary, and appear on the same level. Two other lan-

Telegraph.

Telegraph  
||  
Tennant.

terns are suspended to the ends of the arms, upon fixing which a couple of weights are added to counterpoise them. Each of the two arms by day, and each of the two moveable lights by night, is capable of exhibiting the seven positions, besides position O pointing vertically downwards. The indicator serves to distinguish the low numbers 1, 2, 3, from the high numbers 7, 6, 5, in whatever direction the telegraph may be viewed."

The use of telegraphic communication, important as it may be on land, is far more so in the management of a fleet at sea. On the unfortunate result of Admiral Keppel's engagement, Dr Beatson, in his *Memoirs*, thus expresses himself:—"The defects or impropriety of the signals having thus appeared clearly to be the true and sole cause of the miscarriage which disappointed the reasonable hopes of Britain on this critical and weighty occasion; we may be justified in observing, that if an admiral cannot command all the necessary movements of his ships by signal on the day of battle, he is not upon a footing with an enemy who possesses that advantage; and even with better ships and better men, and more experienced commanders, he may be foiled in his expectations of victory, if not defeated, from his want of the means to direct and to perform the necessary evolutions of his fleet."

In the *Fighting and Sailing Instructions* of the Duke of York (afterwards James II.), a certain number of signals are established for certain movements and manœuvres of the fleet, each flag or flags having their respective objects. The *l'Art des Armées Navales* of le P. l'Hoste, published at Lyons in 1697, contains something like a system of signals, but so awkward and clumsy, as to be of a very limited use. Indeed, the best signals made use of, down to the American war, could only be considered as expedients; the *numerical plan* having never once been attempted, though Dr Hooke, De la Bourdonnois, and some others, had long before suggested it.

TENNANT (SMITHSON), a distinguished Chemist, born at Selby, in Yorkshire, 30th November 1761; was the only child of the Rev. Calvert Tennant, younger son of a respectable family in Wensley Dale, near Richmond, and vicar of Selby; his mother was Mary Daunt, daughter of a surgeon of that town.

His father had been a fellow of St John's College, Cambridge, and began to teach his son Greek when he was only five years old. He had the misfortune to lose him four years after; and before he grew up, his mother also, while he was riding with her, was thrown from her horse and killed on the spot. He was sent, after his father's death, to different schools, at Scerton, Tadcaster, and Beverley; in these he was remembered as a boy retired in his manners, and somewhat melancholy, and indolent with respect to puerile amusements. He learned but little at school, and may be considered as in great measure self-educated; having been fond, almost as a child, of reading books of science, and of amusing himself with little experiments which he

Telegraph  
||  
Tennant.

In 1798 a new signal-book was issued by the Admiralty, containing about 400 sentences, for which flags were appropriated numerically, expressive of certain operations of a fleet, which were sufficiently useful as far as these sentences went; but when it became necessary to issue any order not to be found among them, the communication was obliged to be made by boats—and "a boat from each ship" was ordered. The state of the weather did not always render this practicable; and when it was, men's lives were frequently exposed to imminent risk. To remedy this inconvenience, Sir Home Popham printed at Calcutta a numerical code of naval signals, which was reprinted in England in 1803. He afterwards extended the code very considerably, which, by a recommendation of a committee of naval officers, has been adopted, and is now in general use in the navy. The only objection to this code, which more or less applies to all that have subsequently been proposed, is the great number of flags, &c. required for making numerical signals to the extent as laid down in the code in question; and which consists of nine flags, five cornettes, five triangles, and five pendants. With such a number, it is next to impossible to make out, in calm weather, the *figure* and the *colour* of the flags; and equally so when in situations where, though expanded by the wind, they present only an *edge* to the eye of the observer when the distance is not too great, so as to sink the hull of the ship behind the curvature of the earth. The semaphore or sea telegraph of Sir Home Popham comes in aid of, and indeed entirely removes, those difficulties. It consists of two posts, with a moveable arm to each (see the article NAVY), and may be removed to any part of the deck; but we are not sure, simple as it is, that the *Universal Telegraph* of Colonel Pasley, consisting of one post and two arms, might not be adopted with advantage as a sea telegraph. The former exhibits *eight*, the latter *seven* positions. (K.)

found described in them; and while he was at school at Tadcaster, he took great delight in attending a course of Walker's lectures on experimental philosophy which were given there. At Beverley he was under the care of Dr G. Croft, who had made himself known to the public by some controversial writings; here he never entered much into the pursuits of his contemporaries, but profited by a good library belonging to the school; and among other books which he read with avidity was Sir Isaac Newton's *Treatise on Optics*.

He had entertained a great desire to complete his chemical studies under the immediate instruction of Dr Priestley, who was then enjoying deserved reputation for his recent experimental discoveries; but Dr Priestley's occupations did not permit him to undertake the task of directing his education, however agreeable it might have been to him to have assisted such a pupil. In the meantime he had not neglected his classics, but had acquired a sufficient knowledge of the learned languages to appreciate with correct taste the beauties of the great writers of antiquity.

Tennant.

Notwithstanding his admiration for Dr Priestley, he was an early convert to the antiphlogistic theory of chemistry; which, with all its errors, was still a material step in the advancement of science.

In 1781 he went to Edinburgh, with the view of qualifying himself for the profession of physic, and he had the advantage of attending Dr Black's lectures, which were then in great reputation. In October 1782, he entered as a pensioner of Christ's College, Cambridge, where he became intimately acquainted with the late Professor Harwood, who had been first a surgeon in India, but having lost, by the misconduct of an agent, the fortune that he had there acquired, submitted cheerfully to the toil of recommencing his career as a physician, though already past the middle age: his talents for conversation were such as were extremely likely to captivate a young man of superior discernment; and he formed a friendship with Tennant which continued uninterrupted throughout their lives.

At Cambridge he studied a little of the mathematics, in the works of Newton, but much more of chemistry and botany: he already began to exercise his inventive powers in an attempt to economize the consumption of fuel in distillation, which he did not make public until 20 years after, though he mentioned it at the time to some of his friends. He also occupied himself incessantly in general, and especially in political reading, though he was far from having the air of a student: but his rooms were always in confusion from the mixture of heterogeneous materials that were accumulated in them. His residence at Cambridge was perhaps the happiest time of his life; his spirits unwearied, his health unbroken, his feelings acute, and his conversation brilliant, though simple and unaffected.

In the summer of 1784 he paid a visit to Denmark, to Sweden, and to Scheele, whose acquaintance extremely delighted him, and most of all from the simplicity of the apparatus that he employed in his researches. A year or two afterwards he went to France, and being taken ill at Paris, he was joined there by his friend Harwood, with whom he returned through Holland and the Netherlands; at the time that the bigotted people of the Low Countries were in insurrection against a philosophical despot, while Holland remained free and prosperous.

He was particularly intimate with Dr Milner, the Master of Queen's College, and was recommended by his signature, together with those of Waring, Maskelyne, Jebb, and Watson, as a Fellow of the Royal Society, into which he was admitted in January 1785. He removed, together with his friend Harwood, in December 1786, from Christ's College to Emmanuel, and in 1788 he took a degree of Bachelor of Physic.

In 1791 he communicated to the Royal Society his very interesting discovery of a mode of obtaining carbon from the carbonic acid. Having observed that charcoal did not decompose the phosphate of lime, he concluded that phosphorus ought to decompose the carbonate of lime, and the result fully justified his manner of reasoning.

He paid a third visit to the Continent in 1792, intending to go on through France into Italy, and ar-

rived at Paris not long before the 10th of August; but he saw some indications of an impending convulsion, and was fortunate enough to quit Paris on the 9th. He visited Gibbon at Lausanne, and was much interested in the sagacity that this eminent writer displayed in his conversation. He went on to Rome and Florence, where he was fully impressed with all the admiration that he had been taught to anticipate for the treasures of ancient and modern art possessed by those cities; and in his return through Germany, he was greatly amused by the mixture of knowledge and credulity that he observed among the studious of that country. At Paris he found every thing enveloped in gloom and overwhelmed with terror, in 1793; his friend Lametherie was alarmed by the visit which he paid him, but he had the integrity to preserve for him entire some property of considerable value, with which he had entrusted him.

Upon his arrival in London, Mr Tennant took chambers in the Temple, and was in the habit of living much with some of his early acquaintance, who had adopted the law as their profession; to his own he was in great measure indifferent, neither seeking to practise it, nor being well calculated to succeed greatly in it with the public, though he studied it with attention, and took pains to make himself master of its history and its philosophy, being a particular admirer of Sydenham, when considered in relation to the age in which he lived. He took his degree of Doctor of Physic in 1796, and in the same year he gave the Royal Society a paper on the quantity of carbonic acid afforded by the diamond, which he measured by heating it with nitre, and obtaining a precipitate by the addition of muriate of lime; and he found that the diamond afforded no more carbonic acid than an equal weight of charcoal. A subsequent communication contained the result of his observations on the action of heated nitre on gold and platina.

The love of travelling appeared to be his predominant passion; he studied in his travels, not only the natural and political history of the countries that he saw, but also their languages, and the philosophy of their etymologies. He observed, too, the peculiarities of their agriculture; and, in 1797, he determined, after visiting an agricultural friend in Lincolnshire, to devote his attention to practical farming as a serious pursuit. He purchased some allotments of unenclosed land in that neighbourhood, but he left the management of them chiefly to his friend, and made afterwards considerable additions to the property by further purchases. In 1798 or 1799, he bought a tract of newly enclosed land on the Mendip hills, near Cheddar, where he built a house, and resided for some months every summer through the remainder of his life. These speculations, though their results were at first doubtful, yet succeeded remarkably well on the whole; more especially considering the benefit that his health derived from the travelling and the exercise that they rendered necessary: but they occupied too much of his attention, and of that time which might have been employed so much more to the advantage of the public, and to his own ultimate satisfaction.

Tennant.

In 1799 he gave the Royal Society a paper on the magnesian limestone, or dolomite, which he considers as rather a combination than an accidental mixture; and the forms of the crystals, as they have been determined by later observers, together with the laws of definite proportions, have tended to confirm this conjecture: he found that grain will scarcely germinate, and soon perishes, when sown in the neutral carbonate of magnesia. In 1802 he published his paper on emery, which he showed to be a substance similar to the corundum or adamantine spar of China, and not an ore of iron, as had been commonly supposed. In the month of July he was making some experiments on crude platina, when he discovered in it a singular dark powder, which was left undissolved by the nitromuriatic acid, and which was also observed the next year by Messrs Descotils and Vauquelin. In 1804 Mr Tennant showed that the powder contained two new metals, which he named *Iridium* and *Osmium*; and he received the Copleian medal from the Royal Society in November, as an acknowledgment of the merit of his various chemical discoveries. In 1805 and 1806 he paid two successive visits to Ireland, by way of Scotland, one of them in company with Browne the traveller, for whom he had a high esteem, and to whom he suggested the observation of the temperature of boiling water as a mode of determining the heights of mountains; a method, however, which had been long before recommended by Achard and others.

He became latterly more fond of general society than he had been in his earlier years, and he used to receive miscellaneous parties at his chambers, and to show them prints, and minerals, and novelties of various kinds. In 1812 he was persuaded to convert these mixed exhibitions into a more regular course of lectures, principally upon mineralogy, calculated especially for the ladies of his acquaintance, and which highly delighted all his audience: "Their attention was perpetually kept alive by the spirit and variety with which every topic was discussed, by anecdotes and quotations happily introduced, by the ornaments of a powerful but chastised imagination, and, above all, by a peculiar vein of pleasantry, at once original and delicate, with which he could animate and embellish the most unpromising subjects;" — a circumstance which, though not of much immediate importance to the public, yet probably led him the more readily to accept the Professorship at Cambridge, and would thus, if he had survived longer, have greatly extended the sphere of his utility.

He delivered, in 1813, a lecture on mineralogy to the Geological Society, and gave them also an account of his analysis of a volcanic substance from the Lipari Islands containing the boracic acid, which has since been examined on the spot by Dr Holland. In the month of May he was elected Professor of Chemistry in the University of Cambridge, all opposition having been withdrawn before the election. The following spring he gave his first and last course of lectures there. His introductory lecture still exists in manuscript, and is said to contain a masterly sketch of the history of the science. He communi-

Tennant.

cated to the Royal Society, in 1814, a paper on the easiest mode of procuring potassium, and another on the economy of heat in distillation, proposing to heat a second boiler by the condensation of the steam of the first. In the spring and summer of this year he was occupied in searching for the origin of iodine, and he succeeded in detecting this substance in sea-water, by the test of its tarnishing the surface of leaf silver. One of the last services, that he rendered the Royal Society, was in the capacity of a member of a committee which was formed in order to investigate, at the request of the government, the degree of danger that might attend the general introduction of gas lights into the metropolis; he undertook, together with his friend Dr Wollaston, to make some experiments upon the inflammation of the gas, and they discovered conjointly the very important fact, that the gas contained in a small tube will not communicate the flame: a fact which, in the hands of Sir Humphry Davy, has been rendered productive of consequences so important to the public safety; although Sir Humphry having been abroad at the time of this investigation, and the report of the committee not having been then published, he had to rediscover this truth, and many more, in his most ingenious and successful researches.

It was early in the month of September that Mr Tennant went for the last time to France, being impatient to observe the changes that an eventful interval of twenty years had produced in that highly interesting country. He was greatly delighted with Lyons and Marseilles, and, returning to Paris in November, he lingered there till February 1815; on the 15th of that month he arrived at Calais; the 20th he went to Boulogne with Baron Bulow, in order to embark there; they did embark on the 22d, but were forced back by the wind, and meant to try again in the evening; in the meantime, they took horses and went to see Bonaparte's Pillar, about a league off, and going off the road on their return, to look at a small fort, of which the drawbridge wanted a bolt, they were both thrown, with their horses, into the ditch. Bulow was only stunned, but Tennant's skull was so severely fractured, that he died an hour after.

His papers published in the *Philosophical Transactions* were eight in number. 1. *On the Decomposition of Fixed Air*, 1791, p. 182. 2. *On the Nature of the Diamond*, 1797, p. 123. 3. *On the Action of Nitre upon Gold and Platina*, p. 219. 4. *On the different sorts of Lime used in Agriculture*, 1799, p. 305. 5. *On the Composition of Emery*, 1802, p. 398. 6. *On two Metals found in the Black Powder remaining after the Solution of Platina*, 1804, p. 411. 7. *On an easier Mode of procuring Potassium than that which is now adopted*, 1814, p. 578. 8. *The Means of producing a double Distillation by the same Heat*, p. 587.

9. The analysis of *A Volcanic Substance containing the Boracic Acid* appeared in the *Transactions of the Geological Society*, Vol. I. 1811.

Mr Tennant was tall and slight in his person; his face was thin, and his complexion light; he resembled a little the portraits of Locke; he was general-

Tennant.

ly negligent in his dress, but, on the whole, agreeable in his appearance. He was distinguished for good sense, for quickness of perception, and for penetration; but, as his friend and biographer Mr Whishaw observes, in the admirably energetic sketch that he has given of his character, he was one of those who, to use the words of Dr Johnson, "without much labour, have obtained a high reputation, and are mentioned with reverence rather for the possession than the exertion of uncommon abilities." "His curiosity and activity were incessant; he had a vigilance of observation which suffered nothing to escape him, and was continually gaining new information from a variety of interesting sources. But although the knowledge thus acquired was remarkable for its correctness, and complete for the purposes of its possessor, yet the industry and perseverance, by which it ought to have been embodied and made permanent for the benefit of others, were too often altogether wanting. The ardour and energy of Mr Tennant's mind co-operated unfortunately, in this respect, with his want of method and of systematic habits of application; since he was constantly pressing on to new discoveries, instead of arranging and bringing to perfection those which he had already made. His memory was a great storehouse of discoveries, and hints for discovery, of ascertained facts, probable conjectures, and ingenious trains of reasoning relative to the various important subjects upon which he had at any time been engaged. These he was continually treasuring up, with the intention of reducing them to order, and preparing them for use at a more convenient season. But that period rarely arrived. In the carelessness of intellectual wealth, he neglected those stores of knowledge which he had accumulated, and suffered them to remain useless and unproductive, till his attention was recalled to them, perhaps after a long course of years, by some new fact or discovery, some remark in conversation, or other accidental occurrence."

The effect of his peculiar cast of humour was heightened by a perfect gravity of countenance, a quiet familiar manner, and a characteristic simplicity of language. He was firmly attached to the general principles of freedom, being fully convinced "of their influence in promoting the wealth and happiness of nations; a due regard to these principles, he considered as the only solid foundation of the most important blessings of social life, and as the peculiar cause of that distinguished superiority, which our own country so happily enjoys among the nations of Europe." "The cheerful activity of a populous town, the improvements in the steam-engine, the great galvanic experiments, and above all the novelty and extent of the prospects afforded by that revolution in chemical science which has illustrated our own age and country; these magnificent objects, when presented to Mr Tennant's mind, excited in him the liveliest emotions, and called for the most animated expressions of admiration and delight." "He thought himself passionate and irascible; and certainly his feelings were quick; but they were transitory." He possessed a strong sense of high honour, as well as of duty; and his liberality and

humanity were evinced by some practical occurrences in which he had occasion to exercise them: his steward had defrauded him, and when the day of reckoning came, had destroyed himself: he not only forgave the debt, but provided also for the widow and her family.

"His amiable temper and unaffected desire of giving pleasure, no less than his superior knowledge and talents, had rendered him highly acceptable to a numerous and distinguished circle of society, by whom he was justly valued, and by whom his premature death was sincerely lamented. But the real extent of his private worth, the genuine simplicity and virtuous independence of his character, and the sincerity, warmth, and constancy of his friendship, can only be felt and estimated by those to whom he was long and intimately known, and to whom the recollection of his talents and virtues must always remain a pleasing though melancholy bond of union."

[Whishaw in] Thomson's *Annals*, Vol. VI. 1815. p. 1, 80. (A. L.)

THOMPSON (SIR BENJAMIN, COUNT RUMFORD), a well known Natural Philosopher and Political Economist, was born in 1753, at a village in New Hampshire, then called Rumford, and now Concord.

His father died while he was very young, and his mother married another man, who banished him from her house almost in his infancy: he inherited only a small pittance from an uncle, who died soon after his father. A clergyman named Bernard showed him great kindness, and taught him some of the higher mathematics at an early age, so that at fourteen he was able to calculate and delineate an eclipse of the sun. He had been intended for some commercial employment; but he preferred the pursuit of literature in any form: he attended the lectures of Dr Williams, and afterwards those of Dr Winthrop, the astronomer, at the College of "Harvard;" and while he was still a stripling, he was established in the temporary occupation of a village schoolmaster; hoping, however, for an early opportunity to engage in some more agreeable employment: and at nineteen, he was fortunate enough to obtain the hand of Mrs Rolfe, daughter of Mr Walker, a clergyman, who had been employed with considerable credit in conducting some public business. For a year or two he lived retired and happy: but having obtained a commission of Major in the Militia from the Governor of the province, together with some other distinctions, of a civil nature, he was consequently led to adhere to the party of the Royalists, and he was soon obliged, by the success of the Independent forces, to take refuge at Boston, then occupied by the English troops. It was in November 1773 that he secretly quitted his residence, leaving his wife, whom he never saw again, and his infant daughter, who joined him twenty years after in Europe.

He was employed to raise a regiment for the King's service; but when Boston was evacuated, in 1776, he was sent with some important dispatches to England. Here he soon acquired the confidence of Lord George Germaine, then Colonial Secretary of State, and was appointed Secretary of the province

Tennant  
||  
Thomson.

Thompson. of Georgia, though he never exercised the office: but he remained attached to that department of the public service.

In 1777 he commenced his career as an experimental philosopher, by employing his leisure hours, during a visit to Bath, in making some experiments on the cohesive strength of different substances: and upon his return to London, he communicated them to Sir Joseph Banks, with whom he formed an intimate acquaintance, which he kept up throughout the remainder of his life. In 1778 he was admitted a Fellow of the Royal Society, and he made in that year his first experiments on gunpowder. In order to pursue these experiments, he went, in 1779, on board of the *Victory* of 110 guns, commanded by his friend Sir Charles Hardy. He passed the whole of the campaign on board of the fleet; and the results of the observations, that he then made, furnished the materials of a chapter which he contributed to Stalkart's *Treatise on Naval Architecture*. He added to it a code of signals for the Navy, which was not published. In 1780 he was appointed Under Secretary of State, and he was constantly employed, for some little time, in the office on the business of the war. He succeeded, by means of his American friends and agents, in raising a regiment of cavalry, called the King's American Dragoons, of which he was appointed Lieutenant-Colonel Commandant; and this success induced him to go to America to serve with it. At Charlestown he was entrusted with the command of the remains of the cavalry of the British army;—he speedily restored the discipline of the corps, and gained its confidence and attachment: he often led it on against the enemy, and frequently with considerable success. He proceeded, in 1782, to New York, where he assumed the command of his own regiment, having received the colours from the hand of Prince William Henry, now Duke of Clarence. In the autumn, General Clinton was succeeded by Sir Guy Carlton, whose friendship and confidence he speedily obtained: his regiment was recruited from the fragments of several others, and he was sent for the winter to Huntingdon in Long Island. He was chosen, in 1783, to conduct the defence of Jamaica, which was then threatened by the enemy: but the general peace superseded the necessity of the intended expedition.

After his return to England, he made great efforts in the cause of the loyalist officers, and he was successful in persuading the Ministry to make a proper provision for them: he was himself made a full Colonel, upon the recommendation of General Carlton, only two years after his appointment as Lieutenant-Colonel. He had acquired a strong predilection for a military life, and was desirous of being sent with his regiment to the East Indies: and when the regiment was reduced, he wished to serve with the Austrians in a war which was then meditated against the Turks.

With this view he left England in September 1783, and on his passage to Boulogne, he had an agreeable ship-mate in the person of Gibbon, the historian, who did justice to his merits as a "soldier, philosopher, and statesman." At Strasburg, his appearance

on the parade in his uniform excited the attention of the present King of Bavaria, then Prince Maximilian of Deux Ponts, who invited him to his table, and being delighted with the accuracy and extent of his military knowledge, gave him a strong recommendation to his uncle, then Elector: and instead of a day or two, as he had intended, he staid a fortnight at Munich. He was also very cordially received at Vienna, and passed a part of the winter there; but the war against the Turks not taking place, he went by Venice and the Tyrol again to Munich, where he arrived in the winter of 1784; and being formally invited by the Elector to enter his service, he went to London to ask leave to accept the proposal; and it was granted him, together with the honour of Knighthood. On his return to Bavaria, he was made a Colonel of cavalry, and Aide-de-Camp-General to the Elector. The first four years of his residence at Munich were principally employed in acquiring information, and in preparing his plans of reform: and in the mean time he continued his physical researches. He made his first experiments on heat in 1786, during a journey to Mannheim. In 1785 he was made Chamberlain to the Elector, and member of the Academies of Munich and of Mannheim: in 1786 he received from the King of Poland the Order of St Stanislaus: in 1787 he took a journey to Berlin, and was made a member of the Academy of Sciences of that city: in 1788 he was appointed Major-General of the Bavarian cavalry, and Privy Counsellor of State; and he was placed at the head of the War Department, in order to pursue his plans for the improvement of the army.

It was in 1789 that he established the House of Industry at Mannheim: he founded also the Military Academy of Munich; he improved the military Police of the country; he formed Schools of Industry for the wives and children of the soldiers; and he embellished the city by a new arrangement of the public gardens. The House of Industry at Munich, which he has described at large in his *Essays*, was founded in 1790: and from this period may be dated the total abolition of mendicancy in Bavaria. His exertions were rewarded by the rank of Lieutenant-General of the Bavarian armies, and by a regiment of artillery. In 1791 he was created a Count of the Holy Roman Empire, and obtained the Order of the White Eagle.

His health having suffered from constant application, he obtained permission to take a journey into Switzerland and Italy, and he returned to Bavaria in 1794. He had a severe illness at Naples, and he was not sufficiently recovered, upon his return, to resume his active duties; but he employed himself in writing the first five of his *Essays*. In 1795, he came to England in order to publish the *Essays*, and in hopes of exciting the public attention to the importance of attempting a similar reform among the lowest orders in Great Britain. He went to Dublin in 1796, to pay a visit to Lord Pelham, now Earl of Chichester, then Secretary of State for Ireland; and he was of essential service in the arrangement of several of the public institutions of that country. He

Thompson. was made a Member of the Royal Irish Academy, and of the Society for the Encouragement of Arts; and he received, after having left the country, the public thanks of the Grand Jury of the county of Dublin, and of the Lord Mayor of that city, as well as of the Lord Lieutenant at the head of the Government. Upon his return to London, he superintended some improvements at the Foundling Hospital, and presented several models of machines and implements to the Board of Agriculture: and he established two prizes, for discoveries relating to Heat and Light, by placing two sums of L. 1000 in the British and in the American funds, to be adjudged biennially, for Europe by the Royal Society of London, and for America by the American Academy of Sciences.

He was recalled to Bavaria by the exigencies of the moment, which were such as to cause the Elector to take refuge in Saxony; General Moreau having advanced with his army to the confines of Bavaria. After the battle of Friedberg, Count Rumford was left in command of the Bavarian army, with instructions to act according to his discretion under the circumstances that might occur; and his firmness was such, as to prevent either the Austrians or the French from entering Munich. On the Elector's return, he was placed at the head of the department of the general police of Bavaria. His exertions in this office were such, as to impair the state of his health, and by way of an honourable retirement, he was sent to England in the capacity of Envoy Extraordinary and Minister Plenipotentiary: but being a subject of the King of England, he was judged incapable of being received as the diplomatic agent of a foreign court, and he, therefore, continued to live in England as a private individual.

He was very active about this time in projecting and superintending the establishment of the Royal Institution of Great Britain, which was more particularly intended for the application of science to the conveniences and comforts of civil and domestic life, but which has been no less successful in giving opportunity and facility to some of the most refined researches in chemistry and natural philosophy that have distinguished the age, than in serving as a medium for making the treasures of science accessible to the less studious part of the public, and as a model for a variety of other similar undertakings in different parts of the world.

Count Rumford was soon afterwards officially invited to America by the government of the United States, with an offer of an honourable establishment in a public situation; but he considered it as inconsistent with his engagements in Europe to accept the proposal. In the autumn of 1800, when he went to Scotland, a visit of ceremony was paid him by the magistrates of Edinburgh: he was consulted respecting the abolition of mendicity, and the measures that he recommended were speedily executed with complete success. He was made an honorary member of the Royal Society, and of the Royal College of Physicians of Edinburgh; and he received a gold snuff box as a compliment for his assistance in reforming the culinary establishment of Heriot's Hospital.

After so active and diversified a career, it was not to be expected that he would be satisfied with the monotony of a permanent residence in London: he was so accustomed to labour for the attainment of some object, that when the object itself was completely within his reach, and the labour was ended, the prospect, which ought to have been uniformly bright, became spontaneously clouded, or even the serenity became unenjoyable for want of some clouds to afford a contrast. He had fitted up a small house at Brompton, with every contrivance for comfort and convenience that could render it fit for the abode of hospitality and of luxury; and the arrangements are fully described in the *Bibliothèque Britannique* of his friend, Professor Pictet; but after all he never was known to give a single entertainment in it. The enthusiasm excited by the novelty of some of his inventions had subsided, and he was even mortified by becoming, in common with the most elevated personages of the country, the object of the impertinent attacks of a popular satirist. It was partly, however, if not entirely, the superiority of the climate of France, that determined him to remove to Paris in the spring of 1802: he went in the summer to Munich, and the following year he made a tour in Switzerland and in Bavaria, accompanied by Me. Lavoisier, whom he married soon after their return: but their habits were incompatible with matrimonial comfort, and they separated soon after; Count Rumford retiring to Auteuil, about four miles from Paris, where he occupied a house which had formerly belonged to Helvetius and to Cabanis, while his lady continued to live in the metropolis. His latter years were passed almost wholly in solitude; he saw only his neighbour Mr Caneleux, Mr Underwood, and a Mr Parker, an American: he did not even attend the sittings of the Institute, though he had been made one of its eight foreign associates some time before, and always retained a high esteem for its secretary Cuvier, and for some others of its members. His income was abundantly sufficient for his own expenses, having obtained from the gratitude of the King of Bavaria a pension of L. 1200 a year; and he was allowed by Bonaparte to remain unmolested, though a British subject, when it was found that he had no intercourse with society, amusing himself principally in walking about his garden, and in a solitary game of billiards. He had so completely persuaded himself, in the latter part of his life, of the great superiority of broad wheels above narrow ones, that he drove about the streets of Paris in a broad wheeled chariot; and having rediscovered, after Professor Leslie, that black bodies radiate more heat than others, he wore, in the winter, a white hat and a white coat, in order to economize the heat of his person. "These peculiarities, and a peremptory unyielding disposition," says one of his biographers, "were the causes that set him apart from social intercourse, and in all his connexions in life, seem to have rendered him less the object of personal attachment than of esteem for his talents and activity." He was about to return to England when he died, the 21st August 1814, leaving only one daughter, who still resides in his house at Brompton.

1. Count Rumford's first publication appears to have

Thompson. been the chapter on *Marine Artillery* that he furnished to Stalkart's *Treatise on Naval Architecture*, 1780.

2. *New Experiments on Gunpowder, with the Description of an Eprouvette.* *Phil. Trans.* 1781. P. 230. The effect of the powder on the ball was measured by the recoil of the piece, with a correction deduced from the recoil when the piece was empty. It was observed to be sooner heated when fired without ball than with it. The force of the powder is made at least 1300 atmospheres, upon Robins's principles.

3. *New Experiments upon Heat.* *Phil. Trans.* 1786. P. 273. These experiments relate principally to the conducting powers of various mediums for heat; but the results are unavoidably complicated with the effects of radiation, in consequence of which a vacuum is supposed to possess a conducting power more than half as great as that of common air.

4. *Experiments on the Production of Dephlogisticated Air from Water with various Substances.* *Phil. Trans.* 1787. P. 84. These experiments tend to show that the air obtained, by Priestley and Ingenhousz, from plants under water, was derived rather from the water itself than from the substances immersed in it.

5. *Experiments made to determine the Positive and Relative Quantities of Moisture absorbed from the Atmosphere by Various Substances.* P. 240. He finds that wool is more absorbent of moisture than any other substance compared with it; and hence explains the supposed advantage of woollen worn next the skin.

6. *Experiments on Heat.* *Phil. Trans.* 1792. P. 48. The author attributes the effect of loose substances in obstructing the passage of heat to their attraction for air, and to their impeding its circulation; and he supposes this to be the only manner in which elastic fluids communicate heat.

7. *Account of a Method of Measuring the Comparative Intensity of Light emitted by Luminous Bodies.* *Phil. Trans.* 1794. P. 67. Placing them at such distances, that the shadows cast by each may appear equally dark.

8. *Letter announcing a Donation for a Prize Medal.* *Phil. Trans.* 1797. P. 215.

9. *Experiments to determine the Force of Fired Gunpowder.* P. 272. This force he supposes to amount to between 20,000 and 50,000 atmospheres, instead of 10,000, as Bernoulli computed it; but he makes a great mistake in supposing that the whole of the water which can possibly be contained in the gunpowder would be sufficient to furnish as much steam as would be required, since steam, under a pressure of 20,000 atmospheres, must be considerably more dense than water itself. (See STEAM ENGINE, in this Supplement.)

10. *Inquiry concerning the Source of the Heat excited by Friction.* *Phil. Trans.* 1798. P. 80. The capacity of the chips of iron afforded by friction in boring a cannon, was found not to differ from that of the iron in its original state: hence it is inferred that the heat could not have been furnished by them,

and that it must probably have been generated. Mr Haldatt afterwards repeated the experiment under circumstances still more decisive; and Sir Humphry Davy showed that two pieces of ice rubbed together, in a room below the freezing temperature, would melt each other.

11. *Inquiry concerning the Chemical Properties that have been attributed to Light.* P. 449. He attributes these properties to the effect of an intense heat confined to a small space; but the later experiments on the chemical effects of the spectrum are sufficient to supersede this opinion.

13. *An Account of a Curious Phenomenon observed on the Glaciers of Chamouny, with some Observations on the Propagation of Heat in Fluids.* *Phil. Trans.* 1804. P. 23. An effect depending on the expansion of water in cooling near the freezing point.

14. *Concerning the Nature of Heat, and the Mode of its Communication.* P. 77. He conjectures that cold is a positive quality, capable of being propagated by radiation.

Several of these memoirs were reprinted under the title of *Philosophical Papers*. Vol. I. 8. Lond. 1802.

15. *The Essays* constitute 4 volumes 8vo. Lond. 1795. . . 1800. Reprinted 1800. In French, 2 v. 8. Genev. 1799. *Receuil de Rapports . . . sur les soupes.* Par. 1801. They are 18 in number.

i. Account of an Establishment for the Poor at Munich. In Ital. 8. Venice, 1798.

ii. On Establishments for the Poor in general.

iii. Of Food, and of Feeding the Poor.

iv. Of Chimney Fireplaces.

v. Account of several Public Institutions formed in Bavaria.

vi. On the Management of Fire, and the Economy of Fuel.

vii. On the Propagation of Heat in Fluids, extending to Liquids the doctrine which he had before advanced respecting Elastic Fluids.

viii. On the Propagation of Heat in Various Substances. *Phil. Trans.*

xvii. On the Source of the Light manifested in the Combustion of Inflammable Bodies.

xviii. On the Excellent Qualities of Coffee, and the Art of Making it in Perfection.

16. There are several little papers on *Steam Kitchens*, on the *Strength of Soft Materials*, and on some other similar subjects, in the first numbers of the *Journals* of the Royal Institution. 8. Lond. 1800.

Thompson  
||  
Tides.

17. The series of investigations relating to Heat and Light, which Count Rumford began to communicate to the Royal Society, were continued, and rather more fully detailed, in several of the volumes of the *Memoirs of the Institute*, Mathematical Class; into which they were, of course, admitted as the productions of a Foreign Associate. The first of these is in the sixth volume. 4. Par. 1806. P. 71, containing a *Description of a New Instrument*; a thermoscope, or a differential thermometer, resembling that of Leslie. (18.) The second, P. 74. *Researches on Heat*; showing the effect of the difference of surface on radiation. (19.) iii. P. 88. *Further Experiments*, in the effect of blackening the surface. (20.) iv. P. 97. *Researches Continued*; on the different properties of bodies with respect to radiation, and to conducting power. (21.) v. P. 106. *Further Researches*; some good experiments on the passage of heat through solids. (22.) vi. P. 123. *Experiments on the Heat of the Solar Rays*; which was found not to be affected by their convergence or divergence, or by their having met in a focus and crossed each other. (23.) vii. Vol. VII. i. 1806. P. 78. *Remarks on the Temperature of Water at the Maximum of Density*; making it 41° of Fahrenheit, or 5° centigrade. *Phil. Trans.* 1804. (24.) viii. Vol. VIII. i. 1807. Tides.

26. He was latterly engaged in composing a work on *The Nature and Effects of Order*, which he never completed, although no person was better qualified to write on the subject.

Count Rumford certainly possessed considerable facility of invention, and there was a very laudable spirit of originality in his views and modes of reasoning, although he had never leisure to acquire profound learning in any department of study. "In person he was above the middle size, with a dignified and pleasing expression of countenance, and a mildness in his manner and his tone of voice. He was ambitious of fame and distinction, and had too great a propensity to dictate," without sufficiently regarding the opinions of others who were of equal authority with himself. His mode of life was abstemious, and his health was even supposed to have suffered from too great abstinence, though his regimen was much more the result of medical opinions respecting his health, than of his own peculiar taste for temperance.

[Pictet, *Bibliothèque Britannique*, and Baldwin's *Literary Journal. Gent. Mag.* Vol. LXXXIV. Aikin's *General Biography*, X. 4. Lond. 1805. Chalmers' *General Biographical Dictionary*, XXIX. 8. Lond. 1816.] (A. L.)

## T I D E S.

THE investigation of the phenomena of the tides has been justly considered as uniting some of the greatest difficulties that occur in the various departments of natural philosophy and astronomy. It implies, first, a knowledge of the laws of gravitation, concerned in the determination of the forces immediately acting on the sea, and of the periods and distances of the celestial bodies, which modify the magnitudes and combinations of these forces; and secondly, of the hydraulic theories of the resistances of fluids, and of the motions of waves and undulations of all kinds, and of the theoretical determination of the form and density of the earth, as well as of the geographical observation of the breadth and depth of the seas and lakes, which occupy a part of its surface; so that the whole subject affords abundant scope for the exercise of mathematical skill, and still more for the employment of that invention and contrivance, which enables its possessor to supersede the necessity of prolix computations, wherever they can be avoided.

The history of the theory of the tides is naturally divided into several periods in which its different departments have been progressively cultivated. The ancients, from the times of Posidonius and Pytheas, and the moderns before Newton, were contented with observing the general dependence of the tides

on the moon, as following her transit at an interval of about two hours, and their alternate increase and decrease not only every fortnight, but also in the lunar period of about eight years; the second step consisted in the determination of the magnitude and direction of the solar and lunar forces, by which the general effects of the tides were shown, in the *Principia*, to be the necessary consequences of these forces: the third great point was the demonstration of Maclaurin, that the form of an elliptic spheroid affords an equilibrium under the action of the disturbing forces concerned; while the further contemporary illustrations of the subject by Euler and Bernoulli, though they afforded some useful details, involved no new principle that can be put in competition with Maclaurin's demonstration: the fourth important step was made by Laplace, who separated the consideration of the *form*, affording mere equilibrium, from that of the *motion* occasioned by the continual change of that form, while former theorists had taken it for granted, that the surface of the sea very speedily assumed the figure of a fluid actuated by similar forces, but remaining perfectly at rest, or assuming instantly the form in question. Laplace's computation is however limited to the case of an imaginary ocean, of a certain variable depth,

Tides. assumed for the convenience of calculation, rather than for any other reason. Dr Thomas Young has extended Laplace's mode of considering the phenomena to the more general case of an ocean covering a part only of the earth's surface, and more or less irregular in its form; he has also attempted to comprehend in his calculations the precise effects of hydraulic friction on the times and magnitudes of the tides. As far as the resistance may be supposed to vary in the simple ratio of the velocity, Dr Young's theory is sufficiently complete, and explains several of the peculiarities which are otherwise paradoxical in their appearance; but there still remains a difficulty to be combated with respect to the effects of a resistance proportional to the square of the velocity, and this, it is hoped, will be in great measure removed in the present article, which, however, from the space that is allotted to it, must be considered rather as a supplementary fragment than as a complete treatise. It will be divided into four sections: The first relating to the contemporaneous progress of the tides through the different seas and oceans, as collected from observation only: the second to the magnitude of the disturbing forces tending to change the form of the surface of the earth and sea: the third to the theory of compound vibrations with resistance; and the fourth to the application of this theory to the progress and successive magnitudes of the tides, as observable at any one port.

SECT. I.—Of the Progress of Contemporary Tides, as inferred from the times of High Water in Different Ports.

The least theoretical consideration, relating to the tides, is that of their progress through the different parts of the ocean, and of its dependent seas. The analysis of these ought to be very completely attainable from direct observation, if the time of high water had been accurately observed at a sufficient number of ports throughout the world; and, on the other hand, if the earth were covered in all parts with a fluid of great and nearly uniform depth, the tides of this fluid would be so regular, that a very few observations would be sufficient to enable us to deduce the whole of the phenomena from theory, and to trace the great waves, which would follow the sun and moon round the globe, so as to make its circuit in a day, without any material deviation from uniformity of motion and succession. Having collected, for the actual state of the sea and continents, an abundant store of accurate observations of the precise time of high water with regard to the sun and moon, for every part of the surface, and having arranged them in a table according to the order of their occurrence, as expressed in the time of any one meridian, we might then suppose lines to be drawn on a terrestrial globe, through all the places of observation, in the same order; and these lines would indicate, supposing the places to be sufficiently numerous, so as to furnish a series of tides very nearly contemporary, the directions of the great waves, to which that of the progress of the tides in succession must be perpendicular. If, however, we actually make such an attempt, we shall soon find how utterly inadequate the obser-

vations that have been recorded are, for the purpose of tracing the forms of the lines of contemporary high water with accuracy or with certainty, although they are abundantly sufficient to show the impossibility of deducing the time of high water at any given place from the Newtonian hypothesis, or even from that of Laplace, without some direct observation. It might at least be supposed very easy to enumerate the existing observations, scanty as they may be, in a correct order; but there are a number of instances in which it is wholly uncertain whether the time observed at a given port relates to the tide of the same morning in the open ocean, or to that of the preceding evening; this inconvenience may, however, in some measure be remedied, by inserting such places in two different parts of the table, at the distance of 12½ hours from each other. The following Table is the result of the best approximation that could be obtained in this manner, the principal hour lines having been partially traced on a map of the world, in order to afford some little direction to the correct insertion of the times of high water without the material error of half a day. The three great natural divisions of the Atlantic, the Pacific, and the Indian Oceans, are distinguished into different columns, and some of the places, which seem to form separate systems of tides, are still further subdivided in a similar manner; but this arrangement may easily be neglected by those who are inclined to question its propriety. The principal authorities are the *Requisite Tables*; Lalande's *Treatise*, in the fourth volume of his *Astronomy*; a manuscript *Hydrographical Memoir* by Mr Henry Foster, Lieut. R. N. of his Majesty's ship Conway, Capt. Basil Hall; and *A Series of Observations made at the Island of Ascension in 1820*, by Captain Campbell, R. N., obligingly communicated by Captain Hall to the author of this Article.

Gallapagos to Terra del Fuego, or N. E. and S. W. from Easter Island to New Zealand; or whether both these partial directions are correct: but on each side of this line there are great irregularities, and many more observations are wanting before the progress of the tide can be traced with any tolerable accuracy, among the multitudinous islands of the Pacific Ocean, where it might have been hoped that the phenomena would have been observed in their greatest simplicity, and in their most genuine form.

Lastly, Of the Indian Ocean the northern parts exhibit great irregularities, and among the rest they afford the singular phenomenon observed by Halley in the Port of Tonkin, and explained by Newton in the *Principia*: the southern parts are only remarkable for having the hour lines of contemporary tides considerably crowded between New Holland and the Cape of Good Hope, as if the seas of these parts were shallower than elsewhere.

These inferences respecting the progress of the tides are not advanced as the result of any particular theory, nor even as the only ones that might possibly be deduced from the table: thus the supposition that the direction in which the tides advance must be perpendicular to the hour lines of contemporary tides, is not by any means absolutely without exception, since a quadrangular lake, with steep shores in the direction of the meridian, would have the times of high water the same for every point of its eastern or western halves respectively, and there could be no correctly defined direction of the hour lines in such a case. But if any portion of the sea could be considered as constituting such a lake, its properties would be detected by a sufficient number of observations of high water, and the existing table does not appear to indicate any such cases that require to be otherwise distinguished than as partial irregularities. There may also be some doubt respecting the propriety of the addition of  $12\frac{1}{2}$  hours that has been made to the time of high water in the north eastern parts of the Atlantic: but it seems extremely improbable that the same tide should travel north easterly into the English Channel and into the Northern Ocean, and at the same time westerly across the Atlantic, as it must be supposed to do, if it were considered as primarily originating in the neighbourhood of the Bay of Biscay; on the other hand, the bending of the great wave round the continents of Africa and Europe seems to be very like the sort of refraction which takes place on every shelving coast with respect to the common waves, which, whatever may have been their primitive origin, acquire always, as they spread, a direction more and more nearly parallel to that of the coast which they are approaching: and the suppositions which have been here advanced respecting the succession of the tides in different ports, allowing for the effect of a multitude of irregularities proceeding from partial causes, appear to be by far the most probable that can be immediately inferred from the table, at least in its present state of imperfection.

It may be immediately inferred from this table, first, That the line of contemporary tides is seldom in the exact direction of the meridian, as it is supposed to be universally in the theory of Newton and of Laplace; except, perhaps, the line for the 21st hour in the Indian Ocean, which appears to extend from Socotora to the Almirantes and the Isle of Bourbon, lying nearly in the same longitude. Secondly, That the southern extremity of the line advances as it passes the Cape of Good Hope, so that it turns up towards the Atlantic, which it enters obliquely, so as to arrive, nearly at the same moment, at the Island of Ascension, and at the Island of Martin Vaz, or of the Trinity. Thirdly, After several irregularities about the Cape Verd Islands, and in the West Indies, the line appears to run nearly east and west from St Domingo to Cape Blanco, the tides proceeding due northwards; and then, turning still more to the right, the line seems to run N. W. and S. E., till at last the tide runs almost due east up the British Channel, and round the north of Scotland into the Northern Ocean, sending off a branch down the North Sea to meet the succeeding tide at the mouth of the Thames. Fourthly, Towards Cape Horn again there is a good deal of irregularity; the hour lines are much compressed between South Georgia and Terra del Fuego, perhaps on account of the shallower water about the Falkland Islands and South Shetland.

In the fifth place, At the entrance of the Pacific Ocean, the tides seem to advance very rapidly to New Zealand and Easter Island; but here it appears to be uncertain whether the line of contemporary tide should be drawn nearly N. and S. from the

Tides.

SECT. II.—Of the Disturbing Forces that occasion the Tides.

Since the phenomena of the tides, with regard to their progress through the different oceans and seas, as they exist in the actual state of the earth's surface, appear to be too complicated to allow us to hope to reduce them to computation by means of any general theory, we must, in the next place, confine our attention to the order in which the successive changes occur in any single port, and having determined the exact magnitude of the forces, that tend to change the form of the surface of the ocean at different periods, and having also examined the nature of the vibratory motions, of which the sea, or any given portion of it, would be susceptible, in the simplest cases, after the cessation of the disturbing forces; we must afterwards endeavour to combine these causes, so as to adapt the result to the successive phenomena, which are observed at different times in any one port.

THEOREM A. ("E."—*Nich. Journ.* Jul. 1813.) The disturbing force of a distant attractive body, urging a particle of a fluid in the direction of the surface of a sphere, varies as the sine of twice the altitude of the body.

The mean attraction, exerted by the sun and moon on all the separate particles composing the earth, is exactly compensated by the centrifugal force derived from the earth's annual revolution round the sun, and from its monthly revolution round the common centre of gravity of the earth and moon: but the difference of the attractions, exerted at different points of the earth, must necessarily produce a disturbing force, depending on the angular position of the point with regard to the sun or moon, since the centrifugal force is the same for them all; the disturbing force being constantly variable for any one point, and depending partly on the difference of the distance of the point from the mean distance, and partly on the difference of the direction of the luminary, from its direction with respect to the centre, or, in other words, on its parallax.

It will be most convenient for computation to consider both these forces, for a sphere covered with a fluid, as referred to the direction of the circumference of the sphere, which will differ but little from that of the fluid; and it will appear that both of them, when reduced to this direction, will vary as the product of the sine and cosine of the distance from the diameter pointing to the luminary, that is as half the sine of twice the altitude: for the difference of gravitation, which depends on the difference of the distance, will always vary as the sine of the distance from the bisecting plane perpendicular to that diameter, and will be reduced to the direction of the surface, by diminishing it in the ratio of the cosine to the radius: and the effect of the difference of direction will be originally proportional to the sine of the distance from the diameter, and will in like manner be expressed, when reduced, by the product of the sine and cosine; and each force, thus reduced, will be equal, where it is greatest, to half of its primitive magnitude, since  $\sin \cos 45^\circ = \frac{1}{2}$ . "Thus, the gravitation towards the

moon at the earth's surface, is to the gravitation towards the earth as 1 to 70 times the square of  $60\frac{1}{2}$ , or to 256 217: and the former disturbing force is to the whole of this as 2 to  $60\frac{1}{2}$  at the point nearest the moon, and the second as 1 to  $60\frac{1}{2}$  at the equatorial plane, and the sum of both, reduced to the direction of the circumference, where greatest, as 3 to 121; that is, to the whole force of the earth's gravitation, as 1 to 10 334 000; and in a similar manner we find, that the whole disturbing force of the sun is to the weight of the particles as 1 to 25 736 000." Or, if we call the moon's horizontal parallax  $p$ , and substitute

$\frac{1}{p}$  for the distance, the whole of the lunar disturbing

force in the direction of the surface will be  $\frac{3}{2} \cdot \frac{p^5}{70}$

$= \frac{3}{140} p^5$ ; or, if  $z$  be the moon's zenith distance

from any point of the surface,  $f = \frac{3}{70} p^5 \sin \cos z$ .

THEOREM B. [F]. The inclination of the surface of an oblong spheroid, slightly elliptical, to that of the inscribed sphere, varies as the sine of twice the distance from the circle of contact; and a particle resting on any part of it, without friction, may be held in equilibrium by the attraction of a distant body, [situated in the direction of the axis.]

If a sphere be inscribed in an oblong spheroid, the elevation of the spheroid above the sphere must obviously be proportional, when measured in a direction parallel to the axis of the spheroid, to the ordinate of the sphere, that is, to the sine of the distance from its equator, and when reduced to a direction perpendicular to the surface of the sphere, it must be proportional to the square of that sine; and the tangent of the inclination to the surface of the sphere, which is equal to the fluxion of the elevation divided by that of the circumference, must be expressed by twice the continual product of the sine, the cosine, and the ellipticity, or rather the greater elevation,  $e$ , the radius being considered as unity: so that the elevation  $e$  will also express the tangent of the inclination where it is greatest, since  $2 \sin \cos 45^\circ = 1$ ; and the inclination will be every where as the product of the sine and cosine.

If, therefore, the density of the elevated parts be considered as evanescent, and their attraction be neglected, there will be an equilibrium, when the ellipticity is to the radius as the disturbing force to the whole force of gravitation: for each particle, situated on the surface, will be actuated by a disturbing force tending towards the pole of the spheroid, precisely equal and contrary to that portion of the force of gravitation which urges it in the opposite direction down the inclined surface. Hence, if the density of the sea were supposed inconsiderable, in comparison with that of the earth, the radius being 20 839 000 feet, the greatest height of a lunar tide in equilibrium would be 2.0166 feet, and that of a solar tide .8097: that is, supposing the moon's horizontal parallax about 57', and her mass  $\frac{1}{80}$  of that of the earth.

Tides.

Tides.

**THEOREM C. [G].** The disturbing attraction of the thin shell, contained between a spheroidal surface and its inscribed sphere, varies in the same proportion as the inclination of the surface, and is to the relative force of gravity depending on that inclination, as three times the density of the shell, to five times that of the sphere.

We may imagine the surface of the sphere to be divided by an infinite number of parallel and equidistant circles, beginning from any point at which a gravitating particle is situated, and we may suppose all these circles to be divided by a plane perpendicular to the meridian of the point, and consequently bisecting the equatorial plane of the spheroid: it is obvious, that, if the elevations on the opposite sides of the plane be equal at the corresponding points of each circle, no lateral force will be produced; but when they are unequal, the excess of the elevated matter on one side above that of the other side will produce a disturbing or lateral force. Now, the elevation being everywhere as the square of the distance  $x$  from the equatorial plane, we may call it  $ex^2$ , and the difference, corresponding to any point of that semicircle, which is the nearer to the pole of the spheroid, will be  $e(x'^2 - x''^2) = e(x' + x'')(x' - x'')$ . But  $x' + x''$  is always twice the distance of the centre of the supposed circle from the equatorial plane; and the distance of this centre from that of the sphere will be  $\cos \psi$ , if  $\psi$  be the angular distance of the circle from its pole; and calling  $\phi$  the distance of this pole, from the equatorial plane of the spheroid, the distance in question will be  $\cos \psi \sin \phi$ , and  $x' + x'' = 2 \cos \psi \sin \phi$ : and the difference  $x' - x''$  is twice the actual sine of the arc  $\theta$  in the supposed circle, that is, twice the natural sine, reduced in the ratio of unit to the radius of this circle, which is  $\sin \psi$ , reduced again to a direction perpendicular to the equatorial plane; whence  $x' - x'' = 2 \sin \theta \sin \psi \cos \phi$ : and  $x'^2 - x''^2 = 4 \sin \theta \sin \psi \cos \phi$ . Hence it follows, that, in different positions of the gravitating particle, the effective elevation at each point of the surface, similarly situated with respect to it, is as the product of the sine and cosine of its angular distance  $\phi$  from the equatorial plane, the other quantities concerned remaining the same in all positions. But the inclination of the surface of the spheroid, as well as the original disturbing force, varies in the same proportion of the product of the sine and cosine of the distance  $\phi$ : consequently, the sum of this disturbing attraction and the original force will also vary as the inclination of the surface, and may be in equilibrium with the tendency to descend towards the centre, provided that the ellipticity be duly commensurate to the density of the elevated parts.

Now, in order to find the actual magnitude of the disturbing attraction for a shell of given density, we must compute the fluent of  $4e \sin \theta d\theta \sin \psi \cos \psi \sin \psi \cos \phi$ , reduced first according to the distance and direction of each particle from the given gravitating particle; and we must compare the fluent with  $\frac{4}{3}\pi$ , the attraction of the whole sphere at the distance of the radius or unity. But for the angle  $\theta$ , the por-

tion of the force acting in the common direction of  $\sin \theta$  is to the whole attraction at the same distance as  $\sin \theta$  to 1, so that the attractive force of any point of the semicircle will be  $4e \sin^2 \theta \sin \psi \cos \psi \sin \psi \cos \phi$ , and its fluxion will be as  $\sin^2 \theta d\theta$ , of which the fluent is  $\frac{1}{2}\theta - \frac{1}{2} \sin \theta \cos \theta$ , or when  $\theta = 180^\circ$ ,  $\frac{\pi}{2}$ , and  $\frac{1}{2}\pi \sin \psi$  will express the effect of the disturbing attraction of the semicircles, of which  $\sin \psi$  is the radius, reduced to the direction of the middle point, of which the distance is  $2 \sin \frac{1}{2}\psi$ : the reduction for this distance is as its square to 1; and for the direction, as the distance to  $\sin \psi$ , together making

the ratio of  $\frac{\sin \psi}{8 \sin^{\frac{5}{2}} \psi}$ , and the ultimate fluxion of the force will be  $2e\pi \sin \psi \sin \cos \phi \sin \cos \psi \frac{\sin \psi}{8 \sin^{\frac{5}{2}} \psi} d\psi = 2e\pi \frac{\sin^3 \psi \cos \psi}{8 \sin^{\frac{5}{2}} \psi} \sin \cos \phi d\psi$ ; but  $\sin \psi = 2 \sin \frac{1}{2}\psi \cos \frac{1}{2}\psi$ , and the fraction becomes  $\frac{8 \sin^3 \cos^{\frac{3}{2}} \frac{1}{2}\psi}{8 \sin^{\frac{5}{2}} \frac{1}{2}\psi} \cos \frac{1}{2}\psi = \cos^{\frac{3}{2}} \frac{1}{2}\psi \cos \frac{1}{2}\psi = \cos^{\frac{5}{2}} \frac{1}{2}\psi (\cos^2 \frac{1}{2}\psi - \sin^2 \frac{1}{2}\psi) = \cos^{\frac{5}{2}} \frac{1}{2}\psi - \cos^{\frac{3}{2}} \frac{1}{2}\psi + \cos^{\frac{5}{2}} \frac{1}{2}\psi = 2 \cos^{\frac{5}{2}} \frac{1}{2}\psi - \cos^{\frac{3}{2}} \frac{1}{2}\psi$ . Now, taking the fluent from  $\psi = 0$  to  $\psi = 180^\circ$ , we have  $2 \int' \cos^{\frac{5}{2}} \frac{1}{2}\psi 2d\frac{1}{2}\psi = \frac{8}{5} \cdot \frac{4}{3}$ ,

and  $\int' \cos^{\frac{3}{2}} \frac{1}{2}\psi \times 2d\frac{1}{2}\psi = \frac{4}{3}$ , (Art. FLUENTS, n. 361,

359): the difference being  $\frac{3}{5} \cdot \frac{4}{3} = \frac{4}{5}$ , whence the flu-

ent of the force is found  $2e\pi \sin \cos \phi \times \frac{4}{5} \times \frac{1}{n}$ , call-

ing the density of the fluid  $\frac{1}{n}$ ; or, where it is great-

est,  $\sin \cos \phi$  being  $= \frac{1}{2}$ ,  $\frac{4}{5} \frac{e\pi}{n}$ , while the attraction of

the sphere itself is  $\frac{4}{3}\pi$ , which is to  $\frac{4}{5} \frac{e\pi}{n}$  as 1 to  $\frac{3e}{5n}$ ;

and since the elevation  $e$  expresses also the maximum of the relative force of gravity depending on the tangent of the inclination (Theorem B), it is ob-

vious that the disturbing attraction  $\frac{3e}{5n}$  must be to

the relative force  $e$ , as  $\frac{3}{n}$  to 5.

*Corollary 1.* If  $n=1$ , as in a homogeneous fluid sphere or spheroid, the disturbing attraction be-

comes  $\frac{3}{5}e$ , and this attraction, together with the pri-

mitive force  $f$ , must express the actual elevation  $e$ ,

or  $\frac{3}{5}e + f = e$ , whence  $f = \frac{2}{5}e$ , and  $e = \frac{5}{2}f$ , giving

2.024 and 5.042 for the magnitude of the solar and lunar tides, when  $f = .8097$  and 2.0166 respectively. But this is obviously far from the actual state of the problem.

Tides.

Corollary 2. Supposing  $n=5.4$  (See *Journ. R. I.*

Apr. 1820), we have  $\frac{3e}{27} + f = e$ , and  $e = \frac{27}{24}f = \frac{9}{8}f$ ; so that

the height of the primitive tides of an ocean of water, covering the whole surface of the earth, such as it actually is, ought to be .911 for the solar, and 2.27 for the lunar disturbing force: that is, supposing the sea to be without inertia, so as to accommodate itself at once to the form of equilibrium. But, in the actual state of the irregularities of the seas and continents, it is impossible to pay any regard to this secondary force, since the phenomena do not justify us in supposing the general form of the surface of the ocean such as to give rise to it.

THEOREM D. [H]. When the horizontal surface of a liquid is elevated or depressed a little at a given point, the effect will be propagated in the manner of a wave, with a velocity equal to that of a heavy body which has fallen through a space equal to half the depth of the fluid, the form of the wave remaining similar to that of the original elevation or depression. *Illustr. Celest. Mech.* 378. p. 318.

*Scholium.* The demonstration of this theorem implies that water is incompressible, and that the pressure of each particle placed on the surface is instantaneously communicated through the whole depth of the fluid to the bottom. These suppositions are not indeed strictly accurate in any case, but they introduce no sensible error when the surface of the wave similarly affected is large in comparison with the depth of the fluid. A modern author, of celebrity, seems to have taken it for granted, that the pressure is propagated with the same velocity downwards and laterally; at least, if such is not his meaning, he has been somewhat unfortunate in the choice of his expressions; but there seems no reason whatever, why water should communicate force more slowly when it is perfectly confined, than ice would do; and the divergence of the pressure of a certain portion of the surface of water, elevated a little, for example, above the rest, may be compared to the divergence of a sound entering into a detached chamber by an aperture of the same size with the given surface, which is probably *small* in comparison with its direct motion, but *equally rapid*, and in both cases depending on the modulus of the elasticity of the medium.

THEOREM E. [I]. A wave of a symmetrical form, with a depression equal and similar to its elevation, striking against a solid vertical obstacle, will be reflected, so as to cause a part of the surface, at the distance of one fourth of its whole breadth, to remain at rest; and if there be another opposite obstacle at twice that distance, there may be a perpetual vibration between the surfaces, the middle point having no vertical motion. *Nat. Phil.* I. p. 289. 777.

*Scholium* 1. The elevation and depression of a spheroid, compared with the surface of the sphere of equal magnitude, exhibits a symmetrical wave in the sense of the proposition: and it is not necessary, that the shores should be very rocky or perpendicular, in order to produce a strong reflection; for, even the vibration of the water in the bottom of a common hemispherical basin is considerably permanent.

Tides.

Corollary 2. The vibrations of the water supposed to be contained in a canal, following the direction of the equator, and  $90^\circ$  in length, would be synchronous with the passage of a wave  $180^\circ$  in breadth, over any point of a canal of the same depth, and surrounding the whole globe.

*Scholium* 2. It has been usual to consider the elevation of the tides, as identical with that of an oblong spheroid, measured at its vertex, and therefore as amounting to twice as much as the depression of the same spheroid at the equator, considered in relation to the mean height belonging to a sphere of the same magnitude: but, the supposition is by no means applicable to the case of a globe, covered partially and irregularly with water, so that in almost all cases of actual tides, the elevation must be considered as little if at all greater than the depression, as far as this cause only is concerned; there are, however, some other reasons to expect, that the elevation of the great wave might often arrive at a distant port in somewhat greater force than the depression.

THEOREM F. [K]. The oscillations of the sea and of lakes, constituting the tides, are subject to laws exactly similar to those of pendulums capable of performing vibrations in the same time, and suspended from points which are subjected to compound regular vibrations, of which the constituent periods are completed in half a lunar, and half a solar day [or in some particular cases a whole day].

Supposing the surface of the sea to remain at rest, each point of it would become alternately elevated and depressed, in comparison with the situation in which it might remain in equilibrium; its distance from this situation varying according to the regular law of the pendulum (see Theorem B); and like all minute vibrations, it will be actuated by forces indirectly dependent on, and proportional to, this distance; so that it may be compared to a pendulous body remaining at rest in the vertical line, about which its point of suspension vibrates, and will consequently follow the motion of the temporary horizon, in the same manner as the pendulum follows the vibration of its point of suspension, either with a direct or a retrograde motion, according to circumstances, which will be hereafter explained: the operation of the forces concerned being perfectly analogous, whether we consider the simple hydrostatic pressure depending on the elevation, or the horizontal pressure, derived from the inclination of the surface, or the differential force immediately producing elevation and depression, depending on the variation of the horizontal pressure, and proportional to the curvature of the surface. It becomes therefore necessary for the theory of the tides, to investigate minutely the laws of these compound and compulsory vibrations; which, together with the resistances affecting them, will be the subject of the next section.

SECT. III.—Of the Effects of Resistance in Vibrating Motions, whether Simple or Compound.

THEOREM G. If  $dw + Ads + Bsds + Dwds = 0$ ; we have  $e^{Ds} \left( w + \frac{B}{D}s + \frac{AD-B}{DD} \right) = c$ ; hle being = 1.

*Tides.* *Scholium.* For the better understanding of the mode of investigation which will be employed in these propositions, it will be proper to premise some remarks on the investigation of fluxional equations, by means of multipliers. A person, unacquainted with the language of modern mathematicians, would naturally understand, by a "criterion of integrability," some mode of distinguishing an expression that would be integrated, from one that was untractable: while, in fact, this celebrated criterion relates only to the accidental form in which the expression occurs, and not to its essential nature. If we take, for instance, the well known case of the fluxion of  $hl^{\frac{x}{y}}$  =

$$hlx - hly, \text{ we have } \frac{dx}{x} - \frac{dy}{y} = \frac{ydx - xdy}{xy}, \text{ and making}$$

this = 0, we have also  $ydx - xdy = 0$ ; and this expression no longer fulfils the conditions of integrability,

until we multiply it again by  $\frac{1}{xy}$ , and restore it to

its perfect form. The direct investigation of such a multiplier is generally attended by insuperable difficulties; and the best expedient, in practical cases, is to examine the results of the employment of such multipliers, as are most likely to be concerned in the problem, with indeterminate coefficients, and to compare them with the equations proposed. In common cases, the finding of fluents, when only one variable quantity is concerned, requires little more than the employment of a Table such as that of Meier Hirsch, or that which constitutes the Article FLUENTS in this *Supplement*; and the demonstration of the truth of the solution is in general furnished at once, for each case, by taking the fluxion of the quantity inserted in the Table as the fluent: but for the separation of different variable quantities, where they are involved with each other, the employment of proper multipliers is one of the most effectual expedients; and it is still more essential to the solution of equations between fluxions of different orders, or their coefficients. Such equations require in general to be compared with some multiple of the exponential

quantity  $e^{mt}$ , which affords fluxions of successive orders, that have simple relations to each other, especially when  $dt$  is considered as constant. The multiples of  $\sin Ct$ , and  $\cos Ct$ , are also very useful in such investigations, and for a similar reason; but the solutions that they afford are commonly less comprehensive than the former; though they are often simpler, and more easily obtained. It is not, however, necessary that the exponent of the multiplier should flow uniformly, as will appear from the first example of a problem which has been solved by Euler in his *Mechanics*: the subsequent examples will possess somewhat more of novelty.

*Demonstration.* The fluxion of  $e^{ns} (w + ps + q)$  is  $e^{ns} (dw + pds + (nw + nps + nq) ds) = e^{ns} dw + (p + nq) ds + ndsds + nwdss$ ; and comparing with this  $e^{ns} (d\omega + Ad\omega + Bsds + Dwdss)$ , we have  $n = D$ ,  $np = B$ , and

$$p = \frac{B}{n} = \frac{B}{D}; \text{ and, lastly, } p + nq = A, q = \frac{A - p}{n} =$$

$$\frac{AD - B}{DD}; \text{ consequently the fluxion of } e^{Ds} \left( w + \frac{B}{D}s + \frac{AD - B}{DD} \right) \text{ is equal to nothing, and that quantity}$$

is constant, or equal to  $c$ .

*Example.* Let the given equation be that of a cycloidal pendulum, moving with a resistance proportional to the square of the velocity, or  $\frac{dds}{dt^2} + Bs - D \frac{ds^2}{dt^2} = 0$ .

*Scholium 2.* The space  $s$  being supposed to begin at the lowest point of the curve, the fluxion  $ds$  is negative during the descent on the positive side, and the force  $dds$  is consequently negative, and equal, when there is no resistance, to  $Bs$ ,  $B$  being a positive coefficient, equivalent, in the case of gravitation,

to  $\frac{2g}{l}$  or  $\frac{32}{l}$ ,  $l$  being the length of the pendulum, and

$g$  the descent of a falling body in the first second. The coefficient  $-D$  is negative, because the resistance acts in a contrary direction to that of the force  $Bs$ , as long as  $s$  remains positive, and coincides with it on the negative side. But in the return of the pendulum the signs are changed; so that the equation can only be applied to a single vibration: since the two forces in question oppose each other in the same points of the curve in which they before agreed,

while the square  $\frac{ds^2}{dt^2}$  must always remain positive.

*Solution.* If we multiply the given equation by  $ds$ , and make the square of the velocity, or  $vv = w = \frac{ds^2}{dt^2}$ ,

$$\text{we have } ds \frac{dds}{dt^2} + Bsds - D \frac{ds^2}{dt^2} ds = 0 = \frac{1}{2} dw + Bsds -$$

$Dvds$ , and  $dw + 2Bsds - 2Dvds = 0$ ; which, compared with the theorem, gives us 0 for  $A$ ,  $2B$  for  $B$ , and  $-2D$  for  $D$ ; and the solution becomes

$$e^{-2Ds} \left( w - \frac{B}{D}s - \frac{B}{2DD} \right) = c, \text{ or } w = \frac{B}{D}s + \frac{B}{2DD} +$$

$$ce^{2Ds}; \text{ and if } w = 0 \text{ when } s = \lambda, \text{ we have } \frac{B}{D}\lambda + \frac{B}{2DD} +$$

$$ce^{2D\lambda} = 0, \text{ or, putting } \frac{B}{D}\lambda + \frac{B}{2DD} = \beta, \beta + ce^{2D\lambda} = 0,$$

$$\text{and } c = -\beta e^{-2D\lambda}; \beta \text{ being also } = \frac{B\gamma}{2DD}, \text{ if } \gamma = 1 +$$

$2D\lambda$ . We may also substitute  $\sigma$  for  $\lambda - s$ , and

$$ce^{2Ds} = -\beta e^{2D(s-\lambda)}, \text{ will become } = -\beta e^{-2D\sigma}, \text{ and}$$

$$w = \frac{B}{D}s + \frac{B}{2DD} - \beta e^{-2D\sigma} = \frac{B}{2DD} (1 - \gamma e^{-2D\sigma} +$$

$$2Ds). \text{ Now } e^{-2D\sigma} = 1 - 2D\sigma + 2D^2\sigma^2 - \frac{4}{3}D^3\sigma^3 +$$

*Tides.*

Tides.

$$\frac{2}{3}D^4\sigma^4 - \dots; \text{ and } (1+2D\lambda) e^{-2D\sigma} = 1 + 2D\lambda - 2D\sigma - 4D^2\lambda\sigma + 2D^2\sigma^2 + 4D^3\lambda\sigma^2 - D^4\lambda^3\sigma^3 - \dots;$$

whence  $w = \frac{B}{2DD} (2D\sigma - 2D(\lambda - \sigma) + 4D^2\lambda\sigma - 2D^2\sigma \dots) = \frac{B}{2DD} (4D^2\lambda\sigma - 2D^2\sigma^2 - 4D^3\lambda\sigma^2 \dots)$

$$= B(2\lambda\sigma - \gamma\sigma^2 + \frac{2}{3}D\gamma\sigma^3 - \frac{1}{3}D^2\gamma\sigma^4 + \dots).$$

*Corollary 1.* From this solution we obtain the point at which the velocity is greatest; and, by reversing the equation, we may also find the extent of the vibration. For when  $dw=0$ , we have  $Bsds = Dwd\sigma$ , and  $Bs = Dw$ , which is the obvious expression of the equality of the resistance to the propelling force. Putting the greatest value of  $w=z$ , and the corresponding value of  $s=\zeta$ , we have  $z = \frac{B}{D}\zeta + \frac{B}{2DD} +$

$$ce^{2D\zeta} = \frac{B}{D}\zeta, \text{ since } Bs = Dz, \text{ and } \frac{B}{2DD} = -ce^{2D\zeta} =$$

$$\frac{B\gamma}{2DD} e^{2D(\zeta-\lambda)}; \text{ whence } \frac{1}{\gamma} = e^{2D(\zeta-\lambda)}, \text{ and } \gamma = e^{2D(\lambda-\zeta)};$$

consequently  $hl\gamma = 2D(\lambda - \zeta) = hl(1 + 2D\lambda)$ , and  $2D\zeta = 2D\lambda - hl(1 + 2D\lambda)$ , and  $\zeta = \frac{1}{2D} (2D^2\lambda^2 - \frac{8}{3}D^3\lambda^3 + \dots) = D\lambda^2 - \frac{4}{3}D^2\lambda^3 + \dots$

And since  $z = \frac{B}{D}\zeta$ , we have  $z = \frac{B}{2DD} (2D\lambda - hl[1 + 2D\lambda])$ .

*Lemma.* For the reversion of a series, or of a finite equation, if  $z = ax + bx^2 + cx^3 + \dots$  we have  $x = \frac{1}{a}z -$

$$\frac{b}{a^5}z^2 + \frac{2b^2 - ac}{a^5}z^3 - \frac{5b^3 - 5abc + a^2d}{a^7}z^4 + \frac{14b^4 - 21ab^2c + 6a^2bd + 3a^2c^2 - a^5e}{a^9}z^5 - \dots$$

The proof of this well known formula is the most readily obtained by means of a series with indeterminate coefficients, such as  $x = Az + Bz^2 + \dots$ , which, by actual involution, and by comparison with the proposed series, will give the required values of the coefficients, as expressed in this Lemma.

*Corollary 2.* When  $w=0$ , we obtain from its value, divided by  $B\sigma$ , the equation  $2\lambda = \gamma\sigma - \frac{2}{3}D\gamma\sigma^2 +$

$$\frac{1}{3}D^2\gamma\sigma^3 - \dots; \text{ and by reversing this series, we have}$$

$$\sigma = \frac{2\lambda}{\gamma} + \frac{8}{3\gamma^2}D\lambda^2 + \frac{40}{9\gamma^3}D^2\lambda^3 \dots, \text{ or } \sigma = 2\lambda - \frac{4}{3}D\lambda^2 + \dots;$$

the difference of the arcs of descent and ascent being  $\frac{4}{3}D\lambda^2$ , and the difference of two successive vibrations  $\frac{8}{3}D\lambda^2$ , when the resistance is very small;

this difference being also  $\frac{8}{3}\zeta$ ; so that the displacement of the point of greatest velocity is  $\frac{3}{8}$  of the difference of the successive vibrations.

*Scholium 2.* If  $K$  be the value of  $w$  when  $Dw$  would be equal to the force of gravity, and  $DK = Bl = 2g$ , we have  $D = \frac{2g}{K}$ , or  $H$  being the height from which a body must fall to acquire the velocity  $\sqrt{K}$ , since  $K = 4gH$ ,  $D = \frac{1}{2H}$ , and  $2D = \frac{1}{H}$ .

*Scholium 3.* It is natural to imagine that we might obtain the time from the equation expressing the velocity in terms of the space, if we merely expanded the value of  $\frac{1}{\sqrt{w}}$  into a new series, by means of the Newtonian theorem: but the fluents thus obtained for the expression of the time are deficient in convergency; and a similar difficulty would occur if we expressed  $\sigma$  in terms of  $w$  by reversing the series, and divided its fluxion by  $\sqrt{w}$ . The ingenuity of Euler has, however, devised a method of avoiding these inconveniences, by supposing the time to begin at the point where the velocity is a maximum; and it will be necessary, in this investigation, to follow his steps, with some slight variations.

*Corollary 3.* In order to find the time of vibration, we take  $s - \zeta = \tau$ , and  $x - w = z$ , then  $s = \tau + \zeta$ ,  $\sigma = \lambda - \zeta - \tau$ ,  $w = \frac{B}{2DD} (1 - \gamma e^{-2D(\lambda - \zeta - \tau)} + 2D[\zeta + \tau])$ , and  $x$  being  $= \frac{B}{D}\zeta$ ,  $z = -\frac{B}{2DD} - \frac{B}{D}\tau$

$$+ \frac{B\gamma}{2DD} e^{2D(\zeta-\lambda)} e^{2D\tau}; \text{ but we have seen that } e^{2D(\zeta-\lambda)} = \frac{1}{\gamma}, \text{ and } -z \text{ becomes } \frac{B}{2DD} + \frac{B}{D}\tau -$$

$$\frac{B}{2DD} e^{2D\tau} = \frac{B}{D}\tau - \frac{B}{2DD} (2D\tau + 2D^2\tau^2 + \frac{4}{3}D^3\tau^3 + \frac{8}{12}D^4\tau^4 + \dots) = \frac{B}{D}\tau - \frac{B}{D}\tau - B\tau^2 - \frac{2}{3}BD\tau^3 - \dots$$

$$= -B\tau^2 - \frac{2}{3}BD\tau^3 - \frac{1}{3}BD^2\tau^4 - \dots, \text{ and } \frac{z}{B} = \tau^2 + \frac{2}{3}D\tau^3 + \frac{1}{3}D^2\tau^4 + \dots$$

In order to reverse this series, we must put  $\frac{z}{B} = y^3$ , and  $\tau = Ay + By^2 + Cy^3 + \dots$ , and by substituting the powers of this series for those of  $\tau$  in the value of  $\frac{z}{B} = y^2 = \tau^2 + P\tau^3 + Q\tau^4$

$$+ \dots, \text{ we find } A=1, B=-\frac{1}{3}P, C=\frac{5}{8}P^2 - \frac{1}{2}Q \dots; \text{ and } \tau = y - \frac{1}{3}Dy^2 + \frac{1}{9}D^2y^3 - \dots. \text{ Hence } d\tau = dy -$$

Tides.  $\frac{2}{3}Dydy + \frac{1}{3}D^2y^2dy - \dots$ ; and this fluxion, divided by the velocity  $v = \sqrt{(x-z)}$ , will be the fluxion of

$$\frac{dz}{2\sqrt{B}\sqrt{z}}, dt = \sqrt{\frac{1}{B} \frac{dz}{2\sqrt{(xz-zz)}} - \frac{D}{3B}\sqrt{(x-z)}} + \frac{D^2}{6B\sqrt{B}} \frac{zdz}{\sqrt{(xz-zz)}} - \dots$$

and the fluent becomes  $t = \frac{1}{2\sqrt{B}} \text{arc } v \sin \frac{2z}{x} - \frac{2D}{3B}\sqrt{(x-z)} + \frac{D^2}{6B\sqrt{B}} \left( \frac{1}{2} \text{arc } v \sin \frac{2z}{x} - \sqrt{(xz-z^2)} \right) \dots$ ; the value of

which, taken from  $z=0$  to  $z=x$ , is  $2\frac{\pi}{\sqrt{B}} - \frac{2D}{3B}\sqrt{x} + \frac{D^2}{3B\sqrt{B}}(\frac{1}{2}\pi) \dots$  If we now make  $r$  negative, for the ascent of the pendulum, the coefficients  $P, R, \dots, B, D, \dots$ , will change their signs, and the value of  $t$  will be  $\frac{\pi}{2\sqrt{B}} + \frac{2D}{3B}\sqrt{x} + \frac{D^2}{12B\sqrt{B}}x\pi + \dots$ ,

the sum of both being  $\frac{\pi}{\sqrt{B}} + \frac{D^2x\pi}{6B\sqrt{B}} + \dots$ , which is the time of a complete vibration, and the difference  $\frac{4D}{3B}\sqrt{x} + \dots$ . The effect of the resistance on the whole time involves, therefore, only the second and the higher powers of the coefficient of the resistance  $D$ ; and it also disappears with the arc, as  $x$ , the square of the greatest velocity, becomes inconsiderable with respect to the velocity itself, and to the time  $\frac{\pi}{\sqrt{B}}$ .

**THEOREM H.** If  $\frac{dds}{dt^2} + A\frac{ds}{dt} + Bs = 0$ ,  $dt$  being constant, we have  $e^{mt}(ds + asdt) = c$ ;  $m$  being  $= \frac{1}{2}A \pm \sqrt{(\frac{1}{4}A^2 - B)}$ , and  $a = \frac{1}{2}A \mp \sqrt{(\frac{1}{4}A^2 - B)}$ .

*Demonstration.* The fluxion of  $e^{mt}(ds + asdt)$  is  $e^{mt}(d^2s + adsdt + (mds + amsdt)dt) = e^{mt}(d^2s + (a+m)dsdt + amsdt^2)$ ; and, comparing this fluxion with the proposed equation, we have, for the coefficients,  $a+m=A$ , and  $am=B$ ; whence  $\frac{B}{m} + m = A$ ,  $m^2 - Am = -B$ ,  $m = \frac{1}{2}A \pm \sqrt{(\frac{1}{4}A^2 - B)}$ , and  $a = \frac{1}{2}A \mp \sqrt{(\frac{1}{4}A^2 - B)}$ .

*Example.* Let the equation proposed be that of a cycloidal pendulum, vibrating with a resistance proportional to the velocity; that is,  $\frac{dds}{dt^2} + A\frac{ds}{dt} + Bs = 0$ .

*Scholium 1.* The resistance is here adequately expressed, in all cases, by the term  $A\frac{ds}{dt}$ , so that

the equation is permanently applicable to the successive vibrations. Thus, in the second descent, on the negative side of the vertical line,  $Bs$  being negative, and  $-s$  becoming nearer to 0, the fluxion  $ds$  is positive, and  $A\frac{ds}{dt}$  is of a contrary character to  $Bs$ , as it ought to be.

*Solution.* Since  $m = \frac{1}{2}A \pm \sqrt{(\frac{1}{4}A^2 - B)}$ , and  $a = \frac{1}{2}A \mp \sqrt{(\frac{1}{4}A^2 - B)}$ , it is obvious that the two radical quantities will be either possible or imaginary, accordingly as  $\frac{1}{4}A^2$  is greater or less than  $B$ .

*Case i.* If  $A^2$  is greater than  $4B$ , the resistance being very considerable, the solution becomes

$$e^{\frac{1}{2}At} \pm \sqrt{(\frac{1}{4}A^2 - B)}t \left( \frac{ds}{dt} + [\frac{1}{2}A \mp \sqrt{(\frac{1}{4}A^2 - B)}]s \right) = c$$

and the velocity  $v = -\frac{ds}{dt} = (\frac{1}{2}A - \sqrt{[\frac{1}{4}A^2 - B]})s - ce^{-\frac{1}{2}At} - \sqrt{(\frac{1}{4}A^2 - B)}t = (\frac{1}{2}A + \sqrt{[\frac{1}{4}A^2 - B]})s - c'e^{-\frac{1}{2}At} + \sqrt{(\frac{1}{4}A^2 - B)}t$ ; and if the velocity be supposed to vanish when  $s = \lambda$ , and  $t = 0$ , we have  $0 = \frac{1}{2}A\lambda - \sqrt{(\frac{1}{4}A^2 - B)}\lambda - c = \frac{1}{2}A\lambda + \sqrt{(\frac{1}{4}A^2 - B)}\lambda - c'$ .

*Corollary 1.* Hence it appears that such a pendulum would require an infinite time to descend to the lowest point, since the velocity cannot have a finite value when  $s$  vanishes, the exponential quantity never beginning negative.

*Scholium 2.* The coefficient  $B$  may also be written, for an actual pendulum, as measured in English feet,  $\frac{32}{l}$ , or  $\frac{2g}{l}$ , if we call  $g$  the descent of a falling body in the first second, which is, however, denoted, in the works of some authors, by  $\frac{1}{2}g$  or even by  $\frac{1}{4}g$ . If we make  $\frac{dds}{dt^2} + \frac{32}{l}s = 0$ ; when  $s = l$ , the force

becomes such that  $-d^2s = 32dt^2$ , and  $-\frac{ds}{dt} = 32$ , which is the true velocity generated by such a force in a second of time. Supposing  $k$  to be the velocity with which the resistance would become equal to the weight, we must have, for  $A\frac{ds}{dt} = \frac{32}{k}\frac{ds}{dt}$ , in order that the force represented by  $A$  may become equal to that of gravity, and  $A = \frac{2g}{k}$ ; and if  $h$  be the height from which a body must fall to gain the velocity  $k$ , since  $h = \frac{k^2}{4g}$ ,  $A^2 = \frac{4gg}{kk} = \frac{g}{h}$ . Hence it follows, that when  $A^2 = 4B$ , which is the time of the possibility of alternate vibrations,  $\frac{g}{h} = \frac{8g}{l}$ , and  $h = \frac{1}{8}l$ ,

the resistance becoming equal to the weight when the body has fallen freely through one eighth of the length of the pendulum.

*Case ii.* Supposing now the resistance to be more moderate, and  $\frac{1}{4}A^2$  to be less than  $B$ , and making

Tides.

Tides.  $B - \frac{1}{4}A^2 = C^2$ ; we shall have  $\sqrt{\frac{1}{4}A^2 - B} = \sqrt{-C^2} = \sqrt{-1}C$ ; the solution of the equation,  $\frac{dds}{dt^2} + A\frac{ds}{dt} + Bs = 0$ , will then be  $d\left(e^{\frac{1}{2}At} \pm \sqrt{-1}Ct \left[\frac{ds}{dt} + \frac{1}{2}As \mp \sqrt{-1}Cs\right]\right) = 0$ ; whence, by taking the two different values in succession, and adding together their halves, we obtain  $d\left(e^{\frac{1}{2}At} \left[\frac{e^{\sqrt{-1}Ct} + e^{-\sqrt{-1}Ct}}{2} (ds + \frac{1}{2}As) + \frac{e^{-\sqrt{-1}Ct} - e^{\sqrt{-1}Ct}}{2} \sqrt{-1}Cs\right]\right) = 0$ ; or, since  $\sqrt{-1} = \frac{-1}{\sqrt{-1}}$ ,  $\frac{e^{\sqrt{-1}Ct} + e^{-\sqrt{-1}Ct}}{2} \left(\frac{ds}{dt} + \frac{1}{2}As\right) + \frac{e^{\sqrt{-1}Ct} - e^{-\sqrt{-1}Ct}}{2\sqrt{-1}} Cs = ce^{-\frac{1}{2}At}$ . Now the imaginary exponential quantities, thus combined, are the well known expressions for the sine and cosine of the arc  $Ct$ , (*Elem. Illustr.* § 358); and the last equation may be written thus,  $\cos Ct \left(\frac{ds}{dt} + \frac{1}{2}As\right) + \sin Ct Cs = ce^{-\frac{1}{2}At}$ ; whence  $v = -\frac{ds}{dt} = \frac{1}{2}As + \frac{\sin Ct}{\cos Ct} Cs - \frac{ce^{-\frac{1}{2}At}}{\cos Ct}$ . This fluent, if  $t$  were made to begin when  $v=0$ , would only afford us such expressions as have hitherto been found intractable; but nothing obliges us to limit the problem to this condition, and it is equally allowable to make the time  $t$  begin when  $v = \frac{1}{2}As$ , the corresponding value of  $s$  being called  $\zeta$ , then  $\frac{1}{2}As = v = \frac{1}{2}A\zeta - c$ ; consequently  $c=0$ . The equation will then become  $\frac{ds}{s} + C\frac{\sin Ct}{\cos Ct} dt + \frac{1}{2}A dt = 0$ ; whence  $hl \cos Ct = c' - \frac{1}{2}At = hl \frac{s}{\cos Ct}$ , and  $\frac{s}{\cos Ct} = e^{c' - \frac{1}{2}At}$ , or  $s = \cos Ct \cdot e^{c' - \frac{1}{2}At}$ ; and, when  $t=0$ ,  $s = e^{c'} = \zeta$ ; consequently  $\frac{s}{\zeta} = \cos Ct \cdot e^{-\frac{1}{2}At} = \cos Ct \left(1 - \frac{1}{2}At + \frac{1}{8}A^2t^2 - \frac{1}{48}A^3t^3 + \dots\right)$ . But, since  $v = -ds = s \left(C\frac{\sin Ct}{\cos Ct} dt + \frac{1}{2}A dt\right)$ , it follows that  $v$  must vanish whenever  $C\frac{\sin Ct}{\cos Ct} + \frac{1}{2}A = 0$ , or when  $\tan Ct = \frac{-A}{2C}$ , that is, in the first instance, very nearly when  $Ct = \frac{-A}{2C}$ , and  $t = \frac{-A}{2CC}$ , and  $-\frac{1}{2}At = \frac{AA}{4CC}$ , and  $e^{-\frac{1}{2}At} = 1 + \frac{AA}{4CC}$ , very nearly; so that, calling the primi-

tive extent of the arc of vibration  $s = \lambda$ , we have  $\frac{\lambda}{\zeta} = \cos Ct \left(1 + \frac{AA}{4CC}\right)$ ;  $\cos Ct$  being also, in this case,  $= \sqrt{\left(1 - \frac{AA}{4CC}\right)} = 1 - \frac{AA}{8CC}$ , and  $\frac{\lambda}{\zeta} = 1 + \frac{AA}{8CC}$ , and  $\frac{\zeta}{\lambda} = \frac{8CC}{8CC + AA} = \frac{8B - 2AA}{8B - AA} = 1 - \frac{AA}{8B - AA}$ , corresponding to the verse sine of the time  $\frac{-A}{2CC}$ , or to the arc  $\frac{-A}{2C}$ , in the circle represented by  $Ct$ .

*Corollary 2.* It follows that both  $v$  and  $s$  must vanish continually at equal successive intervals, whenever  $\tan Ct = \frac{-A}{2C}$ , and when  $\cos Ct = 0$ , respectively; the descent, to the lowest point, will therefore occur the time corresponding to  $\frac{\pi}{4} + \frac{A}{2C}$ , and the subsequent ascent to  $\frac{\pi}{4} - \frac{A}{2C}$ : the extent of the vibrations being always proportional to  $e^{-\frac{1}{2}At}$ .

*Corollary 3.* The greatest velocity must take place at the point where  $A\frac{ds}{dt} + Bs = 0$ , and  $AC \tan Ct + \frac{1}{2}A^2 = B$ , or  $\tan Ct = \frac{B - \frac{1}{2}AA}{AC}$ , and  $\cot Ct = \frac{AC}{B - \frac{1}{2}AA}$ , or, if we neglect  $A^2$ ,  $\cot Ct = \frac{A}{\sqrt{B}} = \cos Ct = \frac{s}{\zeta}$ , very nearly.

*Corollary 4.* The diminution of the successive vibrations is expressed by the multiplier  $e^{-\frac{1}{2}At}$ , which, when  $Ct = 2\pi$ , the whole circumference, is  $1 - \frac{A}{C}\pi$ , and  $\frac{A}{C}\pi\lambda$ , or  $\frac{A\pi\lambda}{\sqrt{B}}$  is the diminution of the value of  $s$  when the pendulum returns to the place from which it first set out, that is, the difference between the lengths of two vibrations, each corresponding to a semicircumference, and this difference is to  $\frac{A}{\sqrt{B}}\zeta$ , or  $\frac{A}{\sqrt{B}}\lambda$ , the displacement of the point of greatest velocity, which measures the greatest resistance, as  $\pi$  to 1, or as 3.1416 to 1. We have seen that, for a resistance varying as the square of the velocity, this proportion was as 8 to 3, or as 2.667 to 1.

*Corollary 5.* If the pendulum be supposed to vibrate in a second, the unity of time, the diminution of the arc  $2\lambda$  in each vibration will be  $\frac{1}{2}A \times 2\lambda$ , and the successive lengths will vary as  $e^{-\frac{1}{2}A} 2\lambda$ ,  $e^{-A} 2\lambda$ , and so forth: and after the number  $N$  of vibrations,

Tides. the extent of the arc will be reduced from  $2\lambda$  to  $e^{-\frac{1}{2}NA} 2\lambda$ ; so that if we make  $e^{-\frac{1}{2}NA} = M$ , we have  $\text{hl}M = -\frac{1}{2}NA$ , and  $A = \frac{2}{N} \text{hl} \frac{1}{M}$ . Thus, if in an hour

the vibrations were reduced to  $\frac{2}{3}$  of their extent, which

is rather more than appears to have happened in any of Captain Kater's experiments, we should have  $N$

$$= 3600, \text{ and } M = \frac{2}{3}, \text{ whence } A = \frac{1}{1800} \times .4054651$$

$$= .00022526, \text{ and } A^2 = .00000005075; \text{ and since}$$

$$B = \frac{32}{l} = 9.81, C = \sqrt{B - \frac{1}{4}A^2} = \sqrt{B} \sqrt{1 - \frac{AA}{4B}}$$

$$= \sqrt{B} \left(1 - \frac{AA}{8B}\right) = \sqrt{B} \left(1 - \frac{AA}{78.5}\right); \text{ the fraction}$$

being only  $= .0000000065$ ; or about one second in 1600 millions; that is in about 50 years.

*Scholium 3.* Although the isochronism of a pendulum, with a resistance proportional to the velocity, was demonstrated by Newton, yet Euler appears to have failed in his attempts to carry the theory of such vibrations to perfection; for he observes (*Mechan.* II. p. 312), *Etsi ex his appareat, tempora tam ascensuum quam descensuum inter se esse æqualia, tamen determinari non potest, quantum sit tempus sive descensuum sive ascensuum: neque etiam tempora descensuum et ascensuum inter se possunt comparari. Æquatio enim rationem inter s et u definiens ita est*

*complicata, ut ex ea elementum temporis  $\frac{ds}{u}$ , per unicam variabilem non possit exprimi.*

*Scholium 4.* In confirmation of the solution that has been here proposed, it may not be superfluous to show the truth of the result in a different manner.

Taking  $s = e^{mt} \cos Ct$ , we have  $\frac{ds}{dt} = e^{mt} (m \cos$

$Ct - C \sin Ct)$ , and  $\frac{dds}{dt^2} = e^{mt} (m^2 \cos Ct - Cm \sin$

$Ct - Cm \sin Ct - C^2 \cos Ct)$ ; whence  $\frac{dds}{dt^2} + A \frac{ds}{dt} +$

$Bs = e^{mt} (m^2 \cos Ct - 2Cm \sin Ct - C^2 \cos Ct + Am \cos Ct - AC \sin Ct + B \cos Ct) = 0$ , and  $(m^2 - C^2 + Am + B) \cos Ct - (2Cm + AC) \sin Ct = 0$ : an equation which is obviously true when the coefficients of both its terms vanish, and  $2Cm = -AC$ , or  $m = \frac{1}{2}A$ ; and again  $C^2 = m^2 + Am + B = \frac{1}{4}A^2 - \frac{1}{2}A^2 + B = B - \frac{1}{4}A^2$ . The former mode of investigation is more general, and more strictly analytical; but this latter is of readier application in more complicated cases, and it will hereafter be further pursued.

*Lemma.* If a moveable body be actuated continually by a force equal to that which acts on a given pendulum, the body being in a state of rest when the pendulum is at the middle of its vibration, the space described in the time of a vibration will be to the length of the pendulum as the circumference of a circle is to its diameter. For the force being represented by  $\cos Ct$ , or  $\cos x$ , for the pendulum, it will become  $\sin x$  with regard to the beginning of

the supposed motion, and the velocity, instead of  $\sin x$ , becomes  $-\cos x$ , or  $1 - \cos x$ ; so that the space, instead of  $1 - \cos x$ , is  $x - \sin x$ , which, at

the end of the semivibration, is  $x = \frac{\pi}{2}$ , instead of  $1 -$

$\cos x = 1$ , the space described by the simple pendulum, which is equal to its length.

*Scholium 5.* There is a paradox in the relations of the diminution of the vibration to the distance measuring the greatest resistance, which it will be worth while to consider, in order to guard ourselves against the too hasty adoption of some methods of approximation which appears at first sight unexceptionable. The pendulum, if it set out from a state of rest at the point of greatest resistance, would perform a vibration to the extent of double the distance

of that point, or  $2 \frac{A}{\sqrt{B}} \lambda$ , the initial force being mea-

sured by that distance. Now, when the resistance is very small, its magnitude may be obtained without sensible error from the velocity of the pendulum vibrating without resistance at the corresponding part of the arc; and the velocity may be supposed to vary as  $\sin Ct$ , and the resistance, in the case of this proposition, as  $\sin Ct$  or  $\sin x$  also. Hence it may be inferred, by means of the Lemma, that the whole

diminution of the space will be to  $\frac{A}{\sqrt{B}} \lambda$  as  $\pi$  to 1, or

that it will be equal to  $\frac{A}{\sqrt{B}} \pi \lambda$ , which has already

been found to be the actual difference of two successive semivibrations. The accuracy of this result, however, must depend on the mutual compensation of its errors; for the approximation supposes, that if the resistance vanished at the lowest point, the subsequent retardation would be such as to diminish the space by the effect of the diminution of the velocity acting uniformly through the remainder of the vibration, while in fact the diminution of the space from this cause would be simply equal to a part of the arc proportional to the diminution of the velocity; since the arc of ascent is simply as the velocity at the lowest point. Hence it is obvious, that the effects of the resistance are too much complicated with the progress of the vibration to allow us to calculate them separately; and, accordingly, when the resistance is as the square of the velocity, or as  $\sin^2 x$ , the diminution of the velocity is expressed by  $\frac{1}{2}x - \frac{1}{2} \sin \cos x$ , and that of the space by  $\frac{1}{4}x^2 - \frac{1}{4} \sin^2 x$ , which, at the end of a vibration, becomes  $\frac{1}{4}\pi^2$  instead of  $\pi$ , that is, since the distance of the point of greatest velocity is here  $\epsilon = D\lambda^2$ ,  $\frac{1}{4}\pi^2 D\lambda^2 = 2.467 D\lambda^2$ , while the more accurate mode of computation has shown that the true diminution of the space is  $2.667 D\lambda^2$ . (*Theorem G.*) If we chose to pursue the mode of approximation here suggested, with accuracy, it would be necessary to consider the resistance as a periodical force acting on a pendulum capable of a synchronous vibration, as hereafter in *Theorem K, Schol. 1.*

**THEOREM J.** If  $\frac{dds}{dt^2} + Bs + M \sin Ft = 0$ , we may

Tides. satisfy the equation by taking  $s = \sin(\sqrt{B}t) +$

$$\frac{M}{FF-B} \sin Ft.$$

*Demonstration.* The value of  $s$  here assigned gives us  $\frac{ds}{dt}$

$$= \sqrt{B} \cos \sqrt{B}t + \frac{MF}{FF-B} \cos Ft, \text{ and } \frac{dds}{dt^2} = -B \sin \sqrt{B}t - \frac{MFF}{FF-B} \sin Ft;$$

so that  $\frac{dds}{dt^2} + Bs = B \sin \sqrt{B}t + \frac{MB}{FF-B} \sin Ft - B \sin \sqrt{B}t - \frac{MFF}{FF-B} \sin Ft =$

$$\frac{MB - MFF}{FF - B} \sin Ft = -M \sin Ft.$$

*Corollary 1.* If, in order to generalise this solution, we make  $s = \alpha \sin \sqrt{B}t + \beta \cos \sqrt{B}t + \gamma \sin Ft + \epsilon \cos Ft$ , we may take any quantities at pleasure for  $\alpha$  and  $\beta$ , according to the conditions of the particular case to be investigated; but  $\epsilon$  must be  $= 0$ ; that is, the motion will always be compounded of two vibrations, the one dependent on the length of the pendulum, or on the time required for the free vibration, indicated by  $\sqrt{B}t$ , the other synchronous with  $Ft$ , the period of the force denoted by  $M$ ; the latter only being limited to the condition of beginning and ending with the periodical force.

*Corollary 2.* In the same manner it may be shown that the addition of any number of separate periodical forces, indicated by the terms  $M' \sin F't$ ,  $M'' \sin F''t$ ,  $\dots$ , will add to the solution the quantities

$$\frac{M'}{F'F'-B} \sin F't, \frac{M''}{F''F''-B} \sin F''t, \text{ and so forth.}$$

*Example 1.* Supposing a pendulum to be suspended on a vibrating centre, and to pass the vertical line at the same moment with the centre, we may make  $\alpha$  and  $\beta = 0$ , and  $s = \frac{M}{FF-B} \sin Ft$  only; the vibration being either direct or reversed accordingly as  $F$  is less or greater than  $\sqrt{B}$ , or than  $\sqrt{\frac{32}{l}}$ , which determines the spontaneous vibration of the pendulum.

*Example 2.* But if the ball of the pendulum be supposed to begin its motion at the moment that the centre of suspension passes the vertical line, we must

$$\text{make } s = \frac{M}{FF-B} (\sin Ft - \cos \sqrt{B}t); \text{ and the subse-}$$

quent motion of the pendulum will then be represented by the sum of the sines of two unequal arcs in the same circle; and if these arcs are commensurate with each other, the vibration will ultimately acquire a double extent, and nearly disappear, in a continued succession of periods, provided that no resistance interfere. And the consequences of any other initial conditions may be investigated in a manner nearly similar: thus, if the time of free vibration, under these circumstances, were  $\frac{1}{3}$  of the periodical time, the free vibration, in which the motion must be supposed initially retrograde, in order to represent a state of rest by its combination with the fixed vibration, would have arrived at its greatest excursion

forwards, after three semivibrations, at the same moment with the fixed vibration, and after three complete vibrations more would be at its greatest distance in the opposite direction, so as to increase every subsequent vibration equally on each side, and permanently to combine the whole extent of the separate arcs of vibration. But in this and in every other similar vibration, beginning from a state of rest in the vertical line; that is, at the point where the periodical force is evanescent, the effect of the free or subordinate vibration with respect to the place of the body will obviously disappear whenever an entire number of semivibrations have been performed.

*Corollary 3.* The paradox stated in the fourth scholium on the last theorem may be illustrated by means of this proposition, and will serve in its turn to justify the mode of computation here employed in a remarkable manner. It has been observed, in Nicholson's *Journal* for July 1813, that the mode of investigating the effects of variable forces, by resolving them into parts represented by the sines of multiple arcs, and considering the vibrations derived from each term as independent in their progress, but united in their effects, may be applied to the problem of a pendulum vibrating with a resistance proportional to the square of the velocity; and that for this purpose the square of the sine may be represented by the series  $\sin^2 x = .8484 \sin x - .1696 \sin 3x - .0244 \sin 5x - .00813 \sin 7x - .0029 \sin 9x - .0013 \sin 11x - \dots$  Now, if we employ this series for resolving the resistance supposed in theorem G into a number of independent forces, the greatest resistance being mea-

sured by  $\frac{A}{\sqrt{B}}\lambda$ , we shall have  $.8484 \frac{A}{\sqrt{B}}\lambda$  for the part supposed to be simply proportional to the velocity,

whence, from theorem H, we have  $.8484\pi \frac{A}{\sqrt{B}}\lambda$  for the corresponding diminution of the vibration; that

is,  $2.6653 \frac{A}{\sqrt{B}}\lambda$ . But it has been observed, in the preceding corollary, that the *place* of the pendulum will not be at all affected by any subordinate vibration after any entire number of complete semivibrations; and the slight effect of the *velocity* left in consequence of these subordinate vibrations may here be

safely neglected, so that  $2.6653 \frac{A}{\sqrt{B}}\lambda$  may be considered as the whole effect of the resistance with respect

to the space described, which differs only by  $\frac{1}{2000}$  of

the whole from  $2.666 \frac{A}{\sqrt{B}}\lambda$ , the result of the more direct computation of theorem G.

*Scholium.* An experimental illustration of the accuracy of the theorem may be found in the sympathetic vibrations of clocks, and in that of the inverted pendulum, invented by Mr Hardy, as a test of the steadiness of a support; for since the extent of the

regular periodical vibration is measured by  $\frac{M}{FF-B}$ ,

Tides. it is evident that, however small the quantity of  $M$  may be, it will become very considerable when divided by  $FF-B$ , as  $F$  and  $\sqrt{B}$  approach to each other; and accordingly it is observed, that when the inverted pendulum is well adjusted to the rate of a clock, there is no pillar so steady as not to communicate to it a very perceptible motion by its regular, though extremely minute, and otherwise imperceptible change of place.

THEOREM K. In order to determine the effect of a periodical force, with a resistance proportional to the velocity, the equation,  $\frac{dds}{dt} + A\frac{ds}{dt} + Bs = M \sin$

$Gt=0$ , may be satisfied by taking  $s=\alpha s$  in  $Gt+\beta \cos$   
 $Gt$ ,  $\alpha$  being  $=\frac{GG-B}{(GG-B)^2+AAGG}M$ , and  $\beta=$   
 $\frac{AGM}{(GG-B)^2+AAGG}$ ;  $s$  being also  $=\sqrt{(\alpha^2+\beta^2)} \sin$   
 $\left( Gt + \text{arc ta } \frac{\beta}{\alpha} \right) = \frac{M}{\sqrt{[(GG-B)^2+AAGG]}} \sin$   
 $\left( Gt - \text{arc ta } \frac{AG}{B-GG} \right)$ .

Since  $s=\alpha \sin Gt+\beta \cos Gt$ ,  $\frac{ds}{dt}=\alpha G \cos Gt-$   
 $\beta G \sin Gt$ , and  $\frac{dds}{dt^2}=-\alpha G^2 \sin Gt-\beta G^2 \cos Gt=-$

$G^2s$ ; consequently the equation becomes  $(B-G^2)$   
 $(\alpha \sin Gt+\beta \cos Gt)+\alpha AG \cos Gt-\beta AG \sin Gt+$   
 $M \sin Gt=0$ , and  $(B-G^2) \alpha-\beta AG+M=0$ , and  
 $(B-G^2)\beta+\alpha AG=0$ ; whence  $\frac{\beta}{\alpha}=\frac{AG}{GG-B}$ ; also  $\beta=$   
 $\frac{M-(GG-B)\alpha}{AG}=\frac{\alpha AG}{GG-B}$  and  $(G^2-B)M-(G^2-$   
 $B)^2\alpha=A^2G^2$ ; consequently  $\alpha=\frac{(GG-B)M}{(GG-B)^2+A^2G^2}$

and  $\beta=\frac{AGM}{(GG-B)^2+A^2G^2}$ . And since, in general, if

$b=ta \text{ B}$ ,  $\sin x+b \cos x=\sqrt{(1+b^2)} \sin (x+B)$ ;  $\sin$   
 $(x+B)$  being  $=\sin x \cos B+\sin B \cos x=\cos B$   
 $(\sin x+ta \text{ B} \cos x)$ , and therefore  $\sin x+ta \text{ B} \cos x=$   
 $\frac{\sin (x+B)}{\cos B}=\sin (x+B) \sec B=\sin (x+B)\sqrt{(1+b^2)}$ :

it follows that  $\alpha \sin Gt+\beta \cos Gt=\alpha \left( \sin Gt \right.$   
 $\left. + \text{arc ta } \frac{\beta}{\alpha} \right) \sqrt{\left( 1+\frac{\beta\beta}{\alpha\alpha} \right)}$ ; and  $\alpha \sqrt{\left( 1+\frac{\beta\beta}{\alpha\alpha} \right)}=$   
 $\sqrt{(\alpha^2+\beta^2)}=\sqrt{\frac{(GG-B)^2+A^2G^2}{[(GG-B)^2+A^2G^2]}}M=$   
 $\frac{M}{\sqrt{[(GG-B)^2+A^2G^2]}}$ .

Corollary. If we put  $M \cos Gt$  instead of  $M \sin$   
 $Gt$ , we shall have  $s=\alpha' \sin Gt+\beta' \cos Gt$ ;  $\alpha'$  being  
 $=\beta=\frac{AGM}{(GG-B)^2+A^2G^2}$  and  $\beta'=-\alpha=$

$\frac{B-GG}{(GG-B)^2+AAGG}M$ , and  $s=\sqrt{(\alpha'^2+\beta'^2)} \sin \left( Gt \right.$   
 $\left. + \text{arc ta } \frac{\beta'}{\alpha'} \right) =\sqrt{(\alpha^2+\beta^2)} \sin \left( Gt + \text{arc ta } \right.$   
 $\left. \frac{B-GG}{AG} \right)$ .

Scholium 1. Supposing  $B$  to approach very near  
to  $G^2$ , a case very likely to occur in nature, be-  
cause the effects which are produced, where it is  
found, will predominate over others, on account of  
the minuteness of the divisor; we may neglect the  
part of the denominator  $(G^2-B)^2$ , in comparison  
with  $A^2G^2$ , and the coefficient determining  $s$  will  
then become  $\frac{M}{AG}$ , the extent of the vibrations be-

ing inversely as  $A$  the coefficient of the resistance;  
and, indeed, when the whole force of the periodical  
vibration is expended in overcoming a resistance  
proportional to the velocity, it may naturally be  
imagined that the velocity should be inversely as the  
resistance. It follows also from the proposition,  
that in this case the arc  $\text{ta } \frac{AG}{B-GG}$  approaching to

a quadrant, the greatest excursions of the periodical  
motion and of the free vibration will differ nearly one  
fourth of the time of a complete vibration from each  
other.

Scholium 2. Since  $s$  is a line, and  $B$  its numeri-  
cal coefficient, making it represent a force, and since  
 $\sin Gt$  is properly a number also, the coefficient  $M$ ,  
both here and in Theorem J, must be supposed to  
include another linear coefficient, as  $\mu$ , which con-  
verts the sine into a line, to be added to  $s$ , the dis-  
tance from the middle point: that is,  $M$  must be  
considered as representing  $B\mu$ , in which  $\mu$  is the  
true extent of the periodical change of the centre of  
suspension, and  $B=\frac{2g}{l}$ , as in other cases: so that

$M$  is  $=\frac{2g}{l} \mu=32 \frac{\mu}{l}$ , and  $\mu=\frac{Ml}{2g}=\frac{1}{32}Ml$ .

Corollary. In order to obtain a more general so-  
lution of the problem, we may combine the periodi-  
cal motion thus determined with the free vibrations,  
as computed in Theorem H, the different motions,  
as well as the resistances, being totally independent  
of each other; but the most interesting cases are  
those which are simply periodical, the free vibration  
gradually diminishing, with the multiplier  $e^{-mt}$ , and  
ultimately disappearing.

THEOREM L. If there are several periodical  
forces, the equation,  $\frac{dds}{dt^2} + A\frac{ds}{dt} + Bs + M \sin Gt +$   
 $N \sin Ft + \dots = 0$ , may be satisfied by taking  $s=\alpha$   
 $\sin Gt + \beta \cos Gt + \alpha' \sin Ft + \beta' \cos Ft + \dots =$   
 $\frac{M}{\sqrt{[(G^2-B)^2+A^2G^2]}} \sin \left( Gt - \text{arc ta } \frac{AG}{B-GG} \right)$   
 $+ \frac{N}{\sqrt{[(F^2-B)^2+A^2F^2]}} \sin \left( Ft - \text{arc ta } \frac{AF}{B-FF} \right)$   
 $+ \dots$

*Tides.* For, the equations expressing the space described being simply linear, the different motions and resistances are added or subtracted without any alteration of the respective relations and effects.

*Scholium.* A free vibration may also be combined with this compound periodical vibration, by means of Theorem H; but it will gradually disappear by the effect of the resistance.

*Lemma.* For the addition of the arcs  $a$  and  $b$ , beginning with the well known equation  $\sin(a \pm b) = \sin a \cos b \pm \sin b \cos a$ , we have, by addition,  $\sin(a+b) + \sin(a-b) = 2 \sin a \cos b$ , and  $\sin a \cos b = \frac{1}{2} \sin(a+b) + \frac{1}{2} \sin(a-b)$ : then if  $c = b + 90^\circ$ ,  $\cos b = \sin c$ , whence  $\sin a \sin c = \frac{1}{2} \sin(a+c-90^\circ) + \frac{1}{2} \sin(a-c+90^\circ)$ : but  $\sin(x+90^\circ) = \cos x$  and  $\sin(x-90^\circ) = -\cos x$ ; consequently  $\sin a \sin c = \frac{1}{2} \cos(a-c) - \frac{1}{2} \cos(a+c)$ ; again, if  $c = a - 90^\circ$ ,  $\cos c = \sin a$ , and  $\cos c \cos b = \frac{1}{2} \sin(a+b) + \frac{1}{2} \sin(a-b) = \frac{1}{2} \sin(c+90^\circ+b) + \frac{1}{2} \sin(c+90^\circ-b) = \frac{1}{2} \cos(c+b) + \frac{1}{2} \cos(c-b)$ . Also, since  $\cos a \cos b = \frac{1}{2} \cos(a+b) + \frac{1}{2} \cos(a-b)$ , and  $\sin a \sin b = \frac{1}{2} \cos(a-b) - \frac{1}{2} \cos(a+b)$ , we have, by subtraction,  $\cos(a+b) = \cos a \cos b - \sin a \sin b$ , and, by addition,  $\cos(a-b) = \cos a \cos b + \sin a \sin b$ .

*Corollary.* If  $a+b=c$  and  $a-b=d$ ,  $\cos c + \cos d = 2 \cos \frac{c+d}{2} \cos \frac{c-d}{2}$ ; and  $\cos d - \cos c = 2 \sin \frac{c+d}{2} \cos \frac{c-d}{2}$ ; also  $\sin a + \sin b = 2 \sin \frac{a+b}{2} \cos \frac{a-b}{2}$ ; and  $\sin a - \sin b = \sin a + \sin(-b) = 2 \sin \frac{a-b}{2} \cos \frac{a+b}{2}$ .

**THEOREM M.** The equation,  $\frac{dds}{dt^2} + A \frac{ds}{dt} + Bs + R \sin Ft \sin Gt = 0$  may be solved by taking  $s = \alpha \sin([F-G]t + p) - \beta \sin([F+G]t + q)$ ;  $\alpha$  being  $\sqrt{\frac{\frac{1}{2}R}{[(F-G)^2 - B]^2 + A^2(F-G)^2}}$ ,  $\beta = \sqrt{\frac{\frac{1}{2}R}{[(F+G)^2 - B]^2 + A^2(F+G)^2}}$ ,  $p = \arctan \frac{B - (F-G)^2}{A(F-G)}$ , and  $q = \arctan \frac{B - (F+G)^2}{A(F+G)}$ .

For since  $\sin Ft \sin Gt = \frac{1}{2} \cos(F-G)t - \frac{1}{2} \cos(F+G)t$ , the equation becomes  $\frac{dds}{dt^2} + A \frac{ds}{dt} + Bs - \frac{1}{2} R \cos(F+G)t + \frac{1}{2} R \cos(F-G)t = 0$ ; whence we obtain the solution by comparison with Theorem K and its corollary.

**SECT. IV.—Astronomical Determination of the Periodical Forces which Act on the Sea or on a Lake.**

In order to compute, by means of the theory which has been laid down in the two preceding sections, the primitive tides of any sea or any portion of the ocean, we must compare its spontaneous oscillations with those of a narrow prismatic canal, situated in a given direction with respect to the meridian, which in general must be that of the greatest

length of the sea in question, neglecting altogether the actual breadth of the sea, which, if considerable, may require to have its own distinct vibrations compounded with those of the length, each being first computed independently of the other. Now, supposing the time required for the principal spontaneous oscillation of the sea or lake to be known, we must find the length of the synchronous pendulum,

and taking  $B = \frac{2g}{l} = \frac{32}{l}$ , we must next find a series

for expressing the force in terms of the sine, or cosines of multiple arcs, increasing uniformly with the time.

Now the force is measured, for the direction of the meridian of the spheroid of equilibrium, by  $\sin \cos z$ , (Theorem A),  $z$  being either the zenith distance or the altitude; and it is obvious that, when the canal is situated obliquely with respect to the meridian of the spheroid, the inclination of the surface, and with it the force, will be diminished as the secant of the obliquity increases, or as the cosine of the obliquity diminishes; so that the force will vary as  $\sin \cos Alt. \sin Az$ , if the canal be in an easterly and westerly direction; or if it deviate from that direction in a given angle, as  $\sin \cos Alt. \sin(Az + Dev.)$ : and it is obvious that this force will vanish both when the luminary is in the horizon, and when it is in the vertical circle, perpendicular to the direction of the canal; that is, if we consider the force as acting horizontally on a particle at the middle of the length of the given canal; and the same force may be considered as acting vertically, with a proper reduction of its magnitude, at the end of the canal; for the horizontal oscillations at the middle must obviously follow the same laws as the vertical motions at the end.

The case, however, of a canal running east and west, admits a very remarkable simplification; and since it approaches nearly to that of an open ocean, which has been most commonly considered, it will be amply sufficient for the illustration of the present

theory. For, in general,  $\sin Az = \frac{\cos Decl. \sin Hor. <}{\cos Alt. <}$ ,

and the expression,  $\sin \cos Alt. \sin Az$ , becomes in this case  $\sin Alt. \cos Decl. \sin Hor. <$ . But  $\sin Alt. = \sin(Lat.) \sin Decl. + \cos(Lat.) \cos Decl. \cos Hor. <$ , and calling  $\sin(Lat.)$  for the given canal,  $L$ , and  $\cos(Lat.)$ ,  $L'$ , the force becomes  $L \sin \cos Decl. \sin Hor. < + L' \cos^2 Decl. \sin \cos Hor. <$ . Now,  $\sin Decl. = \cos Obl. Ecl. \sin Lat. + \sin Obl. Ecl. \cos Lat.$

$\sin Long.$ ; and since  $\cos \varphi = 1 - \frac{1}{2} \sin^2 \varphi + \frac{3}{8} \sin^4 \varphi -$

$\frac{5}{16} \sin^6 \varphi + \dots$ , the true value of  $\cos Decl.$  might

be expressed, if required, by means of this series, and its second and fourth powers would in general be sufficient for the computation.

But it will be more convenient to suppose the sun and moon to move in the ecliptic, and the ecliptic to be at the same time so little inclined to the equator, that the longitude may be substituted for the right ascension; a substitution which will cause but little alteration in the common phenomena of the tides. Then if the sun's longitude be  $\odot$ , and the moon's

Tides.  $\delta$ , the horary angles  $t$  and  $t'$ , and the sine of the obliquity of the ecliptic  $\alpha$ ; we shall have  $\sin Decl. = \alpha \sin \odot$ , or  $\alpha \sin \delta$ ; and  $\cos Decl. = 1 - \sin^2 Decl.$   
 $+ \frac{3}{8} \sin^4 Decl. = 1 - \frac{1}{2} \alpha^2 \sin^2 \odot + \frac{3}{8} \alpha^4 \sin^4 \odot \dots$

and  $\sin \cos Decl. = \alpha \sin \odot - \frac{1}{2} \alpha^3 \sin^3 \odot + \frac{3}{8} \alpha^5 \sin^5 \odot \dots$ ; also  $\cos^2 Decl. = 1 - \alpha^2 \sin^2 \odot$ ; whence the sun's force becomes  $L \sin t (\alpha \sin \odot - \frac{1}{2} \alpha^3 \sin^3 \odot + \frac{3}{8} \alpha^5 \sin^5 \odot \dots) + L' \frac{1}{2} \sin 2t (1 - \alpha^2 \sin^2 \odot)$

$\odot) = L \sin t (\alpha \sin \odot - \frac{1}{2} \alpha^3 (\frac{3}{4} \sin \odot - \frac{1}{4} \sin 3 \odot) + \frac{3}{8} \alpha^5 (\frac{5}{8} \sin \odot - \frac{5}{16} \sin 3 \odot + \frac{1}{16} \sin 5 \odot))$   
 $+ \frac{1}{2} L' \sin 2t (1 - \frac{1}{2} \alpha^2 + \frac{1}{2} \alpha^2 \cos 2 \odot) = L \sin t (\alpha' \sin \odot + \alpha'' \sin 3 \odot + \alpha''' \sin 5 \odot) + (\frac{1}{2} L - \frac{1}{4} L' \alpha^2) \sin 2t + \frac{1}{4} L' \alpha^2 \sin 2t \cos 2 \odot$ ;  $\alpha'$  being

$= \alpha - \frac{3}{8} \alpha^3 + \frac{15}{64} \alpha^5 \dots$ ; or about .3645;  $\alpha'' = \frac{1}{8} \alpha^5 - \frac{15}{128} \alpha^5 \dots = .0078$ , and  $\alpha''' = \frac{3}{128} \alpha^5 \dots = .00002$ , and  $\alpha^2 = .1585$ . But  $\sin t \sin \odot = \frac{1}{2} \cos (t - \odot) - \frac{1}{2} \cos (t + \odot)$ , and  $\sin 2t \cos 2 \odot = \frac{1}{2} \sin 2(t + \odot) + \frac{1}{2} \sin 2(t - \odot)$ . Hence the sun's force becomes  $S (L \alpha' [\frac{1}{2} \cos (t - \odot) - \frac{1}{2} \cos (t + \odot)] + L \alpha'' [\frac{1}{2} \cos (t - 3 \odot) - \frac{1}{2} \cos (t + 3 \odot)] + L \alpha''' [\frac{1}{2} \cos (t - 5 \odot) - \frac{1}{2} \cos (t + 5 \odot)] + \frac{L'}{2} (1 - \frac{1}{2} \alpha^2) \sin 2t + \frac{L'}{4} \alpha^2 [\frac{1}{2} \sin 2(t + \odot) + \frac{1}{2} \sin 2(t - \odot)])$ : and that of the moon may be expressed in the same manner, by substituting  $M, t'$  and  $\delta$ , for  $S, t$ , and  $\odot$ .

The effect of that part of the hydraulic resistance, which is proportional to the square of the velocity, must be expressed by an approximation deduced from the periodical character of the force, as depending on that of the primitive forces concerned; taking, however, the precaution to use such expressions only, as will always represent this resistance in its proper character as a retarding force: for if we simply found for it an equivalent expression, denoting accurately the square of the velocity, this square, being always positive, would imply a force acting always in the same direction. Now, we have already seen (Theorem J. Cor. 3), that  $\sin^2 x$  may be considered, with respect to its principal effect, as equivalent to  $.8484 \sin x$ : and, if we neglect, in the determination of the resistance, the effect of the smaller forces, and compute only that of the principal terms  $\frac{1}{2} L' \sin 2t$ , and  $\frac{1}{2} L' \sin 2t'$ , we may call the velocities depending on these forces  $S' \cos (2t + s')$  and  $M' \cos (2t' + m')$ :  $S'$  and  $M'$  representing not exactly the proportion of the primitive forces of the sun and moon, but that of the tides depending on their combination with the conditions of the given sea or lake. The resistance will then be as the

square of  $S' [\cos(2t+s') + \cos(2t'+m')] + (M' - S') \cos(2t'+m')$ : and when least, it will be  $D (M' - S')^2$  and when greatest,  $D (M' + S')^2$ , the difference being  $4DM'S'$ ; so that the difference may be sufficiently represented by  $4DM'S' [\cos(2t+s') + \cos(2t'+m')] \times .8484$ , or rather  $\times (.8484)^2$ , because the

value of  $\cos t + \cos t' = 2 \cos \frac{t+t'}{2} \cos \frac{t-t'}{2}$ , which

is to be squared, requires the reduction from 1 to .8484 for each of its factors; and in this manner we obtain a perfect representation of the period and quality of the resistance, and a very near approximation to its magnitude.

It will, however, be still more accurate to consider the resistance thus determined as comprehended in the value of the coefficient  $A$ , substituting for it, in the case of the solar tide,  $A' = A + 2.88 DM'$ , and for the moon  $A'' = A + 2.88 DS' + .8484 D (M' - S')$ ; this latter part expressing that portion of the resistance  $D$  which observes the period of the lunar tide, and which may therefore be considered as added to the resistance  $A$  for that tide only.

Hence, collecting all the forces concerned into a single equation, the expression will become  $\frac{dds}{dt^2} +$

$$A'' \frac{ds}{dt} + Bs + S (L \alpha' [\frac{1}{2} \cos (t - \odot) - \frac{1}{2} \cos (t + \odot)] + L \alpha'' [\frac{1}{2} \cos (t - 3 \odot) - \frac{1}{2} \cos (t + 3 \odot)] + \alpha''' [\frac{1}{2} \cos (t - 5 \odot) - \frac{1}{2} \cos (t + 5 \odot)] + \frac{L'}{2} (1 - \alpha^2) \sin 2t + \frac{L'}{4} \alpha^2 [1 \sin 2(t + \odot) + \frac{1}{2} \sin 2(t - \odot)]) +$$

$$M (L \alpha' [\frac{1}{2} \cos (t' - \delta) - \frac{1}{2} \cos (t' + \delta)] + L \alpha'' [\frac{1}{2} \cos (t' - 3 \delta) - \frac{1}{2} \cos (t' + 3 \delta)] + L \alpha''' [\frac{1}{2} \cos (t' - 5 \delta) - \frac{1}{2} \cos (t' + 5 \delta)] + \frac{L'}{2} (1 - \alpha^2) \sin 2t' + \frac{L'}{4} \alpha^2 [\frac{1}{2} \sin 2(t' + \delta) + \frac{1}{2} \sin 2(t' - \delta)]) = 0;$$

and from each of these terms the value of the corresponding pair of terms in the value of  $s$  may be obtained independently, by comparison with the  $M \sin Gt$  or  $N \cos Gt$  of Theorem K, which gives us

$$\frac{(GG - B) \sin Gt + AG \cos Gt}{(GG - B)^2 + AAGG} M, \text{ and}$$

$$\frac{AG \sin Gt + (B - GG) \cos Gt}{(GG - B)^2 + AAGG} N, \text{ respectively.}$$

But without entering minutely into the effects of all the terms of the equation of the forces, it may be observed in general that their results, with regard to the space described, will not differ much from the proportion of the forces, except when their periods approach nearly to that of the spontaneous oscillation, represented by  $B$ . Thus since  $\frac{1}{2} \cos (t - \odot) - \frac{1}{2} \cos (t + \odot)$  is the representative of  $\sin t \sin \odot$ , and since these terms will afford results in the form  $\frac{1}{2} \alpha \cos (t - \odot) + \frac{1}{2} \beta \sin (t - \odot)$ , and of  $\frac{1}{2} \alpha' \cos (t + \odot) + \frac{1}{2} \beta' \sin (t + \odot)$ ; and if we neglected the slight difference of  $\alpha$  and  $\alpha'$ , which is that of

Tides.  $\left(1 - \frac{\odot}{t}\right)^2 - B$ , and  $\left(1 + \frac{\odot}{t}\right)^2 - B$ ,  $\frac{\odot}{t}$  being

$\frac{1}{365.254}$  only, we should have  $\frac{1}{2} \alpha [\cos(t - \alpha) - \cos$

$(t + \odot)] + \frac{1}{2} \beta [\sin(t - \odot) - \sin(t + \odot)] = \alpha \sin t \sin \odot + \beta \cos t \sin \odot = \sin \odot (\alpha \sin t + \beta \cos t)$ ; which is the same as if we considered the effect of the force  $\sin t$  separately, and afterwards reduced it in the proportion of  $\sin \odot$ . Hence it is obvious that for all modifications of the forces greatly exceeding in their periods the period of spontaneous oscillation, the effects may be computed as if the forces were exempt from those modifications, and then supposed to be varied in the same proportion as the forces: but we cannot be quite certain of the magnitude of the error thus introduced, unless we know the exact value of  $B$ , which determines the time of spontaneous oscillation.

Considering, therefore, in this simple point of view, the correct expression of the force,  $L \sin \cos \text{Decl.} \sin \text{Hor.} < + L' \cos^2 \text{Decl.} \sin \cos \text{Hor.} <$ , or  $\frac{1}{2} L \sin 2 \text{Decl.} \sin \text{Hor.} < + \frac{1}{2} L' \cos^2 \text{Decl.} \sin 2 \text{Hor.} <$ : we may observe that the phenomena for each luminary will be arranged in two principal divisions; the most considerable being represented by  $\frac{1}{2} L' \cos^2 \text{Decl.} \sin 2 \text{Hor.} <$ , and giving a tide every twelve hours, which varies in magnitude as the square of the cosine of the declination varies, increasing and diminishing twice a year, being also proportional to the cosine of the latitude of the place, and disappearing for a sea situated at the pole: the second part is a diurnal tide, proportional to the sine of the latitude of the given canal, being greatest when the luminary is furthest from the equinox, and vanishing when its declination vanishes.

From these general principles, an attentive student may easily trace for himself the agreement of the theory here explained with the various modifications of the tides as they are actually observed, and as they are recorded by Lalande and Laplace, and as they are enumerated in the Article TIDES of the late editions of this *Encyclopædia*. It remains, however, for us to inquire more particularly into the cause of the hitherto unintelligible fact, that the maximum of the spring tides in the most exposed situations is at least half a day, if not a whole day, later than the maximum of the moving forces.

Now it is easy to perceive that since the resistance observing the lunar period is more considerable than that which affects the solar tide, the lunar tide will be more retarded or accelerated than the solar; retarded when the oscillation is direct, or when  $G^2 - B$  is positive, and accelerated when it is inverted, or when that quantity is negative: and that in order to obtain the perfect coincidence of the respective high waters, the moon must be further from the meridian of the place than the sun; so that the greatest direct tides ought to happen a little before the syzygies, and the greatest inverted tides a little after: and from this consideration, as well as from some others, it seems probable that the primitive tides, which affect most of our harbours, are rather inverted than direct.

If we wish to apply this theory with precision to the actual state of the solar and lunar motions, we

must determine the value of the coefficients, from the tables of those luminaries: and first, making the unit of time a whole solar day, in which the horary angle  $t$  extends from  $0^\circ$  to  $360^\circ$ , the sun's mean longi-

tude  $\odot$  will be  $\frac{t}{365.254}$  added to the longitude at the

given epoch, and the moon's approximate horary angle  $t'$  will be found from the variation, or the moon's age in space.

Now, in Burckhardt's *Tables*, p. 87, we find the variation for the midnight ending 1823, by adding the constant quantity  $9^\circ$  to the epoch for 1824, and  $(11^\circ. 14'. 44''. 44'') + 9^\circ = 11^\circ. 23'. 44''$ , or  $-(6^\circ. 15'. 16'')$ , according to the time of Paris: the movement for 12 hours is  $6^\circ. 5'. 43''$ ; consequently at noon, or 1824 Jan. 1. Oh, astronomical time at Paris, the variation is  $-(9'. 33'')$ , corresponding to the movement of  $18^m. 49$ . in mean time, and the mean conjunction will take place at  $18^m. 49^s$ . Parisian time, which may be more compendiously expressed by calling it the true mean noon, in the time of the island of Guernsey or of Dorchester: and the movement in 24 hours being  $12^\circ 11' 26.5'' = 12.19^\circ$ , we shall have  $t' = 360^\circ - 12.19^\circ = 347.81^\circ$  when  $t = 360^\circ$ ,

or  $t' = \frac{347.81}{360} t = .96614t$ ; and the moon's horary

angle, considered in relation to the circumference as unity, will always be  $.96614t$ , if  $t$  be the number of days elapsed, from the noon of 1st Jan. 1814 at Guernsey.

The sun's mean longitude for the same epoch is  $(279^\circ. 35'. 23.1'') = .77666$ , his longitude for any other time will therefore be  $.77666 + .002738t = \odot$ , and that of the moon,  $\ominus = .77666 + .03386t$ .

We may compute, with sufficient accuracy, the effect of the modifications produced by the change of the moon's distance, or the inequality of her motion in her orbit, or of the periodical change of the inclination of her orbit to the equator, which takes place from the revolution of the nodes, by simply considering the changes which will be produced in the forces concerned by these inequalities, and supposing the effects simply proportional to their causes. If, however, it were desired to determine these modifications with still greater precision, we might deduce approximate formulas for expressing them from the elements employed in the *Tables*.

The epoch of the moon's mean anomaly for 1824 is  $(4^s. 29'. 25''. 23.3'') + 2^\circ = 151^\circ. 25'. 23.3''$ ; the movement for  $12^h. 18^m. 49^s$  is  $(6^\circ. 31'. 57'') + (9'. 47.9'') + 27'' = 6^\circ. 42'. 12''$ , which gives  $158^\circ. 7'. 35''$  for the mean anomaly at noon in the island of Guernsey. The daily movement being  $13^\circ 3.9' = 13.065^\circ$ , the mean anomaly will always be  $158.127^\circ + 13.065^\circ t$ , reckoning  $t$  from the supposed epoch or day. The principal part of the central equation will then be, according to Burckhardt,  $22692.4'' \sin An.$ , or  $(6^\circ. 18.2') \sin (158\frac{1}{2}^\circ + 13.065^\circ t)$ , and its sine will be very nearly  $.11 \sin (13.065^\circ t + 158.127^\circ)$ , which will represent the principal inequality of the longitude and of the variation, so that the variation, instead of  $12.19^\circ t$ , will become  $12.19^\circ t + 6.3^\circ \sin (13.065^\circ t + 158.127^\circ)$ , and this subtracted from  $360^\circ t$ , leaves

Tides  
||  
Tipperary.

Tides  
||  
Tipperary.

347.81°t—6.3° sin (13.065°t+158.127°), the sine of which is nearly sin 347.81°t—cos 347.81°t .11 sin (13.065°t+158.127°).

The equatorial parallax is nearly 57'+187" cos An., or 57'+3.1' cos (13.065°t+158.127°); and the disturbing force, which varies as the cube of the parallax, or of 57' [1+.0544 cos (13.065°t+158.127°)] may be expressed, with sufficient accuracy, by 1+.1632 cos (13.065°t+158.127°).

The supplement of the node for 1824 is (2.10.56) +2'=70° 58', to which we must add (3'.10.6") t for the time elapsed: and the longitude ) will be 279°. 35' 23.1" + (13°. 10'. 35") t.

Although the value of the coefficient B is not directly discoverable, we may still obtain a tolerable estimate of its magnitude in particular cases, by inquiring into the consequences of assigning to it several different values, equal, for example, to the coefficient of the solar or lunar tide, or greater or less than either; while we assume also, for the coefficient of the resistance, A, a great and a smaller value, for instance  $\frac{1}{3}$  and  $\frac{1}{10}$ , supposing D to be inconsiderable. We then find, from the expression  $\sqrt{(a^2 + \beta^2)} M = \sqrt{(a^2 + \beta^2)} B \mu$  (Theorem J, Schol. 2) =

$$\frac{B(S, M)}{\sqrt{[(GG-B)^2 + AAGG]}}$$

for the solar tide, G being 1, if

$$B = \frac{1}{2}, .93442, 1, \text{ or } 4;$$

$$A = \begin{cases} \frac{1}{10}; & -.980, -7.550, 10, 1.3324, \\ \frac{1}{3}; & -.832, -2.742, 3, 1.3252; \end{cases}$$

and for the lunar, G being .96614, and

$$A = \begin{cases} \frac{1}{10}; & -1.122, 10, 8.197, 1.3036, \\ \frac{1}{3}; & -.913, 3, 2.942, 1.2968, \end{cases}$$

respectively.

Hence it appears, that the resistance tends greatly to diminish the variation in the magnitude of the tides, dependent on their near approach to the period of spontaneous oscillation, and the more as the resistance is the more considerable: and supposing, with Laplace, that in the port of Brest, or elsewhere, the comparative magnitude of the tides is altered from the proportion of 5 to 2, which is that of the forces, to the proportion of 3 to 1; the multipliers of the solar and lunar tides being to each other as 5 to

$$6, \text{ we have the equation } \frac{36BB}{(1-B)^2 + A^2} = \frac{25BB}{(n-B)^2 + A^2}$$

whence we find that B must be either .9380 or .6328; and the former value making the lunar tide only inverse, we must suppose the latter nearer the truth; and the magnitude of the tides will become 1.663 and 1.998: and it appears from the same equations, that, n remaining = .93442, A cannot be greater than .632; and B would then be .78540: and if A = 0, the values of B would be .9617 or .6091. It

seems probable, however, that the primitive tides must be in a somewhat greater ratio than this of 2 to 1 and 5 to 3, when compared with the oscillations of the spheroid of equilibrium; and if we supposed B = .9 and A still =  $\frac{1}{10}$ , we should have 7.071 and 9.756 for their magnitude. Now if B = .6328, the tangents of the angular measures of the displacement,

$$\frac{\beta}{\alpha} = \frac{AG}{GG-B}, \text{ becomes } \frac{1}{.3672} \text{ and } \frac{.96614}{.30160} \text{ respectively,}$$

giving us 69° 50' and 72° 40' for the angles themselves: and if B = .9, these angles become 45° and 70° 24' respectively; the difference in the former case 2° 50', and in the latter 25° 24', which corresponds to a motion of more than twenty four hours of the moon in her orbit.

It appears then that, for this simple reason only, if the supposed data were correct, the highest spring tides ought to be A DAY LATER than the conjunction and opposition of the luminaries; so that this consideration requires to be combined with that of the effect of a resistance proportional to the square of the velocity, which has already been shown to afford a more general explanation of the same phenomenon. There is indeed little doubt, that if we were provided with a sufficiently correct series of minutely accurate observations on the tides, made not merely with a view to the times of low and high water only, but rather to the heights at the intermediate times, we might form, by degrees, with the assistance of the theory contained in this article only, almost as perfect a set of tables for the motions of the ocean, as we have already obtained for those of the celestial bodies, which are the more immediate objects of the attention of the practical astronomer. There is some reason to hope, that a system of such observations will speedily be set on foot, by a public authority: and it will be necessary, in pursuing the calculation, on the other hand, to extend the formula for the forces to the case of a sea, performing its principal oscillations in a direction oblique to the meridian, as stated in the beginning of this section.

For such a sea, the calculations would be somewhat complicated, except in the case of its being situated at or near the equator: we should then obtain, by proper reduction, for the volume of the force, putting D the sine of the duration, or of the angle formed by the length of the canal with the equator, and D' its cosine, the expression  $D \sin \cos Decl. \cos Hor. < + D' \cos^2 Decl. \sin \cos Hor. <$ : and the order of the phenomena would be less affected by the alteration of the situation of the canal than could easily have been supposed, without entering into the computation. This expression, when D = 0, becomes, as it ought to do, identical with the former, making L = 0. (A. L.)

uation.

TIPPERARY, an extensive county in the province of Munster in Ireland, bounded by King's and Queen's Counties on the north; Kilkenny on the east; Waterford and Cork on the south; and Galway, Clare, and Limerick, on the west. From Galway and Clare it is separated by the Shannon, which forms the boundary on the south-west. It extends

about 74 miles from north to south, and 40 from east to west, containing 1591 English square miles, or 1,018,240 acres, 12 baronies, and 186 parishes. More than half the parishes belong to the Archbishopric of Cashel, and the rest to the sees of Emly, Lisamore, and Killaloe.

The surface is considerably diversified with moun- Surface.

tent.

Tipperary. tains, some of them covered with heath, and plains of great fertility, of which, however, the latter occupy the larger portion, the former being chiefly confined to the boundaries, or not stretching far into the interior. Among these the Galties and Knockmele-down are the most considerable. The rest of the county is in general very productive; and contains some large tracts, particularly that which is called the *Golden Vale*, and the quarter in which the town of Tipperary is situated, naturally as rich as any land in the United Kingdom. The rivers are the Shannon, which here expands into the noble lake called Lough Derg, and the Suir, which, rising on the borders of King's County, takes its course first south and then east by Clonmel and Carrick, and after joining the Barrow and the Nore, falls into the sea upwards of 100 miles from its source. Many small streams traverse the county, and are lost in these two rivers.

Rivers.

Minerals. Among the minerals are excellent slate in several parts, and lead wrought at Silver Mines on the western side of the county, among the ore of which some virgin silver has been found. Coal is also worked here, on the borders of Queen's County. The climate is so mild, that cattle remain out on their pastures all the year round, the frosts of winter being seldom so severe as greatly to check vegetation.

Estates. This county is divided into estates of various sizes, some of them very large, but a greater number of a medium extent, worth from L. 4000 to L. 6000 a-year. Of the proprietors, the influence of Lord Landaff is by far the most considerable, though several others have estates worth from L. 10,000 to L. 15,000 a-year and upwards. The graziers here, as in Roscommon, have leasehold properties frequently of much greater value than the freeholds, of which also they often become the purchasers. Properties of this description, worth from L. 2000 to L. 4000 a-year, are very common. Tillage farms, however, are generally of small extent, one of ninety Irish acres being thought large; yet the management is in many instances more respectable than in most other parts of Ireland. In some instances the rent of small farms in 1808 was as high as fourteen guineas the Irish acre. But the principal business is grazing, every variety of this kind of land being found here. Leases are commonly for twenty-one years and a life. The cattle, which are long-horned, may be ranked with the best in Ireland, and many of the fine flocks of long-wooled sheep are not inferior, in Mr Wakefield's opinion, to those of Leicestershire. "The charge for tithe," says the author of the *Statistical Account of the Parish of Carrick*, written in 1815, "is, for wheat 12s., oats 8s., barley 12s., potatoes 12s., meadow 8s., sallows 12s., orchards *ad valorem*, which are always compounded, and never taken in kind." The rich lands produce a kind of flax very different from that which is raised in the north; it grows to a great height, and appears to be exceedingly well adapted for sail-cloth.

Farms.

Tithes.

Flax.

Towns. The principal towns are Clonmel, the county town, and the birth-place of Sterne, and Carrick, both upon the Suir, Cashel, Fethard, formerly a walled town, but now in a state of decay, Cahir, Thurles, Roscrea, Nenagh, and Tipperary, the last now in a ruinous condition.

Manufactures. The manufacture of broad-cloth is carried on to

some extent at Carrick; and that of linen, worsted, and coarse woollens, as branches of domestic industry. But the wealth of this extensive district chiefly consists in its cattle and sheep, corn, and other land produce. By means of the Suir, it has access to Waterford and the sea on the south, and by the Barrow and Nore, and a branch of the Grand Canal, to Dublin on the east.

Tipperary

Tooke.

Tipperary sends four members to Parliament; two for the county, in which there are about 12,000 freeholders, and one for each of the burghs of Clonmel and Cashel. Before the Union the number was eight; Cashel, Clonmel, and Fethard, having each two representatives, and the county two. In 1791, the population was estimated at 169,000; by the census of 1821 it was found to be 353,402. According to Mr Wakefield, the number of Protestants is very small; in some places not one in a hundred. The Irish language is still spoken as well as the English. From the want of bog in the low grounds, turf for fuel is sometimes scarce and dear. The wages of common labour, a few years ago, were higher than in most other parts of Ireland; yet the lower classes have been but too ready to take an active part in the disturbances which frequently bring disgrace and misery on the south of Ireland.

See the general works quoted under the former Irish counties. (A.)

TITHES. See TAXATION, p. 629.

TOOKE (JOHN HORNE), an ingenious grammarian and an active politician, born in Westminster, June 1736, was the son of Mr John Horne, a tradesman living in Newport Market.

He was the third of seven children; but his father, having acquired considerable affluence, sent him first for a short time to Westminster School, and then to Eton, where he remained five or six years without particularly distinguishing himself, and was removed sooner than had been intended on account of the accidental loss of an eye. He went, in 1755, to St John's College, Cambridge, and took a degree of Bachelor of Arts there. He then became an usher in a school at Blackheath, kept by Mr Jennings; but he was soon after induced by his father to take deacon's orders, and obtained a curacy in Kent. His own preference, however, was so much in favour of the law, that in 1756 he entered as a student of the Middle Temple; but in 1760 he was persuaded to return to the church, and to receive ordination as a priest; and he officiated for three years in the chapel of New Brentford, which his father had purchased for him; performing his duties with decency, and taking some pains to study the elements of medicine for the sake of the poorer members of his congregation. He then went as tutor to France with the son of Mr Elwes, a gentleman of Berkshire, well known for his riches and his economy.

In 1765, he commenced his political career by writing an anonymous pamphlet in defence of Wilkes and his party. He returned to the continent, and made the tour of Italy in company with a Mr Taylor; and at Paris he formed an intimacy with Wilkes himself, who then found it convenient to reside there. He had altogether laid aside his clerical character in these excursions, but he resumed it for a short time after his return: soon, however, he relap-

Tooke.

sed into his political amusements; exerting himself, with some success, in various elections, as a partisan of his friend Wilkes, and taking up the cause of a Mrs Bigby, in the pursuit of an "appeal of blood," against the murderers of her husband, who were supposed to have obtained a pardon through corrupt interest with the court; though the widow at last disappointed him by accepting a pecuniary compensation for her right of appeal. He was, however, successful, on his own behalf, in repelling a prosecution for a libel on Mr Onslow; and he gained some credit with a party in the city by suggesting to Beckford, then Lord Mayor of London, the reply which he made to the King's answer to their remonstrance, and which may still be seen, engraved on the pedestal of Beckford's statue in Guildhall. He was soon after very active in establishing the Society for supporting the Bill of Rights, and in obtaining the liberation of Bingley, the printer, who had been somewhat hastily committed to prison by Lord Mansfield.

He had reason to be dissatisfied, in the year 1770, with the conduct of Wilkes, in some pecuniary transactions relating to the Society for the Bill of Rights: both parties appeared to the public in a light somewhat ridiculous on the occasion, and neither of them gained in respectability, though the Society did not appear to value Wilkes the less for the exposures that took place; it was, however, shortly after dissolved, and most of its members, except the particular friends of Wilkes, were incorporated into the Constitutional Society. The next year, Mr Tooke completed his academical course at Cambridge, by taking the degree of Master of Arts, though not without some opposition. He exerted himself greatly about this time, in procuring the publication of the debates of the House of Commons in the daily papers, notwithstanding the well-known standing Orders of the House; and so far as he was instrumental in carrying this point, he appears to have rendered at least one very essential service to his country; but Wilkes, and especially Almon, the bookseller, are said to have a still stronger claim to the merit of this transaction, whatever may have been its character.

He had also a sharp contest with the anonymous "Junius," against whose hasty attack he defended himself with great spirit and energy, and with unexampled success. In 1773, he made a formal resignation of his living, and meant at the same time completely to lay aside his clerical character, though no person seems to have felt himself authorised to accept this part of his resignation; and he began to study the law very diligently, intending to make it the occupation of his life. He adopted soon after a singular method of forcing himself upon the notice of the public, and of the House of Commons in particular: an inclosure bill being about to be hurried, as was reported, a little too rapidly through the House, he wrote some paragraphs in a newspaper, which reflected very severely on the conduct of the Speaker, on purpose that he might be summoned to appear before the House; and being placed at the bar, he gave such reasons for his conduct as produced some animated discussions, and in the end was supposed, though probably without foundation, to

VOL. VI. PART II.

Tooke.

have caused the bill to be modified in some oppressive clauses. By these means he obtained the favour of Mr Tooke of Purley, who thought himself aggrieved by the bill in its original state, and received from him such assurances of testamentary favours as induced his nephew, Colonel Harwood, to agree upon a partition of their joint interest in the reversion of his estate; though Mr Horne never received, first and last, more than L. 8000 from the property, notwithstanding the subsequent change of his name about the year 1782, in acknowledgment of his patron's kindness, and his long continued intimacy and frequent residence at Purley; the principal legatee, after all, being a Mr Beaseley.

Mr Horne Tooke was, of course, a strenuous opposer of the American war; and in 1777, he published a very offensive advertisement, in which the sufferers in the battle of Lexington were described as having been murdered by the King's troops. For this attack on the Government, he was tried at Guildhall, in July 1777; he conducted his own defence, but he was found guilty of the libel, and sentenced to a year's imprisonment in the King's Bench, and a fine of L. 200. It was on this occasion that he first appeared before the public as a grammarian, in the criticisms which constitute his celebrated *Letter to Mr Dunning*. The next year he suffered a still severer punishment, in the refusal of the society of the Inner Temple to admit him to the bar, on account of his having taken orders; so that his prospects of professional advancement were utterly annihilated. This occurrence made him still more bitter against the existing Government, and in 1780 he printed some severe remarks upon the measures of Lord North. He attempted to establish himself as a practical farmer in Huntingdonshire; but he caught an ague, and soon became disgusted with an agricultural life; he returned to London, and occupied for some years a house near Soho Square. His ideas of Parliamentary reform, contained in a second letter addressed to Mr Dunning, were by no means extravagant, and he continued to adhere, in this respect, rather to the party of Mr Pitt than to that of Mr Fox.

The publication of his grammatical dissertations, under the title of the *Diversions of Purley*, afforded but a slight and imperfect intermission of his political pursuits, for his etymological works are as replete with the politics of the day as his speeches and his pamphlets; another of which appeared in 1788, under the title of *Two Pair of Portraits*, being intended to serve the cause of Pitt's party in their elections. But in 1790 he became himself a candidate for the representation of Westminster, in opposition to Mr Fox and to Lord Hood; and he distinguished himself sufficiently as a popular orator, though he was not successful in the contest.

He was tried, in 1794, for High Treason, together with several other members of the Corresponding Societies, who had been active in attempting to introduce some imitations of the French Revolution in the plans of reform which they brought forward. He exhibited on the trial somewhat more of firmness than of good taste: one of his associates had before been acquitted, and the jury speedily returned a similar verdict with respect to himself. He after-

4 R

Tooke. wards dedicated the second volume of his *Diversions of Purley* to his counsel, Gibbs and Erskine, and to the jury who tried him.

In 1796, he again became a candidate for the representation of Westminster; but again without success: and, notwithstanding his strong opinions respecting a reform in Parliament, he afterwards condescended to accept from Lord Camelford, in 1801, a seat for the nominal burgh of Old Sarum. It was then to be determined if a clergyman could sit in the House of Commons; but the ministry, instead of contesting the point with respect to his particular case, brought in a bill to decide the question in the negative for the future, and he remained in the House till the dissolution of the Parliament in the next year, but without particularly distinguishing himself in its proceedings.

His last public effort, as a party man, was made in espousing for a short time the cause of Mr Paull, as candidate for Westminster; but, he abandoned this gentleman in a subsequent contest. The later years of his life were chiefly passed in the society of a select circle of friends, who frequently partook of his hospitality at Wimbledon. He died in March 1822, leaving his property to some natural daughters; for he had never been married. He was buried in Ealing church, and not in his garden, as he had directed; his executors thinking themselves the less bound by these instructions, as a literal compliance with them might have been unfavourable to the "sale" of the property.

1. His earliest publication was a pamphlet entitled *The Petition of an Englishman*, 1765. It consisted principally of apologies, for the private conduct and immoral writings of Wilkes.

2. He also published *A Sermon* while he continued in the church, that is, before the year 1773: but it attracted little notice.

3. *A Letter to Mr Dunning*, 1778. The rudiments of his grammatical system, arising out of remarks on the particles employed by the Attorney-General in his indictment, and by the judges in his sentence: it was afterwards incorporated into the *Diversions of Purley*.

4. *Facts*, 1780: consisting of remarks on the administration of Lord North; with some additions relating to finance, by Dr Price.

5. *A Letter on Parliamentary Reform*, 1782: addressed to Mr Dunning, afterwards Lord Ashburton.

6. *EPEA PTEROENTA, or Diversions of Purley*, 8. 1786. Ed. 2. 4. Part I. 1798. Part II. 1802. His great and celebrated work: rich indeed in etymology and in wit, but meagre in definition and in metaphysics.

7. *A Letter to the Prince of Wales*, 1787: relating to the supposed marriage with a Catholic.

8. *Two Pair of Portraits*, 8. 1788. The two Pitts contrasted, in opposite columns, with the two Foxes, in colours by no means favourable to the latter.

9. Many of his *Letters* have been printed in *Stephens's Life of Tooke*, 2 v. 8. Lond. 1813.

It is from the last mentioned publication, that this historical sketch of Mr Tooke's life has principally

been extracted: it now becomes necessary to add some remarks on his literary and moral qualifications; and in both these points of view, the subject has been treated in so masterly a manner by the author of an article in the *Quarterly Review*, who is supposed to be a near relation of Tooke's most intimate friend, the late Colonel Bosville, that it would be presumption in any man to go over the same ground, without adopting very nearly the eloquent and energetic expressions, which that noble and learned person has employed.

"Mr Tooke," says the accomplished Reviewer of the *Memoirs of his Life* (Q. R. Vol. VII. No. xiv. p. 325), "was possessed of considerable learning, as indeed his writings sufficiently show. To other more casual acquirements, he united a very extensive acquaintance with the Gothic dialects, of which he has so copiously and so judiciously availed himself in his etymological researches." But it must be remarked, that a person more intimately acquainted with the "Gothic dialects" as living languages will easily discover, that his knowledge of them was in truth but superficial, or that he was indebted for it more to grammars and dictionaries, than to any extensive study of the authors who had written in those languages, or to any habit of speaking them; and such a person will easily find a variety of instances, in which a very different etymon to that which he has assigned, will naturally suggest itself as the true origin of the word in question.

(P. 320.) "Though Mr Tooke's philosophical works are the results of no common talent and industry, yet they are neither written in a truly philosophical spirit, nor do they display traces of a mind, which, even if it had been wholly dedicated to the study of metaphysics, would have much enlarged the bounds of our knowledge in that nice and intricate branch of science. His object seems to have been rather to retard, than to advance the progress of philosophy, by recalling us from those sound conclusions as to the nature and operations of the human mind, which are built upon observation and experience, to vague speculations, drawn from the imperfect analogy existing between the moral and the physical world. There can be no doubt, that the proposition, which he has succeeded in establishing, is highly interesting and important; and that, in the illustration of it, he has shown great learning, ingenuity, and research. But then, on the other hand, he has so monstrously exaggerated its importance, and so widely mistaken its tendency, and has attempted to raise so vast a superstructure upon such a narrow, slippery, and inadequate foundation, that we are quite lost in amazement, when we recollect how completely the sagacity, which guided him so well in the investigation of his principal fact, appears to desert him, when he comes to apply that fact to the purposes of a theory. The distance between what he has proved, and what he wishes us to believe that he has proved, is enormous. What he has proved is, that all words, even those that are expressive of the nicest operations of our minds, were originally borrowed from the objects of external perception; a circumstance highly curious in the history of language, consequently in the

Tooke. history of the human mind itself, and the complete demonstration of which, of course, reflects great credit upon its author. What he thinks he has proved is, that this etymological history of words is our true guide, both as to the *present* import of the words themselves, and as to the nature of those things, which they are intended to signify: a proposition so monstrous, that he has nowhere ventured to enunciate it in its general form, but has rather left it to be collected from the tenor of his remarks upon particular instances. In truth, the inferences at which Mr Tooke arrived, far from being warranted by his facts, are directly the contrary of those to which he ought naturally to have been led by the result of his own studies, when they were most successful. In tracing upwards, through all the mazes of etymology, the origin of words, he ought to have seen more clearly, if possible, than any body else, that their *real present* sense is not to be sought for in their primitive signification, or in the elements of which they were originally composed, but that, on the contrary, their *actual import*, with which alone in reasoning we have to do, hardly ever corresponds with their etymological meaning, although the one always bears to the other a certain resemblance, more or less accurate, according to the greater or less effect of time and accident. One could without difficulty understand, how a person, unaccustomed to such considerations, and misled by a few instances partially chosen, should adopt a theory like that which Mr Tooke was desirous to establish; but how a philosopher, minutely acquainted with the whole subject, and proceeding upon a most copious induction of particulars, should not have perceived that, in ninety-nine instances out of a hundred, such a doctrine would lead to absolute absurdity, is, to us at least, inconceivable."

The Reviewer then follows Mr Dugald Stewart in some very just criticisms, which this acute metaphysician had already made on several of Mr Tooke's examples, fully proving the complete fallacy of the system which so completely confounds the definition of a term with its etymology. Mr Tooke has, indeed, the merit of having demonstrated pretty clearly that all the parts of speech, including those which grammarians had often considered as expletives and unmeaning particles, may be resolved more or less completely into nouns and verbs: but on the one hand it has been observed, that the very same doctrine may be clearly traced back to the works of Aristotle; and on the other, it may be asserted with equal truth, if we wish to carry the theory to its utmost extent, that language consists only of nouns and *one verb*: since all verbs may in fact be resolved into participles, or adjectives, compounded with auxiliary verbs, as well as those which exhibit this complication in their exterior form.

"In the ordinary intercourse of life," Mr Tooke "was kind, friendly, and hospitable."—(P. 325.) "We doubt whether his temper was naturally good; but if it was not, he had a merit the more; for he had so completely subdued it by care and self-control, as never to betray, under any provocation, the slightest mark of that irritability which often accompanies talent, and which gains so rapidly upon those who

know not how to guard against its approaches. Indeed, the aspect under which he appeared in private was by no means such as the stern cynicism and ferocious turbulence of his public conduct would have led one to expect; and those, whose opinion of him has been formed exclusively upon his political character and his writings, will have some difficulty in believing that the curate of Brentford was one of the best bred gentlemen of the age. In this respect he was a sort of phenomenon. He was born in a low station: at no period did he appear to have possessed any remarkable advantages for the study of good breeding; on the contrary, the greater part of his life was spent in constant intercourse with coarse, vulgar, and uneducated men; yet his natural taste was so good, and he had profited so judiciously by whatever opportunities he enjoyed, that courts and high stations have seldom produced a better example of polite and elegant behaviour, than was exhibited by the associate of Messrs Hardy and Thelwall. Indeed, his manner had almost every excellence that manner can display: grace, vivacity, frankness, dignity. Perhaps, indeed, in its outward forms, and in that which is purely conventional, his courtesy wore the air of the 'vieille cour,' and was rather more elaborate, than is consistent with the practice of this lounging unceremonious age; but it was never forced or constrained, and it sat not ungracefully upon an old man." It may, however, deserve to be remarked, in contemplating this paradox, though rather as a collateral coincidence than as a satisfactory explanation, that even from his infancy Tooke had actually seen something of the very highest society, having been admitted once or twice a week at Leicester House as a play-fellow to the late King: and though he may have learned but little from imitation of the manners of the young Prince, yet the early habit of self-restraint, imposed by such a presence, may easily have imprinted some courtly traces on his character, which were not easily effaced, and which an association with the heirs of the first families of the kingdom, throughout his boyhood, at Westminster and at Eton, must naturally have made still more distinct and permanent.

"He never appeared to greater advantage than in conversation." "He possessed an inexhaustible fund of anecdotes, which he introduced with great skill, and related with neatness, grace, rapidity, and pleasantry: he had a quick sense of the ridiculous, and was a great master of the whole art of railery, a dangerous talent, though the exercise of it in his hands was always tempered by politeness and good humour."

"In spite of labour and dissipation (p. 328), his life was protracted to a period which indicated an originally sound and vigorous frame. For the last twenty years, however, he was subject to several severe, distressing, and incurable infirmities. These he bore with a patience and firmness which it was impossible not to admire: to the very last he never suffered himself to be beaten down by them, nor ever for one moment indulged in complaint, or gave way to despondency. In the intervals of pain, nay, even when actually suffering under it, he preserved a self-command, which enabled him to converse, not

Empire.

only with spirit and vigour, but with all his accustomed cheerfulness and pleasantry, never making any demand upon the sympathy of his friends, or mentioning his own situation at all, except when occasionally, and by a very pardonable exercise of his sophistry, he amused himself in exalting its comforts, and explaining away its disadvantages; displaying, in this respect, a manly spirit and a practical philosophy, which, if they had been brought to bear upon his moral, as well as upon his physical condition, if they had been employed with as much effect in reconciling him to his political exclusion as to his bodily sufferings, might have produced, not the very imperfect character we have been attempting to delineate, in which the unfavourable traits bear so large a proportion to those of a nobler and more benign cast, but the venerable portrait of a truly wise and virtuous man."

Reid's *Memoirs*, 8. Lond. 1812; *Quarterly Review*, June 1812; A. Stephens's *Life of Tooke*, 2 v. 8. Lond. 1813; *British Critic*, N. S. Vol. I. p. 79, 193; (Aikin's *General Biography*, IX. 4. Lond. 1814; Chalmers's *Biographical Dictionary*, XXIX. 8. Lond. 1816.) (A. L.)

**TURKISH EMPIRE.** Although this empire has undergone but slight alterations since the account of it contained in the *Encyclopædia* was written, yet, as its statistics have had some new light thrown on them by recent publications, we shall give a brief sketch of its present state.

Extent.

The extent of this empire has been variously estimated by different writers; and, after consulting them, we rather concur in the calculations made by Hassel, the latest of them, founded on the charts of Reichart and Niedls, because they are corroborated by the last map constructed by Arrowsmith, and by that of Lapiess. In this account of the extent of the empire we have included all those countries over which Turkey claims the sovereignty, although in many of them that sovereignty is either not acknowledged or very feebly exercised.

	Square Miles.
Turkey in Europe contains.....	180,074
Turkey in Asia on the Continent...	436,629
Islands of Turkey in Asia .....	11,050
The African Dominions .....	276,480
	904,233

Population.

In countries where no censuses have been taken in modern times, in which no registers of births or deaths are preserved, where no general conscription has been introduced, and where even the number of houses is not known, the accounts of population must be mere estimates or rather conjectures; and, therefore, it is not extraordinary that different writers should have presented results so distant from each other as those we have examined. Two censuses have, indeed, been instituted; one in the middle of the sixteenth, and the other at the beginning of the seventeenth century. Their results are not, however, now known; and if they were, they would scarcely be tolerable guides at this day, when

the whole state of affairs has undergone such great alterations. Hassel, in 1816, calculated the whole number of Turkish subjects at 24,070,000; and, in 1819, Lichtenstern estimated them at 24,880,000, whilst Gräberg reckoned them to be in round numbers 23,000,000. Though these industrious writers thus approached nearly to each other in their totals, they differ most widely in the component parts. Thus, in Asia Minor, they disagree to the extent of five or six millions; and in Egypt and its dependencies to the extent of three or four.

Finances.

The financial affairs of the Turkish empire are involved in still greater obscurity than the state of the population. From the system, which uniformly prevails, by which every governor of a province collects imposts, and expends them on the local objects under his management—that which is received into the general treasury bears no proportion to that which is extracted from the subject. Many of the provinces are compelled to deliver contributions in their productions, which productions are appropriated to some specific public department. Thus Egypt was required to deliver to the arsenal 1000 quintals of hemp, 200 jars of oil, 2000 pieces of linen, and 140 quintals of linen yarn; and to the Seraglio 36,000 measures of rice, 45,000 okas of sugar, 2000 measures of pease, besides stipulated quantities of ginger, cinnamon, pepper, and other smaller articles. The other provinces are required in a similar manner to contribute to the demands of the Imperial Government. The annual sum which flows into the treasury has been estimated, by Contemir and Thornton, at about L.3,000,000 Sterling, and by Eton at near L.4,000,000. Whatever may be the amount of the public income, it is distinct from the revenues which accrue to the Emperor personally, of which no account can be obtained; but it is imagined that they amount to much more than the expenditure of the imperial establishment, and that vast sums have been accumulated in the household treasury. These personal revenues arise from domains, from confiscations, from presents, and from the sale of governments and other offices. Count Marcellus, in a work published at the Hague in 1732 (*Stato Militare de Imperio Ottomanno*), asserts, that, at the death of Ibrahim in 1639, his successor, Conrad IV., found L.33,000,000 Sterling in money; and that, as, by a religious law, every Emperor is bound to increase this treasure, during his reign, it had been vastly augmented at the time he wrote.

This accumulation of private treasure is deemed an indispensable part of the state policy of Turkey, where, as in every despotic government, the individual filling the throne is exposed to sudden insurrections and interior revolutions. Meusel thinks that this treasure was much reduced by the war with Russia, which terminated in 1812, when the private hoards were compelled to come forth in aid of the national treasury to a very great, but unknown, extent; as the army was then paid with coins of very ancient dates. The expenses of the government are involved in as much obscurity as the income from which they are defrayed. The greater part of the military costs but little in time of peace; being fur-

Turkish Empire.

nished with necessaries by the several provinces in which they are quartered, and which are collected from their feudatories by the governors of them.

The debt of the state, which, in 1803, amounted to only L.3,500,000 Sterling, has been increased by the various unfortunate events that have occurred since that period to upwards of L.70,000,000; and, in spite of forced loans, to which the government has had recourse, and of large contributions from the religious establishments, the state-obligations pay an interest at the rate of 12 per cent.

Army and Navy.

Under a government, where all land is held on the condition of military service, the number of soldiers must be great in proportion to the population; but in Turkey the numbers have been kept down by the want of means to provide the necessary arms and equipments. According to the most recent accounts, the regular army amounts to 125,000 infantry, artillery, artificers, sappers, miners, and armourers, included; and 12,500 cavalry; but to the latter may be added 100,000 feudal horsemen, who may be made available for internal defence. The Janisaries make 80,000 of the infantry; and these are rather garrison militia, for the most part, than regular troops. The best corps consist of those called the new regulars, amounting to 24,000 men, who, as well as the artillery, are armed and disciplined after European models. The navy of Turkey has of late declined. It now consists of 15 ships of the line, the same number of frigates, and about 30 smaller vessels. Very few of these ships are fit for service; and the naval arsenal is so destitute of stores that fewer still can be equipped. At all times the best seamen in their fleet consisted of Greeks; and, since the insurrection of that nation, greater difficulties than before have been found in working and fighting their ships. This accounts for the different disasters which the Turkish navy has experienced during the course of the existing contests with their Greek subjects.

Productions of the Soil.

As the greater part of the inhabitants of the Turkish dominions are collected in and around the towns for security, the intervals of land between these towns are almost wholly uncultivated. Where any cultivation is practised, the soil is highly grateful, and produces abundant returns for the labour bestowed on it in corn, wine, oil, fruits, flax, hemp, cotton, wool, madder, and other dyeing materials. The woods afford excellent timber in abundance. Horses, cows, sheep, goats, and game, are plentifully reared. The fisheries, both in the rivers and seas, are much neglected, except by the Greeks, who have occasion for them from the numerous fasts prescribed by their religious tenets. Honey and wax are liberally supplied; and silk is collected in all the provinces south of the Danube. The mineral products are now almost wholly confined to iron, though mines of gold and silver were formerly worked in the mountains of Bosnia, and those of Moldavia and Wallachia are rich in minerals.

Manufactures.

The manufactures in Turkey are neither numerous nor abundant. The best of them is leather of various colours and qualities. Dyes of several kinds, but especially that made from madder, and univer-

Turkish Empire.

sally known through Europe by the name of Turkey-red, are supplied. Cottons are made in several places, as are coarse woollen cloths and carpets. Silks and silk gauzes, of a very delicate texture, are made at Constantinople, Salonica, and at Scio. Iron, and especially steel wares, are furnished from several parts of the empire. Besides these, the smaller articles, snuff, soap, sail-cloth, glass ware, porcelain, are produced, but not in quantities equal to the demand.

Commerce.

The commerce of Turkey is almost exclusively in the hands of the Greek and Armenian subjects, or of Europeans established in the commercial cities, who are collectively distinguished by the name of Franks. The chief exports consist of cotton wool, silk, tobacco, oil, currants, rosin, wine, horses, cows, skins and hides, leather, linseed, corn, cheese, Turkish yarn, and carpets. The chief imports are—cloths of wool, silk, and cotton, colonial wares, glass, watches, hardware, paper, paints, cabinet ware, Nuremberg wares, precious stones, jewellery, and male and female slaves from Africa, from Georgia, and the Caucasian territory. The greatest traffic is with Austria, partly by land. The next in amount is with England, and then follows that with France, Italy, and Russia. The internal trade of Turkey is extensive, chiefly in the hands of Armenians, who exchange the productions of Europe for those of Asia, including India and China. Nearly the whole mercantile shipping belongs to the Greek subjects of the empire, whose resistance to its authority has an injurious effect on its general commerce. The chief trading cities in European Turkey are Constantinople, Salonica, Gallipoli, and Galatz.

The Turkish divisions of the empire are purely military, founded on feudal principles, and even retaining the military names. The whole dominion is divided into twenty-five districts, which are subdivided into sandshaks (*Standards*); each sandshak contains a number of tracts, called tiamars or siamets (*Sabres*). Besides these, there are other divisions, used purely for the civil and financial purposes of the government.

The European part of Turkey comprehends the four provinces of Roumelia, Bosnia, the Islands, and the principalities of Moldavia and Wallachia.

European Turkey.

Roumelia is subdivided into sandshaks or standards, and contains about 6,000,000 inhabitants. The most populous cities, and their estimated inhabitants, as calculated by Andreossy in the year 1815, according to the consumption of bread, were the following:

Constantinople, 597,000; Adrianople, 100,000; Salonica, 60,000; Sofia, 46,000; Ruschak, 30,000; Philopoli, 30,000; Ionina, 30,000; Larissa, 25,000; Sistove, 21,000; Varna, 16,000; Misetra, 16,000; Scutori, 16,000; Tripoliza, 12,000; Sillistra, 10,000; and Baba, Nicopoli, Stovi, or Uskub, and Pristina, from 9000 to 10,000 each.

Bosnia contains about 850,000 inhabitants. The cities are Bosna-Serai, with 65,000; Banjaluka, with 15,000; Zwornick, with 14,000; and Trebon, with 10,000 souls.

The Ejalet Dschesair, or Province of the Islands, according to Lichtenstern, contained in 1819 about

Turkish  
Empire.

525,000 inhabitants, chiefly Greeks, and the following cities: Galipoli, with 17,000; Castorea, with 18,000; Betaglea, with 15,000; Hydra, with 40,000; Candia, with 15,000; Negroponte, with 16,000; Canea, with 12,000; and Athens and Levadia, with 10,000 inhabitants each.

Wallachia and Moldavia are rather under the nominal than the real government of Turkey, though the Waiwode is nominated by the Porte. He is always appointed from some of the noble Greek families, generally for a short period, and uniformly by means of bribery. Wallachia contains about 1,000,000 inhabitants, chiefly of the Greek church, and they are governed by ancient feudal laws, which are corruptly administered by magistrates who owe their authority to barefaced corruption. Bucharest, the capital, contains from 50,000 to 60,000 inhabitants.

Moldavia has been contracted by cessions to Russia, and now contains about 500,000 inhabitants, who are of the same religion, and under a government similar to that of Wallachia. Jassy, the capital, contains 27,500 inhabitants. Galatz, a trading city on the Danube, has about 8000 regular inhabitants, and a vast number of strangers, who resort to it for commercial purposes.

Turkey in  
Asia.

Turkish Asia comprehends the following countries: 1st, The peninsula of Asia Minor, with the island of Cyprus, and some smaller islands in the Egean and the Mediterranean seas, and in the sea of Marmora. 2d, That part of Georgia which has remained to Turkey since the last peace with Russia. 3d, A portion of Armenia. 4th, The whole country of Mesopotamia, that of the Curdo, and a part of Irack. 5th, The whole of Soristan or Syria, with which the Turks include the district of Yemen in Arabia, over which they have no actual power, and the cities of Mecca, Medina, and Jeddo, which have been lately again taken by them from the Wahabees, but which properly form a part of Arabia. These natural or ancient divisions are now scarcely regarded by the Turks. The whole dominion is, for purposes of administration, divided into twenty-one governments, viz.

1st, Anatolia, including that portion of Asia Minor which comprehends the provinces of Bithynia, Paphlagonia, Galatia, Phrygia, Mysia, Lydia, Lycia, Caria, and Pisidia. The chief cities are, Kutakia, or Cotyaum, with, according to Malte-Brun, 50,000 inhabitants; Brussa, with, according to Kinneir, 50,000; Bergamo, the ancient Pergamos, Anatolia, with, according to Beaufort, 8000; Kara-hissa, with 60,000; Angora, with 20,000; Kastimuni, with 13,000; Sinope, with 10,000; Smyrna, with 100,000; Scalanuvo, with, according to Galt, 20,000; Scio, in the island of that name, with 25,000, according to Galt, 20,000; to Wittman, 25,000; and to Olivier, 30,000; almost wholly Greeks, and lately destroyed.

2d, Kibris, or the island of Cyprus, with about 120,000 inhabitants, of whom 16,000 are in the city of Nicosia.

3d, Itschill, a part of Asia Minor, comprehend-

ing the ancient Cilicia, Isauria, and Pamphylia. Its chief cities are Adana, with 30,000 inhabitants; and Tarsus, with 30,000.

Turkish  
Empire.

4th, Caramania, comprehending a portion of Asia Minor, which was formerly Cappadocia, and parts of Galatia, and Phrygia Major. Its chief cities are, Konia, or Iconium, with 30,000 inhabitants; Larenda, or Caraman, with, according to Kinneir, 15,000; and Aeschier, or Antioch, with 60,000.

5th, Merash, extending over part of Cappadocia, of Armenia Minor, and of Cilicia Campestris. The principal cities are, Merash, with 9000 or 10,000 souls; Aintab, with 20,000; and Melitene, with 8000.

6th, Sewas, including the greater portion of the ancient Pontus, whose principal cities are, Oskal, with 16,000 inhabitants; and Amasia, with 35,000.

7th, Trebisond, comprehending, to the eastern of the ancient Pontus, a portion of Armenia on the border of the Black Sea. The capital of the same name contains, according to Kinneir, 15,000 inhabitants; and Rise, or Irisch, not lately visited, but in the middle of the last century, a flourishing, manufacturing, and commercial city, has 30,000 inhabitants.

8th, Tschalder, or Chaldea, a part of Armenia, with which what remains to the Turks of Georgia is comprehended. The only city is Akhirsra, or Akalzike, on the great road to the passes through the mountains, which lead to the ports on the Black Sea, supposed to contain from 12,000 to 15,000 souls of all descriptions and nations.

9th, Kars, a part of Armenia. The chief city in lat.  $40^{\circ} 56'$ , and long.  $43^{\circ} 25'$ , of the same name, as well as the other towns, have not been recently visited, and their population is not ascertained.

10th, Erzerum, also a part of Armenia, supposed, by Morier, to contain from 500,000 to 600,000 inhabitants, and represented by him to be both fertile and beautiful. The capital of the same name is variously described by Tournefort, Morier, Gardanne, Kinneir, and Von Hammer; the lowest estimation making the inhabitants amount to 80,000; the highest (Morier) to 250,000. Karahissar contains 10,000, and Hamischkane 7000 souls.

11th, Wan, a part of Armenia and of Kurdistan. The capital, from which the province derives its name, has not been recently visited; Betlis is stated by Kinneir to contain 12,000 inhabitants.

12th, Schersur, a part of Kurdistan. This province is so called from its capital, in lat.  $35^{\circ} 46'$ , and long.  $45^{\circ} 21'$ , which, with all the other places, are of small consideration.

13th, Bagdad, a part of Mesopotamia, and the ancient Babylon, with a portion of Kurdistan. This extensive province is very thinly peopled, and recent travellers represent it as fast going to decay. Bagdad, the city which gives its name to the province, is stated by De Sacy to contain 95,000 inhabitants, or more than one-fifth of the whole population; the other towns are small.

14th, Basra, or Bussora, a part of Chaldea, and of Arabia. The capital of the same name contains from 45,000 to 80,000 inhabitants, according to the differing accounts of Neibuhr, De Sacy, and Von Hammer. Korna, at the junction of the Tigris with

Turkish  
Empire.

the Frat, is a commercial city of some importance; but its population is not ascertained.

15th, Mossul, a part of Mesopotamia, and of Assyria. The capital which gives its name to the province is on a fine plain, watered by the Tigris, and contains, according to Kinneir, 35,000; according to Olivier, 65,000 inhabitants.

16th, Diarbekr, that part of Mesopotamia which was called Bekr formerly. The capital from which the province derives its name contains, according to Kinneir, 38,000 inhabitants; but according to Gardanne, 80,000. Siwerh, a trading city on the river Frat, has a population of 10,000. The other towns are very small.

17th, Raeca, the western part of Mesopotamia, and a part of Syria. The inhabitants live more in tents than in towns. The capital of the same name, though known in Europe more commonly by the names of Nicephorium or Kallinicum, is represented, by recent travellers, to contain from 30,000 to 40,000 inhabitants. Biredschik, a trading town on the Frat, has about 6000, and no other place more than 2000 inhabitants.

18th, Haleb, the northern part of ancient Syria. It is represented as a fertile, manufacturing, and commercial province, with 500,000 industrious inhabitants. Haleb, the capital, the ancient Beroe, now called Aleppo, has a population of, according to Volney, 100,000; to Setzen, 150,000; to Rosseau, 200,000; to Arvieuz, 280,000; and to Dr Russel, 235,000. It has a great trade carried on by the numerous Franks established there. Killis contains 12,000; Antokia 15,000 inhabitants. The population of Scanderoon and Latakia are not ascertained.

19th, Tarablus, the middle part of Syria, westward of Lebanon. The name of this province is derived from that of its capital, known to Europeans as Tripoli; which, according to Browne, contains about 16,000 souls. No other town is noticed by travellers.

20th, Akka, the ancient Phoenicia, and a part of Palestine. The capital of the province, Acre, or St John's d'Acre, the ancient Ptolemais, contains about 16,000 souls. The population of the other cities, except Bairut, or Beritus, which has 7000 inhabitants, is not ascertained.

21st, Damas, this includes the greater part of ancient Syria, extends over 26,850 square miles, and has a population of 1,250,000 souls. The province takes the name of its capital, Damas, or Damascus, which has about 200,000 inhabitants. Hamah has, according to Ali Bey, 100,000; Emessa, 30,000; Jerusalem, according to the same traveller, 30,000 to 40,000; Razza, the ancient Gaza, 5000; Ramla, or Arimathea, 10,000; and Jaffa, or Joppa, 5000 inhabitants.

The Turkish government claims a kind of authority over some very large portions of Africa; but the local authorities can scarcely be considered as subjects of the Porte. The most important of these, Egypt, has been largely treated of in Part I. Vol. IV. of this *Supplement*. The states of Barbary, Algiers, Tunis, and Tripoli, pay, when it suits them, some

tribute as acknowledgment of dependance. Nubia has been recently subjected to the Pasha of Egypt; but it is hard to define how far that country can be considered as a branch of the Turkish empire, when the conqueror of it scarcely acknowledges his dependance. The limits allotted to this article will not allow us to draw up, even in a compressed form, such particulars as have reached us respecting the northern parts of Africa; and, indeed, they more properly belong to other articles.

(w. w.)

TYRONE, a county in the province of Ulster, in Ireland, having Londonderry on the north, Armagh on the east, Monaghan and Fermanagh on the south, and Donegal on the west; extends about 42 miles from north to south, 54 from east to west, and contains 1271 square miles, or 813,440 English acres. It is divided into the four baronies of Dungannon, Strabane, Omagh, and Clogher or Upper Dungannon, and 35 parishes which belong to the sees of Armagh, Derry, and Clogher.

The greater part of this district is mountainous, particularly the baronies of Strabane and Omagh on the west. In the former are two hills of great height, called Bessy Bell and Mary Gray,—names celebrated in Scottish song. Dungannon, on the east, is a rich and fertile tract, and Clogher, on the south, also contains a considerable proportion of good land; but, generally speaking, the territorial value of this inland and northern district is much inferior to that of most of the other Irish counties. Besides the usual varieties of soil, clay fit for bricks of various colours, and particularly pale bricks, which are deemed the most durable, occur in almost every parish and townland; and about Fintona, in the barony of Clogher, other sorts of clay are made into a great variety of earthenware for country use. The best pottery, perhaps, in Ireland is in the barony of Dungannon, where all sorts of coarse crockery-ware, fire-bricks, and tiles, are made of as good a quality as any that are imported. At Coal Island, in the same quarter, coal is wrought to some extent, though, according to Mr Wakefield, it is bituminous and of a bad quality. This is one of the few districts of Ireland in which there is little or no limestone. A great many small streams, having their source in the high grounds, traverse the county in every direction. The more considerable are the Blackwater, which, rising near Clogher, soon after forms the boundary on the south and south-east, till it falls into Lough Neagh, and the Mourne, which falls into the Foyle near Strabane. The Foyle also washes its north-western extremity in its course from Lifford to Londonderry, but does not properly belong to this county. Lough

Tyrone.

**Tyrone.** Neagh, which Tyrone touches on the east, is the largest lake in Ireland, covering, according to Wakefield, 173 square miles, or upwards of 110,000 English acres; but it is less celebrated for its scenery than some of the other Irish lakes.

**Estates.** Tyrone is divided into estates of very great extent, many of them worth from L.5000 to L.7000 a-year, and its productive or arable land into very small farms, not often exceeding 20 Irish acres. The chief proprietors are the Marquis of Abercorn, Lords Belmore, Northland, and Mountjoy. The leases are for various periods,—thirty-one years and three lives, three lives, and twenty-one years and a life.

**Leases.** On some estates the land passes through the hands of middlemen, in portions of various sizes, till it reaches the actual cultivator, for the most part, in very minute subdivisions. It is customary for several persons to be concerned in one townland, which is held in what is called *rundale*, the cultivated land being divided into shares, which are changed every year, and the cattle pasturing in common,—a system utterly inconsistent with profitable occupation, or the amelioration of the soil and live stock. The cattle and sheep are accordingly of a very inferior description; and the latter, which are not numerous, may frequently be seen tethered upon the small patches of herbage which are interspersed among the shares of these partnership concerns. The tillage land, too, is more frequently stirred with the spade than the plough; and where a plough is used, the team, consisting of horses, bullocks, and even milk cows, must be supplied by the contributions of three or

four neighbours, who unite their means for the purpose, each attending its operation, lest his poor animal should have more than his proper share of the labour. Potatoes, oats, and flax, are the principal crops.

The towns are Omagh, the county town, Newton-Stewart, Strabane, and Dungannon, the two latter places of considerable extent and population; besides a number of villages. Augher and Clogher, though Parliamentary boroughs before the Union, are very small places. The linen manufacture is carried on to a great extent, and the potteries and collieries before noticed also employ a considerable number of hands; to which we may add illicit distillation, which prevails throughout all the north-western counties of Ireland. The food of the lower classes is oatmeal and potatoes,—wheaten bread and butcher meat never being used but on extraordinary occasions.

The county, which has 20,000 freeholders, sends two members to Parliament, and the borough of Dungannon a third. Before the Union, Tyrone had ten representatives in the Irish Parliament.

In 1791 the population was computed at 157,700; and by the census of 1821 it was 259,691. According to Mr Wakefield, the Catholics are to the Protestants as 6 to 1; but property is chiefly in the hands of the latter. Many of the Protestants are of the Presbyterian persuasion.

See the general works referred to under the former Irish counties, and M'Evoy's *Statistical Survey of Tyrone.* (A.)

## UNITED STATES OF NORTH AMERICA.

United States.

No single event in modern history has been of, so much importance to mankind as the discovery of America. That great continent, which had been hid from the eyes of civilized nations for so many ages, comprises nearly one-third of the habitable globe. In soil and climate, it rivals the best parts of the old continent. It is not, like Asia and Africa, infested by the larger and more dangerous species of wild animals, nor deformed by vast deserts, which present insuperable obstacles to civilization. But its great and peculiar advantage lies in the unrivalled magnitude and number of its navigable rivers, which enable its most remote inland parts to hold commercial intercourse with each other, and with foreign states, with unparalleled ease and rapidity. The position of these great rivers, whose estuaries all open to the east, points out the western side of the old continent as the region with which it is destined by nature to be most closely connected. Two great classes of colonists, widely dissimilar in character and circumstances, came from Europe to occupy this new world. The Spaniards, who were first in order of time, took possession of the most populous and fertile regions; but their natural advantages were rendered abortive by political and moral evils,—a rapacious spirit, a corrupt religion, and a vicious system of government. The English, the other great class of colonists, owed their better fortunes in some measure to their apparent disadvantages. Having neither gold mines to work, nor wealthy Indians to rob, they cultivated with greater diligence the natural riches of the soil, and laid the foundation of future prosperity in habits of order and industry. Neglected by the government as a band of destitute refugees, they enjoyed what was then an unusual degree of civil and religious liberty. Their industry flourished, because it was unfettered and unburdened. They were well governed, because they were left to govern themselves. And if they wanted the aid of the mother country when that aid might sometimes have been useful, they were, on the other hand, exempted from those incessant exactions and vexations to which the Spanish colonists were exposed, from the ignorant, meddling, grasping, bigoted spirit of their European rulers. The troubles they experienced from the hostility of the Indians diminished as their own numbers increased, and, except at first, were never extremely detrimental. Their common dangers served in some measure as a bond of union among themselves, and perhaps favoured their social improvement, by acting as a slightly compressing force to prevent the indefinite diffusion of the population over a large surface. To their free spirit, virtuous habits, intelligence, and industry, the English colonists certainly owed much of their early success; but we must not forget that a series of fortunate changes, not directly the consequence of their own exertions, have greatly contributed to place them in the enviable situa-

tion they now occupy. Had the Dutch, French, Danish, and Swedish colonies planted in North America spread as fast and as far as those of England, and continued separate and independent, we should have seen, in the space between the Mississippi and the Atlantic, the same medley of nations and languages, with the same diversity of manners, religion, institutions, and clashing interests, which foster everlasting feuds and jealousies in Europe, engender desolating wars, load the people with oppressive taxes and military tyrannies, and present a formidable barrier to the circulation of knowledge and the progress of society. The conquests of England, which blended all these colonies into one nation, have secured to the United States an exemption from half the evils which afflict civil society in Europe, and prepared for them a career of peaceful grandeur and growing prosperity, which divided Europe cannot hope to enjoy, and which has had no parallel in the history of mankind. The people of the United States find themselves in a condition to devote their whole energies to the cultivation of their vast natural resources, undistracted by wars, unburdened by oppressive taxes, unfettered by old prejudices and corruptions. Enjoying the united advantages of an infant and a mature society, they are able to apply the highly refined science and art of Europe to the improvement of the virgin soil and unoccupied natural riches of America. They start unincumbered by a thousand evils, political and moral, which weigh down the energies of the old world. The volume of our history lies before them: they may adopt our improvements, avoid our errors, take warning from our sufferings, and with the combined lights of our experience and their own, build up a more perfect form of society. Even already, they have given some momentous and some salutary truths to the world. It is their rapid growth which has first developed the astonishing results of the productive powers of population. We can now calculate with considerable certainty, that America, which yet presents to the eye, generally, the aspect of an untrodden forest, will, in the short space of one century, surpass Europe in the number of its inhabitants. We even hazard little in predicting, that, before the tide of civilization has rolled back to its original seats, Assyria, Persia, and Palestine, an intelligent population of two or three hundred millions will have overspread the new world, and extended the empire of knowledge and the arts from Cape Horn to Alayska. Among this vast mass of civilized men, there will be but two languages spoken. The effect of this single circumstance in accelerating the progress of society can scarcely be calculated. What a field will then be opened to the man of science, the artist, the popular writer, who addresses a hundred millions of educated persons?—what a stimulus given to mental energy and social improvement, when every new idea, and every useful dis-

United States.

United States.

covery, will be communicated instantaneously to so great a mass of intelligent beings, by the electric agency of the post and the press? With the united intellect and resources of a society framed on such a gigantic scale, what mighty designs will then be practicable? Imagination is lost in attempting to estimate the effects of such accumulated means and powers. One result, however, may be anticipated. America must then become the centre of knowledge, civilization, and power; and the present leading states of Europe (Russia perhaps excepted), placed on the arena amidst such colossal associates as the American Republics, will sink to a subordinate rank, and cease to exert any greater influence on the fate of the world than the Swiss Cantons do at the present day.

Extent and Limits.

The territory of the United States is situated between the 25th and 49th degrees of north latitude, and between the 67th and 124th degrees of west longitude from London. Its extreme length east and west is 2780 miles, its greatest breadth north and south 1230 miles, and its area, according to Mr Mellish, 2,076,410 square English miles. It is bounded on the east by the Atlantic Ocean, on the north by the British possessions, on the west by the Pacific Ocean, and on the south by Mexico and the Mexican Gulf. The Mississippi divides it into two parts nearly equal in extent. In the north-east angle of this territory, there is a space of more than 100 miles square, of very barren ground, interposed between New Brunswick and Lower Canada, the possession of which has long been the subject of negotiation between the British and American Governments. On the west coast the Americans have an unquestioned claim to the country, between the 42d and 47th parallels; but Russia disputes the right of possession with them to the tract of country between the 49th and 60th parallel. As the admitted boundaries are in general very distinctly marked on the common maps, we shall not describe them in detail.

Natural Divisions.

Two chains of mountains separate this extensive territory into three great natural divisions. 1. The Atlantic region, or the country lying east of the Alleghany mountains. 2. The valley of the Mississippi, or the country watered by the Mississippi, Missouri, and their numerous branches. 3. The Pacific region, or the country lying west of the Rocky mountains.

The Alleghany mountains commence in Lower Canada, below Quebec, and passing along the northern boundary of Maine, and through New Hampshire, Vermont, New York, Pennsylvania, Virginia, and the two Carolinas, they terminate in the upper parts of Georgia and Alabama, preserving a south-west direction throughout. They consist of three, four, five, or more distinct ridges, with wide and fertile vallies interposed. Their entire length is 1100 miles, their breadth varies from 110 to 150. In the northern half their height is greatest, but most

unequal, detached peaks are numerous, and the ridges indistinctly marked. In the south, the ridges are lower, but better defined, and their summits are often distinguished by a very uniform continuous level. They attain their greatest height in New Hampshire, where Mount Washington has an elevation of 6600 feet. Their greatest height in New York is 3800, in Pennsylvania 2500, in Virginia 3900, in South Carolina 4000. The mean height is said by Mr Mellish to be from 1000 to 1800 feet, but his average is undoubtedly formed on wrong principles. That of the highest chain cannot be less than from 2000 to 2500 feet.\*

The Rocky mountains, known but imperfectly, are a continuation of the Mexican Cordilleras, and extend to the Polar Ocean. They pass through the territory of the United States, at the distance of 500 miles from the Pacific Ocean, and consist of several elevated chains, occupying a breadth of 300 miles, with deep vallies between them. They rise abruptly from their base, and are supposed to reach the elevation of 12,000 feet in their highest summits, many of which are covered with perpetual snow. There are, however, several passes through them, which, with a little improvement, might be traversed by loaded waggons. †

The Atlantic Region was the first settled, and is the most populous and improved portion of the United States, but not the most favoured as to soil and climate. It may be considered as the eastern slope of the Alleghanies. Including all the countries watered by rivers flowing into the Atlantic and the Gulf of Mexico, east of the Mississippi, it is about 1700 miles in length, with an average breadth of 250, and embraces an area of 400,000 square miles. It includes three well marked varieties of soil and surface. 1. The alluvial district, consisting of sand, gravel, and clay, comprising a stripe of level land, extending along the coast from New York southward, with a breadth varying from 20 miles to 100. The surface is level or slightly undulating; and it embraces large tracts of marsh near the coast. The soil is poor and sandy, producing almost nothing but pines, except in the alluvial tracts which skirt the rivers. About one-half of the surface of New Jersey, Delaware, and Maryland, one-fifth of Virginia, one-third of the Carolinas, Georgia, Florida, and Alabama, fall under this description. 2. The upland country, extending from the alluvial tract to the foot of the mountains, with a breadth varying from 20 to 200 miles. The soil here is chiefly formed from the detritus of the primitive rocks, and is generally fertile, and well adapted for tillage. 3. The ridges of the Alleghanies, and the vallies between them, which bear a strong growth of natural wood, have generally a rich soil capable of tillage, wherever the surface is not rocky or too steep; and are almost free from marshes. In part of Pennsylvania, New York, and in

\* Mellish's *Geographical Description of United States*, Philadelphia, 1822, p. 20. Warden's *Statistical, Political, and Historical Account of United States*, 1819. Introduction.

United  
States.

the six New England States,\* where the Alleghanies spread out into an irregular broken surface, the soil possesses a mixed character. The northern parts of New England are mountainous, the southern hilly or uneven. The soil, comparatively speaking, is rocky, has little depth, and is better adapted for pasture than tillage, and improves generally as we advance inwards from the coast. The south-east section of New York corresponds in character with New England. But Pennsylvania contains the largest portion of good soil on the east side of the mountains, of all the old States. The woods originally covered all this Atlantic region, except some tracts called by the Americans *prairies*, on which, from causes not well explained, no natural growth of timber exists. These are not meadows or wet grounds, as the French term might be supposed to indicate; but lands bare of wood, whether wet or dry, level or uneven. As the population thickens, the forests disappear; but even in the most densely peopled parts, the woodlands occupy so large a proportion of the surface, that the country generally presents, to the eye of a European, the aspect of a natural wilderness, but broken by patches of cultivation, which are numerous round the great cities, but grow less frequent as we recede from the shore, till they terminate in the boundless forests of the Alleghanies.

Valley of  
Mississippi.

The basin or *Valley of the Mississippi*, which extends from the Alleghanies to the Rocky mountains, is not so large as the basin of the Amazon by one-third, but being situated in the best part of the temperate zone, it may be pronounced the finest valley in the world. Its breadth east and west is 1400 miles; its length in the opposite direction 1200, and its area 1,400,000 square miles. It comprehends a great diversity of soil, surface, and climate. 1. The basin of the Ohio, including the Cumberland, 700 miles long and 300 broad, is a rich and beautiful country; the garden of the United States. The lower parts of the surface are from 500 to 800 feet above the level of the sea, and are finely diversified with round topped arable hills, rising 400 or 500 feet above their base. The rivers generally run in deep hollows, sometimes mere ravines, but often spreading out into vallies, which include lands of exuberant fertility. This district includes Kentucky, Tennessee, with part of Virginia, Pennsylvania, Ohio, Indiana, and Illinois. 2. The territory extending from the basin of the Ohio north-westward to Lake Superior, including the country between the Missouri and Upper Mississippi. The surface is sometimes undulating, sometimes so level that the waters stagnate on it, till carried off by evaporation; and it is not broken by any notable elevations, except one long ridge extending between the Missouri and Mississippi, and two low eminences called the Ocooch and Smoky mountains. The soil is naturally rich, and covered with luxuriant herbage; but the climate is severe,

United  
States.

and the woods so thin, that the bare ground or prairies occupy three-fourths of the surface on the east side of the Mississippi, and nineteen-twentieths on the west. The absolute elevation of the northern parts is probably not under 1500 feet, for Cassina lake, 30 miles below the sources of the Mississippi, is 1330 feet above the sea. (Mellish, p. 32. James's *Expedition*, III. 204.) 3. The last and largest division of this great valley, extending from the Mississippi and Missouri to the Rocky mountains, consists of two very different qualities of soil, which graduate into each other, but, on the great scale, may be conceived to form two parallel tracts of nearly equal extent, parted by the 98th meridian. In the middle of the eastern section, and, as it were, in the very bottom of the great basin of the Mississippi, lie the Ozark mountains, a chain like the Alleghanies, of great length and breadth and small height, rising only from 1000 to 2000 feet above the sea. (James's *Expedition*, III. p. 313.) Mr Mellish erroneously calls the height 3500 feet. Their breadth is from 100 to 150 miles: their sides, which slope with gentle declivities, are deeply furrowed with streams, and partly covered with small timber. The Arkansas and Red River are the only streams which cut their way through this chain. On the east side of the Ozark chain is the Great Swamp, 200 miles long and 20 broad, which is converted into a lake by the annual overflow of the Mississippi, but is dry during the heats of summer, and rendered impenetrable at all times by a thick growth of cypress. The country round it is rich bottom or meadow land, clothed with excellent timber. The country for one or two hundred miles west of the Ozarks is also good, but less wooded; and in the eastern section, taken altogether, the open ground occupies nineteen-twentieths of the surface. The western section, extending from the meridian of 98° to the Rocky mountains, is comparatively dry and sterile, and much of it an absolute desert, destitute of herbage, and unfit for human habitation. As we approach the mountains, the ground, which is at first hilly, subsides into smaller undulations, and these terminate in table lands, nearly flat on the top, with steep, and sometimes precipitous sides, and rising 600 or 800 feet above the common level. These table lands, consisting of alternate beds of sandstone and breccia, increase in number and diminish in extent, as we approach the base of the mountains, which is believed to have an elevation of 3000 feet above the sea. The desert aspect of the country, however, is not the effect of its elevation, but more probably of its aridity;—for vallies among the mountains, which are still higher, are fertile. The rivers in this frightful solitude often spread out to a breadth of one or two miles, and dry up in the warm weather. Salt springs are numerous, and salt incrustations cover many square miles. Trees are only to be seen at some spots along the rivers, and are rather more abundant in the south than in the

\* As the name of New England occurs often in American books, it may be proper to mention, that the appellation is applied to the six States east of the Hudson,—Connecticut, Rhode Island, Massachusetts, Vermont, New Hampshire, and Maine.

United States.

north; but throughout the whole section, the wood does not cover the thousandth part of the surface. Of the basin of the Mississippi altogether, it may be observed, that the western side is a barren desert; the middle contains much good lands, but abounds in swamps; the east side, comprehending the basin of the Ohio, is the richest, and the most eligible for human habitation. The woods, in their natural state, increase continually as we advance from the Rocky mountains to the Atlantic, a proof, perhaps, that the summer heat, and the quantity of atmospheric moisture, follow a similar law.\*

Pacific Region.

The *Pacific Region* extends from the Rocky mountains to the ocean, and (exclusive of disputed ground) from latitude  $42^{\circ}$  to  $49^{\circ}$ , embracing an area of 300,000 square miles. It consists almost entirely of the basin of the Columbia river. A chain of mountains runs through it from south to north, about 150 miles from the coast, between which and the Rocky mountains there is a high valley, 300 miles broad, intersected by smaller chains, but well wooded and watered, and enjoying a pure air and a fruitful soil. The land between the outer chain and the coast is nearly of the same description, but much lower, and overcharged with moisture from frequent and heavy rains. The climate is remarkably mild and equable, resembling that of France and Spain much more than that of the Atlantic coast. Frost is rarely seen in winter at the mouth of Columbia river, though it is in the same latitude as Quebec, where the ice lasts five or six months.†

Climate.

The United States, whose territories almost touch the tropic on the one side, and reach to districts where frost lasts five or six months on the other, embrace greater varieties of climate than any other single state in the world. Generally speaking, the climate of the United States is distinguished from that of Europe by three peculiarities. 1. It is absolutely colder for the corresponding degrees of latitude, the mean temperature of the year, according to Humboldt, being nine degrees of Fahrenheit lower on the east coast of America than on the west coast of Europe at the latitude of  $40^{\circ}$ , and  $12\frac{1}{2}^{\circ}$  lower at the latitude of  $50^{\circ}$ . 2. The thermometer has a greater range, as the heat of summer and the cold of winter reach greater extremes. 3. The climate changes more rapidly as we proceed from south to north, or a greater variety of climates is comprised within the same range of latitude. The mean temperature of Quebec, at one extremity, is  $42^{\circ}$ , and of Cape Sable, at the other,  $72.7^{\circ}$ . Between the parallels of 33 and 50, a degree of latitude which make a change of  $1.13^{\circ}$  (Fahrenheit) in Europe, makes a change of  $1.57^{\circ}$  in the United States; and the same annual temperature which is found at a given degree of latitude in the United States, is found seven degrees farther north in Europe. The

seasons are also very differently distributed. Philadelphia, for instance, has the summers of Rome and the winters of Vienna. In Florida, at New Orleans, and at St Mary's in Georgia, snow is never seen; but in Pennsylvania snow lasts three months, in Massachusetts four, and in Maine five.‡ In the two latter states, the ice bears loaded waggons, and the sea is sometimes frozen to a considerable distance from the coast. In all the low country, from Florida to the St Lawrence, the extreme summer heat is nearly the same, from  $90^{\circ}$  to  $98^{\circ}$ , and the varieties of climate are marked chiefly by the intensity and duration of the winter's cold. The climate in the basin of the Ohio, compared with that of the Atlantic coast, possesses no very striking peculiarities, but seems, on the whole, to have its mean annual heat a little higher, to be rather more steady and equable, to be less frequently visited by the frigorific north-west winds, and to have fits of cold weather almost equally severe, but more transitory. The great lakes appear to mitigate the winter cold in the country immediately around them, and probably in the basin of the Ohio too, for on the west and north-west of this district the climate is much more rigorous. At Council Bluffs, on the Missouri, in latitude  $41\frac{1}{2}^{\circ}$ , the thermometer descends to  $-22^{\circ}$  in winter, and rises to  $105^{\circ}$  in summer. At St Peter's Fort, on the Mississippi, in latitude  $45^{\circ}$ , it ranges from  $92^{\circ}$  to  $-30^{\circ}$ , and the mean temperature of January is about Zero. The absolute height of the fort, which cannot exceed 1000 feet, does not account for this excessive cold. We have already mentioned the equable temperature of the basin of the Columbia; and, from the observations made on the Missouri and Upper Mississippi, we have reason to believe that the mildest and the most rigorous winters known in any similar latitude are to be found at once on the opposite sides of the great rampart of the Rocky mountains. (On the subject of Climate, see Mellish, p. 59—77.)

United States.

So many local circumstances affect the annual depth of rain, that little confidence can be put in general estimates. We find that it was 42 inches at Charlestown, on an average of some years, 40 at Natchez, 30 at Philadelphia, 36 at Cincinnati. The mean fall of rain for the inhabited part of the United States (latitude  $41^{\circ}$ ) should be about 34 inches. (See the Article PHYSICAL GEOGRAPHY.) The frequent failure of the streams, and the scarcity of verdure in the country near the Rocky mountains, indicates a deficiency of atmospheric moisture in that region. Snow falls to the greatest depth on the borders of the great lakes. On the sea coast it is rarely seen farther south than Northfolk, latitude  $37^{\circ}$ ; but in the interior, it is found four or five degrees farther south. Compared with the middle countries of Europe, the United States, occupying a more southern position, have rains more regular and heavy,

Rain and Winds.

\* This account of the basin of the Mississippi is entirely taken from Major Long's *Memoir*, published in the third volume of James's *Account of the Expedition to the Rocky Mountains*.

† Morse's *American Universal Geography*, 7th edition, 1819, Vol. I. p. 671. Mellish, p. 417.

United States. and greater in absolute quantity, but a smaller number of wet days. Of the winds, the most remarkable are, 1. A moist and warm south or south-west wind, which is supposed to be a branch of the trade-wind, and is felt all over the Atlantic States as far as the Potowmac, and occasionally in New England. 2. Another wind, possessing the same qualities, and believed also to be a branch of the trade-wind; it blows from the Mexican Gulf up the course of the Mississippi, and seems to send off subordinate branches, which ascend the courses of the Ohio and Missouri. In Louisiana and Arkansas, it is a south wind; at Council Bluffs, on Missouri, it is a south-east; and in Ohio and Kentucky, a south-west wind. It is the prevailing wind in all these districts. 3. The north-west blows occasionally on the west side of the Alleghanies, but more frequently on the east side, and is most prevalent in New England. It everywhere produces intense cold, depressing the thermometer to  $-7^{\circ}$  or  $-8^{\circ}$  in Ohio, and sometimes to  $-20^{\circ}$  in Massachusetts. 4. The north-east is a cold wind, which, transporting the fogs of the Newfoundland bank, occasions showers of snow. Various facts observed in the United States seem to show, what some meteorologists have doubted, that clearing and cultivation improve the climate, at least so far as regards the growth of the cercalia.\*

ology. If we draw a line from New York to the east end of Lake Ontario, the peninsula lying north-eastward between the St Lawrence and the sea consists of primitive rocks, interspersed with some patches of secondary. From this line southward, the country has a different geological character. A belt of alluvial soil, beginning at Long Island, extends along the shore of all the southern states to Natchez on the Mississippi, having an average breadth of a hundred miles, and including, probably, all Florida, except some high ground in the interior. It is everywhere penetrated by the tide water in the rivers. On the west side of this is a region of primitive rocks, from 100 to 200 miles broad, in which gneiss predominates. It embraces the eastern ridges of the Alleghanies, with the rolling country at their foot. On the west side of this, again, is a long narrow zone of transition rocks, including the western ridges of the Alleghanies, and extending from Lake Champlain to the north-west angle of Georgia. From this transition formation, which forms, as it were, the eastern edge of the basin of the Mississippi, immense beds of secondary limestone, sandstone, and shale, cover the country to the Rocky mountains, interrupted only by the alluvial formations on the banks of the rivers, and by the Ozark mountains. These mountains are formed, like the Alleghanies, of the same formations, disposed in the same order. The Rocky mountains, so far as they have been explored, consist of primitive rocks, granite, gneiss, quartz rock, &c., covered

on the east side by an extensive formation of old red sandstone. †

That important mineral, coal, is found on both sides of the Alleghanies. The two principal formations on the east side are, 1. On the river Apomatox, above Richmond (Virginia), where a seam of excellent coal, which occupies a basin 20 miles long and 10 broad, has been long worked, and employs 5000 persons; 2. At various spots along a narrow tract of country, from the sources of the Juniata and western Susquehannah to Providence Bay. At Lehigh, and other parts within this district, the coal is worked. On the western side of the Alleghanies, an immense formation of coal, probably the largest in the world, extends from the head waters of the Ohio southward to those of the Tombigbee, and westward, with some interruptions, beyond the Mississippi. A similar bed appears on the west side of the Ozarks, which is also traced far up the course of the Missouri; and there is a third bed, of unknown extent, on the east side of the Rocky mountains. ‡

Salt, another mineral of primary importance, is distributed in considerable abundance over the United States territory, especially those parts that are remote from the sea. A great formation of rock salt (and gypsum), indicated by numerous salt springs, is believed to accompany the coal formation over a great part of the basin of the Mississippi. Salt springs are numerous at the foot of the Rocky mountains, and extensive plains occur covered with salt, one of which, the Grand Saline, is 30 miles in circumference, and in hot weather is covered with a crust of clear white salt, from two to six inches deep, and superior in quality to manufactured salt. On the east side of the Alleghanies, salt is generally obtained from the ocean, or imported.

Iron is found in nearly all the States, and is worked to such an extent, that of 50,000 tons consumed, according to computation, in the country, only 10,000 are imported. (Morse, I. 236.) A bed of magnetic iron ore, from eight to twelve feet thick in gneiss, and another from two to twenty feet, extend, with some interruptions, from the White mountains, on the one side, and from Lake Champlain, on the other, to the northern limits of New Jersey. Iron ore, of various kinds, is also met with in Maryland and Virginia. On the west side of the Alleghanies it is abundant, and is extensively worked at Pittsburgh, and in Kentucky and Tennessee. The whole number of furnaces, forges, and bloomeries, in 1810, was 530. Ores of copper are smelted in New Jersey, and are found in various other parts of the Union. Native copper is said to exist in great quantities near the river St Croix, in the north-west territory; but at present, the United States are supplied with this metal chiefly from Mexico. Lead is

United States.

Minerals.

United States.

found in Massachusetts and Pennsylvania, but it exists most abundantly in Missouri, at the north-east angle of the Ozark mountains, where 45 mines are worked, which yield three millions of pounds annually. (Mellish, 366.) Gold and silver are met with, but only in minute quantities. Mercury and tin have not been found. Cobalt, antimony, manganese, and ores of zinc, occur in some few spots. Nitre is obtained in vast quantities from the limestone caves in Kentucky. On a general view, it may be said that the United States, so far as explored, are nearly destitute of the precious metals, but have a supply of coal, salt, iron, lead, and probably copper, adequate to their own consumption.

Lakes.

The United States have no considerable lake, entirely within their territory, except Michigan. But a series of fresh water lakes, by far the largest in the world (for the Caspian Sea is salt), and connected with one another by the St Lawrence, extend along their northern frontier. The following is their extent, and their elevation above the level of the sea:

Lakes.	Length.	Breadth.	Area.	Height in Feet.
Superior, .....	350	150	35,000	642
Huron, .....	220	150	17,000	589
Michigan, .....	310	70	18,000	—
St Clair, .....	30	30	900	570
Erie, .....	230	55	10,300	560
Ontario, .....	170	50	7,200	110
			88,400	

Reckoning from Quebec to the western extremity of Superior, these lakes afford a line of 1550 miles of inland navigation, which will be increased to 4500 miles if we include the whole extent of their shores. But Quebec is far from the open sea, and the shortest and best route to the Atlantic from Lake Erie and the waters above will be by the New York canal. Lake Erie is about twenty fathoms in average depth, Ontario eighty, and Lakes Huron, Michigan, and Superior, are said to be still deeper. All these inland waters can be navigated with advantage; and will be crowded with vessels at some future period, when an active population covers the north-west territory. The principal interruptions at present are, 1st, At the rapids between Montreal and Kingston, where it is proposed to cut a canal. 2d, At the rapids and the great fall of Niagara, where a canal is also projected. 3d, In the stream of the river between Lakes Huron and Erie, where there are also rapids, and in Lake St Clair, which is full of shallows. 4th, At the falls of St Mary, between Huron and Superior, amounting to twenty-three feet in half a mile. All these obstructions, it is believed, can be surmounted by art. These various lakes evidently occupy the bottom of a raised plateau, the outer sides of which are not very distant; and hence they receive very few rivers of any magnitude. Their shores are beset with ice for two, three, or four months in the year.

Lake George, 36 miles long and 7 broad, pours

its waters into Lake Champlain, which is 160 miles long and 18 broad, and communicates by the River Sorelle with the St Lawrence. A canal, 22 miles long, now nearly finished, connects Lake Champlain with the Hudson. We pass over the other lakes of smaller size.

United States.

The rivers of the United States belong to four Rivers. different systems; 1st, Those which water the Atlantic region. 2d, The Mississippi and its branches, which water the great central valley of North America. 3d, Those which flow into the St Lawrence; and, 4th, The Columbia and its tributaries, which flow into the Pacific Ocean.

Eastern Rivers.

The rivers which fall into the Atlantic, and the Gulf of Mexico, from Maine to the eastern boundary of Louisiana, all rise in the Alleghanies, except the Susquehannah and the Hudson, which pass entirely through the principal chains. Their length varies from 200 to 450 miles, increasing gradually with the breadth of the level country, as we advance southward. The tide-water ascends in all these rivers to the outer boundary of the primitive formations, where falls regularly occur, except on the Hudson. In this river, the tide reaches to Albany, 160 miles from its mouth, to which point there is an uninterrupted navigation for sloops of 80 tons. This peculiar advantage has made the Hudson the scene of a more active inland trade than any river, perhaps, in the world, of the same magnitude. Tide navigation reaches a very short way up the great rivers in the northern states generally; but in those south of the Susquehannah, it reaches generally from 100 to 130 miles. Boats ply on these rivers much farther up, but the navigation is seldom uninterrupted. The following are the principal rivers on the Atlantic side, with their approximate lengths.

	Miles.		Miles.
Connecticut, ...	290	Roanoke, .....	230
Hudson, .....	300	Pedee, .....	290
Delaware, .....	270	Santee, ...	300
Susquehannah, .....	350	Savannah, .....	280
Potowmac, .....	260	Catahouche, .....	400
James' River, .....	200	Alabama, .....	440

The rivers that fall into the St Lawrence, and its lakes, are comparatively small, and probably do not carry off one-tenth part of the water that falls on the east side of the Mississippi. The most considerable are the Fox River, which falls into Lake Michigan, the Miamie of Lake Erie, the Genessee, and Seneca of Lake Ontario, and the Saurelle or Richlieu, which joins the St Lawrence below Montreal.

Northern Rivers

The majestic Mississippi drains a greater surface than any river in the world, except the Amazon, and in the magnitude of its stream is only surpassed by the Amazon and the Plata. It has been computed to convey to the Mexican Gulf  $\frac{1}{8}$  of all the water which the ocean receives from the dry land. (See PHYSICAL GEOGRAPHY.) The extreme length of the Mississippi Proper, including all its sinuosities, is generally computed to be 2500 miles, but reckoning to the head of the Missouri, which is the largest branch, it is nearly 4000. It has three bars at its mouth, the deepest of which affords only 17 feet of water. (Warden, I. 114.)

Mississippi

United States. Sloops of this draught can navigate to Natchez, 350 miles from its mouth. There is depth sufficient at all times for sloops drawing six feet to the Ohio, and for vessels drawing three feet to the junction with the Missouri. (James's *Expedition*, III. 258.) But, during the floods in May, June, and July, the waters rise 50 feet, and are then navigable by vessels of any size. The Mississippi, from its junction with the Ohio to the sea, is about 1000 yards, or two-thirds of a mile in width, and below Red River it is about 120 feet deep. From the junction of the Arkansas, its banks form an elevated ridge or platform, which support the stream at the height of ten or twenty feet above the level of the adjacent lands. In its floods, it sometimes bursts the barriers which confine it, and inundates the flat country below. Of the two great branches, the Missouri, and Mississippi Proper, the former stream is the larger, and more rapid, and also more turbid, from the quantity of travelled soil it transports. But its waters, generally occupying a wider channel, are more loaded with bars and sandbanks, and the navigation is more intricate. (James's *Expedition*, III. 259.) The Platte, Kansas, and some other tributaries of the Missouri, often spread out to a breadth of one or two miles, and during the warm season, dry up entirely. But these, and all the branches of both rivers, generally admit of boat navigation for nine-tenths of their course, during a longer or shorter period every year. In the Ohio, the boating season is from 20th February to the middle of June. Before this period the waters are ice-bound; after it, they are too shallow, except for very small craft. The length of the Mississippi, from its mouth to the junction of the Ohio, is about 1200 miles, and to its junction with the Missouri, 1300. The length of the Missouri, above the junction to its remotest branch, is, by Lewis' and Clarke's measurement, 2575 miles. The length of the Ohio, above the point of confluence, is 1188 miles. The other large branches of the Mississippi are the Red River and Arkansas, in the lower part of its course. The chief tributaries of the Missouri are the Osage, Platte, Kansas, and Yellowstone; of the Ohio, the Tennessee, Cumberland, and Wabash. The whole extent of the navigable waters above the confluence of the Missouri and Mississippi has been estimated at 23,000 miles, to which, if we add 12,000 for the Ohio, Arkansas, Red River, &c. and their branches, we shall have 35,000 miles of boat navigation in the basin of the Mississippi. To this we may add 10,000 miles more for the eastern section of the States, with 5000 for the lakes and their tributary streams, and 2000 for the River Columbia, making altogether 51,000 miles of river navigation, which is probably three times greater than all the rivers of Europe afford. Except in New England, Pennsylvania, and New York, the rivers of the United States flow over a surface which has rather a small declivity. Of the two sides of the great cen-

tral valley, the western in the steepest. The base of the Rocky mountains is computed to have an elevation of 3000 feet. That of the beds of the rivers, where they begin to be navigable, may be about 2000; and estimating their average length of course to the sea to be about 2500 miles, the mean fall will be about nine or ten inches *per* mile. The Mississippi Proper, at 2500 miles from the sea, has a height of 1330 feet, or a mean fall of six or seven inches *per* mile. The Ohio, at Pittsburgh, 2200 miles from the sea, has a height of 600 feet, or a mean fall of four inches. In the Amazon and the Ganges, from the point where they leave the mountains, and in the Wolga, from its source, the average rate of descent is from four to five inches *per* mile. In the middle and south of Europe, generally, the fall of the rivers is probably twice as great.\*

Cultivated Plants. The variety of cultivated plants in North America corresponds to the diversity of its climates. At one extremity, the sugar cane of the tropical regions thrives, and at the other, oats and barley, the staple crops of the Arctic regions, are leading articles of cultivation. The high summer heat, however, in all parts of the United States, makes some plants, which cannot be raised in England, succeed in the coldest districts of the north. Of this description is maize, or Indian corn, an indigenous American plant, which is cultivated from Maine to Louisiana. It is a vegetable in universal use in the United States, yields generally double the produce of wheat, and is adapted to a greater variety of situations. The maple tree, which grows in all the States, yields a juice from which sugar is made. Nearly ten millions of pounds of maple sugar were made in 1810. Wheat is raised from one extremity of the Union to the other, but succeeds best in the middle and western States, and in the uplands of the southern. The cultivation of tobacco begins in Maryland, about the parallel of 39° or 40°, and continues through all the southern States, and through those in the west, south of the Ohio. The climate favourable for cotton is not found farther north than about the latitude of 37°, though it can be raised as far north as 39° on both sides of the mountains. The best grows in South Carolina and Georgia, in dry situations upon the sea coast. The rice crops, which require a marshy soil, and a great heat, commence about the same parallel with cotton, and have nearly the same geographical range. The sugar cane grows in low and warm situations, as high as the latitude of 33°, but the climate favourable for its cultivation does not extend beyond 31½°. Oats, barley, hemp, and flax, succeed well, except in the low grounds of the southern States. The vine can be advantageously raised as far north as Pennsylvania. The olive, orange, lemon, and fig, are injured by the frost in South Carolina, but it is believed, that these trees, as well as the banana, will succeed in Florida.† The forest trees of the United States com-

United  
States.

Animals.

prise almost all the valuable and useful species of wood.

The United States contain about one-fourth of the known species of quadrupeds. Some are common to both continents, others are peculiar to the western. Comparing individuals of the same species, some are perfectly similar; between others there is some difference in size, colour, or other circumstances. In a few instances, the animal of the eastern continent is larger than the American; in most the reverse is the case. The following is a catalogue of the quadrupeds of the United States.

Mammoth (an extinct species),	Lynx,	Flying Squirrel,
Bison or Buffalo,	Kincagou,	Field Mouse,
Moose Deer,	Weasel,	— Bat,
Caribou,	Ermine,	Ground Mouse,
Red Deer,	Martin,	Wood Cat,
Fallow Deer,	Mink,	American Rat,
Roe,	Otter,	Shrew Mouse,
Bear,	Fisher,	Purple Mole,
Wolverene,	Skunk,	Black Mole,
Wolf,	Opossum,	Water Rat,
Fox,	Wood-Chuck,	Beaver,
Catamount,	Urchin,	Musquash,
Spotted Tiger,	Hare,	Morse,
Sallow Cougar,	Raccoon,	Seal,
Gray Cougar,	Fox Squirrel,	Manati,
Mountain Cat,	Gray Squirrel,	Sapajou,
	Red Squirrel,	Sagoin.

Nine-tenths of these animals yield a fur, which is used for dress or in manufactures. The bison, or wild ox (improperly called the buffalo), is, according to some American naturalists, of the same species with the common neat cattle of the United States, the difference being the effect of the domestication of the latter. Buffon, however, thinks otherwise. The bison is larger than the domestic ox, has a fleshy or grisly substance extending along his shoulders and back, and has on his neck and shoulders a woolly hair, which admits of being spun or wrought into hats. The moose-deer, now rare, is a gigantic animal, one variety sometimes reaching the height of 12 feet. The caribou is probably the reindeer of Scandinavia. The bear is of two species. The short-legged lives chiefly on vegetable food, and is probably not carnivorous. He dozes away the winter in a torpid state, sucking his paws, and expending the fat he had previously acquired. The ranging bear is larger, but more lean. He destroys calves, sheep, pigs, and sometimes children, and in winter migrates southward. The wolf, like the bear, is found in all the States. It is a voracious animal, scaling into sheepfolds at night, attacking deer, hogs, and small cattle, and sometimes hunting in packs. The catamount is of the size of a large dog, and extremely ferocious, but it is rarely seen. The spotted tiger is scarcely seen, except near

Louisiana. It is from five to six feet long. The cougar or American panther is about the same size, but more common. It destroys sheep, calves, and hogs, and, when hungry, will attack large cattle. The urchin differs in several respects from the European hedgehog. The lion, leopard, striped or true tiger, hyena, elephant, rhinoceros, hippopotamus, camelopard, are unknown in the New World. The horse, the ass, the sheep, the goat, the hog, and the camel, did not originally exist there, but have been naturalized. The latter, however, are not numerous, and have never been introduced into the United States. Of the birds and reptiles our limits will not allow us to speak in detail. The eagle, pheasant, grouse, partridge, swan, Canadian goose, ptarmigan, are less or more numerous. In general, the small birds of America surpass those of Europe in the beauty of their plumage; but are much inferior to them in the melody of their notes. Among the reptiles, the most remarkable is the alligator or American crocodile, from 12 to 23 feet long, very strong and active. Of serpents, the rattlesnake, from four to six feet long, is the most formidable.\*

Perhaps no single circumstance connected with the United States has attracted so much attention as the rapid growth of their population. Philosophers had shown, from the laws which govern propagation, that the human species might double its numbers in a short period. But this was only known as a speculative truth, applicable, it was supposed, to small tribes under extraordinary circumstances, but not to a great nation of many millions. The Spanish colonies, planted a hundred years earlier than the United States, should have made this principle familiar to the world long ago, but ignorance and misgovernment, intercepting the bounty of nature, inflicted all the vices and evils of old societies upon these colonies, and a jealous policy threw a veil of secrecy over their condition.

The first European emigrants settled in the United States in 1607. From that period, colonists continued to flock to the country in small parties or large bodies. The last new settlement on a considerable scale was in 1733, when, by means of a grant of L. 10,000 from Parliament, and various sums raised by private contributions, 618 persons were sent out from England to Georgia.† The growth of the colonies was rapid and obvious; but much more of it was probably attributed to the influx of settlers from the mother country than was consistent with the truth. No accurate enumeration of the inhabitants was made till the first census was taken in 1790. That for the year 1753, in Marshall's *Life of Washington*, is undoubtedly erroneous. The ratio of increase being ascertained by the four separate enumerations, and having continued remarkably uniform for forty years, we can now, by calculating backwards, obtain results more deserving of confidence than the rude guesses made from uncertain

\* Morse, Vol. I. p. 263, &c. Warden, Chap. 6. Buffon's *Quadrupeds*, Vol. II. London edit. 1775.

† For an account of this and the earlier settlements, the reader may consult the *History of the British Empire in America*, 2 vols. 8vo, Lond. 1741.

United States. data. The period of doubling at present is  $24\frac{1}{6}$  years; but, taking it at 25 years, and reckoning backwards from 1790, we find the population at the under mentioned periods would be,—

1790 .....	3,921,000	1715 .....	490,000
	(by census)	1690 .....	215,000
1765 .....	1,960,000	1665 .....	122,000
1740 .....	980,000	1640 .....	61,000

Beyond the last mentioned period we cannot, for

obvious reasons, carry our calculation. If we suppose 1000 settlers to have come from Europe annually for the first 33 years, these, by natural multiplication, would amount to about 60,000 at the time alluded to, that is, in 1640. The following Table, constructed from documents afforded by Seybert and Mellish, with several new calculations, gives an interesting view of the progressive changes in the different states, and in the two great classes of the population.

Free Persons, .....	3,227,046	4,429,881	6,074,562	8,110,108					

It will be observed from this table, that the rate of increase is very unequal for the different sections of the Union. The older states of Connecticut and Massachusetts have only added one-fifth to their population, in the same period in which the new states of Kentucky and Ohio have quadrupled theirs. The reason obviously is, that the more densely peopled parts of the Union, and, in particular, New England, serve as a nursery to the new states, to which they are continually sending out large draughts of emigrants. There is thus a constant stream of population pouring across the Alle-

ghanies, from the east side to the west, to occupy the vast plain of the Mississippi; and by this gradual generation of a mighty people, as it were from a central stock, a uniformity of language, manners, and institutions, is diffused over the whole, which will cement their union, in spite of local diversities of interest, and which promises to make the countless millions, who will by and by cover North America, from sea to sea, more truly *one people* than the inhabitants of Austria, Prussia, France, Spain, or Britain, are at this day.

If we calculate prospectively from the present rate

United States.

of increase, assuming that it will continue permanent for some time, the population, at the under mentioned periods, will be,

1845 ...	20,000,000,	1895 ...	80,000,000,
1870 ...	40,000,000,	1920 ...	160,000,000.

Before this last result is realized, some retardation will probably take place in the rate of increase. But even were the vast population alluded to in existence, the average density for the whole territory would not be greater than it is at this day in Massachusetts, and only half as great as in Italy, France, and the British Isles.

The rapid growth of the population in America becomes much more striking when we contrast it with the scarcely perceptible progress of communities in the Old World. France, which had 19,094,000 inhabitants in 1700, according to the enumeration of Marshal Vauban, had 26,363,000 in 1791. Now, according to the rate of increase which this indicates, that country would have *doubled* its population in 195 years; but the population of the United States in the same period would have increased to 220 times its first amount. The following table, which we have calculated from the best data to be obtained, shows the comparative rate of increase in different countries.

	Annual Increase on each 10,000 Persons.	Period of Doubling.
United States (according to census of 1810 and 1820),	} 291	24 $\frac{1}{8}$ years
France, from 1700 to 1791,		195
Ditto — 1791 to 1821,		144
England — 1801 to 1821,		51
Europe for the last 30 years,		90

Slaves.

Slavery is nearly extinguished in all the New England States, and is hastening to its extinction in Pennsylvania, New York, New Jersey, and Delaware. In Ohio it does not exist. In Indiana and Illinois it will soon cease. In Maryland, though there has been a small absolute increase in the slave population, their number, compared with that of the whites, has diminished. In two important circumstances there is a wide difference between slavery as it exists in North America, and in the West Indies. In the former, the number of slaves no where equals that of the free inhabitants, except in South Carolina, where there is a trifling excess of the former,—and in the States where slavery exists, taken altogether (excluding those northward of Kentucky and Delaware), the blacks form only one-third of the population. But in the West India Islands, the blacks are ten, or sometimes twenty times more numerous than the whites.\* In the second place, it is well known that the slaves in the West Indies continually decrease, and would speedily die out, unless kept up by new importations; but, in the United States, they double

United States.

their numbers in 29 $\frac{1}{2}$  years, without any importation whatever. It may be safely said, that the superior humanity of the Americans in the treatment of the blacks is the greatest obstacle to that abolition of slavery which they so ardently wish to accomplish, and that, were their slaves worked and fed like those in the West Indies, the race of blacks, instead of multiplying tenfold in the course of one century, would be entirely extinguished. The existence of slavery is a bequest from Britain; it is not the crime of the Americans, but their misfortune. It is an evil which they deplore, and of which they would gladly rid themselves if they knew how. The difficulty is, how to dispose of the slaves, whom many would be willing to manumit. The plan of carrying them back to a colony on the African coast seems absolutely chimerical; and the strong distinction of colour, with the rooted prejudices of the whites, form an insuperable bar to such an amalgamation of the two races as took place when the serfs of Western Europe were incorporated with the freemen in the fifteenth and sixteenth centuries. Time alone promises a certain alleviation of the evil, though not an absolute cure. If we separate the white and black races, the former double their numbers in 23 $\frac{7}{12}$  years, and the latter in 29 $\frac{1}{2}$ , a difference apparently trifling, but which produces important results, if we reckon forwards. Supposing the ratio of increase to remain steady, in 118 years the slaves will have multiplied to 16 times, and the whites to 32 times their present numbers. And in this period, the relative proportions of the two races would be so changed, that the slaves, who form at present  $\frac{1}{5}$  of the population, would then form only  $\frac{1}{3}$  or  $\frac{1}{4}$ th. If we add the free blacks, indeed, the increase is more rapid than here assumed, but we throw these out as a compensation for the mulatto or mixed race, who are the progeny, not of blacks alone, but of blacks and whites, and a large part of whom must ultimately melt into the mass of the white population.

In France and England, and probably in Europe at large, the females exceed the males by 2 or 3 *per cent.*; but, in the United States generally, the males exceed the females by nearly 4 *per cent.* In the newest States, the excess is as high as 19 *per cent.* (Seybert, p. 42.) The difference is still more striking in what relates to ages. In the United States, children form a much greater, and aged persons a much smaller, proportion of the population than in Europe. In Sweden, according to Wargentin's *Tables*, the persons under the age of 16 form 36 *per cent.* of the population; in Britain, according to the last census, 40, and in the United States 50 *per cent.* The persons aged above 45 form 22 *per cent.* of the whole population in Sweden, 18 *per cent.* in Britain, and 12 *per cent.* in the United States. This peculiarity arises from the rapidly progressive state of the population. Since the inhabitants of the United States quadruple their numbers in 50 years, a person born half a century ago belongs by his birth to a society of two millions and a half of persons, but now lives in a society of ten millions, which will fur-

Males and Females.

\* Colquhoun's *Wealth, Power, and Resources of the British Empire*, p. 40.

United States.  
Immigration.

nish four times as many old men to a future and equidistant period. The annual amount of immigration (to borrow an American word) is very variable, and its effects have been greatly overrated. The whole number of passengers who arrived, in 1817, at the ten principal ports, was 22,240, including citizens and persons on business who did not mean to remain in the country. In 1816, it was estimated at 20,000; in 1818 and 1819, at 28,000 each, not more than one-half of whom, very probably, were strangers come to settle. In 1820, the true number of immigrants, according to the *National Calendar*, was 7001, of whom 5042 were males, consisting of 997 agricultural persons, 1461 commercial, 1407 manufacturers, artizans, &c. Dr Seybert thinks the average number of foreigners who come to settle in the United States does not exceed 6000 *per annum*; but assuming it to be 8000 or 9000, this is only from  $\frac{1}{30}$  to  $\frac{1}{35}$  of the whole annual increment, which must amount to 290,000 persons to make the population double in  $24\frac{1}{6}$  years.\*

Mortality.

This rapid increase does not greatly affect the rate of the annual mortality, which is proportionally rather greater among the persons under 25 than among those of all ages. In the absence of proper data for ascertaining the annual mortality of the whole country, or of any single state, we can only refer to a single fact. The average number of deaths in Philadelphia, for eight years (1807 to 1814), was found to be about  $\frac{1}{43}$  of the contemporaneous population. (Seybert, p. 50.) In Birmingham, in the ten years ending 1811, it was about  $\frac{1}{30}$ , in London  $\frac{1}{31}$ , and in all England, including the army and navy, about  $\frac{1}{44}$  or  $\frac{1}{45}$ . (Milne's *Annuities*, p. 456.) This single fact, therefore, so far as it goes, bears testimony to the salubrity of the climate, and to the comfortable condition of the inhabitants of the United States.

Classes.

The active population in the United States is proportionally greater, and the idle population less than in any other country. They have few public functionaries, preachers, or annuitants, and a very small army and navy. According to a table which will be found farther on, the active population amounts to 27 *per cent.* of the whole, or 2 *per cent.* more than the number of males above the age of 16. The proportions employed in agriculture, manufactures, and commerce, according to the census of 1820 were,—

Agriculture,.....	83.7 <i>per cent.</i>
Manufactures,.....	13.5
Commerce, .....	2.8
	100.

But the number assigned to commerce evidently does not include mariners, or includes only those who resided on shore at the time the census was taken. For the sake of comparison, we give the general result of the British returns for 1811, re-

United States.

marking, however, that the two classifications are not constructed on the same plan, the second head in our arrangement corresponding to the second and third in the American.

Agriculture (by families).....	35 $\frac{1}{2}$ <i>per cent.</i>
Trade, manufactures, and handicraft	
(do.) .....	44 $\frac{1}{2}$
Other persons (the unproductive class, military, placemen, clergy, &c.).....	20 $\frac{1}{2}$
	100

The situation of the labouring classes in the United States is confessedly far superior to that of the same description of persons in any other part of the world. Wages are so high, compared with the price of provisions, that an American labourer, who should live exactly as labourers live in other countries, might always save the half of his earnings. The average wages of a labourer were estimated at 75 *cents* a day by Mr Blodget, and more recently at 80 *cents* by Mr Niles, wheat being 1 $\frac{1}{2}$  dollar *per* bushel. (Warden, Introduction.) In such circumstances, a very moderate degree of industry suffices to place a man above want, and pauperism can only be the lot of those who are debilitated by old age or disease. Accordingly, it is a proud distinction for North America, that this moral deformity, except so far as it is the consequence of natural and unavoidable misfortunes, is almost unknown within her borders. It is not there as in the old countries of Europe, where a person, who is able to provide comfortably for his own wants, has still his feelings exposed to daily laceration from the sight of multitudes of miserable beings, who exhibit human nature in its most loathsome and degraded state, and whose wretchedness it is beyond his power to relieve. It is Rochefoucault, we think, who remarks, that he had seen only one beggar in the United States. Mendicity does exist, but except in the large cities where foreigners are often found in a state of destitution, it rarely obtrudes itself on the eye, and may be said generally to be as rare in that country as it is abundant every where else. In Europe, the paupers have been supposed, on a rough calculation, to amount to one-twentieth part of the population. In the United States, they were estimated by Mr Niles, some years ago, at one person in 250 on the Atlantic coast, and one in 350 in the interior. But, in times of great public calamity, the proportion is much higher. In the New England States, and in some of the others, though not the whole, each parish is obliged to provide for the support of its own poor, according to the humane spirit of the English laws. (Morse, Vol. I. 293. Warden, *passim*.)

Wages and Pauperism.

The North American Union comprehends at present *twenty-four* distinct States, each governed by its own constitution; *three* territories, in which civil governments are established, without constitutions;† and

pre-States.

\* Seybert, p. 28. Carey's *Essay on Political Economy*, 1822, p. 453, 467. Nile's *Register*.  
 † A territory becomes a state when its inhabitants, amounting to not less than 60,000 persons, have met and formed a constitution. Previous to this, they are placed under the civil authority of a governor, appointed by the President and Congress.

United States.

three other territories, which are yet unoccupied by a civilized population. To these we must add the district of Columbia, comprising a space of ten miles square round Washington, which is placed under the exclusive authority of that Federal Government.

The following Table gives a view of the extent, population, and representation of each State, and of the proportion of its inhabitants engaged respectively in agriculture, manufactures, and commerce, according to the census of 1820.

The thirteen original States which concurred in the declaration of independence on the 4th July 1776, were New Hampshire, Massachusetts, Rhode Island, Connecticut, New York, New Jersey, Pennsylvania, Delaware, Maryland, Virginia, North Carolina, South Carolina, Georgia. Vermont was then an appendage to New York, and Maine to Massachusetts. The extent of the several States is very unequal. Rhode Island and Delaware are specks in the map, rather smaller than Devonshire or Perthshire. New York, Pennsylvania, and the New States generally, are each larger than Ireland or Scotland; while Virginia, Georgia, Missouri, and Illinois, severally exceed England in extent. The density of the population varies from one person *per* square mile to

67. It diminishes pretty regularly in every direction as we recede from Massachusetts, and in that State, where it is greatest, it rather exceeds that of Spain, or Poland, or Europe, taken altogether. The mean density for all the States east of the Mississippi, and including Louisiana, is 13 persons to the square mile, which rather exceeds that of Sweden and Norway.

Some writers, who derive their political ideas from the old institutions of Europe, disapprove strongly of the division into states, with distinct local governments. But this arrangement, though originally the effect of accident, is admirably adapted to the circumstances of the country, and deserves to rank as an improvement in the science of legislation. It is

State Governments.

United  
States.

the only system by which the great advantages of union could be combined, in such a gigantic empire, with a due attention to the separate interests of all the parts. The federal compact, by preserving peace and friendship among states that would otherwise be rivals and enemies, exempts them from the scourge of frequent wars, gives unbounded freedom to their internal trade, and, while it enables them to dispense with that sort of strong government which is scarcely compatible with liberty, it gives them an aggregate strength, which secures them against external attacks. On the other hand, each separate district, acting by its own legislature, is invested with the entire regulation of its local concerns, which can never be entrusted to others without the certainty of mismanagement. No single legislative body, even were its sessions perpetual, could properly conduct the local business of such an empire as that now forming in North America. In our own Parliament, it is notorious, that, from the multiplicity of business transacted, the general style of legislation is most slovenly, and bills of all kinds, but especially local bills, are often grossly mismanaged. How great an impediment is it felt to be to the redress of grievances, or the promotion of improvements, in the remote parts of Scotland and Ireland, that witnesses, parties, and agents, must be carried six or seven hundred miles at a vast expence, and that, when at the seat of legislation, their success must greatly depend on the votes of persons who either understand their business imperfectly or not at all, and who are only prevailed upon to bestow a slight attention upon it by private solicitation. The division into states supplies the only remedy to this great evil. It encourages local improvements by uniting those whose situation gives them a community of interest as to certain objects. It lessens corruption in the general government, by subdividing patronage. In times of public frenzy, it multiplies the securities against the persecution of individuals, because such persons will always find protectors in some one of the state governments. It has, indeed, one disadvantage; the state legislatures may become the strong-holds of faction, as exemplified in Massachusetts during the last war. But, as the number of States increases, the weight of each in the confederacy, and its power to disturb the union is diminished. Even out of this danger a security arises against another. The existence of the separate state governments forms a strong barrier against despotism, because it creates so many distinct centres of power, from which resistance might be made, if a military tyrant should master the general government, as Cromwell mastered that of England, and Bonaparte that of France. Some inconvenience, no doubt, arises from the unavoidable diversity of laws in such an aggregation of republics; but the evil is not much felt or complained of practically, and it is the necessary concomitant of a union producing boundless advantages. An iron despotism may subject all its slaves to the same laws without regard to the dis-

tinctions of climate, character, or situation; but freemen will not associate voluntarily on such a principle. Liberty consists, not in being governed by the laws that are absolutely best, but by those which are deemed best by the people who obey them. No wise and liberal statesman will hold it necessary that the fishermen of Massachusetts, the husbandmen of Pennsylvania, and the sugar planters of Louisiana, should live under one perfectly uniform system of jurisprudence. Such a uniformity could not be enforced without rending asunder the union. And let it be recollected, that the diversity of laws, such as it exists, is much less than it would be if the federal compact were dissolved, and the several States entirely independent. In short, if it is possible by any device to reconcile freedom with extensive empire; to unite all the parts of a vast continent together in the bonds of peace and commercial intercourse; and yet not to trench materially on the natural rights of each part, or the free use of its natural powers and advantages; it must be by a federative system similar in its essential characters to that of the United States. The experiment is by far the most interesting that has ever been made in the science of legislation, and the steadiness and success with which it has hitherto proceeded opens up the most encouraging prospects as to the future destiny of mankind.

The federal government, of which we shall speak afterwards, possesses merely those specific powers which are vested in it by the Constitution. All other powers and rights remain with the state governments, in whom the sovereignty essentially resides. The territory of each state is not the territory of the Union, but of that particular State. The people and militia are the people and militia of the several States, not of the Union. Lands are held under the laws of the States; descents, contracts, and all the concerns of private property, the administration of justice, and the whole criminal code, except in the case of breaches of the laws of the federal body, are regulated by state laws.\* All the twenty-four States have written constitutions, formed subsequently to the Revolution, except Rhode Island, which is still governed by the charter granted by Charles II. in 1663. These constitutions are purely republican, though the right of suffrage (for the term *franchise* is inapplicable and odious where voting is a general right, not a special privilege) is restricted in one or two States, and unequally divided in one or two others. In every one of the States the legislature consists of two chambers, both chosen by direct popular election, except in Maryland, where the senators are chosen by delegates. In nineteen States out of the twenty-four, the representatives (or members of the Lower House, according to our phraseology) are elected annually, and in five triennially, viz. in South Carolina, Tennessee, Louisiana, Illinois, and Missouri. The period of service in the senates (or Upper Houses) varies from one to four years, except in Maryland, where it is five: in some cases one-third

United  
States.State Con-  
stitutions.

\* *Views of the President of the United States on the subject of Internal Improvements, laid before Congress, 4th May 1822.*

United States.

or one-fourth, in others one-half of the members are renewed every year; in others, one-half every two years. In some of the States the right of suffrage was formerly limited to freeholders or corporations, but by amendments in most of the old constitutions, these odious and really impolitic restrictions have been abolished; and the right of suffrage, though variously defined in the different States, is substantially universal in them all, except in New Jersey and Virginia. In these two States, the possession of a small amount of property still constitutes the citizen's title to vote. In many of the States there are certain qualifications prescribed for the persons elected. A senator must, in general, be a freeholder, and not under 30 years of age; a representative not under 25. The governors act, in some cases with, in others without a council, and hold their offices, some for one year, some for two, some for three, but none for more than four years. In all the constitutions recently framed an express provision is introduced for adopting amendments. The rule generally is, that if any alteration is judged necessary and approved of by two successive legislatures, it may then be submitted to the people, who appoint a special convention to decide upon it. In some cases it is provided that a convention shall meet periodically to revise the constitution. The existing legislature is always considered as exercising a trust, in the terms of which it has no power to make the smallest change. By this principle, legislation is founded on a clear and rational basis. It gives stability to institutions that might otherwise be the foot-ball of domineering factions; it checks the growth of sinister interests, and, while it affords a safe and easy remedy for grievances, it is so far from being an inlet to rash innovations, that it is the best guarantee against them; as the history of the United States demonstrates. To suffer those who exercise the supreme power of a country to change at pleasure the conditions by which they hold it, is equally as absurd as to suffer the judge to make the laws he administers, or the steward to fix the terms of the engagement which invests him with the management of an estate. Under such a system, the steward unavoidably becomes a speculator, the judge a tyrant, and the legislature a junta of conspirators against the public weal.

Agriculture.

The agriculture of the United States varies according to the climate, soil, and situation, of the several divisions of the country; but, taken altogether, it differs materially from that of Britain,—in the nature of the productions cultivated, in the condition of those who are engaged in it, and in the general principles by which it is conducted. Besides our staple productions, wheat, barley, oats, pease, beans, turnips, and potatoes, the soil of the United States yields rice, Indian corn, indigo, cotton, sugar, tobacco, the vine; and Florida will probably add to these the olive and the banana, which scarcely succeed in the other States. The staple produce of New England is Indian corn; that of the middle States, wheat and tobacco; that of the southern, cotton, rice, and, to a limited extent, sugar. Dr Morse indicates the proportional quantity of each species of produce raised, by naming them in the following order, the greatest be-

ing first: In New England, Indian corn, grass, rye, oats, flax, wheat, buck-wheat, barley, and hemp; in the middle States, wheat, Indian corn, tobacco, grass, oats, buck-wheat, flax, barley, potatoes, spelts, rye; in the southern States, cotton, wheat, tobacco, Indian corn, rice, indigo (formerly), barley, and hemp. The western States, along the Ohio, correspond in their productions to the middle States, on the Atlantic. Good soils, carefully cultivated, in the United States, yield 100 bushels of Indian corn, or 50 of wheat *per acre*. But the average produce of the cultivated land in Ohio and Kentucky, districts not inferior in soil to any in the Union, is estimated as follows: maize 40 bushels *per acre*, wheat 22, rye 26, oats 35, barley 30, tobacco 12 to 15 cwt., cotton 5 to 7 cwt. in the seed, or from 150 to 200 pounds cleaned. (James, Vol. III. p. 199.) An acre sown in rice yields from 1200 to 1500 pounds on what are called tide lands, and from 600 to 1200 on inland plantations. An acre planted in canes yields about 1000 or 1200 pounds of sugar, with an equal quantity of molasses. The necessity of renewing the canes annually by planting, in consequence of the winter's frost, renders the cultivation less advantageous than in the West Indies. In 1817, however, it was calculated that 20,000,000 of pounds of sugar were made in Louisiana alone, which was estimated to be about  $\frac{2}{7}$  of the whole annual consumption of the United States. (Warden, II. p. 483, 541. Morse, I. p. 668.)

The rural population of the United States presents an extraordinary contrast in its constituent parts to that of every country in Europe. The class of extensive proprietors living on their rents, and the class of peasants living merely by their labour, are almost equally unknown. The great bulk of the inhabitants consists of farmers, who are the owners of the lands they occupy, and the greater proportion of whom work with their own hands. "The number of those who are mere labourers," says Dwight, "is almost nothing, except in a few populous towns, and almost all these are collected from the shiftless, the idle, and the vicious. A great part of them are foreigners. Every young man hired to work upon a farm aims steadily to acquire a farm for himself, and hardly once fails of the acquisition." (Dwight's *Travels*, Vol. IV. p. 335.) Except in some few spots near large towns, there is scarcely any land rented. The price is generally so low, that a small addition to the sum necessary for stocking a farm suffices to purchase it; and even where the value is higher, an individual who has money enough to stock a large farm will prefer buying one of half the size. Of the State of New York, only one-fifth, and of the whole inhabited country east of the Mississippi (excluding Michigan and Florida), only about one-tenth part is yet cleared and cultivated. Of course, the best soils are first used, and, till population thickens and produce rises, soils of the second and third quality will not repay the expense of culture; and as a necessary consequence, those of the first quality yield no rent. The farms occupied by the owners are seldom large, because, where wages are high, agriculture cannot be advantageously conducted on an extensive scale; and the large property in land occasionally acquired by an individual is soon broken up by division among

United States.

his children. Thus situated, the rural population certainly enjoy a greater share of happiness in the United States than in any other country in the world. They are exempted from the fluctuations incident to the commercial and manufacturing classes; they feel none of the evils of dependence, and are far above want; without possessing that wealth which engenders idleness and vanity, and often becomes a snare to its possessor. They have the means of settling their families well, without making great sacrifices; they live in the enjoyment of all the substantial comforts of life, and can look forward to old age with less anxiety and apprehension than any class of men in any other country.

The system of agriculture is necessarily less perfect in the United States than in Britain. Where prime soils can be had for almost nothing, where the price of labour is high, and that of produce low, the elaborate and costly modes of cultivation adopted in Britain cannot be advantageously applied. Some English farmers, who have gone out to America with an impression that large gains might be made by introducing our improved system of husbandry, have found themselves disappointed. Something the Americans may learn from us; but, till the country is more densely peopled, it will be more profitable to cultivate a large surface rudely than a small one laboriously. In the middle and eastern States, however, where produce brings a considerable price, farming is carried on with care and skill. In Pennsylvania, which holds the first rank as an agricultural state, in New York, Massachusetts, Connecticut, and Jersey, agricultural societies exist, and much attention is paid to the cultivation of the indigenous grasses and to the use of manures. Grazing is well understood in New England, where it is considered the most profitable species of farming. Much care has been bestowed on the breeding of sheep, and Merinos are now spread over all the northern, middle, and western States.

Hutchins reckoned that  $\frac{1}{6}$ ths of the land east of the Mississippi was covered with a strong fertile soil. The remaining  $\frac{5}{6}$ ths were occupied by lakes and rivers, or consisted of land too poor or too steep for cultivation. In 1811, Mr Blodget estimated the land under "actual improvement" to be 40,950,000 acres, or  $5\frac{1}{4}$  acres for each inhabitant, a proportion which is found to be near the truth. In 1798, when a census was taken for the imposition of a tax, the quantity of land valued and taxed in sixteen States was one hundred and sixty-three millions of acres out of three hundred and eight millions, the estimated value of which was four hundred and seventy-nine millions of dollars. The value *per acre* varied widely. In Connecticut it was fifteen dollars *per acre*, in Pennsylvania six, in Georgia three-fourths; but the average for the whole was about three dollars. The value of the houses was estimated at a hundred and forty millions of dollars, or two-sevenths of that of the land. When new returns were procured in 1814, the value of lands and houses conjointly had risen from six hundred and twenty to one thousand six hundred and thirty millions of dollars. From these two documents, which afford a curious view of the state and growth of property in the republic, we find

United States.

that, in the sixteen States organized, in 1798, rather more than one-half of the surface was the property of individuals. In the old States, such as Massachusetts and Connecticut, the appropriated land embraced nearly the whole surface; in New York, it embraced about four-sevenths, in Georgia one-third. The number of acres appropriated for each individual of the population was about thirty, of which five and one-half or six acres were cleared or "improved." The estimated value of the houses and lands was at the rate of 125 dollars for each individual of the contemporaneous population in 1798, but had risen to 200 dollars in 1814. Supposing every other species of property to have grown as rapidly, the rate of increase would be about  $6\frac{1}{4}$  *per cent. per annum*, and the capital of the country must double itself in  $11\frac{1}{4}$  years, or it increases twice as rapidly as the population. With a stationary population, the rate of increase would be 5, 4 *per cent.*, and the period of doubling  $13\frac{1}{4}$  years. We have no similar data for other countries to found a comparison on, but we are certain that such a velocity of accumulation is unknown anywhere else.

The value of houses, lands, and slaves, in 1814, was, according to the returns, 1902 millions of dollars. If we add one-eighth for omissions and under estimates, and for Louisiana, which was not included, with 50 millions for state lands, and two-thirds additional for all other species of property (this being nearly the proportion in Colquhoun's estimate for Britain); namely, agricultural stock, manufactured goods on hand or in progress, ships, harbours, canals, roads, public buildings, &c.—the whole will be 3550 millions of dollars, equal to 780 millions Sterling, or about L. 95 for each individual of the contemporaneous population. Colquhoun's estimate for Britain was 2700 millions Sterling, or L. 150 for each inhabitant. This gross amount, increasing at the rate of 6 *per cent.* would become 1400 millions Sterling in 1824, and the annual increment, or the value added to the national capital every year, should be about 80 millions Sterling. The whole annual produce of the national industry, which affords a saving of 80 millions, cannot be less than four times as much, or 320 millions, that is, L. 32 *per head* on the population. Colquhoun's estimate for the British Isles in 1812, was 430 millions, or L. 24 *per head* on the population. (Colquhoun, p. 55, 65.) These calculations are founded on the returns taken as they stand. It is probable, however, that the second census would be more accurately taken than the first, and that the growth of the national capital is not quite so great as it appears.

The large profits which farming yields, and the high price of labour, are discouragements to manufactures and manufacturing industry in the United States. The arts in which they have made the greatest progress, are cabinet and coach making, shoemaking, steam-boat and ship building, the construction of mill machinery and wooden bridges, and bank-note engraving. Piano-fortes are respectably made. The saw gin for cleaning cotton from the husks, and the nail-making machine, are American inventions. The woollen manufacture is almost entirely domestic, being carried on in the houses of the farmers; but the cotton manufac-

Manufac-  
tures and

Arts.

United States.

ture is partly conducted in large works. This last, as well as several other manufactures, received a great stimulus during the late war with Britain, but they have declined since the peace, though a few of the works then established are still carried on with advantage. It was computed by a Committee of Congress, that the cotton manufactures, which consumed only 10,000 bales of the raw material in 1810, consumed 90,000 in 1815; employed 100,000 hands (10,000 men, 66,000 women and girls, 24,000 boys), and produced 81,000,000 yards of cloth, valued at 24 millions of dollars. The value of the woollen manufacture was estimated at 19 millions of dollars, and was supposed to employ 50,000 hands constantly, and as many more occasionally. (*Reports of 13th February and 6th March 1816.*) According to the returns made in the census of 1810, the whole annual value of the manufactures of the United States was 127,694,602 dollars. But Mr Tenche Coxe calculated, that, making allowance for articles omitted or under-estimated, the true value would not be less than 172,700,000 dollars (L. 37,500,000.) If the increase in this branch of industry has kept pace with the growth of the population, it should now amount to 240 millions (L. 52,000,000.) But the value of the manufactured goods imported in 1821 was only 32 millions of dollars, and deducting five millions re-exported, the quantity which remains for home consumption is only 27 millions, or *one-ninth* part of the whole. It is against this small fraction of the annual consumption that such an outcry is made; and that the Americans, borrowing our exploded maxims, are fencing themselves by such an apparatus of protecting duties, prohibitions, and restrictions. For the purpose of comparison we may mention, that Chaptal estimated the annual value of the French manufactures, in 1820, at L. 72,800,000, which is probably a good deal under the truth; and that Colquhoun estimated that of the British manufactures at L. 116,000,000 in 1812, exclusive of the raw material. Of the manufactures returned in the census of 1810, valued at 127,694,602 dollars, the following were the most considerable:

Goods manufactured by the loom	39,500,000 dollars.
Machinery of various kinds.....	6,100,000
Hats .....	4,300,000
Iron manufactures.....	14,360,000
Leather .....	17,900,000
Distilled and fermented liquors...	16,530,000
Wooden articles .....	5,540,000

According to the returns, there were 153 iron furnaces, 34 rolling and slitting mills, 325,392 looms, 122,647 spindles for yarn, 141,191 distilleries, producing 22,977,167 gallons of spirits from grain, and 2,827,625 from molasses, 132 breweries, 208 gunpowder mills. Nearly one-fourth of the manufactures were in Pennsylvania; Massachusetts ranks next, then New York, Virginia, Maryland, Connecticut, North Carolina, New Jersey, Vermont, Ken-

tucky. It may be remarked, that the effect of the high price of labour in discouraging manufactures is counteracted by three circumstances. 1. The United States being far distant from Europe, the expence of freight, and still more that of inland carriage, makes a material addition to the prime cost of all bulky or heavy articles. 2. As the use of machinery comes to be substituted more and more for manual labour, the disadvantage of high wages gradually vanishes; and the Americans, who possess great mechanical genius, have the means of procuring steam and water power to an unlimited extent. 3. The American women prefer working in factories to domestic service, which they consider degrading; and hence female labourers are not scarce, and may be procured at moderate wages.\*

The commerce of the United States has made much greater progress than their manufactures. The wars and convulsions of Europe, consequent on the French Revolution, threw a great proportion of the general carrying trade into their hands; and in the interval, from 1790 to 1807, their exports increased from 20 millions to 108 millions of dollars. But the Berlin Decrees and the British Orders in Council gave a sudden check to this growing prosperity, and the foreign trade of the United States has never since reached so great a height. The following table shows the amount of exports, distinguishing foreign from domestic produce, from 1800 to 1821:

Years.	Exports.	Domestic Growth, Produce, or Manufacture.	Foreign.
1800	70,971,780	31,840,903	39,120,877
1801	94,115,925	46,377,792	46,642,723
1802	72,483,160	26,182,173	35,774,971
1803	55,800,033	42,205,961	13,594,072
1804	77,699,074	41,467,477	36,231,597
1805	95,566,021	42,387,002	53,179,019
1806	101,536,963	41,253,727	60,283,236
1807	108,343,150	48,699,692	59,643,558
1808	22,430,960	9,433,546	12,997,414
1809	52,203,283	31,405,702	20,797,531
1810	66,757,970	42,366,675	24,391,295
1811	61,316,833	45,294,043	16,022,790
1812	38,527,236	30,032,109	8,495,127
1813	27,855,997	25,008,152	2,847,845
1814	6,927,441	6,782,273	145,169
1815	52,557,753	45,974,403	6,583,350
1816	81,920,452	64,781,896	17,138,556
1817	87,671,566	68,313,500	19,358,066
1818	93,281,133	73,854,437	19,426,696
1819	70,142,521	50,976,838	19,165,683
1820	69,691,669	51,683,640	18,008,029
1821	64,974,382	43,671,894	21,302,488

The imports have not been regularly published. For 1821, they amounted to 62,585,724 dollars in

\* Seybert, 6, 8. Mellish, 90. Warden, III. 262. Fearon, 389, &c.

United States. value, from which deducting bullion and articles re-exported, there remain for domestic consumption 43,696,405, of which the leading articles were,—

Woolens .....	6,959,000	Wines .....	1,632,000
Cottons .....	6,665,000	Spirits .....	1,640,000
Silks .....	3,430,000	Molasses .....	1,708,000
Linens .....	2,318,000	Teas .....	1,081,000
Iron and iron-ware .....	2,969,000	Coffee .....	2,403,000
Hemp, &c. ...	1,271,000	Sugars .....	1,905,000

The imports and exports were chiefly from the following countries :

	Imports from	Exports to
Russia .....	1,852,199	628,894
Holland .....	1,938,958	3,694,205
British Isles .....	25,087,108	20,777,479
France .....	5,989,940	5,528,559
Spain .....	542,393	539,746
Portugal .....	356,116	147,792
Italy and Malta .....	973,463	1,099,667
Sweden .....	759,753	217,181
Cuba .....	6,584,849	4,540,680
Hayti .....	2,246,257	2,270,601
Spanish South American Colonies ...	1,114,117	1,037,735
Hanse Towns and Germany .....	990,165	2,132,544
Brazil .....	605,126	1,381,760
China .....	3,111,951	4,290,560
British East Indies .....	1,530,799	1,966,279
British West Indies ...	927,346	265,102

The following table (from Carey and Lea's *Atlas*) shows the tonnage of each State, and of the whole Union, in 1821 :

Maine .....	122,856
New Hampshire .....	23,335
Massachusetts .....	316,069
Rhode Island .....	39,314
Connecticut .....	45,724
New York .....	244,338
New Jersey .....	34,533
Pennsylvania .....	83,575
Delaware .....	10,043
Maryland .....	125,149
District of Columbia .....	24,677
Virginia .....	63,326
North Carolina .....	38,864
South Carolina .....	29,944
Georgia .....	14,662
Mississippi .....	6,131
Louisiana .....	38,815
Kentucky and Ohio .....	598
Michigan .....	665

1,262,618

Registered tonnage employed in foreign trade .....	619,029
Enrolled and licensed tonnage employed in coasting trade .....	588,014
Ditto ditto in fisheries .....	55,575

1,262,618

It will be seen from these tables, that since the peace, foreign produce or manufactures constitute about one-fourth, and domestic three-fourths of the exports. The leading articles are raw produce. Cotton forms about 46 per cent. of the domestic exports; wheat, Indian corn, and other breadstuffs, 15 per cent.; tobacco, 13 per cent.; lumber, bark, &c. 6 per cent.; horses, beef, &c. 5 per cent. The leading imports are the fine products of the loom in wool, cotton, silk, linen, or articles not raised in the country, such as tea, coffee, sugar, wine. In hemp, iron, and leather, the imports are small. About four tenths of the whole imports come from Britain, and only about one-tenth from France.

The internal and coasting trade of the United States has increased more rapidly than their foreign commerce, and is undoubtedly far greater than that of any other state with an equal population. The enrolled and licensed tonnage, which was only 184,000 tons in 1795, had risen to 588,000 in 1821. It is now equal to the registered tonnage, of which it formed only one-third in 1795, and it has more than tripled in the period in which the population has doubled. The Hudson, which is the great channel of inland trade, for districts containing nearly two millions of inhabitants, has, according to Palmer and other recent travellers, 2000 sloops and schooners plying upon it,—a greater number than belonged to all Scotland in 1810. The Delaware, Susquehanna, Potowmac, and other large rivers farther south, are all the scene of an active and growing traffic. The majestic Mississippi, though it does not yet rival the Hudson, must in time far surpass it. The invention of steam-vessels has done for the navigation of rivers what the invention of sails did for that of the ocean. The United States had the honour of introducing this admirable improvement; and they make a more extensive use of it than any other country in the world. In the evidence given by Mr Perkins of New York before a Committee of Parliament in 1822, he stated there were about 300 steam-boats employed in the United States, and of these about one-half used high pressure engines. On the Mississippi alone, according to a recent American paper, there were 78 in 1823, measuring 14,338 tons, or about 184 tons on average.

The great facilities for inland navigation which nature has bestowed on the United States, have been improved by art; and considering the sparseness of the population, the number of canals which have already been formed is truly surprising. The Middlesex Canal, in Massachusetts, completed many years ago, is 31 miles long and four feet deep, and cost 700,000 dollars. The Lake Champlain Canal, which joins the Hudson at Fort Edward, is 22 miles long, and four feet deep, and was to be finished in 1823. A canal, 22 miles long, connects Chesapeake Bay with Albemarle Sound. Another of the same length joins Santee and Cooper Rivers in South Carolina. Besides these, ten or twelve canals, from one mile long to seven or eight, either finished or in progress, are enumerated by American writers. Many others are projected, among which are one of 28 and another of 22 miles in length, to connect the Rariton and Delaware rivers with Chesapeake Bay. If these were completed, an uninterrupted inland navigation

United States.

would exist for nearly 500 miles, from New York to Pamlico Sound. But the greatest work of the kind in the United States, and perhaps in the world, is the Great Canal which unites the Hudson with Lake Erie. It begins in the neighbourhood of Albany, passes along the course of the Mohawk River to Rome, then proceeds westward, keeping at a variable distance of 10, 15, or 20 miles from Lake Ontario, and terminates in Lake Erie at Black Rock, a mile from Buffalo. It is 362 miles long, 40 feet wide at top, 28 at bottom, and four in depth. Its termination in Lake Erie is 564 feet above its origin in the Hudson; but the aggregate rise and fall is 654 feet, and is effected by 81 locks. The canal, which is the property of the State, was begun in 1817, and finished in 1823, except about 30 miles, which will be completed in 1824. It is believed the whole expence will rather fall short of the estimate, which was five millions of dollars (L. 1,100,000). The freight is about a dollar *per* ton, each 100 miles, to which is to be added tolls at the following rates: for salt and gypsum 50 cents—grain, flour, &c. 150 cents—and merchandise, 300 cents *per* ton for each 100 miles. This great undertaking, almost equaling in magnitude, and far surpassing in utility, the most magnificent works of Imperial Rome,—executed by a State with a million and a quarter of inhabitants, affords a gratifying proof of the energy and enterprise generated by free institutions.

Banks.

No country has suffered so much from the mania for banking, or been so deluged with depreciated and worthless paper money, as the United States. There were 400 banks in existence in 1819, three-fourths of which probably had only fictitious capital. They were got up generally by knots of speculating tradesmen and lawyers, often without depositing a dollar beyond what was necessary to pay for paper and engraving. Even the respectable banks issue notes for a single dollar; but in the western country, where these establishments were on the worst footing, notes were issued for a half, a quarter, an eighth, and even a sixteenth of a dollar! The immense mass of worthless paper money they put into circulation created a transient and hollow prosperity, which was followed by a degree of embarrassment and distress that had almost the character of a general bankruptcy. The paper bubbles burst, one after another, with extraordinary celerity, and involved multitudes in ruin. Of a hundred banks in Ohio, Kentucky, Tennessee, and Indiana, there were only two whose notes were received at the land offices. In some of these States acts were passed by the legislature suspending legal proceedings to compel payment of debts. It may be imagined what an extraordinary derangement was produced in the state of property, when the circulating medium was reduced in three years (1815 to 1819) from 110 to 45 millions of dollars.\*

Revenue.

The United States present the singular spectacle of a government supported without internal taxes. The public revenue is derived entirely from the customs and the sale of public lands; for the post-office

merely defrays its own expence, and the sums that stand in their accounts as bank dividends, are but the produce of money previously invested. Small imposts, indeed, are levied for the support of the state governments, but these on an average probably do not exceed one dollar for each inhabitant, or ten million of dollars for the whole Union. The public revenue of the federal government amounted to 14,264,000 dollars in 1821, and to 20,232,427 for 1822. For 1823 they were estimated at 20,444,035 dollars, and for 1824 at 18,550,000, composed of the following items—

United States.

	Dollars.	In British Money.
Customs -	16,500,000	L. 3,630,000
Public lands -	1,600,000	350,000
Bank dividends -	350,000	77,000
Arrears & repayments	100,000	22,000
	<u>18,550,000</u>	<u>L. 4,079,000</u>

The estimated expenditure for 1824 was—

	Dollars.	In British Money.
Civil, Diplomatic, and Miscellaneous,	1,814,057	L. 399,000
Military department, including Fortifications, Ordnance, Pensions, Army, Militia, and Indian department,	5,122,268	1,127,000
Naval service, including gradual increase of the Navy,	2,973,927	654,000
Public debt, -	5,314,000	1,169,000
	<u>15,224,252</u>	<u>L. 3,349,000</u>

The public debt, which amounted to 123,630,000 of dollars in 1816, was reduced to 90,177,962 dollars (L. 19,800,000 Sterling) at the 1st January 1824; one-fourth of the whole having been paid off in the intervening eight years. A farther reduction of ten millions will, it is supposed, take place at the 1st January 1825, from an accumulating balance or surplus in the Treasury. The Democratic party, however, would have acted more wisely, had they availed themselves of the existence of this debt to repair their great error—the abolition of internal taxes—by keeping up some of the duties imposed during the late war, till the whole amount was discharged. When peace brings an entire exemption from taxes, the burdens, which even a just and necessary war imposes, will be borne very impatiently, and the government will not receive the support necessary to carry it through an arduous struggle. During the last short war in 1813 and 1814, the clamours of the people, in consequence of burdens and embarrassments not half so serious as are patiently borne in Europe, had almost compelled the government to sacrifice the national honour by accepting peace on shameful terms.

The free spirit of the Americans, and still more, Army.

\* Report of Secretary of Treasury on Currency, 1820. Flint's Letters from America, Nos. 16 and 17.

United States.

their parsimonious habits in public matters, make them averse to the existence of a large standing army. In this, as in some other things, they, perhaps, carry their opposition to the practice of the European States too far. Regular troops can be effectually opposed only by regular troops; and, in the present condition of the world, the state which denudes itself of efficient defensive weapons, may be said to court disaster and disgrace. To supply the want of a small number of regular troops by masses of raw militia six times as numerous, who leave their homes under great personal and pecuniary sacrifices, is not economy, but the reverse,—to say nothing of the certain losses it occasions, and the humiliations these produce to natural feeling. After the close of the late war, the Congress, by act of 3d March 1815, fixed the strength of the regular army at 9980 men, but it has since been reduced, and its actual strength, as reported to Congress in March 1822, was—

Engineers .....	23
4 Regiments of Artillery .....	1977
7 Do. of Infantry .....	3367
Ordnance men .....	53
	5420

The army is distributed at about fifty posts and places along the sea-coast and inland frontier. The pay of a colonel of infantry is seventy-five dollars (L. 16, 10s.) per month, and six rations a day—of a captain, forty dollars and three rations—of a first lieutenant, thirty dollars and three rations—of a sergeant, eight dollars and one ration—of a private, five dollars and one ration. The aggregate expence of the army in 1822 was 1,929,179 dollars, and the average charge for each man 299 dollars (L. 66). The Americans have a well conducted military academy at West Point, on the Hudson, where 230 cadets, between the ages of fourteen and twenty-one, are instructed in the branches of knowledge necessary to form engineers. The period of service is five years, and the expence for each pupil is about 500 dollars per annum. But the chief military force of the United States is the militia, consisting properly of all the males between eighteen and forty-five, but always less or more deficient. A return at the close of 1823 makes the number amount to 993,281. When called out to the field they have the same allowances as the regular army, and their period of service is limited to six months. The American militia are under the charge of the State governments. They generally, if not universally, elect their own officers, and are said to be very indifferently disciplined.\*

The exploits performed by the American ships in the last war have made the navy extremely popular. The United States had not a single ship of the line ready for sea till near the close of the contest, and they have now twelve built, or building. In 1816, Congress appropriated a million of dollars per annum for eight years to increase the navy. In

United States.

1821, the grant was reduced to 500,000 dollars, and continued till 1825. A small number of vessels are kept always in commission, and stationed partly in the West Indies, and partly in the Mediterranean. According to an American journal, the strength of the navy in November 1823 was as follows:—

	In Commission.	In Ordinary.	Building.
Ships of the Line ...	1	6	5
Frigates .....	3	4	5
Smaller Vessels .....	12	2	—
Steam Frigates .....	—	3	—

To these must be added vessels on the lakes, viz. two of 74 guns on the stocks, one of 44, one of 36, one of 32, one of 26, two of 24, with eleven smaller vessels, and fourteen gun-boats, some of which are much decayed. The American vessels are built larger than ours of the same class, and carry heavier guns. Their steam frigates are an improvement yet untried in actual service, but which may probably lead to an important change in maritime war. The navy is managed by a Board of three commissioners, and a secretary. A small tax of twenty cents per month is paid by all officers and seamen, both in the navy and merchant service, for the relief of sick and disabled mariners, part of whom are lodged in hospitals.

The American Federal Government is a genuine Government. democracy, admirable for the simplicity and harmony of its principles, and supposed by many to produce a greater amount of public good and private happiness than any political institution that ever existed. Its establishment was an experiment which was deemed doubtful and hazardous, even by the enlightened men who were its founders; but, to use the words of Mr Monroe, "it has succeeded beyond any calculation that could have been formed of any human institution;" and it now exhibits a model in the science of government, which approaches more nearly to ideal perfection than statesmen or sages had dreamed of.

The legislative power is vested in a Congress, consisting of a Senate and House of Representatives. The senate is composed of two members from each State, chosen for six years, by the respective State legislatures, and the seats of one-third are vacated every two years. A Senator must be thirty years of age, an inhabitant of the State for which he is chosen, and he must have been a citizen of the United States for nine years. The members of the House of Representatives are chosen every second year by the people, in the proportion of 1 for every 40,000 inhabitants, excluding the Indians, and two-fifths of the people of colour. The electors being the same as for the most numerous branch of the State legislature, the right of suffrage may be described as universal. A representative must be an inhabitant of the State for which he is chosen, of twenty-five years of age, and he must have been seven years a citizen

\* Warden, III. 402, &c. Nile's Register, 16th and 30th March 1822, and American Papers.

United  
States.

of the United States. No law can be passed without the concurrence of both Houses. When that is obtained, it is presented to the President, who, if he approves, signs it; if not, he returns it, with his objections, for the reconsideration of Congress, and it cannot in that case become a law without the concurrence of two-thirds of the members. The executive power is vested in a President, who is elected for four years, by a number of electors chosen for the purpose by the people, distinct from the senators and representatives each State sends to Congress, but equal to them in number. The President must be a native born citizen of the United States, and not under thirty-five years of age. His salary is 25,000 dollars (*L.5500 per annum*).

The Congress has power to impose taxes and duties to pay the debts and provide for the defence of the republic; to borrow money; to regulate commerce; to establish uniform laws of bankruptcy and naturalization; to coin money, and fix the standard of weights and measures; to establish post offices; to constitute tribunals; to declare war, raise and support an army and navy; to call forth the militia; and to provide for organizing, arming, and disciplining it. The President is commander-in-chief of the army, navy, and the militia, when in active service. By and with the advice of the Senate (two-thirds concurring), he makes treaties, and nominates ambassadors, ministers, consuls, and judges.

The Federal Judiciary consists of the Supreme

Court (formed of a chief judge and six associate judges), which sits at Washington, and a District Court in each State, in which one judge sits. The chief judge has 4000 dollars a year, an associate judge 3500, and a district judge from 800 to 2000. The Supreme Court, deriving its authority from the Constitution, is not bound by the proceedings of the legislature farther than they are consistent with that charter. It has, accordingly, set aside several acts of the State legislatures, and even of Congress itself, on the ground that they contravened an express provision of the Constitution, by annulling or impairing the validity of contracts. The laws of the United States are substantially the same with the laws of England, but differently modified in each State by causes springing out of the physical, moral, and political situation of the people.

There is no national church in the United States; each congregation pays its own minister, and each sect regulates its own concerns. Notwithstanding this, wherever the population is dense, the means of religious instruction are as ample as in any country in Europe. It is computed that there are above 8000 churches, or religious societies, of which about 3000 belong to the Baptists, 2000 to the Methodists, 1200 to the Congregationalists, 900 to the Presbyterians, 600 to the Episcopalians, and a small number to the Catholics, Dutch Lutherans, Universalists, and other sects.

## VACCINATION.

Vaccination. THE *Encyclopædia* contains no separate article on the subject of Vaccination; but *Small-pox*, in the article MEDICINE (224), is concluded, with a notice of its introduction. We now propose to give a condensed view of the subject, and of the present state of medical opinion on the merits of Vaccination.

On the 14th of May 1796, Edward Jenner, a physician in Berkeley, near Gloucester, first applied to the arm of a healthy boy of eight years, by means of two superficial incisions, the morbid fluid secreted by a sore on the hand of a dairy-maid, who had contracted Cow-pock from the udders of her master's cows. The seventh day after the operation he had uneasiness in the arm-pit; on the ninth, became chill, had headache, lost appetite, was otherwise indisposed, and spent a restless night; but the following day, was free from complaint. Of the appearances of the local sore, we have no particular information, but that it resembled a bluish pustule, was surrounded by an erysipelatous or red circle, and afterwards formed scabs and eschars without producing other inconvenience. The object of this operation, which was chiefly experimental, was to ascertain the degree of immunity from small-pox contagion thus obtained; and on the 1st of July, therefore, variolous matter was inserted by inoculation, but without being attended with the usual disease; and when this was repeated some months after, the same effect was observed. Further inquiry was prevented, in consequence of the disease disappearing till the spring of 1798, when it once more made its appearance among the dairies of Gloucestershire. On the 16th of March, a child of five and a half years was inoculated with matter taken from the teat of an infected cow. On the 6th day after the operation, he was unwell, and vomited; but on the 8th appeared to be in his usual health. The progress of the local vesicle was similar to that of the former case, except in the absence of the livid or bluish tint observed. On the 28th of March, the disease was transferred from the arm of this patient to that of William Pead, a boy of eight, with the usual appearances, and especially the red circle, quite similar to that which is observed after variolous inoculation. To this redness Dr Jenner first applied the term *areola*. From the fluid produced in this case, several patients, both young and adult, were infected, and in all, the phenomena appear to have been pretty uniform; or, at least, with deviations so trifling, that they do not require particular notice. From the previous conclusions derived from persons who had been affected with cow-pox, and who resisted the variolous action, it might be presumed to be unnecessary to try how far those who had been artificially subjected to cow-pock could resist small-pox. To render his conclusions more certain, however, Dr Jenner tried it without effect on his first vaccinated patient; and with the second and last cases, his nephew was equally unsuccessful.

Such were the first trials of the effect of vaccine fluid on the human subject; and so far as they were carried by Dr Jenner, the results appeared to warrant the main conclusion, that the process of vaccination renders the human body unsusceptible of being acted on by the infection of small-pox. We must not omit to remark, however, that the *Inquiry* of Dr Jenner shows that he had formed, in the year 1798, no very distinct idea of the nature and phenomena of the vaccine disease, or, at most, that he imagined it to be identical with small-pox. It is evident, that, in his early researches, Dr Jenner believed that the origin of small-pox could be traced to the heel of the horse; and that though cow-pox was a disease transmitted from the horse, and modified by the system of the cow, it was *specially* identical with, or allied to *variola*, and differed in variety only. On this principle, he applied to it the denomination of *variola vaccinae*; and it is obvious that he was confirmed in this opinion by observing, that a person who had suffered the vaccine disease is not liable to be affected with small-pox contagion.

The singular facts announced in the *Inquiry*, and their more extraordinary application, recommended by Dr Jenner, attracted much attention; and shortly after its publication, Dr Pearson of St George's Hospital commenced an investigation, in which he collected many facts tending to render its history more complete, and to demonstrate its power in enabling the human body to resist the contagion of small-pox. In one point only did he disagree with Dr Jenner,—the origin of the cow-pox from the heel of the horse; in denying which, he was supported by the arguments of Dr Parr, and the experiments of Mr Simmons of Manchester.

Dr Pearson's examination of this subject was followed at no long time with *Further Observations* by Dr Jenner, the chief purpose of which was to confirm the conclusions delivered in the *Inquiry*, and to establish the leading fact, that vaccination renders the human system unsusceptible of small-pox. As some cases had come to light of this disease occurring in the persons of those who had undergone the vaccine disease, Dr Jenner, by ascribing these to a *spurious form* of cow-pock, conceived he had removed any exception to the truth or general accuracy of his doctrine. Of the spurious form, he conceived there were four sources: The 1st, From pustules on the nipples or udder of the cow, without specific virus. 2d, From matter, which, though originally specific, had undergone decomposition. 3d, From an ulcer proceeding from the genuine disease, but at an advanced stage. 4th, From matter generated by the human skin, after contact with peculiar morbid matter, formed in the system of a horse. These various positions Dr Jenner illustrated or proved by arguments, either direct or analogical, derived chiefly from similar phenomena, exhibited in the progress of variolous poison. Of these arguments, the most import-

**Vaccination.** ant are those which relate to differences or variations induced in the genuine poison by elementary decomposition, or by the process of ulceration, after the period of the proper lymph was passed. The propriety of admitting the 4th cause as a source of ineffectual vaccination is intimately connected with the origin assigned to cow-pox by Dr Jenner; for if a modifying effect on equine matter be assigned to the udder, it is impossible to suppose that the former can have a genuine influence on the human constitution, or on the small-pox.

The interest excited by the singular facts disclosed in Dr Jenner's writings, with the confirmation which they derived from Dr Pearson's inquiry, quickly gave rise to the wish of bringing the truth of the doctrines thus advanced to the test of experiment; and men were eager to ascertain what practical advantage was likely to result from the introduction of cow-pox artificially excited, and the substitution of a mild disease, derived from a brute animal, for a human malady, which, even in the most favourable circumstances, was liable to be attended with much danger. The merit of this practical application was reserved for Dr Woodville, who, in January 1799, introduced into the Small-pox Hospital of which he had the charge, vaccine matter derived from the milk-cows in Gray's Inn Lane. On the 21st January 1799, Dr Woodville applied, by a single puncture, to the arms of seven persons, matter in a *purulent state*, obtained from the teats of a cow labouring under the disease; and on the 24th he infected three persons with vaccine matter taken from the sores of Sarah Rice, a young woman who had contracted the disease in the course of milking. From these two sources, this physician affected 600 persons, of various ages, with the vaccine disease; of whom the circumstances of 200 are recorded in the *Reports* of his practice. In most of these patients, inoculation of small-pox matter was performed at various periods after the application of the vaccine disease, with a view to ascertain the genuine power of the latter, and to discover what influence it could exercise in deranging or modifying the progress of the variolous disease. The general result of these experimental cases may be given in the following terms: 1st, In about three-fifths of the whole number, the operation was followed, at intervals of various length, by an eruption of pustules, more or less numerous, over the cutaneous surface. (P. 151.) In one case, in which these pustular eruptions appeared about the seventh day, and was attended with convulsive motions, death took place on the eleventh day after insertion of matter. (P. 149.) 2d, In persons on whom vaccine matter and variolous matter are inserted at different arms, but at the same time, the local affections resulting from each application preserved their characteristic appearances through the whole course of the disease. (P. 139.) 3d, When the two fluids (variolous and vaccine) are rubbed together, and inserted by a lancet dipped into the mixture, sometimes the vaccine pock, sometimes a variolous pustule, has been produced, the

respective characteristics being in either case retained throughout; and in some rare instances, both diseases are thus produced. (P. 104.) 4th, If inoculation be performed alternately with variolous and with vaccine matter every day till fever take place, both inoculations make progress; and as soon as the whole system is disordered, they appear to be all equally advanced in maturation. (P. 145.)

It cannot now be doubted, that, though the experiments of Dr Woodville have thrown much light on the nature of the vaccine disease, and on its true influence over the poison of Small-pox, yet they were conducted without due regard to the legitimate mode of ascertaining the truth. 1st, The patients on whom Dr Woodville operated were exposed to the atmosphere of a small-pox hospital, where, of all other places, the air was most likely to be thoroughly impregnated with variolous effluvia. 2d, In the greater number of the patients vaccinated by this physician, inoculation with variolous matter was performed at a period a great deal too early to ascertain the counteracting force of the vaccine disease. 3d, It is doubtful whether, in his selection of vaccine matter, he chose the proper period; for he informs us that the matter was taken from the animal in a *purulent state*, which we now know is very unfavourable to the success of the vaccinating process. (Jenner, p. 113.) 4th, Dr Woodville formed a very erroneous notion of the nature and distinctive characters of the vaccine and variolous diseases; not only in considering, like Dr Jenner, "the vaccine *variola*, and the human *variola*, to be only varieties of the same disease, rather than distinct species" (p. 152, 153); but in the further error of supposing Cow-pock capable of exciting a general affection of the skin. Our more perfect knowledge of Cow-pock has shown, that its *action on the skin* is confined to those spots only to which it is applied, and that it never hitherto has been known to produce general eruptions similar to itself. This error is intimately connected with another committed by Dr Woodville, in believing cow-pox capable of communication by effluvia, or by any other manner than that of absolute contact.\*

The results of Dr Woodville's experiments, so different from those obtained by Dr Jenner, were communicated to this gentleman at first apparently in a private manner (p. 129); and, in order to submit the matter to a fair trial, London vaccine fluid was transmitted to Dr Jenner, who inoculated several persons, (twenty,—eighteen at the manufactory, two previously, p. 133), without any other difference of effect than a greater degree of local inflammation, and with an eruption of a few red spots, which quickly disappeared without maturing.

It was in a subsequent publication, however, that Dr Jenner undertook the task of examining the experiments of Dr Woodville, and showing the circumstances from which the different results proceeded. The anomalous appearances he here ascribed to the action of variolous matter which had crept into the constitution with the vaccine; 1st, Because a great

\* Jenner, p. 86. *Further Observations*. Pearson, p. 50, Proposition VI.

number of the persons vaccinated by Dr Woodville were inoculated on the 3d or 5th day with variolous matter; 2d, Because, in the Gloucestershire dairies, where cow-pox had been known time out of mind, no pustular eruptions had ever been known to appear on the general cutaneous surface; and 3d, Because, though the proportion of pustular cases was at first 3 out of 5, they afterwards diminished so much, that of the last 100 persons inoculated, only seven had pustular eruptions.

To bring this matter to a more satisfactory determination, Dr Jenner procured fluid from an affected cow belonging to a farmer in Kentish Town, and transmitted it to Dr Marshall, who was then extensively engaged in vaccination in Gloucestershire. Under his care 423 persons had undergone, in the course of some weeks, the process of vaccination; and of this number it appears that 127 were infected with the matter sent by Dr Jenner from London; yet Dr Marshall positively states, that neither in the first set of cases, nor in those thus vaccinated, had any pustular eruption occurred, or been observed. (P. 158, 159.) In one case only did a pustule appear in the elbow of the inoculated arm, and it matured. The same result was obtained in the vaccinations conducted by Dr Jenner personally, and in those by his relation, Mr Henry Jenner. (P. 162.) From these facts, therefore, Dr Jenner concluded, that the vaccine matter obtained from an animal reared in the neighbourhood of London was not different, at least in its effects, from that which was obtained from animals affected with the disease in Gloucestershire. It is proper to notice, however, that Dr Jenner acknowledged that some of his correspondents had mentioned the appearance of eruptions at the commencement of their vaccinating operations; but "in these cases," he remarks, "the matter was derived from the original stock at the small-pox Hospital."

Another point in this inquiry, viz. the immunity from subsequent small-pox afforded by vaccination, came under the investigation of Dr Jenner at this period. Although the evidence upon this point had been already conclusive, yet, as various facts were constantly coming to the knowledge of Dr Jenner to prove the protecting power of vaccination, and its influence in counteracting small-pox, even when the system is under variolous action, he published several of these proofs, in order to show the true power of the vaccine disease. These cases are in every respect similar to many others which have since occurred, and it is unnecessary to bestow further notice on them. Shortly after, a second Tract appeared from Dr Woodville; and though his object was to refute the assertion of Dr Jenner regarding the adulteration of the vaccine matter of the Small-pox Hospital in London, his testimony was of the utmost advantage to the anti-variolous power of vaccination. It will be remembered, that, towards the conclusion of Dr Woodville's vaccinations, the varioloid or pustular eruptions which had been so frequent at the beginning, began gradually to diminish, and finally almost to disappear; and in the further prosecution of this physician's experimental investigation, we find that these eruptions were found al-

most never to succeed the process of vaccination. In his *Observations on the Cow-pox*, which appeared in July 1800, many important facts were disclosed, which tended directly to unfold the true properties of the vaccine disease, and the relation which subsists between its action and that of small-pox. It is unnecessary, at this distance of time, to enter into the merits of the charge which Dr Woodville conceived Dr Jenner brought against the vaccine matter of the Small-pox Hospital, and of the mode in which Dr Woodville attempted to repel it; and as we do not conceive it tended, in the slightest degree, to illustrate the question, of the cause of the pustular appearances after vaccination in that Hospital, it may be passed over in silence. The more important and not less interesting subjects of Dr Woodville's pamphlet were the fact of the disappearance of these pustular eruptions, and the circumstances under which they disappeared. 1. The vaccine matter of the Small-pox Hospital, after which pustular eruptions had so generally appeared, was employed in two situations in the country, in vaccinating more than 1000 persons, in two of whom only did any pustules, resembling those of small-pox, appear. 2. Though Dr Woodville denied adulteration of the vaccine matter with matter of small-pox, he was, however, obliged to admit, that the cases of vaccination in the Hospital "had been, and still continued to be, influenced by some adventitious cause, independent of cow-pox." This was proved by the results of vaccination practised in the hospital by matter obtained from many different animals: by the results of vaccination practised on persons at their own houses, in various districts of London, by Dr Woodville and other medical gentlemen who employed the matter from the same stock; and more decidedly by the result of vaccination practised on three patients at Hospital, with matter obtained from the same cow, from which Dr Jenner took the matter employed in the vaccinations of Dr Marshall. In one of these patients no fewer than 100 varioloid pustules appeared; and other instances, equally conclusive, appear to have taken place. 3. Among many children residing in various parts of London, to whom Dr Woodville transferred the disease, through the medium of the Hospital matter, no instance of matured pustules had occurred during the twelve months succeeding to the introduction of the practice. 4. The pustular eruptions which had been so common after vaccination, at the early period of the practice, became much less frequent. Of 310 cases of vaccination, after the publication of the first *Reports*, 39 were attended with pustular eruptions in the following order:—In the first 100, 19; in the second 100, 13; and in the last 110, only 7; and at a later period they appeared in the proportion of 3 or 4 only in the 100.

From these various facts, Dr Woodville very justly drew the inference, that the cases vaccinated at the hospital differed from those vaccinated elsewhere, in being placed in the centre of a variolated atmosphere, to the operation of which the pustular eruptions were to be ascribed. In forming this conclusion, however, he committed the singular paralogism of supposing that the cow-pock excited these pustules, or was, in

Vaccination. other words, the direct cause of the varioloid disease; and he, therefore, imagined that the variolated atmosphere of the Hospital, the existence of which he willingly admitted, was only a co-operating cause. It is obvious that this extraordinary doctrine owed its birth to the previous opinion which, we have already remarked, he formed of the nature of the vaccine disease,—that it was not confined to the spot to which lymph is applied, but was capable of extending its action over the whole cutaneous surface. Had Dr Woodville not allowed himself to be misled by this erroneous principle, there is a strong presumption, from the language in which he expresses himself, that he would have arrived at the true conclusion which recent and accurate observation have at length succeeded in establishing.

When the facts above noticed are considered, we conceive it will not be difficult for our readers, if they keep in mind the points originally ascertained by Dr Jenner, respecting the local action of the vaccine disease, and the necessity of its being communicated by application of its proper fluid, to comprehend, that the pustular eruptions over the cutaneous surface of the vaccinated were not excited, as Dr Woodville concluded, by cow-pock, nor arose, as Dr Jenner suspected, from mixture of variolous matter with vaccine, but were the immediate results of the variolous atmosphere in which the individuals were placed. The different degree in which they appeared in the early and more recent period of Dr Woodville's vaccinations, will form no valid objection to this conclusion, when it is remembered, that the frequency of pustular eruptions in the first vaccinations, depended on the abundance of variolous effluvia necessarily existing in a small-pox Hospital, or the saturation of its air with this matter;—while their subsequent rarity was the effect of its gradual diminution by the division or diminution of its cause, and of its final extinction by the substitution of another disease. That admixture of variolous matter had not taken place, there is every reason to conclude; as we know, from the experiments of Dr Woodville, that it is impossible to produce in this manner a mixed or neutral disease, but that each preserves its distinctive and appropriate characters. The post-vaccine pustular eruptions should have suggested another conclusion,—that the vaccine disease does not entirely extinguish the variolous, or prevent its appearance, but renders it milder, less tedious, and, to a certainty, destroys the chance of its fatality. That this conclusion escaped Dr Woodville is by no means wonderful, especially when it is remembered, that the general belief of the profession was, that a second attack of small-pox was an occurrence so rare, as to be considered next to impossible. "Happy is it for mankind," says Dr Jenner, "that the appearance of the small-pox a second time on the same person beyond a trivial extent, is so extremely rare, that it is looked upon as a phenomenon. Indeed, since the publication of Dr Heberden's paper on the *Varicellæ* or chicken-pox, the idea of such an occurrence, in deference to authority so truly respectable, has been generally relinquished." It is worthy of

Vaccination. remark, also, that Dr Woodville not only admitted this inference in its fullest extent, but applied it, in the same unlimited construction, to the immunity afforded by vaccination against the variolous disease. "This circumstance, then," says he, (that is, the immunity afforded by cow-pox), "appears to be as much a general law of the system, as that a person having had the small-pox, is thereby rendered unsusceptible of receiving the disease a second time." (*Reports*, 155.) On this subject it is only necessary to remark, that Dr Thomson of Edinburgh has shown, in the most convincing manner, that the non-recurrence of small-pox has been admitted on far too slender grounds; and that the writings of physicians contain sufficient evidence, that small-pox may occur at least twice, if not three times, in the person of the same individual. Had this important proposition been known, or admitted to its just extent, at the period when vaccination was introduced, there is reason to believe, that the appearance of pustules on the persons of those who had been vaccinated, would not have occasioned so much perplexity to the friends of the practice, or triumph to its enemies, and that its true merit would have been more justly, and not less quickly appreciated.

During the progress of Dr Woodville's experimental inquiries, the merits of vaccination began to be understood, and the practice had been coming into general and extensive use, both in London and in the more remote counties of England. The publication of Dr Woodville's second Tract may be regarded as marking the epoch of its general admission, and announcing the adoption of it in Public Charities, and in the practice of the most eminent surgeons. The united efforts of Drs Pearson, Lettsom, MM. Moore, Ring, &c. and other philanthropic or professional individuals, contributed powerfully to its general introduction; and though opposition was at first shown, the more candid and intelligent part of the profession at length admitted the advantages of vaccination over artificial variolation. It is unnecessary to bestow any notice on the objections which were urged by writers of a certain class, and which, as they were founded on prejudice have now sunk into a well merited oblivion. The efficacy of vaccination, as an anti-variolous agent, was, indeed, so generally admitted, and the practice was so widely introduced, that its benefits were extended, in the course of a few months, to many thousand persons, in different towns of the kingdom; and were conveyed by different channels to Paris, to Vienna, to most of our colonies, and to the United States of America. In the meantime, the impression created at first by the appearance of pustules in the vaccinations of Pearson, Woodville, Ring, Dunning, Goldson, and others, seemed to have worn off completely, or to have been forgotten; and the great bulk both of the profession and of the public considered the occurrence of small-pox eruptions, after vaccination, either impossible or so rare as to be regarded as a physiological anomaly. The general credence of this maxim did not arise from the complete absence of pustular eruptions after vaccination, as we shall see, but evidently depended on the idea of the distinctive nature of chicken-pox, or the inaccurate notions of small-pox itself then prevalent; and also on the great

Vaccination. expectations formed of the powers of the vaccine disease in counteracting or extinguishing the poison of small-pox.

The truth of these assertions is abundantly confirmed by the subsequent history of vaccination, and of small-pox eruptions occurring either sporadically or epidemically in various parts of the country. We have already seen, that Dr Jenner was led to infer the absolute immunity from small-pox conferred by the process of vaccination, and to consider the vaccine disease so similar to small-pox, that when the human body had undergone the former, it was no longer liable to attacks of the latter. This doctrine was admitted by many professional persons in terms much more unlimited, if possible, than those in which it had been understood, even by its first promulgator. Dr Jenner was, indeed, inclined to qualify it in some degree; but the professed partizans of vaccination, from a well-meant idea, perhaps, that it would weaken public confidence, and render the adoption of vaccination less easy than was consistent with public safety, opposed every approach to such an opinion, and defended strenuously the anti-variolous properties of the vaccine disease.

It is scarcely necessary to mention here, that, since the time of Dr Heberden, a vesicular, or vesiculopustular disease, not unlike small-pox in its local appearances and constitutional symptoms, had been distinguished from it as a separate affection under the name of *Chicken-pox*. Almost all the instances of pustular or small-pox-like eruptions which were observed after vaccination, were referred to the head of chicken-pox; or if they were not sufficiently similar to this disease, to be referred to it, they were admitted to be small-pox, but occurring only in persons on whom vaccination had been imperfect in action, or improperly performed. In other instances, the appearances of the eruption were so fallacious, or the ideas of the observers so little precise, that of those who saw them some contended that they were chicken-pox, and others small-pox.

Although cases were not unfrequent in which practitioners of experience and knowledge were obliged to admit the occurrence of small-pox, in the persons of those who had undergone vaccination, Dr Willan appears to have been the first who had courage and patience sufficient to examine the matter coolly, and to show the exact weight of evidence by which it was supported. In the fourth section of his interesting treatise on *Vaccine Inoculation*, this physician has collected several cases which occurred to himself, or within his own personal observation, and referred to those collected by authors since the introduction of the practice of vaccination. As many of these were thought by several physicians and surgeons to have been chicken-pox, and as this indicated want of precision in the characteristics of the disease, Dr Willan, in his seventh section, gave an account of those marks by which he conceived chicken-pox in three different forms could be recognised. And it is by no means unimportant to observe, that the distinctions which Dr Willan established among the various forms of cutaneous inflammation, and the precision with which he expected the eruptive diseases to observe those characters, prevented him from tak-

Vaccination. ing those general and more just views of post-vaccine small-pox in which physicians have since coincided. Little change, therefore, appears to have taken place in the opinions of professional men, farther than to admit the occurrence of chicken-pox, and of a modified small-pox after vaccination; or, if the appearances were too strong for this construction, to consider the vaccination as imperfect and ineffectual. Such, in general, was the tenor of the *Reports of the Vaccine Institutions*, of our various public charities, and in some instances of scientific Colleges; and so unanimous and decided was the language of those bodies, that individuals were unable to form their own opinions on objects of daily observation, or were prevented from expressing them by the fear of being regarded as either incapable of observing, or unable to communicate the genuine and perfect form of the vaccine disease; or, in short, as enemies to a practice, the pious object of which was to counteract a foul and fatal disease, and to increase the probable chances of human life.

The publication of these *Reports* did not, however, cause the complete extinction of post-vaccine small-pox, or prevent the appearance of the disease; and cases continued to occur even after the process of vaccination was admitted to be satisfactory, and in the observations of physicians, whose knowledge and experience gave no ground for doubting the fact. It cannot be expected, that all these cases have been published, or that their full extent can now be ascertained; for it is easy to see, that they would be often disregarded, and sometimes studiously concealed. To understand, however, the merits of vaccination, and its influence in controlling small-pox, sporadic or epidemic, it is indispensably necessary, for the unbiassed inquirer, to be aware of the evidence which may be obtained from the cases of variolous or varioloid eruptions in the persons of the vaccinated already recorded. It was to Dr Thomson of Edinburgh that was reserved the merit of ascertaining the true powers of vaccination, and of placing in a just point of view the benefits conferred on mankind by the introduction of the practice. The cases of pustular eruption, in the persons of the vaccinated, were scattered in various works, their evidence was neglected and overlooked, and the inferences which they tended to establish were not understood, or they were disregarded. It was only by comparison with those afforded by subsequent observation, that real advantage could be derived from them. An opportunity for this investigation occurred in 1816, when small-pox began to appear in one or two points of the country, and eventually spread over a considerable extent. Had the appearance of small-pox been confined to one or two towns or villages, it is not unlikely that they might have been viewed in the same indifferent light in which they had been since 1800, and that they would have continued to give rise to the same doubts, and similar imperfect explanations, which they had previously done. Appearing, however, as they did in many different points of the Island, successively or simultaneously, and, as was afterwards learnt, in several countries of Europe, the public mind became alarmed, professional curiosity was

Vaccination awakened, and physicians resumed the task of investigating a disease which, it had been fondly but prematurely hoped, vaccination would render practically unknown. In the year 1816, accounts of small-pox,—occurring in persons of all kinds, those exposed to contagion and those not exposed,—the vaccinated, the unvaccinated, the imperfectly vaccinated,—and even in those who had previously undergone the disease, began to be transmitted to the various periodical publications; and during the four subsequent years, the epidemic continued to appear or subside at intervals, and to furnish matter for the observation and reasoning of physicians, whether vaccinators or inoculators. In Edinburgh, and various parts of Scotland, they prevailed to a very considerable extent, attended with a mortality of 1 in 4 to the unvaccinated and unvariolated, and affecting the vaccinated in the rate of 1 to 2 nearly. Though the individual cases have been observed and collected by many different professional gentlemen, it is to Dr Thomson almost entirely that we owe the thorough investigation which the subject has at length undergone, and from whose researches have been derived the certain and satisfactory results which we now possess. This physician, equally distinguished by acuteness of reasoning, sound judgment, and habits of accurate observation, examined personally the whole of the cases almost that occurred in Edinburgh and its vicinity; and where the distance rendered personal examination inconvenient, procured, from intelligent correspondents, correct accounts of the phenomena. It was in a letter addressed to the Editor of the *Medical and Surgical Journal* in September 1818, that Dr Thomson first expressed his opinion of the incorrectness of the prevalent doctrines on the effects of the vaccine disease, and of the common doctrines on small-pox, chicken-pox, and modified small-pox, with which these opinions were intimately connected.

In consequence of the publication of this letter, and a subsequent one containing a series of queries tending to illustrate or ascertain the doubtful points of the subject, a great body of evidence was in a short time collected, and in various forms laid before the profession. The results, with those of Dr Thomson's very extended observation of the disease, may be found in the two works which he has recently published; and in which he has canvassed, with the greatest judgment, and in the most liberal manner, all the problematical and assumed points of the subject.

The circumstances, however, which merit particular attention, in this recent epidemic, are the strong confirmation of the truth of many of the earliest observations since the introduction of vaccination; and especially of those views which we have already shown, the experimental inquiry of Dr Woodville, if properly understood, would have suggested. The varioloid disease, at least in Edinburgh and its vicinity, and so far as can be discovered, throughout Scotland, occurred in three classes of persons; those who had undergone neither small-pox nor cow-pox, those who passed through small-pox, and those who had undergone, in a satisfactory manner, the process of vaccination.

In these several classes of patients, it was found that the different forms of varioloid eruptions described as pure small-pox, modified small-pox, and chicken-pox, co-existed during the epidemic, and were capable of producing each other. It was observed, for example, that individuals who, after vaccination, presented eruptions, termed modified small-pox or chicken-pox, were capable of communicating to those who had neither undergone vaccination, nor had been affected with small-pox, an eruptive disease which could not be distinguished by competent judges from small-pox. (Thomson, *Varioloid Disease*, p. 45, and p. 207.) It was also found, that the same contagion or the same infecting source, produced cases of coherent or confluent small-pox in the unprotected; and cases of chicken-pox, or modified small-pox in the vaccinated, or even in persons who had many years before passed through small-pox. The obvious conclusion from these facts is, that if small-pox and its modifications, and chicken-pox be admitted to derive their origin from a contagious source, that contagion must be one and the same for all; and that whatever opinion be formed as to the nosological differences of small-pox and chicken-pox, as pustular or vesicular eruptions, it must be granted, that they spring from the same generating cause; and that the variations in appearance depend on something totally unconnected with the contagious agent which causes their formation. There is no means of accounting for this relation of diseases, Dr Thomson has justly remarked, unless in supposing two contagious causes, specifically distinct, existing at the same time, and in the same place, and producing their respective effects on the persons of those exposed. But, independent of the general improbability of this doctrine, it might be easily shown, that of two such distinct contagious causes as we have supposed, not only would one or other have produced its characteristic effects on a much greater proportion of the community; but these effects could not possibly have been so frequently interchanged, or so uniformly have appeared in place of each other, as the experience of the recent epidemic has shown. To render this point, which is liable to be misunderstood, especially by our general readers, more obvious and intelligible, let it be supposed, as was done after the time of the elder Heberden, that chicken-pox arose from one morbid cause, and small-pox from another, utterly different; and let it also be admitted, that both contagions are occasionally found to appear in a community epidemically; then it must follow, that the disease which depends on chicken-pox contagion ought at all times, and in all cases, to preserve distinctive characters, and that small-pox should likewise preserve the same unvarying peculiarity of appearance. No approach of characteristic features, much less complete interchange, ought to take place; and the phenomena of chicken-pox ought to be as distinct from those of small-pox, as they are from those of plague, of itch, or of leprosy. These results, however, which unquestionably flow directly from the admission which we have made of distinct contagious agents, were completely contradicted by every thing observed in the variolous epidemic of 1817-

Vaccination. 18, and the subsequent years; and it is impossible to resist or deny the conclusion, that small-pox, chicken-pox, and modified small-pox, owe their birth to the same source, are children of the same parent, and members of the same family.

It may be expected, since we adopt the conclusions to which the modesty and good sense of Dr Thomson induce him to apply the name of *hypothesis* only, that we ought to prove, by direct arguments, the nosological error committed by Dr Heberden, in separating chicken-pox as a distinct genus from small-pox. To this we reply, that it is not by direct arguments that the point can be proved; for, without subjecting to strict scrutiny the characters on which Dr Heberden assigned a separate place to chicken-pox, it is now agreed that the minute distinctions of Dr Willan completely failed in establishing a satisfactory difference in the generating causes of chicken-pox and small-pox. Had Dr Willan indeed given a due degree of weight to the fact which he states in the very outset of his 7th section, that he had seen since 1800 no fewer than 74 cases of varicella, which were by many persons deemed small-pox after vaccination, and the remarkable counterpart of this fact, that the eruptions described in his 4th section were at first regarded as chicken-pox by several physicians and surgeons, he must have been convinced of the impossibility of establishing a difference between these diseases on no other ground than that of their vesicular or pustular character. We adhere in this case to the acknowledged maxim in philosophical inquiry, to admit no more causes than are adequate to account for the effect; and while we allow the excellence of the distinctions introduced by Dr Willan as mere terms for characteristic appearances, we deny the inference that has been drawn, that these are adequate to establish a nosological difference. It is, indeed, with those who contend for the specific or generic difference of small-pox and chicken-pox, that the task of proving this rests; and it is incumbent on them to bring forward more substantial proofs and arguments than those on which the distinction has been admitted, and which are undoubtedly inconclusive.

Though the hypothesis to which we have here adverted, evidently does not require to be supported by different arguments derived from other quarters, yet it is equally due to the merit of Dr Thomson, and to that of other physicians, whose observations have led them to similar researches, to remark, that the identical origin of small-pox and chicken-pox is an opinion at length adopted by others, both in this country and on the Continent. Our limits prevent us from entering largely or particularly into this division of our subject; but we must not leave it, without adverting to the opinions expressed by MM. Berard and De Lavit of Montpellier, and Dr Hodenpyl of Rotterdam. Small-pox prevailed epidemically in the former city in 1816, and in the latter, and various parts of Holland, in 1817 and 1818; and in both situations, not only were chicken-pox at the same time extensively prevalent, but the phenomena of both diseases were found to be frequently and generally interchanged; and they were, in other respects, so similar to those observed in Edinburgh

and various parts of Scotland, that the conclusions which we have above noticed were irresistible. It is interesting to observe, not only as a confirmation of the accuracy of Dr Thomson's views, but as an example of different observers, unconsciously and unknown to each other, forming the same conclusions from similar researches, that MM. Berard and De Lavit were led to announce, in 1818, at Montpellier, an opinion which Dr Thomson first published in September 1818, at Edinburgh; and that Dr Hodenpyl of Rotterdam, in the course of the same year, was led to express his opinion, that chicken-pox was the primitive form of small-pox, and could be shown to originate from the same parent stock.

The view which the hypothesis of Dr Thomson enables us to take of varioloid and varicellous eruptions, and of the relation in which they stand to the vaccine disease, suggests a more satisfactory explanation of the phenomena which these eruptions present, and of the *sequences*, as we may name them, which they observe, than either denying the anti-variolous efficacy of vaccination, or supposing it imperfect, or improperly performed; or, indeed, than any other explanation hitherto adopted by physicians. It has been a prevalent error with medical observers to attach a degree of mathematical precision to the phenomena of eruptive diseases, and especially to those of the several forms of variolous or varicellous eruptions; and to imagine that their appearance and effects in the human body were regulated by laws of the utmost precision. The mixture of truth and of error exhibited in this doctrine is the reason of its admission without question, and its propagation without resistance. For while it is certain that extended observation proves that small-pox may affect the same individual more frequently than once, and that its first occurrence by no means secures the individual from a second attack, it is undeniable that the maxim is so far correct in general terms, that the disease is rarely known to appear twice with the very same characters, or with the same severity in the same individual. While, therefore, the first appearance of the disease does effect some change in the susceptibility of the frame to a second attack, it is obvious that this change is neither so marked nor so uniform, nor so absolute as the opinions of physicians had hitherto represented it to be. (Thomson's *Varioloid Epidemic*, p. 201.) It is precisely this error which has given rise to mistakes so general on the anti-variolous power of vaccination. It was the same mode of thinking that led the more zealous partizans of vaccination to expect a form of action more absolute and determinate, and an immunity more complete than the laws of organic motions ever sanctioned. It may be urged, indeed, that to predicate what the laws of organic motions are, or what they sanction, is a mere *petitio principii*, a sort of assumed principle, unless we adduce facts or arguments to prove what we advance; but is it to be doubted, that the actions of living bodies, and the influence exercised on living objects by exterior agents, are not regulated by laws mathematically exact? Has the most sedulous observer ever been able to trace or to demonstrate that certainty of action, or regularity of effect, which is exem-

Vaccination. plified in matter endowed with properties merely physical? Has attentive observation of the phenomena of living bodies, and, above all, of those of the human frame, not shown, that the results of every process are influenced by numerous circumstances, and modified by causes too complicated to allow their operation to be appreciated? Such, we may now conclude, has it been with the practical application of the vaccine disease, and such will it be with every measure which is adopted in medicine, with too little regard to the character of those objects on which the physician has to operate.

It must now be obvious, that vaccination is not the positive and exact action, which it was thought to be at the moment of its introduction; and, that it does not effect on the human body that absolute change which it was originally represented to do. That it does effect a change of some kind must be inferred, not only from the phenomena of those forms of small-pox which occur in the persons of the vaccinated, but also, in a more conspicuous and forcible manner, from the phenomena of vaccination performed a second time on the same individual. The vesicle produced in Mr Bryce's test-vaccination, or even any vesicle thus produced at a period subsequent to the first one is evidently a modified cow-pock (*vaccinella*), and bears the same relation to the first cow-pock, that modified small-pox or chicken-pox bear to the first attack of small-pox.\* But the occurrence of this *vaccinelline* vesicle must be regarded as a direct proof that the change is not absolute, but limited; and the occurrence of pustular eruptions, whether variolous or varicellous, in the vaccinated, must be admitted in evidence to establish the same conclusion. It may, indeed, be regarded as the genuine result of extensive observation, conducted in the most accurate manner, that the process of vaccination is not exempted from those uncertainties which have long formed the impediments to exact principles and positive rules in medicine; and that it does not render the human body universally or absolutely unsusceptible of subsequent attacks of small-pox in various degrees of severity.

Nor will the results to which we have cursorily adverted, admit of more easy explanation by the objection which has so often been sought in the interruption or imperfection of the process of vaccination. It is not to be denied that vaccination has been sometimes rendered imperfect by one or other of the ordinary causes, and that it is reasonable to think that persons thus vaccinated are more likely to be subsequently affected with small-pox than those in whom the vaccine process has been regular and complete; but no proof has been afforded that post-vaccine small-pox was confined to those in whom vaccination was imperfect; and in innumerable instances in which small-pox succeeded vaccination, the latter process was ascertained to be as perfect as in those who were not subsequently the subjects of varioloid eruptions. Had there been any force in the circum-

stance, it was reasonably to be expected that the degree of modification should be in the inverse ratio of the perfection of the vaccine process, and in the direct ratio of the interval between the period of vaccination and the appearance of varioloid disease. No result of this kind has been observed either in the Edinburgh epidemic, or in those described by Mr Cross and MM. Berard and De Lavit, or that of Holland, as described by Hodenpyl; nor has it appeared, that those affected with modified small-pox had been vaccinated with fluid taken at an improper time, or had cutaneous eruptions, or other disturbing causes, to a greater extent than those in whom varioloid eruptions never took place.

The experience of the recent epidemic has amply confirmed the conclusion, that vaccination, though quite regular, and performed in the most satisfactory manner, does not preclude a subsequent attack of small-pox, in one or other of its forms, and does not furnish a positive immunity any more than natural small-pox, or artificial variolation. And it is satisfactory to think that this inference has been substantially admitted by the unbiassed declaration of the Board of the *National Vaccine Establishment*.

But while we are obliged to qualify the doctrines of the original vaccinators with these limitations, it cannot fail to be gratifying, not only to the lovers of truth, but also to the sincere and temperate friends of vaccination, to find that the great practical results are not materially affected; and to know that our experience has shown the benefits of the practice in as strong a point of view as its most sanguine advocates could wish. Though the process of vaccination does not positively prevent a subsequent attack of small pox, it has been incontestably proved, that it not only mitigates the severity of such future attacks, but diminishes the chance of their fatality almost to a fraction, or an infinitely small quantity. The clearest method of showing the truth of this proposition is, by contrasting the mortality of cases of secondary small-pox, that is, occurring either after the natural or artificial disease, with the mortality of cases of small-pox occurring after vaccination. According to the observations of Dr Thomson, the proportion of deaths in secondary small-pox, if two infections be admitted, is 1 in 25, and if one infecting source be admitted, 1 in 75 only (*Varioloid Epidemic*, p. 202); but death has taken place in small-pox after vaccination in one only of above 330 cases, which is between  $\frac{1}{3}$  and  $\frac{1}{5}$ , or, in exact terms,  $\frac{1}{2\frac{1}{2}}$  less frequently than it occurs in iterated small-pox. If to this statement be added the allowance that must be made for the numbers of the vaccinated who were *not* at all affected with subsequent varioloid eruptions, the rate of post-vaccine eruptions terminating fatally will be reduced to an infinitely small quantity. In the varioloid epidemic described by Mr Cross, at Norwich, of 10,000 vaccinated persons,  $329\frac{6}{11}$  were affected with

\* See Dr Thomson's remarks at the conclusion of Dr Stoker's *Letter* in No. 77 of *Edin. Med. and Surg. Journal*.

vaccination. variolous eruptions,\* of whom only one case appears to have terminated fatally. The coincidence of this proportion with that given by Dr Thomson induces us to place the greatest confidence in its accuracy; and we feel certain, that if observations be made on future cases, even this proportion will diminish. At present, in estimating the decided superiority of vaccination, in diminishing the chance both of danger and of death from small-pox, two elements must be kept in mind:—1st, That all the vaccinated are not affected with small-pox or varioloid eruptions, and even the proportion of these appears to be smaller than in instances of inoculation, or any other method except natural small-pox;—and, 2dly, That of those so affected, not above one case in 330 terminates unfavourably. These results establish, in the most convincing manner, the powers of the vaccine disease as an antidote to the ravages of small-pox; and cannot fail to prove, to the satisfaction of its most sceptical opponents, that the strong and plausible objections to which the recent epidemic was at first calculated to give rise, have been of no other use than to place the merits of vaccination in a clearer and more forcible point of view.

It is in its power of diminishing the mortality of small-pox, therefore, that the superiority of vaccination consists; and it is on this strong ground only, that its partisans and true friends should defend its general adoption. Let the governors of charitable institutions, the guardians of the poor, the parents of families, and the public at large, be convinced of the facts which we have now stated, and the inferences derived from them, and it cannot be doubted that the practice of vaccination, instead of being opposed, or apprehended as a source of new and disastrous maladies, or ridiculed as a useless and inefficient ceremony, will be dispassionately estimated, and raised to that rank among the benefits of science, to which its happy effects unquestionably entitle it. It is surely superfluous to show the duty incumbent on all ranks to extend vaccination as widely as possible, if for no other reason than to preserve the lives of their relatives during the prevalence of epidemic small-pox,—and to say that, in proportion as vaccination is general, the infection of small-pox must be gradually limited and confined, until it is almost entirely expelled from the habitations of men. There cannot be a doubt, that every variolous epidemic, especially in large cities, is developed much more readily in consequence of the practice of variolous inoculation, or suffering children to be exposed to the infection of natural small-pox; and it is equally certain, that where vaccination is general, the introduction of variolous infection is either difficult, or when introduced, it is disarmed of its gigantic strength.

Two points connected with this subject have

Vaccination. given rise to so much speculation, that we must not omit to notice them, however briefly. The introduction of vaccination, and its effects in diminishing the mortality of small-pox, have been naturally supposed by many writers to have a great influence on population, and to increase the numbers of the living at different periods of life. Some have gone so far as to imagine, that in this respect it would operate to an injurious extent, and increase the population of most countries beyond the limits of subsistence; while others have conceived, that an increase of different diseases would be necessarily occasioned by the extirpation of small-pox; and that this would be one of the great means employed by Providence, to keep the rate of population in due proportion to the means of procuring food.

There cannot be a doubt that one of the most salutary effects of the practice of vaccination is to diminish very much the mortality occasioned by small-pox, and consequently to augment, in a considerable degree, the numbers of the community in which it is practised. To understand distinctly, however, in what manner this diminution is operated, it is requisite to show the effect which unresisted small-pox exercises on the population of a community, and for this purpose we employ a familiar example derived from estimates formed in this country. In the year 1795, when the population of Great Britain and Ireland was estimated, according to the returns, at 14,724,000, it was calculated that the numbers annually destroyed by small-pox, according to one estimate, amounted to 34,260, and according to another, to 36,000. If we state it in round numbers at 35,000 as a medium, this mortality amounts to the enormous proportion of 1 in every 420; or, in other words, small-pox destroys annually 1-420th part of the whole population of the country. As it is obvious, that the population can be increased by the number of births only, as it is diminished by the number of deaths, it follows, that to obtain a just notion of the effect of small-pox in diminishing the population, we must deduct this 1-420th part from the numbers which are annually added by births. According to the most correct observations and calculations, it appears, that at the period which we have selected, the proportion of births to the whole population of the country was as 1 to 30, or for every 30 persons in the whole nation, only one is annually added by births. (Malthus, Book II. chap. 9, and *Additions*.) It therefore follows, that as the proportion destroyed by small-pox must be taken out of this annual addition to the numbers of the country, the fraction of  $\frac{350}{420}$  or  $\frac{1}{12}$  annually, will represent the exact rate at which small-pox retards the increasing numbers of a country, or acts as a positive check on population. It is to be remarked, that the elements on which these calculations are

\* Mr Cross nowhere gives this proportion exactly; but it is correctly deduced from the average of his data in the following manner:—Dr Yellowly, from inquiries similar to those of Mr Cross, estimates the vaccinated in Norwich at  $\frac{1}{4}$  of the whole population, or 10,000; and of 603 persons under the personal observation of Mr Cross, 200 had small-pox, 91 had been vaccinated, 2 of whom had modified small-pox, and 1 chicken-pox; the remaining 312, who had small-pox formerly, had no subsequent eruption during the epidemic; consequently, we have the following proportional numbers, 91 : 3 :: 10,000 : 329 $\frac{1}{3}$ .

Vaccination. founded, are derived from that period at which it is generally admitted that small-pox inoculation was most favourably conducted, and at which the smallest number of deaths is supposed to have taken place from small-pox, since it first began to prevail as a destructive epidemic among the habitations of men.

We have given this familiar, and we trust quite intelligible view of the influence of small-pox on population, because we fear, if we had attempted to follow the circuitous, but very beautiful and accurate train of analytic calculation, by which Duvillard has investigated the subject, we should have added much to the length of this article, without interesting our general readers, or affording information universally intelligible. This author, who has investigated the matter in the soundest manner, and with the most profound applications of modern analysis, has given formulæ and tables for almost every possible question which the inquiry can suggest. He appears, on the principles which he has adopted, to have made the destructive or depopulating power of small-pox greater even than we have shown it to be. He gives the following results of his analytic investigations, as applied to the population of France. According to the law of mortality, in the natural state, the

	Both sexes and all ages.
Entire population of France is - -	28,763,192
Those already passed through small-pox,	23,212,998
Those not passed through it are -	5,450,194
Those that die without passing through it,	667,749
Those who must have it at some period,	4,782,445
Those that take it and escape, - -	4,445,041
Those that die of it,	337,404

that is, 85,685 in the current year.

Now, in the natural state, 85,685 children, add to the population of 28,763,194, only 337,404 individuals, and by immunity from small-pox, they furnish farther 3,492,583, which raises the population to the number of 32,255,776. If such be the influence of vaccination, in increasing the numbers of mankind, it might appear, a conclusion sufficiently natural to imagine, that the population of many nations would increase so rapidly, as to exceed the means of subsistence, and overcrowd the space allotted for occupation. In point of fact, however, notwithstanding the operation of this cause, for at least twenty years, in several countries of Europe and America, the result has not been realized; and, though the nations of Europe were perhaps never so populous as at the present moment, this evidently depends on other causes than that which prevents the mortality of small-pox.

It is a fact which has been said to be ascertained by many respectable observers, that while the destruction occasioned by small-pox has been much di-

minished, other diseases, equally fatal, have been found to be more prevalent. We will not question the correctness of this observation, or deny it absolutely, but we must have it established on more certain and unquestionable facts and documents before it be admitted. But whether this be the case or not, it is not difficult to see that vaccination cannot possibly render the human race immortal; that children, and adults also, must die of other diseases besides small-pox; and that, as the numbers of a young community are increased by being snatched from one disease, a greater number must be preserved to become a prey to others.

We by no means, however, countenance the opinion that the mortality of other diseases will increase exactly in the ratio in which that of small-pox has been diminished; nor do we believe that this mortality is a necessary result of vaccination. It is found, on the best authority, that a perceptible diminution of mortality in children under ten years has taken place in every situation in which vaccination has been general; and it must therefore be concluded, that the number of individuals living at that age is augmented. It is obvious, however, that, unless we lose sight of the most fixed principles in the theory of population, this will have but a trifling effect in increasing the numbers of mankind, when it is remembered that it is ready to be counteracted by the positive checks to which we already alluded, but especially by the preventive check on which the number of marriages and of births depends.

VAN DIEMAN'S LAND. See the Article AUSTRALASIA, in this Supplement. It appears, from a Statement of the Receipt and Income raised in this colony, and of the Disbursement thereof, for the last seven years, printed, by Order of the House of Commons, in June 1823, that the former was L.23,915, and the latter L.20,055.

## VEGETABLE PHYSIOLOGY.

**Vegetable Physiology.** **I**N the Article ANATOMY, VEGETABLE, of this Supplement, we exhibited a view of the structure and forms of vegetables through their several gradations from the seed to the perfect plant. We then observed, that, to accomplish these changes of form, the operation of certain external agents was required, by the aid of which alone the several functions of vegetables could be instituted and maintained. It is to these functions that we have now to direct our attention,—the description of which properly constitutes what is termed the PHYSIOLOGY of plants.

In a subject of such great extent and difficulty, and concerning which so much diversity of opinion prevails, we must bespeak the indulgence of our readers, not only for the imperfections, but for the errors into which we may fall. From the narrow limits, too, within which we are necessarily circumscribed, we are constrained to give rather the results than details of experiments; to avoid all discussion of disputable points; and to reject many practical illustrations and much historical narration. Neither have we room to enlarge on the general distinctions between plants and animals; on the importance of vegetables in the scale of being; their geographical distribution; the nature of their living power or vitality; their sensibility, perceptivity, and many other properties which have been ascribed to them. Our aim will be solely confined to give, as concisely and perspicuously as we are able, such a general view of the leading and more important functions of the more perfect vegetables as the present state of our knowledge will permit. To the article above mentioned we shall continually refer for such anatomical details as our physiological explanations may require: and, proceeding on the views of structure there delivered with regard to the Elementary Systems of plants, we shall follow nearly the order observed when treating of their individual members and organs, and commence our discussions with a description of the germination of seeds.

### CHAP. I.

#### OF THE GENERAL FUNCTIONS OF VEGETABLES.

##### SECT. I.

##### *Of the Germination of Seeds.*

In the article referred to we have detailed pretty fully the anatomy of seeds (§ 173), and described particularly their tunics and the nucleus contained within them. This nucleus consists of the organized parts, or embryo, and the inorganic matter destined to afford it nourishment. In size and figure the organized parts vary much in different seeds, and thereby constitute an embryo more or less developed or perfect. In its more complete forms, this embryo consists of the radicle, the stem, and the plume. The stem, however, is often not distinguishable. When present, it connects the radicle with the plume, and the place of its junction with the radicle is denominated the *neck* of the embryo. In the progress of evolution, the radicle descends to

form the root, and the plume rises and constitutes the first bud of the new plant.

Beside the organized parts just mentioned, there are others called cotyledons, which derive their origin from the embryo. Many seeds have two cotyledons, and some more than two; others have only one, and some seeds have no cotyledon. When present, the cotyledons exhibit different forms; and between them and the embryo, a vascular communication is established, as may be seen in the dissection of a bean, represented in Plate XV. fig. 26, of Vol. I. Beside vessels, the cotyledons are partly made up of cells, within which the nutrient matter of the seed is contained. In some seeds, however, this matter is only partially contained in the cotyledons; in others, as that of wheat, it is wholly contained in a cellular tissue produced from the inner tunic. Lastly, the cotyledons of some seeds rise above the ground during germination, and perform the function of leaves: in others they continue beneath the soil. In all seeds their existence is temporary, for they perish after having yielded their nutrient matter to the embryo.

This matter, called *albumen* by Grew and Gærtner, is a secretion made by the vessels into the cells during the formation of the seed; and, though itself inorganic, is contained in an organized tissue. It is of various colour and consistence in different seeds. Its bulk, compared with that of the organized parts, is, in some seeds, very small; in others very large. Its appearance in the cells of the cotyledon of the bean, and of the inner tunic of wheat, is represented in Plate XV. figs. 24 and 25; and described in § 203, 204, 205, of our former article.

Such is a brief notice of the more important parts which construct the seed, and which it is necessary clearly to understand before we can properly appreciate the nature and effects of the actions that go on during its germination. In considering these actions, we have to inquire into the circumstances or conditions in which the seed requires to be placed—the agents which then act upon it—the change of quality and condition which these agents themselves suffer, and the effects which, in consequence, they produce in the seed—and, lastly, the physiological phenomena which thence arise, and terminate in those alterations of form and structure which constitute the evolution of the seed.

In general, seeds, when placed to grow, are buried more or less deeply in the earth, but this condition is not essential; for they readily shoot forth and display their forms, when confined in vessels of air. In whatever situation their germination is attempted, a certain temperature, and a certain portion of moisture, are necessary to its commencement; and the access of air is afterwards required to carry on the process. We have, therefore, to inquire into the operation of water, heat, and air, in commencing and carrying on the germination of the seed.

Water, in the first instance, penetrates the tunics of the seed apparently by simple attraction or imbi-

**Vegetable Physiology.**

tion; and the force with which this attraction is exerted is well illustrated in the experiments of Boyle and Hales. They filled strong bottles with dry beans or pease, over which water was poured, and the bottles were then closely stopped. As the seeds imbibed the water, they readily burst the bottles asunder; or, if small iron cylinders, closed by a plug, were employed, the plug was gradually raised by the expanding seeds, though pressed by a weight of nearly 200 lbs. It is by the exertion of such a force, that certain seeds, as those of the peach and apricot, are able, says Du Hamel, to burst open their stony envelope. This expansion from the imbibition of water occurs not only in seeds which retain the faculty of germinating, but in those also which have lost it. We must, therefore, regard this first step in germination as similar to the attraction of water by inanimate bodies. Accordingly, if, after water has been thus imbibed, air be excluded, the radicle never increases beyond a certain size; and, if the seed be kept wholly immersed in water at a temperature of 60°, decomposition of its substance ensues.

To this imbibition of water, a temperature above that of freezing is necessarily required; and, within a certain range, the rate of expansion will be more or less influenced by that of temperature. Cold, however, does not destroy, but only suspends, the germinating faculty in seeds.

When, by the combined operation of heat and moisture, the seed is brought into a condition fit for germination, then the presence of air is required. Many experiments were made by Boyle and others, to prove the necessity of air to germination; and, since the composition of the atmosphere was made known, many more have been instituted to ascertain why the air is thus necessary, the nature of the changes it undergoes, the extent to which they proceed, and the manner in which they are accomplished. On all these points much information has been gained, and the results obtained are, in general, so precise, as to leave little doubt as to the nature and extent of the facts, whatever difference of opinion may exist as to the mode of their occurrence. We must refer those who desire full details on these subjects to the writings of Scheele, Cruickshank, Gough, De Saussure, Huber, and Senebier, &c. The results of their labours are given, more or less completely, in most of our chemical works, and are more fully detailed in Mr Ellis's *Inquiries into the Changes induced on the Air by the Vegetation of Plants*, &c. Parts I. and II.

From these results we learn, that atmospheric air is useful to germination, from containing oxygen gas: that, by the germinating process, the oxygen gas of the air is changed into an equal bulk of carbonic acid gas; and that the azotic portion of the air remains unchanged in composition, and in volume unaltered.

The nature and extent of the change induced on the air being thus ascertained, we have next to inquire into the mode in which it is brought about,—that is, how the carbonic acid is formed? Now, when the experiment is conducted in close vessels, no other substance, but the seed, is present that can

afford carbon: and this fact, taken in connection with the circumstance that the seed actually contains carbon, and yields it, like other organized substances, to the atmosphere that surrounds it, authorizes the conclusion, that, while the air supplies the oxygen, the seed yields the carbon by which the carbonic acid of germination is formed.

Granting, however, that carbon is afforded by the seed, and combines with the oxygen of the air,—where, it may be asked, and in what manner, is this combination effected? A certain degree of moisture in the seed is necessary to enable it to yield its carbon; for, when perfectly dry, little or no reciprocal action goes on between the seed and the air. Neither does the living faculty of the seed seem necessary to this combination; for carbon is afforded by seeds when they are confined in vessels of azote or hydrogen gas, and even under actual decomposition. We may therefore regard the formation of carbonic acid, in the first stages of germination, as purely chemical; and as taking place either on the surface, or within the substance of the seed. Now, from the dense structure of the investing tunics, and the circumstance of the vessels of the seed being already filled with fluid, we see no way in which air can enter the seed, so as to act either on its organized or inorganic matter; and, consequently, we incline to the opinion, that the formation of carbonic acid takes place exterior to the tunics of the seed. Such, then, are the changes in composition which the air, employed in germination, suffers, and such appears to be the mode in which they are accomplished.

While these changes are produced in the air, others not less remarkable occur in the form and qualities of the seed itself; for not only are its organized parts gradually evolved, but its inorganic matter, besides being softened by the imbibed water, acquires, in many seeds, a sweetish taste. These facts, which had long been observed in the process of malting, were more distinctly ascertained by Cruickshank. He found that seeds of barley, when placed to grow in vessels, either of atmospheric air or of pure oxygen gas, acquired, in a few days, a sweetish taste, and were more or less completely converted into malt.

In what manner then, or by what agency, must we suppose this change in the inorganic matter of the seed to be accomplished? This matter, though denominated albumen, does not resemble the albumen of chemists. In vegetable physiology, the term comprehends the whole inorganic matter of the seed, although that matter may contain no real albumen, but consist of several distinct substances, or “proximate principles,” as they have been called. The principal ingredients of seeds, which afford nutrient matter to the embryo, are mucilage, starch, and sugar. For a full account of the chemical properties of these substances, we must refer to the writings of chemists: our limits permit only a very slight notice of them.

*Mucilage*—the soft and liquid state of gum—is inodorous and insipid; soluble in hot or cold water, but insoluble in alcohol. *Starch* (*fecula*) is obtained from the flour (*farina*) of the more nutritive seeds. It is also insipid and inodorous: insoluble in alcohol, and even in water, unless raised to the

Vegetable Physiology. temperature of 160°. If heated to 180°, the solution then jellies, and, by evaporation, may be reduced to a substance closely resembling gum. Sugar exists abundantly in the juice and fruits of plants; but in seeds, it is formed chiefly during their germination. It is soluble both in hot and cold water, and also in alcohol. Other ingredients, as *gluten*, albumen, and oil, are found in particular seeds.

Of the "proximate principles" which contribute to vegetable nutrition, chemists have attempted to ascertain not only the elements, but the proportions in which they enter into the several compounds. All

Vegetable Physiology.

agree in making these elements to consist chiefly of carbon, hydrogen, and oxygen, and a few find also a minute quantity of azote; but the proportions assigned by different analysts for the same substance differ scarcely less than those allotted for the composition of the different substances. In the tabular view below, we have given the results obtained by different chemists, in analyses of mucilage, starch, and sugar—the three substances more immediately connected with our present purpose; and also of woody fibre, which they contribute to form.

Substance.	Carbon.	Hydrogen.	Oxygen.	Azote.	Analyst.

From this view, it is clear that no conclusion, with regard to the sensible properties of these substances, can, in the present state of chemical analysis, be inferred from their elementary composition.

Deriving, from the ultimate analysis of these substances, but little aid in explaining the chemical changes they undergo, we must recur to other modes of accounting for those alterations in their sensible qualities which germinating seeds exhibit. In the germination then of many seeds, the hard and insipid albumen is gradually reduced to a milky form, and acquires a sweetish taste; while the organized parts become, at the same time, softened and expanded, and prepared to take on those actions, and exhibit those specific forms, which constitute the developement of the embryo. Now, the only agents which act simultaneously on the several parts of the seed, when this developement occurs, are water, heat, and air; and, as far as we have been able to trace their operation, the changes produced in the seed must therefore arise, more or less, from the action of heat and moisture; or from the loss of carbon; or from some specific agency exerted directly by the oxygen gas of the air; or arising indirectly out of its conversion into carbonic gas; or from the combined operation of these several agents. Let us then examine their operation, both separately and conjointly, and try to discover the share which each exerts in the production of these changes.

It has been shown that neither heat alone, nor moisture alone, nor both united, are able to produce

the developement of the seed; but that these agents contribute to bring it into a proper state for being acted on by the air. In what manner, then, does the air act on the germinating seed? No direct effect can be ascribed to its azotic portion: for that gas neither suffers nor produces change in germination, and the process goes on perfectly well either in pure oxygen gas, or in gaseous mixtures which contain no portion of azote.

But oxygen gas is essential to germination, and by that process is uniformly converted into carbonic acid gas. This disappearance of oxygen has led to the belief, that while a part of it was converted into carbonic gas, another portion actually combined with the seed, and contributed to its developement. But it is well ascertained, that oxygen gas, by its conversion into carbonic acid, suffers no change of volume; and as the bulk of that acid gas, produced in germination, equals exactly that of the oxygen which has disappeared, it follows, that no portion of the oxygen, lost by the air, combines with the seed, but really exists exterior to it in the form of carbonic acid gas. The only other source from which the seed, in the experiments referred to, could derive oxygen, is from the decomposition of water; but germinating seeds, says M. De Saussure, emit neither hydrogen nor oxygen, but only convert the oxygen gas of the air into an equal bulk of carbonic acid gas. It seems, therefore, to be quite certain that the changes produced in the germinating seed cannot arise from the combination of oxygen.

Neither, in conformity to the opinion held by some, that the mucilage of the seed becomes sugar by losing a part of its carbon, can we ascribe the change of quality in the seed to the loss of that substance: for the portion of carbon given off by the germinating seed is exceedingly small, and we have no evidence that it is afforded by its mucilaginous matter. Were it even granted that the albumen of the seed yielded the carbon, this would not prove that it is thereby converted into sugar: for we have no evidence that the sensible qualities of bodies depend so immediately on their elementary composition; and a reference to the tabular view before given, will show that, while one chemist makes the carbon in mucilage to be less than in sugar, another makes it to be more, and a third makes it, in both substances, to be almost precisely the same. We shall presently see, too, that the chemical change, by which mucilage is converted into sugar, takes place in circumstances where there is no reason to ascribe it to the loss of carbon.

Since, then, neither the operation of heat and moisture, nor the loss of carbon, will account for the changes that occur in the germinating seed, and since all the oxygen lost by the air exists in the carbonic gas that is formed, we must look for an explanation of the *uses* of the air, not to its ponderable elements, but to the action of that caloric which is extricated whensoever its oxygenous portion is converted into carbonic acid gas. We shall not at present speculate on the state or condition in which this caloric, at the moment of its extrication, exists, nor on the mode of its action upon the seed; but we may observe, that ignorance of the mode in which an agent may act is no valid argument against the fact of its operation. If the agent employed be actually present, and every other assumed agent be excluded, we are entitled to decide in favour of its agency, although we may not know the mode of its operation. Those who formerly believed that oxygen produced these changes, or who may still believe so, never explained the mode of its operation. Their belief rested on the supposition that a part of the oxygen that disappeared really combined with the seed; but as no such loss of oxygen occurs, no such combination can be allowed to follow.

Beside the caloric derived from the air, a portion of heat may be afforded by the imbibed water; for Mr Leslie has shown that very small portions of water, when imbibed by dry vegetable substance, give out heat; and M. De Saussure has rendered it probable that a portion of water loses its fluidity in vegetation, and that its elements combine with the vegetable substance,—an opinion which would agree well with the analysis of Gay Lussac and Thenard, should future experience confirm their views, that oxygen and hydrogen, in the proportion necessary to form water, constitute a large portion of vegetable matter.

That the combined action of heat and moisture will produce on the *fecula* of seeds changes analogous to those which occur in germination, has been long known. Dr Irvine long since remarked, that the farinaceous matter of seeds could thus be rendered sweet. Hence distillers, says he, often mix not only

grain imperfectly malted, but raw meal, with their malt; and the whole being then mixed with water, and submitted to distillation, becomes sweet, and forms wine and spirits. MM. Fourcroy and Vauquelin obtained sugar and alcohol from bruised unmalted barley, by the combined use of water and heat; and Dr Thomson has remarked, that the wort made from raw grain is nearly as sweet as from that which has been malted. In the experiments of M. Kirchoff and others, starch was converted into sugar by 36 hours boiling in four times its weight of water; and, from some later trials, it would seem that saw-dust and other vegetable matters, as linen rags, may, by a similar process, be made to experience a like conversion. From these experiments we learn, that the conversion of the *fecula* of seeds into sugar is an operation purely chemical, effected by the combined and continued action of heat and water; and since, in germination, the albumen of the seed is made to undergo a similar chemical change, under the varied operation of the same agents, may we not presume that it is accomplished in a manner somewhat similar?

When, by germination, the albumen of the seed has been thus changed from a solid and tasteless, to a fluid and sweetish substance, it is brought into a condition fit for the nutrition of the embryo. For this purpose, it is taken up, or absorbed from the cells in which it had been deposited, and conveyed, in the course of the mammary vessels, to the neck of the embryo, where a part of it is carried downward to feed the radicle, and another part upward to nourish the plume. We have elsewhere (§ 79) given reasons for believing that the same vessels, which, during the *formation* of the seed, secreted the nutrient matter into the cells, are employed, at the period of its *evolution*, in absorbing it from them, and consequently possess the power, by thus acting at different times, and under different circumstances, of executing opposite functions.

Connected with the structure that determines the course which the nutrient matter takes on reaching the neck of the embryo, appears to be that tendency in the plume and radicle to pursue opposite directions, in whatever position or circumstances the seed be placed to grow. These tendencies have been ascribed to the action of light on the plume, and of earth on the radicle: but the radicle equally descends, although no earth be present, and the plume rises, although light be excluded. Others have attributed the descent of the radicle to the greater weight of its sap, and the ascent of the plume to the lighter condition of that fluid: but there is no evidence that, in these parts respectively, any such difference of sap exists. More lately, it has been supposed that gravitation acted in causing the descent of the radicle; and attempts have been made to counteract this force, by keeping seeds, during their evolution, in continued motion on vertical or horizontal wheels: but the results obtained seem only to prove, that, in such circumstances, the radicle and plume pursue, as usual, opposite directions, without affording any reason, why, in natural growth, the one always rises and the other descends. It is worthy of remark, that this tendency to descend exists only in the

primary radicle or tap-root : for the lateral shoots it puts forth extend themselves, says Du Hamel, nearly horizontally. In like manner, the rootlets that spring from the extremity of a cutting descend perpendicularly, while those that issue from its sides proceed horizontally. We may observe, too, a corresponding peculiarity in the plume and its productions. It is very singular, continues Du Hamel, that a tree which springs from a seed raises its stem very straight: it is the same with a cutting taken from a straight stem: but a cutting taken from a lateral branch, or the bent shoot of a tree, bends much in its growth, especially if its wood be of a hard nature. Some trees, we know, have branches so feeble as to be unable to support themselves, and are therefore always pendent: and Du Hamel once saw a branch of a walnut tree, which, contrary to all the other branches of the same tree, descended straight to the earth, and all its leaves followed the same direction. These facts seem to show, that the directions pursued by these several parts in their ordinary growth, depend rather on conditions of internal structure, than on the operation of external agents.

Both the radicle and plume, as they receive nutriment, increase in all their dimensions; that is, both in length and breadth. The elongation of the radicle, according to Du Hamel, is produced only by the addition of new matter to its extremity, an opinion which the observations of Mr Knight confirm. In the more succulent plume, Du Hamel has shown, by satisfactory experiments, that elongation is produced by an extension of parts already formed, as well as by the addition of new particles; but this extension is not observed when the new parts have acquired a certain degree of hardness. In their diametral growth, it is probable that both the radicle and plume experience, in their tender state, some degree of expansion from the motion of their contained fluids, as well as from the addition of new matter to their exterior surface.

In this brief account of germination, we have supposed the process to be carried on in closed glass vessels, in which the progress of evolution can be observed, the agents concerned in carrying it on made known, and their action, to a certain extent, be appreciated. In such vessels the development of the seed can be continued until all the nutrient matter is exhausted, and the organized parts assume their peculiar forms, and execute their appropriate functions. If, indeed, water and air be duly supplied, the seeds of various herbs will grow and produce flowers and fruits without coming in contact with earth, as M. Bonnet ascertained; and in other experiments of Du Hamel, the seeds of different trees, which had been made to germinate on wet sponges, and their roots afterwards set in bottles so as to be in contact with water, continued to vegetate for several years, and produced annually new leaves, bark, and wood, by the aid of water alone; so that, "without attempting to explain how the parts of this fluid become solid, it is certain," says this excellent writer, "that water the most pure is able to furnish the nourishment necessary to plants." For a description of the daily appearances exhibited in the evolution of several kinds of seeds, we must refer to § 209, &c. of our

former article, and to Plates XV. and XVI., for accurate representations of them.

In ordinary germination, however, by the time the nutrient matter of the seed is exhausted, the radicle has sent forth rootlets through the soil, which at once serve to fix the plant in its place, and to draw from the earth fresh materials to sustain its growth. These materials, as will afterwards be shown, undergo certain changes in the young leaves, which have now sprung forth from the plume, and in part execute the function of cotyledons. The cotyledons, if they have risen above the surface, now fade and fall; if they have remained beneath it, they decay and perish. In addition to water, heat, and air, the only agents required to carry on the germination of the seed, light now becomes necessary to give perfection to the plant; and its operation in bestowing colour and other peculiar properties on plants will be more particularly noticed hereafter. In this account of germination, we have given attention chiefly to the physical phenomena it exhibits, reserving what we have to say of the seed, as a living body, to another occasion.

## SECT. II.

*Of the Vegetation of Plants.*ART. I.—*Of Soils and of the Food of Plants.*

The plant, like the seed from which it sprang, is constructed of two elementary systems, denominated vessels and cells. For a detailed account of these, and of the opinions held concerning them, we must refer to our former article. By these systems, variously blended and combined, the several Textures, denominated Cuticle, Bark, Wood, and Pith, are composed. The structure of these textures, as they occur in different varieties of herbs and trees, has likewise been described in § 104, &c. of that article.

Though the vessels of plants differ in form and structure, yet, with regard to use, they appear to be but of two kinds:—those, namely, which receive and convey the common sap or lymph, and are named, therefore, Sap or Lymphatic Vessels,—and those which contain and convey the juices proper to each species of plant, and are therefore denominated "Proper Vessels." In trees, the sap-vessels are found chiefly in the wood, and the "proper vessels" in the bark; but in many herbs and in palms, both kinds of vessels are associated together through the entire stem. Whether they occupy distinct places in the vegetable, or are associated together, their functions are respectively the same—the sap-vessels being employed always in raising the sap upward, and the proper vessels in conducting its descent.

In all parts of plants, the vessels are in contact with cells, which serve sometimes the purpose of a connecting medium; sometimes to fill up vacuities or augment the bulk of parts; and sometimes as receptacles for various secretions. Between the vessels and cells a vascular communication exists (§ 132); so that matter deposited at one time in the cells of the plant may, at another, be taken up and again mixed with the fluids, as occurs in the germinating seed: and these functions of internal secretion and absorption seem to be performed in plants, as well as in seeds, by the alternate exercise of the same vessels,

Vegetable Physiology. acting at different times and under different circumstances.

Although, as we have seen, plants not only grow, but produce flowers and fruits without the aid of soil; yet, in ordinary circumstances, they draw the materials of their food from the earth. In an inquiry, therefore, into the nutrition and growth of plants, we have to consider the nature and properties of soils, which afford them habitation and nutriment—the absorption of this nutriment and its conveyance through the vessels—the changes of quality it experiences in its course, so as to fit it for nutrition—the agents required to effect these changes, and the mode in which they act—and lastly, the manner in which this nutrient matter, after having undergone its destined changes, is applied to nourish and augment the plant.

The soils in which plants grow are composed of organized and inorganic matters in various proportions. Of inorganic substances, the earths which prevail most are silica, alumina, and lime. With these earths, magnesia and certain metallic oxides, particularly that of iron, are often met with. To these we may add alkaline matter, and animal and vegetable substances in different stages of decomposition and mixture. According to the proportions in which these mineral and organized remains are present and blended together, the soil will vary greatly in texture, in its property of retaining heat and moisture, and in its degree of fertility. To say, however, what mixture of substances constitutes the most perfect soil would be very difficult: for not only does climate greatly modify the natural condition of soils, but plants themselves exhibit the greatest diversity of choice or liking in this respect. Hence it is, that the soil and climate best suited to one plant, are ill adapted or unsuited to another; and that every part of the earth's surface, in which heat and moisture sufficient to sustain vegetation are present, is more or less clothed with its appropriate species of plants.

In considering physiologically the *uses* which the different ingredients of soils serve in vegetation, we must bear in mind that certain chemical elements seem essential to the constitution of vegetable matter; while others, though present and highly useful, are not so indispensably necessary. Thus we have seen, that the vegetable substances, gum, starch, and sugar, are composed essentially of oxygen, hydrogen, and carbon; and that woody fibre, when freed from all adventitious matter, is found to be composed of the same elements, united nearly in the same proportions. Now, considering woody fibre as the basis of the vegetable organs, and as formed, in germination, directly from the *fecula* of the seed, and probably the water in which it is dissolved, we may presume, that the elements which thus compose *fecula*, water and woody fibre, are the true constituents of vegetable matter.

In certain kinds of vegetable matter, which approximate to animal substance, azote, however, is a necessary ingredient. In other kinds, the vegetable substance partakes largely of the earthy materials of the soil. Hence lime and silica are abundant in certain plants; but as such substances can enter plants only in a state of solution, the earths met with in vegetables may not, says De Saussure, depend so

much on those which constitute the basis of the soil, as on those held in solution by the water it contains. Some have even supposed that the earths may be formed or generated in plants by the vegetative process; but the facts alleged in support of this opinion are not sufficiently precise. While, therefore, it is admitted, that earths are carried into plants, and, in certain tribes, enter largely into the composition of some of their textures, we have no evidence that they contribute directly to nutrition, or form an essential element in the composition of vegetable matter. Their use in affording station or habitation to vegetables is sufficiently obvious; and the temperature and moisture of the soil will also depend much on their kinds, proportions, and intermixture.

Together with the earths, chemical analysis shows, that sulphur, phosphorus, some metallic oxides, and particularly alkaline matter, exist in plants. Certain saline substances seem, indeed, necessary to vegetation. Marine plants languish in a soil destitute of common salt: and it is well known, that potash forms a large portion of the incombustible matter of land vegetables, and is especially abundant in the leaves. De Saussure found phosphate of lime in every plant he analysed. Certain plants thrive well only in soils containing nitrates of lime or potash; and sulphate of lime or gypsum accelerated much the growth of lucerne and trefoil. These saline ingredients are highly useful, and the alkalis, in particular, seem necessary to the due perfection of the vegetative process; but, as the elements of these substances do not form a necessary constituent of the vegetable fibre, they cannot be considered as an essential part of the food of plants. Perhaps they may be regarded as condiments which aid in the process of assimilation; and, as will appear, they are otherwise highly useful in the vegetable economy.

With regard to the organized remains, which form so large a portion of the most fertile soils, they are not only soluble in water, like the other ingredients, but are composed of the same elements as vegetable substance. M. De Saussure found pure vegetable mould to yield, by distillation, products similar to those of the undecayed wood from which it had been formed, differing chiefly from it by containing a larger proportion of charcoal and some azote. Water dissolved a portion of this mould, and when deprived of this soluble portion, the residue, though unaltered in appearance, did not support the growth of plants so well as before. The part thus dissolved by water exhibited the properties of *extractive*,—a principle found in the sap, and especially in the bark of plants. Hence it appears, that decayed vegetable matter, and the same may be said of animal remains, is not only conveyed into plants, but, being formed of the same elements as the living plant, may be conceived to furnish materials necessary to its growth.

But in all soils adapted to vegetation, water is a necessary ingredient, whether it be regarded merely as a vehicle for the conveyance of other substances, or as forming itself a portion of the food of plants. To the experiments of Van Helmont, Boyle, Bonnet, Du Hamel, and Braconnot, tending to prove that water alone affords nutriment to plants, it has

been objected, that the water they employed, though apparently pure, held in solution both earthy and saline matters; but, unless we suppose these matters convertible into oxygen, hydrogen, and carbon—the only essential elements of vegetables—the presence of these earths and salts in the water could not supply the elements required for the production of vegetable matter. If, on the other hand, with Du Hamel and De Saussure, we suppose water, though not decomposed, to lose its fluidity, and become fixed in vegetables, then we have at once two of the elements of woody fibre, combined, too, in that proportion which the experiments of Gay Lussac and Thenard exhibit them as holding in the composition of vegetable substance.

Of the source of the other element, carbon, it is not less difficult to speak. It is an ingredient of vegetable mould, and of the carbonic acid carried into plants with the sap, either in a free state, or in combination with alkaline matter; so that, by these means, it is pretty largely supplied to plants. On the other hand, M. Hassenfratz endeavoured to show that plants which vegetated in the open air by the aid of pure water, yielded, on analysis, less carbon than the seeds or bulbs from which they had sprung. M. De Saussure obtained similar results when he analysed plants that had grown in pure water, and in a place weakly illuminated; but when they grew under the direct influence of light, then the proportion of carbon in the plant nearly doubled that in the seed. This carbon M. De Saussure supposes to be derived from that decomposition of carbonic acid which is carried on by the leaves of plants growing in sunshine. Admitting this to be the fact, we may perhaps regard the carbon thus deposited in the leaf as contributing rather to the formation of the inflammable products of the plant, than as undergoing *assimilation*, and being applied to the production of new vegetable substance. And hence, as will afterwards be shown, plants which grow in darkness not only contain less carbon than those which grow in light, but are at the same time destitute of those inflammable ingredients which plants growing in light possess.

Beside the earth and water, the air also has been supposed to furnish food to plants. That plants obtain moisture from the air will not be denied; and in as far as water is concerned in vegetable nutrition, the moisture thus obtained may contribute to vegetable growth. But they have also been supposed to derive carbon from the atmosphere, by decomposing its carbonic acid. Since, however, the atmosphere contains less than  $\frac{1}{1000}$ th part of carbonic acid gas, the portion of that gas decomposed by plants in the open air must, even in sunshine, be necessarily very small, and the quantity of carbon thus obtained is probably much exceeded by that continually given off by plants to unite with the oxygen gas of the atmosphere, through every period of active vegetation. M. De Crell, indeed, deeming the carbon that could be afforded by the atmosphere insufficient to account for the addition of that substance which plants, during their growth, receive, was led to suppose they possessed the power of forming carbon by the aid of water, air, and light; and M. Braconnot has main-

tained that vegetables find in pure water every thing necessary for them to assimilate; that mould and manures yield no nutriment; and that earths, alkalis, metals, sulphur, phosphorus, and charcoal, are developed from water, by the organic powers of plants assisted by solar light.

“But the experiments,” says Sir Humphry Davy, “in which it is said that alkalies, metallic oxides, and earths, may be formed from air and water alone in processes of vegetation, have been always made in an inconclusive manner: for distilled water may contain both saline and metallic impregnations; and the free atmosphere almost constantly holds in mechanical suspension solid substances of various kinds. The conclusions of M. Braconnot,” he adds, “are rendered of little avail in consequence of these circumstances. In the only case of vegetation in which the free atmosphere, in his experiments, was excluded, the seeds grew in white sand, which is stated to have been purified by washing in muriatic acid: but such a process was insufficient to deprive it of substances which might afford carbon, or various inflammable matters.

“In the common processes of nature,” continues this illustrious chemist, “all the products of living beings may be easily conceived to be elicited from known combinations of matter. The compounds of iron, of the alkalies and earths with mineral acids, generally abound in soils. From the decomposition of basaltic, porphyritic, and granitic rocks, there is a constant supply of earthy, alkaline, and ferruginous materials to the surface of the earth. In the sap of all plants that have been examined, certain neutro-saline compounds, containing potash, soda, or iron, have been found. From plants they may be supplied to animals; and the chemical tendency of organization seems to be rather to combine substances into more complicated and diversified arrangements, than to reduce them into simple elements.” (*Phil. Trans.* 1808.) To these views of the economy of living beings, we yield our cordial assent, and hold them to be not less consistent with the most advanced state of chemical science, than with the justest conceptions we can form of the varying structure and powers of organic beings.

#### ART. II.—Of the Course of the Sap, and the Causes of its Motion.

In the warmer regions of the earth, the sap flows, in certain plants, through the whole year; but in more temperate climes the functions of vegetables are suspended during the winter season. Early in spring, however, it begins to rise in trees, and continues daily to ascend till it reaches the extremities of the branches. This sap is absorbed from the soil by the extremities of the capillary rootlets, and conveyed upwards through the vessels of the root to the trunk. In its ascent it rises only through the wood; for, at this early period, no sap is found in the bark, nor between it and the wood, nor in the pith. (§ 12.) This rise of the sap occurs *before* the buds have shot forth into leaves; and as no outlet for its escape by transpiration then exists, it rises or falls in the vessels in which it is contained according to the temperature of the atmosphere. If at this period of its flow,

its course, in certain trees, be intercepted, by piercing the vessels of the trunk in any part, it issues forth, and may be collected for examination. In this way the vine, the birch, and sugar-maple, yield sap, or *bleed*, as it is called, very abundantly. They bleed also from the extremity of a cut branch, if the experiment be made sufficiently late in the season, but still *before* the appearance of the leaves.

Early in February, before the sap began to flow, Dr Walker made several incisions, at different heights, in a birch tree, in order to observe its motion. No sap was visible at the lowest incision in the trunk till the temperature of the atmosphere rose to  $46^{\circ}$  in the shade: after which, as the temperature augmented, the sap continued daily to rise. When the highest incision in the trunk, at the height of thirty feet, bled, the thermometer was at  $52^{\circ}$ ; and when the tree bled, not only from the incisions in its trunk, but from every cut extremity of its branches, it was at  $56^{\circ}$ . During the whole experiment, when the temperature was nearly the same, the sap continued nearly stationary,—rising again, as the temperature rose, just like the fluid in a thermometer. To the cut extremity of a vine branch, Dr Hales, in the bleeding season, cemented long glass tubes, so that he could readily observe the movements of the sap. Into these tubes it would rise many feet through the morning after the sun was up; but while in this rising state, if there was a cold wind, or the sun was clouded, the sap would immediately subside, at the rate of an inch in a minute, for several inches: but as soon as the sunbeams broke out again, the sap would immediately return to its rising state, just as any liquor in a thermometer rises and falls, says Dr Hales, with the alternations of heat and cold.

To ascertain the force and velocity of the sap's motion at this season, Dr Hales made many experiments. He found it to rise in glass tubes at the rate, sometimes, of an inch in three minutes, and to attain the height of more than 20 feet. In other experiments, it exerted a force sufficient to sustain a column of mercury at the height of 38 inches—a force, says he, five times greater than that of the blood in the crural artery of a horse. In the chief bleeding season, the sap continued to rise by night and by day, but more in the day, and most of all in the greatest heat of the day: and when the sun shone hot upon the vine, a continued series of air-bubbles rose through the sap, so as to make a large froth on its top.

Such are the phenomena exhibited by the rising sap *before* the appearance of the leaves: when they have shot forth, a great change is observed in its movements. It still, however, continues to rise through the trunk; but if the wood be now pierced, none of it flows out, as it did in the bleeding season. In the excellent experiment of Dr Walker, already referred to, the birch tree continued to bleed from the 5th of March to the 24th of April, on which day it bled from every incision in its trunk, and every cut extremity of its branches. On the 30th of April, vernal or budding began, and the young leaves shot forth. As they advanced, the bleeding gradually lessened, till at length, on the 10th of May, when the leaves were fully expanded, all the

incisions, says Dr Walker, which had yielded sap so freely were every where dry; and this, not from evaporation by the leaves, but from a general diffusion of the sap from the wood through the bark at that season. In conformity with these observations, Dr Hales remarks, that, after the appearance of the leaves, the bark, which was before dry and adhered to the wood, becomes lubricated with sap, and separates easily. Even after the bark has thus been brought to separate from the wood in a young tree full of sap, if all the leaves, says Du Hamel, be stripped off, the bark, in two days, will again adhere to the wood, and continue to do so through the winter. These facts distinctly prove that, after the leaves have sprung forth, the sap of plants is no longer confined to the wood, but finds its way into the bark; and we have next to trace its route into that texture.

MM. De la Baisse and Bonnet traced the sap of plants from the extremities of the roots into the leaves and flowers; and when the plants were set in coloured liquors, the fluid was seen to pass from the vessels of the leaf into its cellular tissue, and the bark of the petiole afterwards to become tinged. The communication thus established between the wood and the bark, M. Bonnet considered to occur in the extreme ramifications of the leaf, where, as he supposed, the ligneous and cortical vessels mutually anastomose. In a plant of Euphorbia, set in a coloured liquor, Dr Darwin observed the fluid to run along the inner ring of vessels in the petiole to the upper surface of the leaf; while on its under side, a white fluid was seen to return from the extremities of the same leaf, and to descend, by the exterior ring of vessels in the petiole, into the bark. In similar experiments on the apple branch, Mr Knight followed the returning fluid through the bark, by the vessels of which it seemed to be conveyed to the roots. These facts show that the sap, which is observed in the bark, after the leaves have sprung forth, gets into that texture by passing through those organs.

The leaves, which thus form the organs of communication between the wood and the bark, not only vary the course of the sap, but greatly influence its motion. Before their appearance, no natural outlet for its escape existed, and it therefore rose, continued stationary, or fell in the same vessels, chiefly according to variations of temperature. But when the leaves are developed, a large portion of the sap, in its passage through them, is thrown off by transpiration, and the remainder is conveyed into the bark; so that, by these means, the vessels of the tree are emptied, and put into a condition to attract fresh portions of fluid. Hales found, accordingly, that amputated branches of trees, which were furnished with leaves, and set in glass tubes of water, attracted from fifteen to thirty ounces of water in the course of the day; while similar branches, from which the leaves had been stripped off, imbibed, in the same time and circumstances, not more than one ounce. In like manner, a growing vine, which was perspiring abundantly by its leaves, ceased at once to yield sap from its stem, when cut over *below* the leaves. He found also that amputated branches, when plunged in water, imbibed from the small end to the great

end as well as in the opposite direction; that they imbibed also when deprived of their bark, but not when stripped of their leaves; and that they would imbibe water from their small cut extremity, while still attached to the trunk. Hence it appears, that, after the period of vernalion, the flow of the sap is promoted chiefly by perspiration from the leaves; and, therefore, if the leaves be removed, or their perspiration counteracted by a cold and humid atmosphere, then, as Hales found by experiment, the attraction of fluid by the sap-vessels is proportionally diminished.

To find the force and velocity with which the sap moved in this more advanced stage of vegetation, Dr Hales cemented branches of trees, furnished with leaves, in glass tubes filled with water, and then set the lower end of the tube in a vessel of mercury. As the water was attracted by the branch, the mercury rose into the tube, in one instance to the height of twelve inches in seven minutes. When the mercury had reached its greatest height, it would hold to that height for several hours in a warm sunshine, which favoured perspiration from the leaves; but as the sun declined or set, perspiration decreased, and the mercury ceased to rise. So great at this season is the attractive force of the leaves, that if a notch be cut in the trunk of a tree through which the sap is rapidly flowing, yet will the notch remain dry; "because," says Hales, "the attraction of the perspiring leaves is much greater than the force of trusion from the column of water." By other experiments he ascertained, that, when once the motions of the sap have been brought under the dominion of the leaves, the sap-vessels of the root no longer possess the same power of forcing the sap upward, as they did in the *bleeding* season; but so long as the leaves throw off the sap, the roots more or less abundantly attract fresh supplies of it from the earth.

In these various motions of the sap, both before and after the bleeding season, Dr Hales ascertained that the tree underwent no variation in its dimensions; yet, whenever it rained, the stem very sensibly dilated, and when the weather again became dry, it subsided as much. "This shows," he adds, "that the sap, in all stages of vegetation, is confined in its proper vessels, and does not confusedly pervade every interstice of the stem, as the rain does, and thereby dilate it." Du Hamel also noticed this alternate augmentation and diminution in the size of trees, under the different states of a humid and dry atmosphere.

Beside this perpendicular ascent, there is also, in certain circumstances, a *lateral* motion of the sap. Dr Hales cut four large gaps in the branches of different trees, at several inches distance from each other. The cuts were carried down to the pith, and opposed, in position, to the four points of the compass. If the cut branches were then amputated and immersed in water, they imbibed that fluid by their extremities; but not so abundantly as before, and continued to give it off freely by their leaves; if they remained attached to the tree, after such gaps were made in them, both the leaves and fruit of the branch flourished as well as those on other branches of the same tree—proving, says Hales, a very free

*lateral* passage of the sap, where the direct passage had been several times intercepted. In these gaps, no moisture could, at any time, be either seen or felt, notwithstanding much fluid was passing by, because the stem, above the gaps, was in a strongly attracting state to supply the great perspiration of the leaves. Mr Knight made similar incisions on the opposite sides of apple branches during the winter season; yet, through these branches, the sap flowed in spring, and pushed forth the buds as usual.

From the facts stated above, it appears, that, *before* the period of vernalion, temperature is the chief agent in promoting the flow of the sap; and that, *after* that period, its progress is aided principally by perspiration from the leaves. There must, however, exist in the plant itself some condition or structure which favours the operation of these agents. At different periods, different causes have been assigned for the ascent of the sap. It has been supposed to exist in the state of vapour, and its ascent been ascribed to its levity; others have attributed its rise to some imagined action of the spiral vessels; others to fermentation, or to the mechanism of valves; and others to a power of contraction and dilatation in the vessels, or to capillary attraction. Of these alleged causes, the two last alone deserve particular notice. That a contractile power, derived from a vital source, is not necessary to the motion of the sap in plants, seems certain from the fact of the ready transmission of fluids through dead vegetables. Even the dissevered particles of vegetables, as the ashes of wood, were found by Hales capable of attracting water with a force nearly equal to living organized structures. From these and other facts, he considered the rise of the sap to be produced by capillary attraction, aided by temperature, and especially by perspiration from the leaves. "For, without perspiration, the sap," says he, "must necessarily stagnate, notwithstanding the vessels are so curiously adapted, by their exceeding fineness, to raise the sap to great heights in a reciprocal proportion to their very minute diameters."

The force of capillary attraction, when thus aided by evaporation, is strikingly illustrated by an experiment of Professor Leslie: he found that the attractive force, exerted by the very fine pores of a thin hollow ball of earthenware, from which water was continually evaporating, was more than sufficient to support a load of mercury, in a tube attached to the ball, equal to that of 400 inches of water, or a column of 34 feet of that fluid. He estimates the diameters of the pores in the ball at the 10,000th part of an inch, and supposes the pores in the leaves of plants to possess nearly the same dimensions. "As fast, therefore," says he, "as their humidity is exhaled into the atmosphere, it is constantly supplied by the ascent of sap from the roots."—(*Elem. Nat. Phil.* I. p. 328, 329.)

Still, however, though capillary attraction, when aided by perspiration from the leaves, may exert great influence over the motion of the sap, it is yet probable that some power or property, inherent in the vessel as a living organ, assists its action. The direct effect of heat in promoting the flow of the sap in the bleeding season, and of cold in retarding it,

Vegetable  
Physiology.

seems to be more connected with some living property in the vessels, than with their powers as simple capillary tubes. If this heat be supposed to dilate the vessels, it ought to check capillary action, and cold, by diminishing their diameters, ought to increase it: but the results afforded are exactly the reverse of these. "If a capillary tube," says Dr Thomson, "be taken of such a bore that a fluid will rise in it six inches; and if, after the fluid has risen to its greatest height, the tube be broken short three inches from the bottom, none of the liquid in the under half flows over."—"But if we cut a plant, the *Euphorbia peplis*, for instance, in two places, so as to separate a portion of the stem from the rest, the milky juice of that plant flows out at both ends so completely, that if afterwards we cut the portion of the stem in the middle, no juice whatever appears. Now, the diameter of these vessels is so small, that, if it were to continue unaltered, the capillary attraction would be more than sufficient to retain their contents, and consequently not a drop would flow out. Since, however, the whole liquid escapes, it must be driven out forcibly, and consequently the vessels must contract."—(*System of Chemistry*, Vol. IV.) From similar experiments, Du Hamel inferred that the "proper juice" is forced out by a contraction of the vessels that contain it.

ART. III.—*Of the Qualities of the Sap, and the Changes it undergoes in the Leaves from the Agency of the Air.*

Having said so much of the *motion* of the sap, and of the powers by which it is accomplished, let us next direct our attention to its *qualities*. If collected during the bleeding season, it is almost without taste, but sometimes a little sweet. It ordinarily yields, by evaporation, only a little mucilage, but that of the maple of Canada is said, by Du Hamel, to afford nearly 5 per cent. of sugar. The sap of the elm (*Ulmus campestris*) was examined by M. Vauquelin at successive periods of vegetation. In his first analysis he found 1039 parts of it to consist of

1027·904	water and volatile matter;
9·240	acetate of potass;
1·060	vegetable matter;
0·796	carbonate of lime.

At a later period, the vegetable matter was in greater quantity, and the saline ingredients had diminished; and, at a period still later, these changes were still more evident. Other saps were analysed, and found to possess similar ingredients; and some others in addition. The sap of the beech contained gallic acid and tannin; and that of the birch, sugar, and acetites of alum and lime. The sap of the vine, examined by Dr Prout, resembled river water in appearance and specific gravity, but was sweetish to the taste. It yielded, by evaporation, a minute portion of *residuum*, consisting of a peculiar vegetable matter and carbonate of lime.

The increase of vegetable matter observed in the sap as the season advances, suggests the idea that it becomes mixed with matter previously deposited in the tree. This idea occurred to Malpighi, who considered the sap, as it rose through the vessels, to be partly deposited in the cells, where it underwent

changes which fitted it for supplying the first nutriment to the young buds and tender leaves. A similar opinion was held by Darwin, who also regarded the sweet juices found in certain roots, and in the knots and stems of some of the grasses, to serve the same purpose. From finding the specific gravity of the sap to increase as it rose higher in the tree, and the alburnum of a tree, felled in winter, to be heavier than in other seasons, Mr Knight also supposed a deposition of nutrient matter to be made in the alburnum, through the latter part of summer and autumn; so as to be ready to mix with the sap in the following spring, and afford nourishment to the buds and leaves. Hence, we may consider the young bud, like the embryo of the seed, to draw its first nutriment from matter previously secreted, and in part deposited in cells, and afterwards reabsorbed and applied to its destined use.

The bud, thus nourished in its early growth by the ascending sap, is more or less rapidly developed, and the tree soon becomes clothed with leaves. Of the changes in the *motion* of the sap when vernal occurs, we have already spoken, and have now to describe others which are effected in the *qualities* of that fluid. The first action of the leaves upon the sap is to throw off a large portion of it. The insensible perspiration of plants has been particularly investigated by Drs Woodward and Hales, and by MM. Bonnet and Guettard. Woodward found that a sprig of mint, weighing only 27 grains, imbibed, in seventy-seven days, 2558 grains of water: yet its weight was increased only 15 grains; and it must therefore have given off in that time 2543 grains of fluid. Hales calculated that a sun-flower, the area of the surface of which above ground was equal to 5616 square inches, gave off, by perspiration, in a warm dry day, about 20 ounces of fluid. In a warm dry night, without dew, it exhaled only three ounces. When the dew was sensible, there was no perspiration; and when the dew was abundant, or the night wet, then the weight of the plant was increased. The more succulent leaves perspired more than those of firmer texture, and deciduous leaves more than those of evergreens. In plants of the same species, and placed in similar circumstances, perspiration is proportional to the extent of perspiring surface: but in all plants, cold and humidity, more or less diminish or entirely suspend this function.

The fluid thus perspired was collected by Hales as it issued from the leaves of various herbs and trees. The liquor in all was very clear, nor could he distinguish any difference in its taste. It had nearly the specific gravity of water, but when exposed to a hot sun it began sooner to putrify. M. Senebier evaporated the perspired fluid of a vine: the *residuum* consisted of minute portions of resinous and gummy matter, and of carbonate and sulphate of lime, which ingredients seemed to augment as vegetation proceeded.

By the loss of its more aqueous parts, the proportions of the remaining ingredients of the sap must be much changed. Grew, Malpighi, Du Hamel, and others, have pointed out the great differences produced in the consistence, colour, odour, and taste of the sap during its transmission through the leaves,

Vegetable  
Physiology.

Vegetable  
Physiology.

—differences peculiar to each species of plants, and which have obtained for the sap, at this stage of its movement, the appellation of "Proper Juice." It is in this "proper juice," says Du Hamel, that the narcotic power of the poppy, the corrosive quality of the fig, the diuretic virtue of the fir, and the purgative property of jalap, resides: and even the peculiar products obtained from the sugar-cane and maple arise probably from the intermixture of the proper juice with the common sap: whence we may infer that the virtue of plants resides principally in their "proper juice."

It is difficult to collect these juices in a pure state. Those which have been examined differ much in their chemical properties. In some of them, mucus is the predominant ingredient, and such juices are generally mild and nutritious. Of the milky juices some are mild, others hot and acrid. From the "proper juice" of Euphorbia, M. Chaptal obtained, by the agency of chlorine, a white precipitate, consisting of two parts resinous matter and one part woody fibre. The juice of the *Carica papaya*, a tree that grows in Peru, yielded M. Vauquelin a substance very like the fibrine of animal matter. From other juices, gums, resins, turpentine, balsams, tannin, sugar, and various other products, have been obtained: so that, in their sensible qualities, these juices differ as much from each other as they do from the common sap; but all of them appear to contain a substance resembling in character the woody fibre.

That the difference of quality observed in the common sap and proper juices is effected chiefly in the leaves, seems now to be generally admitted. Some part of this difference is doubtless attributable to the concentration these juices experience from the exhalation of so much water; but a much larger part is to be ascribed to the effects which result from the combined agency of light and air. That air is essential to the vegetative process, and that the leaves of plants more especially act on the air, are positions long since established by decisive evidence; but physiologists are not yet agreed as to the nature and extent of this action; nor, consequently, as to the mode and degree in which it affects the vegetable fluids. This discordance appears to us to have arisen partly from imperfect experiment; and in part also from blending together two actions performed by the leaves, which, in their nature, are quite distinct; and which, though they commonly go on together, may be easily separated, and the peculiar and specific results of each better observed and estimated.

In the ordinary circumstances of growth, plants are exposed, at the same time, both to light and air; and each agent exerts on them peculiar and specific effects. If deprived of air, when in a state of active vegetation, plants not only cease to grow, but soon die; but the exclusion of light is not followed by suspension of growth, and still less by death. Hence, in favourable circumstances as to heat and moisture, plants continue to vegetate even through the night; and are frequently seen to grow in situations from which light is wholly excluded. They then lose, however, many of their peculiar and more active properties; but they augment in size, and dis-

play their specific forms. Air, therefore, is essential to vegetation; but light, though necessary to the development of certain properties, is not essential to the growth of plants. It will be convenient, therefore, to consider the functions of the leaves, first, in relation to air; and, secondly, in relation to light.

The late Dr Priestley led the way in pointing out the nature of the changes which the air suffers in vegetation; but from not clearly ascertaining, at that early period, the composition of the air he employed, nor the extent of change it suffered, nor being fully aware of all the circumstances which might vary his results, he arrived at contradictory conclusions as to the effects which vegetation ultimately produces in the air. On the whole, however, he considered the atmosphere, when vitiated by other processes, to be purified by the growth of plants. His illustrious contemporary, Scheele, by previously removing the carbonic acid from the foul air he employed, found that plants, by their vegetation, either in sunshine or in shade, constantly deteriorated the air. Similar results, as to the deterioration of the air, in ordinary vegetation, were obtained in many of the experiments of Ingenhousz, Senebier, Woodhouse, and De Saussure; and they have since been extended and confirmed by Mr Ellis in the work already referred to. By these experiments, it is proved, that plants, like the seeds from which they have sprung, require, in the atmosphere in which they are set to grow, the presence of oxygen gas; that, by their vegetation, they convert this gas into an equal bulk of carbonic acid gas; and that the azotic portion of the air, as well in volume as in composition, remains unaltered.

As the seed, in its germination, supplied carbon to unite with the oxygen of the atmosphere, so does the plant yield that element for the same purpose, during its vegetation. Most vegetable substances, either dead or living, solid or fluid, when placed in suitable circumstances as to heat and moisture, deteriorate the atmosphere by forming carbonic acid gas: and the experiments of MM. Huber, Senebier, and De Saussure, show, also, that, when all the oxygen of the air has been consumed, they still yield carbon to unite with its other ingredient, so as to form carburetted azotic gas; or, if hydrogen gas has been employed instead of azote, then carburetted hydrogen is formed. Neither, therefore, the living state of a plant, nor the presence of oxygen gas, is essential to the separation of carbon from vegetable matter; and we may, therefore, presume that its separation is owing not so much to any attractive force excited by the gas employed, as to some spontaneous change in the vegetable compound itself, whereby its carbon is enabled to combine with the gases that surround it, in the order of its affinity for them. In low temperatures, or when the plant is very dry, its functions are more or less completely suspended, and the formation of carbonic acid is then proportionately reduced; while, on the contrary, a vigorous exercise of the vegetative powers gives rise to a corresponding production of that gas. In what state or form the carbon exists, at the moment of its combination with elastic fluids, is not yet known; but it is probably held in solution by water,

Vegetable  
Physiology.

and acquires and retains its elastic state, only while in union with a permanently elastic body. It may farther be asked, in what part of the plant does this union of its carbon with the oxygen gas of the air take place? and in what manner is it accomplished? In the living plant, it is chiefly by the leaf that carbonic acid is formed. To discover the mode and place in which it occurs, we must take into view not merely the change produced in the air, but the structure of the living organ by which that change is effected; for it is only by combining a strict regard to anatomy with our chemical knowledge, that we can ever hope to arrive at true physiological conclusions, and avoid the crude and fanciful notions that have too often usurped their name.

The leaf, then, is formed of a vascular system, of cellular tissue, and of a cuticular covering that invests it on all sides. To this organ the sap is brought by vessels which spring from the alburnum or wood, and which, after forming several fasciculi in the petiole, proceed to the base of the leaf, and there, by their expansion and distribution, produce a minutely reticulated structure. With these sap-vessels, "proper vessels" are every where associated (§ 361), which appear to communicate with the sap-vessels, and to convey the sap they receive into the inner bark. Grew considered the vessels, which form the reticulations of the leaf, to be of the same size in every part, and never to inosculate or anastomose, except end to end, or mouth to mouth, after they have come to their final distribution. Malpighi, on the other hand, believed them to anastomose in every part (§ 8 and 9): and, in regard to the minuter transverse fasciculi, given off from the longitudinal bundles, he has been followed by Mr Todd Thomson, who, however, though he considers them as "distinct vessels, uniting with the longitudinal bundles in a singular manner," has never been able to determine "whether there is any opening directly into the longitudinal vessel on which the extremity of the transverse vessel is applied." It is during the course of the sap, through the two orders of vessels in the leaf, that it undergoes those changes in its properties which fit it for nutrition; but whether these changes are effected in the sap-vessels, or the "proper" vessels, or partly in both, has not yet been determined.

The minute network formed by the vessels is everywhere filled up with cellular tissue, constituting the parenchyme of the leaf. The cells of this tissue contain fluids derived from the neighbouring vessels, and are likewise the seat of the green colouring matter. There must, therefore, be a ready communication between the vessels and cells; and this many have supposed to be accomplished by the medium of pores in the sides both of the cells and vessels. But the best observers represent the cells as close cavities (§ 87 and 88), having no visible communication with each other. Were we even to admit the existence of pores, we should find it difficult to conceive how the contents of the cells could be set in motion and transmitted through their own sides, and those of the vessels also, so as to be conveyed and deposited in the several parts where growth takes place, with all the regularity we actually observe. To us no

other means occur of accomplishing these operations, consistently with the integrity of the cellular structure, than the exercise of those alternate functions of secretion and absorption, which, from so many other considerations, we have supposed to be carried on in every vegetating part of the plant.

The cuticular covering of the leaf is the organ through which, under different circumstances, the fluids that are exhaled and absorbed must pass; and through which also both light and air exert their peculiar action on the vegetable juices. The structure of this organ has excited particular attention, and the opinions held concerning it have been detailed in § 138, &c. of our former article. It is there described as being composed of a proper cuticle, beneath which is a vascular network, the vessels of which, springing from the larger fasciculi, form at various points an oval ring, § 148, from whence go off two or more radiating filaments, which terminate at the cuticle in an oval pore, more or less elongated. It is by the vascular filaments, which thus terminate at the pores of the cuticle, that the exhalation of fluids is held to be performed; and hence it is, that, in different plants, this function is more or less abundantly carried on, in proportion to the number of cuticular pores (§ 77): and that plants, and parts of plants, which have but few pores, perspire little, and those that are destitute of pores not at all. Precisely the same coincidence between the number of pores in leaves, and their power of absorbing fluids, has also been remarked (§ 71 and 72): and we have elsewhere (§ 77 and 78) given reasons for coinciding in opinion with M. Decandolle, that the vascular pores, on the surfaces of the leaves and of porous stems, are the organs by which the functions both of exhalation and absorption are alternately carried on, according to the existing condition of dryness or humidity in the surrounding atmosphere.

Beside the function of exhalation, it has lately been maintained by Mr Todd Thomson, who has bestowed great attention on the structure of the leaf, that the pores are the organs by which the function of respiration in plants is performed. According to him, the pore is not a superficial aperture, but "a short cylindrical tube, penetrating completely through the cutis and terminating in a cul de sac, which is impressed into a vesicle that appears to communicate with the oblong cells immediately beneath the cutis. But although the aperture penetrates the cutis, there is no opening through the epidermis, which, on the contrary, enters into the tubular part of the pore, and lines it throughout." (*Elements of Botany*, Vol. I. p. 614.) In different leaves, the form of the pore, of its short tube, and of the vesicle beneath, are said to vary: but the cuticle or epidermis dips down and lines the cavity in all. By the funnel-shaped pore above described, the air is said to be admitted into the vesicle situated beneath it: and as this vesicle probably communicates with the cuticular cells, which are in general filled with air, the aqueous contents of the cells that form the parenchyme of the leaf, are thus brought into immediate contact with the atmosphere. (*Ibid.*, p. 622 and 623.)

If this account of the respiratory organs be received, then we must suppose, that, in herbs, respi-

Vegetable  
Physiology.

ration is carried on by both surfaces of the leaves, but in trees, only by the under surface; for it is on those surfaces respectively that pores are found. It can hardly, however, be admitted that the existence of pores is indispensable to the production of that chemical change in the air which constitutes respiration; for, according to MM. Decandolle and Rudolphi, § 151, &c., the petals of flowers, the cuticle of fleshy fruits, the tunics of seeds, the stems and leaves of etiolated plants, most of the lower tribes of vegetables, and all roots and bulbs that grow beneath the soil, are alike destitute of pores; and yet the united experience of Priestley, Scheele, Ingenhousz, and De Saussure, bears testimony that all these parts are capable of acting on the air like porous leaves. Mr Thomson, indeed, states that some of the lower tribes of vegetables, and certain etiolated leaves, are really furnished with pores; but even granting this to be the case, there still remain other parts of plants, which grow beneath the soil, and yet act upon the air, like porous parts that vegetate on the surface. Without denying, therefore, the probability that porous surfaces, such as Mr Thomson describes, may favour the exercise of the respiratory function, we are compelled to admit that surfaces, not yet discovered to be porous, are capable of producing similar changes in the air. There is also an anatomical difficulty in Mr Thomson's view of this part of the respiratory function which we cannot readily get over; for while he describes the epidermis that lines the pore as having "no opening" in any part, he seems to think that the air passes to and fro, not only through this epidermis, but also through the cells of the parenchyme, which Hooke and others, from actual experience, declare to be impervious to air.

But whether, in porous leaves, the air enter the pores in order to be changed, or in leaves and parts not porous it be changed at their surface; or whether, by some unknown means, it permeate the cuticle, cells, and vessels, so as to act directly on the fluids they contain—it seems certain that these fluids acquire the properties, which fit them for nutrition and growth, directly through the agency of the air. How then does the air act in producing such effects? No specific action can be ascribed to its azotic portion, since that gas is not essential in vegetable respiration; and when present, it neither suffers nor produces any known change. Neither can we suppose the effects produced to arise from the loss of carbon, for were it proved that this carbon is extracted directly from the juices contained in the vessels, rather than afforded by the fluids they exhale, still the quantity given off is too minute to be considered as the cause of such remarkable changes; and it is more reasonable to believe that they proceed rather from something derived from the air, than from anything given off from the plant. They have accordingly been very generally ascribed to the combination of oxygen with the juices of the plant. Setting aside, however, the difficulty of conceiving how the oxygen can permeate the several textures of the leaf, so as to combine with these juices, it so happens, that the whole of that gas that disappears in vegetation ex-

Vegetable  
Physiology.

ists, not in the plant, but exterior to it, and in union with the carbon afforded by the plant to form the carbonic acid gas produced in that process. Consequently, no part of the oxygen of the air can have combined with the juices of the plant; and, therefore, as far as the air is concerned, nothing remains but the caloric, extricated by the conversion of its oxygen gas into carbonic acid, to which these changes in the properties of the vegetable juices can be truly ascribed. How this caloric acts in the production of these effects, we do not, at present, undertake to explain.

ART. IV.—*Of the Mode in which the Proper Juice is applied to the Purposes of Growth.*

It is only after the common sap has been duly changed in the leaf by the agency of the air that it is rendered fit for the formation of vegetable matter. For this purpose, it descends in the "proper vessels," which in trees are commonly situate in the bark. If at this period, therefore, a circular portion of that texture be cut away, the proper juice is seen to issue from the upper lip of the wound; but this soon ceases, and its accumulation in the vessels then forms an enlargement around that part. Sometimes the proper juices exude, and form concretions of a gummy, saccharine, or resinous nature on the surface of the bark, and sometimes they are effused into the sap-vessels or cells. Where the bark is young and succulent, the juices receive probably some farther change in their descent; for such stems act on the air like leaves, and, in some species of plants, which are destitute of leaves, the functions of the leaves are performed by the stem alone. In ordinary trees, however, the bark is unable to form nutrient matter without the aid of the leaves, as an experiment of Hales distinctly shows. He removed circular portions of bark, half an inch in breadth, from a thriving branch of pear tree, so as to leave several ringlets of bark, three quarters of an inch distant from each other. All these ringlets, except one, had a leaf-bearing bud on them, and all but this one swelled at their bottoms and grew; and the more leaves the bud produced, so much more did the bark on which it grew swell at the bottom, while the leafless ringlet did not swell or increase at all. From facts before stated, it also appears, that a portion of the nutrient matter that descends from the leaves is found in the alburnum, as well as in the bark; and this will be still more clearly shown when we come to treat of the regenerating powers of the alburnum.

In discoursing on the trunk of trees (§ 274, 275), it was stated that a layer of bark, called *liber*, and a circle of wood, named *alburnum*, are annually formed; and that between this *liber* and *alburnum* the new matter that adds to the bulk of the tree is deposited, and becomes organised. Malpighi believed the *liber* to form the new parts, and that these parts were afterwards converted into wood. Grew also considered the new wood to be formed by the bark, but not that the *liber* was converted into wood. Hales, on the other hand, supposed the new wood to be formed by the old; while others have held that both bark and wood contribute to form new matter.

Are, then, the new layers which are annually added to the tree formed by the bark, by the wood, or by both? By very satisfactory experiments, which we have not room to detail, M. Du Hamel ascertained, first, that the bark is able to form new wood, and that this power resides not in its outer layers, but in the part called *liber*. Secondly, By another series of experiments, he ascertained that the *alburnum* is also able to produce new wood and bark, but that this power is not possessed by the older and more hardened vessels of the wood.

The process by which new vegetable matter is formed in trees is thus described by the same excellent writer. When a portion of bark has been removed from a tree, a glairy mucilaginous fluid is first seen to flow from beneath the remaining bark, or, in certain circumstances, from the alburnum. It differs in appearance from the proper juice, and was named *cambium* by Grew. To observe the process more completely, Du Hamel enclosed the stems of young elms and cherry trees, from which portions of bark had been removed, in glass tubes, closed at each end by cement. For a few days, the glass was obscured by vapour, which gradually disappeared; so that it was then easy to see what passed within. At first, a small tubercle appeared beneath the upper lip of the wound, and one still smaller at the lower lip. After this, granules of gelatinous matter issued from the alburnum: they were isolated, and had no connection with the tubercles just mentioned; their colour was at first greyish, but, in about twelve days, passed to a greenish tint. All these new parts continued to extend through the summer; the tubercle from the upper lip of the wound enlarged greatly, but that below, very little; so that it was principally by the growth from above that the wound was healed. The bark of the cicatrice having been formed by the union of new productions from the upper and middlepart of the wound, was very rough, and in some places entirely wanting; but all the regenerated parts duly performed their appropriate functions, and the stems augmented so much as, in some instances, to burst asunder the glass tubes that enclosed them.

That the gelatinous matter or *cambium* that issued from the alburnum was not an extravasated mucilage, but a substance resembling the granulating matter by which wounds are healed in animals, Du Hamel inferred from observing that the process of regeneration went on, though more slowly, when the glass tubes were filled with water, which, as he supposed, would have dissolved simple mucilage. He likewise found, by other experiments, that the bark may be made to reproduce new parts from the sides or lower lip of the wound, as well as from the upper lip; that the new layer, annually produced, is made up of many others extremely thin, which envelope each other, and appear to be formed in succession so long as the sap flows; that, while roots extend only by the addition of new matter to their extremities, the young and succulent shoots of trees are elongated not only by the addition of new parts, but the extension of those already formed; but that this elongation, by extension, ceases as soon as the new ligneous parts become hardened. For a description of the mode in which, according to Du Hamel, trees augment, both in length

and breadth, through all the successive years of their growth, we must refer to § 301 and 351 of our former article, and to the diagrams fig. 10, Plate XVII. and fig. 10, Plate XVIII. there given in illustration of it. Du Hamel farther ascertained, that the diametral growth continues in trees after that in length has ceased. Most of these facts have been confirmed by the experiments of Mr Knight, who found that the alburnum not only formed new wood and bark, as stated by Du Hamel; but that, when both the bark and alburnum were cut away, the more interior vessels of the wood were alike capable of yielding an organizable fluid; so that a vascular bark, capable of executing the ordinary functions of that texture, could be produced, in certain circumstances, by vessels lying deeper than the alburnum. Whether, in the ordinary growth of trees, the new matter is formed by the bark or the wood singly, or by both united, it is not easy to say; but it seems certain that, under favourable circumstances, each texture is capable either of adding to itself, or of reproducing the other. We have before remarked (§ 68) that, when the parts of plants have been once formed, they continue permanent, unless removed by accident or disease: that vegetables possess no power of removing decayed organs by *internal* absorption, as occurs in the animal system; but that their powers of regeneration are confined to the reproduction of parts or organs that have been removed by decay, by accident, or disease.

ART. V.—*Of the Changes the Sap undergoes in the Leaves from the Agency of Light.*

In what has hitherto been said, we have supposed the functions of nutrition and growth in plants to be carried on, as in seeds, by the combined agency of water, heat, and air, without the access of light. Light is injurious to the growth of seeds, by impeding that change of *fecula* into sugar, which is so favourable to germination: and that it also retards the formation of saccharine matter in plants, is proved by many facts familiar to every one in the cultivation of celery and other plants, which, when secluded from light, not only lose their colour, but acquire a mild, and even sweetish taste. If a plant, says M. Achard, be covered with a glass vessel, it is observed sometimes to change from a sweet to a bitter taste; but if the vessel be opaque, the same plant, in its subsequent growth, will retain its sweetness. In the year 1774, the late Professor Robison observed, that tansy, mint, and other plants, which had grown in a dark coal mine, although they thrive well in darkness, lost their colour, their odour, and their taste: But when they were brought up and set to grow in day-light, their white parts died down, and the stocks then produced the proper plants in their usual dress, and having all their distinguishing properties. When deprived of light, says Dr Irvine, all plants nearly agree in the qualities of their juices. The most pungent vegetables then grow insipid; the highest flavoured, inodorous; and those of the most variegated colours are of an uniform whiteness. Vegetables which grow in a natural situation, he adds, readily burn when dry; but a vegetable, bred in a dark box, contains nothing inflammable. The results of analysis accord perfectly with these observations: for etiolated

Vegetable  
physiology.

Vegetable  
Physiology.

plants are found to yield more saccharine matter, carbonic acid and water, and less inflammable matter than those which are green.

From the facts above stated, it appears, that, when deprived of light, plants continue to grow: that the juices, which support this growth, are then nearly alike in all: and that they acquire their peculiar properties as to colour, odour, taste, and inflammability, only when vegetation proceeds under the direct influence of light. To the agency of the air, therefore, we may ascribe those changes in the vegetable juices, which render them fit for nutrition and growth: while light bestows on them those more obvious and active qualities, on which their colour, odour, savour, and combustibility more immediately depend. The first series of effects resembles those which are exhibited in the germination of seeds, from which process light is excluded; the second series is superadded to the former, and is directly attributable to light. It is on the leaves and succulent stems of plants that light chiefly acts; and it is in those parts that the "proper juices," which give colour and peculiar character to plants, more especially reside. Are we then able to trace out the mode in which it produces any of these singular effects?

In all periods of active vegetation, plants uniformly convert the oxygen gas of the atmosphere into an equal bulk of carbonic acid gas; and if, at the same time, they grow in obscurity, they soon lose their green colour and become white. On the other hand, if they be made to grow in impure air under exposure to sunshine, they not only resume their green colour, but occasion a production of oxygen gas. This curious discovery was first made by Priestley. It has since been extended and confirmed by the experiments of Ingenhousz, Senebier, Woodhouse, and Davy; and more lately the subject has been treated with still greater precision by M. De Saussure. From the united labours of these writers we learn, that air, which has been depraved by animal respiration or combustion, is again, in certain circumstances, rendered pure by the aid of plants: that the air, which experiences this purification, must contain a portion of carbonic acid, either in an elastic form, or held in solution by water, and that it must be exposed, with the plant confined in it, to the influence of the solar rays: that neither the plant alone, nor light alone, will effect the decomposition of carbonic acid gas, which is accomplished only by their united agency: that only the leaves and other *green* parts of plants are able, by this decomposition of carbonic acid, to produce oxygen gas: and that the bulk of oxygen produced in these circumstances is exactly *equal* to that of carbonic gas which has disappeared. Hence, if plants be made to vegetate in a given bulk of atmospheric air, and placed alternately in obscurity and sunshine, carbonic acid is successively formed and decomposed; so that, as M. De Saussure ascertained, the air suffers no permanent change either in its bulk or composition.

This operation of plants in purifying air was deemed by Priestley a *vegetative* function carried on by the aid of light; and by Ingenhousz it was ascribed not to vegetation, but to the influence of light combined with a certain state of vegetable

structure. As plants grow in obscurity, where they produce no oxygen gas, this operation cannot be deemed essential to vegetation: and, on the other hand, the decomposition of carbonic acid is effected by the combined agency of plants and solar light, in situations and under circumstances where vegetation cannot exist. Thus, if plants be placed in sunshine, they produce oxygen gas either when immersed in vessels of water saturated with carbonic acid, or when confined in pure carbonic gas. So likewise a similar decomposition of this gas is accomplished by plants, with the aid of light, in temperatures many degrees below freezing, and in such a state of mutilation as is incompatible with the proper exercise of their vegetative powers. Hence, in these different instances, the decomposition of carbonic acid is effected by plants without the aid of that oxygen gas, or that degree of heat, or that condition of structure, which are essential to vegetation; while, on the contrary, it occurs only under exposure to light, which, as we have seen, is not necessary to vegetable nutrition and growth.

But the operation of light, which is thus necessary to the decomposition of carbonic acid, is required also to produce the *green colour* in plants; and exclusion of light, which prevents this decomposition, prevents also the appearance of that colour. The two effects, indeed, are not only accomplished by the same agents, acting in the same circumstances, but, as far as observation extends, are simultaneously performed: whence it may be inferred, that some necessary connection subsists between them; and, could we discover this, it might lead us to an explanation of the green colour of plants.

M. Senebier observed, with great care, the operation of light in rendering white leaves green. At first, yellow spots are seen, in different places, which gradually become deeper, and at length green. These spots multiply, extend, and meet on the face of the leaf, till at last it is rendered entirely green. If part of a white leaf be secluded from light, by covering it with tinfoil, that portion continues white, while the other parts become green: or, if a green portion be similarly covered, so as to exclude the light, it gradually loses its green colour, while the neighbouring parts retain it. From these and similar facts, M. Senebier considered the green colour in plants to be effected by the direct agency of light, independently of vegetation. He remarked, too, that a singular relation subsists between the parts of green leaves that furnish most oxygen, and those parts of white leaves which first become green: and from the circumstance of carbonic acid being decomposed and its oxygen expelled only when these parts became green, he was led to ascribe the green colour to the retention of the carbon of the decomposed gas, and its deposition in the cellular tissue of the leaf.

Granting, however, this deposition of carbon in the manner above stated, we know of no fact or analogy that lends probability to the idea that it is able to change the colourless juices of the leaf to a green hue. These juices are of a resinous nature, and may be extracted by alcohol without loss of colour; but this colour is then readily discharged by acids, and restored by alkalis; so that the action of these re-

agents on the green colouring matter of the leaf resembles that which they exert on ordinary vegetable infusions. Acids also discharge, more or less completely, the green colour of entire leaves, and alkalis more or less perfectly restore it. Since, then, the colouring matter of leaves, when extracted by water or alcohol, and even entire leaves themselves, are thus variously affected by acids and alkalis, may we not presume that the same reagents will exert a similar action on the juices of the living leaf, if acid or alkaline matter be made to predominate in them?

Now, that alkaline matter is an abundant ingredient in leaves is familiar to every one; and the observations of Hales, Du Hamel, Coulomb, Knight, and others, show also, that, in the ordinary growth of plants, carbonic acid is largely carried in with the sap, either in solution or in combination with alkaline matter. With the alkali already present in the leaf, the excess of acid carried in with the sap will readily combine, and according to the proportion in which acid and alkali are present, the leaf will be variously coloured. If the acid abound, as in etiolated leaves, the leaf will be white; but if means can be found to withdraw this acid, and render the alkali predominant, then the green colour will appear. "Now, the decomposition of carbonic acid in plants, by the agency of solar light, seems to be the mean employed by nature to accomplish this purpose; for by this mean," says Mr Ellis, "the acid is not only withdrawn from its combination, and its oxygen expelled, but the alkali at the same instant becomes predominant, and exists, therefore, in a state fitted to exert its specific action on the colourless juices of the plant, which, in consequence, are rendered green. The coloration of the leaf, therefore, is not owing immediately to the decomposition of carbonic acid and expulsion of oxygen, but to the predominance of alkali which that decomposition occasions. Hence, in the earlier stages of the process, we cannot so properly say that the green leaf affords oxygen, as that it becomes green when that gas is expelled; and thus it is that the decomposition of carbonic acid in leaves, by the agency of solar light, gives rise at once to the production of oxygen gas, and the formation of the green colour in plants."

But though light thus appear to be the active cause of colour in plants, yet, as it acts only by rendering alkali predominant in their juices, it follows that if, from the soil, or in any other manner, a similar predominance of alkali arise, these juices will be rendered green. Hence certain buds and the germs of some seeds, and parts which lie within the bark of certain herbs, exhibit a greenish hue, though perfectly secluded from light; so that it is not to be doubted, as Senebier remarks, that plants, and parts of plants, may become green, although light should not act immediately upon them.

If thus the predominance of alkali occasion a green colour, then deficiency of it, and still more, excess of acid, should have a contrary effect. Accordingly, when light is excluded from plants, no carbonic acid is decomposed in the leaf; and then its retention and accumulation, by saturating the alkali, subdues the green colour, and give rise to the white appearance observed in etiolated plants. So, likewise, the

changes of colour which leaves exhibit in autumn seem to arise from the abundance of acid matter, not, however, occasioned by the absence of light, but developed under the various conditions of decay and decomposition in which they are then placed.

From the facts stated above, with regard to the alternate consumption and production of oxygen gas by growing plants, a question has arisen, whether, on the whole, vegetables purify or deteriorate the atmosphere. We cannot enter farther into this question than to observe, that it is not to be decided altogether by experiments made in close vessels of artificial mixtures of air; but demands a comprehensive survey of vegetation in different climes, and a knowledge of the times and circumstances in which the one or other process prevails, or is variously accelerated or retarded. Since, too, the production of oxygen arises solely from the decomposition of carbonic acid in the plant, we must also know the modes and quantities in which that gas is supplied to plants: for the power of plants to produce a large excess of oxygen, when confined in artificial atmospheres that contain from 7 to 10 *per cent.* of carbonic acid, does not at all apply to the natural condition of the atmosphere, which contains less than a thousandth part of that gas. We have already remarked, that carbonic acid is largely carried into plants with the rising sap; and various facts seem also to prove, that, when plants are confined in close vessels containing carbonic acid, that gas enters the leaf in an elastic form. Other gases, as oxygen, hydrogen, and azote, under similar circumstances, obtain admission also; and fleshy leaves, in particular, take up, through the night, a volume of oxygen greater in bulk than themselves, which, according to De Saussure, they again give out when exposed to a bright sunshine. It is not yet determined in what way elastic fluids thus obtain admission into leaves, and are again expelled from them; but the indiscriminate mode of their entrance and expulsion, at times, too, and under circumstances, in which vegetation is completely suspended; their long retention in a bulk greater than the containing body, and other circumstances, which we have not room to detail, lead to the belief that the phenomena are quite distinct from those which properly constitute vegetation, and are attributable to the conjoined operation of mechanical and chemical causes, aided by a certain condition of structure in the vegetable organs.

When, in the experiments of M. De Saussure, plants were made to vegetate in atmospheric air, and placed alternately in sunshine and in darkness, the decomposition of carbonic acid in the former case so exactly balanced its previous formation in the latter, that the air suffered no permanent change either in purity or in volume. Even in sunshine, continues the same author, plants, growing in close vessels, continue to produce carbonic acid, and it is only because they then also decompose it, that they do not permanently vitiate the air: hence, if a substance that attracts the carbonic acid as fast as it is formed be placed in the vessel, the air of the vessel no longer preserves its volume, nor its proportion of oxygen gas. Whether, in the free atmosphere, plants

*Vegetable Physiology.* also decompose the carbonic acid which they have previously formed, may well be doubted; but if they do, this adds nothing to its purity, but only restores what before had been taken away. And certainly, as the atmosphere at no time, whether vegetation proceeds or stands still, contains more than a thousandth part of carbonic acid, plants cannot, from that source, afford to it more than an equal portion of oxygen gas. As far, therefore, as the atmosphere is concerned, we believe that growing plants deprave rather than purify the air: but whether the decomposition of the acid gas, carried in with the sap, may not compensate, or more than compensate, for this depravation, we do not, at present, venture to decide.

Beside contributing to their colour, light, as we have seen, exerts a direct action on the substances that impart odour, taste, and combustibility to vegetables. These several qualities depend immediately on the oils, volatile and fixed—the resins, gum-resins, balsams, and turpentine—the alkalis and acids—the earthy and saline compounds—and the tannin, extractive, and other principles met with in the proper juices. It is probable that these substances are formed in the leaves and other corresponding structures, chiefly by peculiar secreting organs; but either the functions of the organs, or the products they yield, appear to experience great modifications and changes from the direct action of light; and hence, if this agent be wholly excluded, these vegetable products are either sparingly formed, or not at all produced. When formed, they become mixed with the sap in its course through the leaves, and variously change its sensible properties, so as to constitute juices proper to each species of plant. Thus blended with the sap, they are conveyed, more or less abundantly, through the organized parts, and impart to them those properties of colour, odour, taste, &c. observed in the several textures. Sometimes the gummy and resinous matters exude on the surface of the tree, or stagnate in the vessels or cells of the bark and wood—forming those collections and concretions met with in different parts of those textures, as described in § 63, 65, of our former article. All these ingredients of the proper juice serve, in vegetation, purposes different from those of the mucilage, starch, and sugar, from which the secretion called *cambium* is derived, and which is more immediately employed in the production of new vegetable matter.

In these operations of light on plants, it is probable that the several species of rays that compose the solar beam exert specific but varied actions. The violet rays, or rather the invisible rays associated with them, were observed by M. Senebier to act most powerfully in producing the green colour of plants; and he likewise ascertained that they act by their own peculiar quality, and not by their heating or illuminating power. This agrees with the acknowledged power of this portion of the solar beam in producing decomposition, since it is through the decomposition of carbonic acid in plants that their green colour is obtained. The experiments of De Saussure show also that by this decomposition of that acid gas, not only is oxygen gas expelled from the plant, but the proportion of its carbon

increased; but whether this carbon contributes to the formation of any of the more active ingredients of the “proper” juices, or of those which impart colour; or whether the calorific power of the solar beam acts in their production, nothing yet known enables us to determine.

## CHAP. II.

### OF THE FUNCTIONS OF THE INDIVIDUAL MEMBERS AND ORGANS OF VEGETABLES.

#### SECT. I.

#### *Of Buds, and of the Members and Organs produced from them.*

##### ART. I.—*Of Buds.*

Having thus exhibited a brief outline of the leading facts which constitute vegetation, as exemplified in the nutrition and growth of plants, we have now to notice, in a manner still more brief, the functions of certain parts and organs which serve different uses, and afford various products; and more especially those by which the continuance of their race is maintained. Some plants pass rapidly through the several stages of their existence, and having produced their seeds, fade and die; others continue for one or more years; and many prolong their existence to very distant periods. Even in these latter, the more active organs of vegetation, after producing their fruits and seeds, fade and fall like plants of shorter duration; and when the season adapted to the growth of *annuals* returns, then also *perennials* reproduce all the organs necessary to growth and fructification. In ordinary cases, reproduction in *annuals* is continued only by seeds; in *perennials*, both by seeds and buds. For an account of the species of buds, and of their formation and structure, we must refer to § 324 of our former article: at present we can afford space only for a few observations on those varieties of buds which produce branches, leaves, and flowers.

During summer and autumn, when perennial plants add to their bulk by the formation of new layers, they also form new buds on the sides and at the extremities of their branches. These buds continue to enlarge through the autumn, and in part through the winter; so as to be ready, on the return of spring, to shoot forth, and supply the place of those that annually decay. Some buds chiefly produce wood; others, leaves; others, flowers; and others, both leaves and flowers; and this variety of production may be so modified by culture as to enable us often to substitute one species of bud for another. The wood and leaf buds are the result of vigorous growth, and are primarily of the same structure. As the plant approaches to maturity, or when the vigour of its growth abates, then flower buds augment in number.

Buds naturally remain attached to the parent tree, and there execute their allotted functions: but they may also be made to grow as individuals, or be transferred, in various modes, to another stock, and perform the same functions on it, as on their proper parent. Though supplied then with sap from a different tree, they retain the power of effecting in that fluid the same changes, and forming with it the same

products as they would have produced on their native stock. The bud of the tree, therefore, like the embryo of the seed, must be held to possess individuality of character, and to be capable of producing new individuals perfectly similar to itself. To the embryo of the seed, however, as to every organized body, is assigned certain periods of infancy, maturity, and decay, which may be varied in duration from accidental causes, but can never, beyond certain limits, be changed. What is true of the primary embryo of the seed, is true also of all the buds propagated from it, whether they remain on the parent stock, or are transferred to another. Hence, when the period arrives in which the function of reproduction naturally ceases in the buds of the parent tree, all the buds, growing on foreign stocks, indicate the same character of age, and cease to bear fruit; and for the permanent continuance of the species recourse must then be had to a seminal progeny. Mr Knight has very ingeniously applied these principles to account for that failure in bearing fruit which the oldest and best varieties of trees in the cyder districts exhibit. Although grafts from these trees still grow on foreign stocks, yet they do not now yield fruit as formerly, because the trees, from which they have been taken, have outlived the fruit-bearing period.

#### ART. II.—*Functions of Branches, Thorns, and Tendrils.*

In its progressive growth, the bud, under its various forms, gives origin to Branches, with their various appendages of thorns and tendrils; of leaves and flowers. Of the structure of these several members and organs, an account has been given in § 292, 302, and 305, of our former article. The functions of the branch may be considered as similar to those already delivered of the trunk; which, indeed, it so nearly resembles in structure and growth, that, if cut off and planted, it readily, in many species, puts forth rootlets and buds, and becomes a perfect tree. Of the origin of branches from successive layers of wood, as explained by Du Hamel, a description has likewise been given in § 301.

The Thorns of trees may be regarded generally as abortive branches, which take on the form they bear chiefly from defective nutrition; and hence, as Malpighi observed, they often disappear under higher culture. Sometimes, however, they derive their origin from the degeneration of other organs, as from the stalks of leaves and flowers: they serve as a defence to plants, and protect them from the ravages of animals.

The several varieties of *fulcra* called Claspers and Tendrils have the same structure as branches; and originate sometimes, like thorns, from abortive leaves and flowers. Their obvious use is to connect the different parts of a plant with one another for mutual support, or to attach themselves, for the same purpose, to the bodies near them. Sometimes this purpose is assisted by means of a viscous secretion which they yield, and which glues them to neighbouring bodies with much force.

#### ART. III.—*Functions of Leaves.*

The Leaves spring from the buds chiefly of young

branches, and by their number, forms, and colour, constitute the chief ornament of trees. If they exhibit less splendour than flowers, they enjoy a longer existence. They furnish to animals a large part of their subsistence, afford them shade and shelter, and spread everywhere beneath and around us, that "all refreshing green," on which the eye, fatigued and distracted by the glare of other colours, always loves to repose.

We have already discoursed largely of the functions of the leaves as organs of respiration and of transpiration. Besides this transpiring power, the leaves exercise also an absorbent function. From the experiments of M. Bonnet, it appears, that the leaves of many herbs, when laid upon water, absorb equally well by both surfaces, but those of trees only by the under surface: and these facts correspond with the observations of Decandolle and Rudolphi, as to the existence of pores on these surfaces respectively (§ 151). The power of the leaves to absorb moisture from the air was also abundantly proved in many of the experiments of Hales and Du Hamel, and more recently by those of Knight. This absorption appears to be carried on by the minute vascular terminations which open at the pores (§ 72); and is performed apparently by the same vessels, which, at a different time, and under different circumstances of temperature and humidity, execute the function of exhalation (§ 77). In thus ascribing to the terminations of these vessels the double capacity of exhalation and absorption, we do no more than what is allowed by all to be performed by the vessels of the branch from which they originate; for, when a branch has been separated from the trunk, and set to grow in an inverted position, the functions of its vessels, in relation to exhalation and absorption, become inverted also.

Beside the aqueous fluids given off by leaves, others are sometimes afforded, which seem to be secreted by peculiar organs. On the leaves of different plants, mucilaginous, saccharine, resinous, or oily fluids are sometimes seen; or if invisible by the eye, they are often sensible to taste and smell. In some leaves, these secretions appear to proceed from minute glandular organs, seated in the cellular tissue: in others, small follicles in the cuticular texture seem to afford them. Of the structure of these minute organs little is known, and still less of the mode in which they execute their functions. Of the influence of light on the secreted fluids of the leaf we have already spoken; and also of the mode in which it contributes to the production of its green colour. M. Bonnet has likewise shown that light exerts a great power over the motion or direction of leaves, of which some notice will be taken hereafter.

#### ART. IV.—*Functions of Roots.*

So nearly does the root agree in structure with the trunk, that, as Malpighi observes, we may consider it as a production of the trunk beneath the soil. From the principal root or stock proceed the buds that give origin to the primary rootlets; and these give off finer ramifications, which are the true absorbents of the root. These fine absorbents take

Vegetable Physiology. up the nutrient matter from the earth, and convey it to the root, from whence it is sent to the trunk. Where these absorbents extend, the earth is exhausted of its nutrient matter, and not in the neighbourhood of the larger roots. In a severe winter, Du Hamel found these fine rootlets to die, and to be abundantly replaced by others, when the temperature became milder. Not only the root, but the branch of a tree, readily produces rootlets, if it be amputated, and set to grow in water or in soil. The form of the root is much influenced by the texture of the soil. If the soil be easily penetrable, the root descends in the form of a long tap-root; but if it be hard and resisting, then the root remains shorter, and divides into lateral branches. Du Hamel remarks too, that roots extend into that portion of soil which is richest, while the barren parts are nearly destitute of them; so that the qualities of the soil, as well as its texture, exert the greatest influence on their direction and growth: in regard, however, both to composition and texture, different soils are best suited to different kinds of roots. We have before remarked, that the elongation of roots and rootlets is made by the addition of new matter to their extremities, not, as in succulent branches, by the simple extension of parts already formed. The diametral growth of roots is effected, like that of the trunk, by the formation of new layers between the bark and wood.

ART. V.—*Functions of Flowers.*

Flowers may be regarded not only as the last, but the most elaborated organs of the vegetable system. Whether we contemplate the beauty of their forms, the splendour of their colours, or the delicious fragrance they everywhere breathe around us; or whether, with a physiological eye, we survey the delicacy of their structure, and investigate the peculiar functions they perform, we cannot but feel the greatest admiration of the skill with which, in a compass so small, and by means apparently so simple, such a series of actions, terminating in results so varied and important, can at once be combined and regulated.

The flower is attached to the plant that bears it by the peduncle, on the extremity of which is placed the cup or calix, which, in its turn, supports the corolla, and the organs of reproduction. Of these organs, the male parts consist of one or more stamens, formed by the filament, bearing on its top the anther, which contains the fecundating particles, named pollen. The female organs consist of one or more pistils, the style of which bears on its top the stigma, and terminates below in the ovary, that contains the rudiments of the seeds. For an account of the structure of these several parts, see § 366 of our former article.

Various as are the forms, colours, and functions of the several parts of the flower, yet, in structure, they are so similar, that, under a change of circumstances, almost any one part or organ can be made to assume the character of any other. Thus, not only are the petals of the corolla, or the stamens and pistils, sometimes abortive; but, at other times, the stamens become simple filaments or petals, or the petals take

the form of stamens. Sometimes, again, the style of the pistil changes into a petal: in other instances, the petal becomes a floral leaf, or the calix is changed into real leaves. In like manner, too, as leaves, or their petioles, are sometimes transformed into clasps and tendrils, so the peduncles and petals of the flower now and then exhibit similar transformations. Nor are these transformations confined to the leaves and flowers: they extend to the more solid and permanent members of the plant. Thorns, we before remarked, were but abortive branches: and as a branch, by surrounding it with earth, may be made to throw out rootlets instead of buds, so a root, when brought into light and air, will, on the contrary, put forth buds. Even an entire tree may be inverted, and the roots and branches, by being placed in circumstances respectively opposite to their nature, may be made gradually to assume each other's character, and execute each other's functions. These facts demonstrate a great uniformity of structure in all parts of vegetables, and show with what facility modifications of form and of function are induced, by varying the application of those external agents and conditions, concerned in the development of vegetable organization.

1. *Colours of Flowers.*—The colours of flowers are not less diversified than their forms. They present every variety of tint and every shade of intermixture; and not unfrequently the same flower, at different times, or even at the same time, exhibits great diversity of colour. Grew remarked that no flower has its proper colour in the bud; that many of them are then pale or white; and that the full and proper colour is formed only when they expand. Even after their expansion, the colour of some flowers, as that of the rose, may be made to disappear by secluding it from light, as Sir Humphry Davy remarked; and the flower of honeysuckle, which continues white while the light is excluded, acquires its red hue on exposure to light and air. In what manner, then, do light and air contribute to the coloration of flowers?

It has been long known that the colourless infusions obtained from flowers are variously affected by chemical re-agents. Grew, Becker, Geoffroy, Lewis, and Delaval, extracted from various flowers, both by water and alcohol, a colourable matter, which, on the addition of an acid, became red; and then by an alkali was made to pass into violet, blue, or green. The changes of colour thus produced in the infusions of flowers were also exhibited by the petals themselves, when immersed in acid and alkaline liquors; so that the existence of a colourable matter in flowers, capable of exhibiting a great diversity of tint, according as acid or alkaline matter is made to predominate, cannot be doubted; and in this respect the facts which regard the coloration of flowers coincide with what has been delivered concerning the colours of leaves. Many leaves, indeed, possess naturally a red tint, others yield to water different shades of yellow and red; and in autumn, almost all leaves commonly exhibit some variety or combination of those colours; so that, as Grew observes, "the colours of most flowers are begun in the leaves, only green being therein the predominant colour, as a veil spread over them, conceals all the rest."

Vegetable  
Physiology.

In leaves which yield oxygen gas in sunshine, we have seen that alkaline matter is rendered predominant by the decomposition of the carbonic acid previously combined with it; but the united experience of Priestley, Scheele, Ingenhousz, and De Saussure, goes to prove that flowers never, under any circumstances, afford oxygen gas by the agency of light. In flowers, therefore, no carbonic acid is decomposed. Consequently, no predominance of alkali can be looked for; and, therefore, although flowers contain juices which are readily rendered green by alkalis, yet in them no green colour is produced.

Although flowers, which bloom in the shade, are paler than those which grow in light, yet, says Du Hamel, as their different parts are commonly coloured in the interior of the bud, light is not so necessary to their coloration as to that of leaves. From an experiment of M. Senebier, it would seem that, in some flowers, air contributes to the production of their colours; for he found that the petals of the rose, which had been whitened by digestion in alcohol, recovered their red hue when confined in vessels of common air, but not in those of azotic gas. Now, experience shows, that flowers, both in sunshine and in shade, uniformly convert the oxygen gas of the air into carbonic acid: and if this acid gas was retained in the vessel, it is probable that it contributed to restore the red colour of the petals, which restoration did not take place in azotic gas, because no carbonic acid was then formed. Perhaps, in the ordinary circumstances of growth, less alkali is carried into the flower than the leaf, and, therefore, the acid, that enters with the sap, will more readily contribute to its coloration; for as none of it is decomposed by light, it must be considered to abound in the juices of the flower. Hence, while in leaves, the green colour proceeds directly from the predominance of alkali, occasioned, as we suppose, by the decomposition of their carbonic acid; in flowers, where no such decomposition occurs, the retained acid acts either in destroying colour, as in etiolated plants, or exists variously in excess, and gives rise to those several grades of colour, from whiteness up to perfect redness, which different flowers exhibit. How far light may act in modifying the composition of those juices, on which the colours of flowers seem to depend, has not been sufficiently ascertained.

It is, however, probable that the chemical condition of these juices themselves, or the textures by or through which their colours are reflected or transmitted, are modified by variations of structure in the organs, which altogether escape detection, and become known only in their effects. Du Hamel considered many varieties of colour in the flower to arise from the intermixture of different species and varieties of plants, at the period of fecundation. Poppies and primroses, which grow wild in our fields, are respectively red and yellow; but the same plants, transferred to our gardens, furnish a prodigious number of varieties. If the wild variety of primrose be removed from its natural place, and set to grow among cultivated varieties of the same kind which possess different colours, the seeds obtained will produce many yellow flowers, because the parent plant will have been fecundated by some of its own stamens;

Vegetable  
Physiology.

but it will also afford other varieties, because some of the seeds will have been produced by fecundation of neighbouring plants. Many of the fine varieties of flowers which Florists procure by means of seeds, seem to be thus obtained. They, indeed, attribute them to some particular infusion with which they have watered their seeds, or to some colouring matter they have mixed with their soil; or even to some differently coloured bodies they have presented to their plants, or to a singular good fortune peculiar to themselves. "I have tried without success," says Du Hamel, "these infusions and these mixtures of colours; and I deem it unnecessary to resort to experiment to destroy the two other means." In the ultimate production of colour, modifications may also proceed not only from the texture of the parts, but the configuration of their external surface, as exemplified in the prismatic tints of "mother of pearl," which, according to the beautiful observations of Dr Brewster, owe their existence to the configuration of the surface alone.

2. *Odour of Flowers.*—Next to colour, the property in flowers that most strikes our senses is their odour. Other parts of plants, indeed, possess odour; but the finer and more diffusible fragrance that emanates from them proceeds commonly from the flower. Of the peculiar organs in flowers which form and emit odorous particles but little is known. Their ordinary seat is probably in the *corolla*, since many flowers, which are wholly destitute of sexual organs, emit their peculiar odours. Of the nature of the odorous matter, all we at present know is, that it is inflammable: and this property, M. De Saussure considers to depend rather on the presence of an essential oil, than on any variety of hydrogen gas. That light is more especially concerned in its production seems probable from the fact, already stated, that the most pungent odours cease to be formed in plants which are kept secluded from light; but are speedily produced in them when restored to its presence. In climates, too, and situations where the sun exerts the greatest influence, plants possess the most exalted odours and the most active inflammable ingredients: but of the mode in which the solar rays act in thus contributing to produce odour and inflammability in plants, little is at present known.

3. *Savour of Flowers.*—Connected with the odour of plants, at least in the mode of its production, is the property they possess of imparting sensations of taste. This property is more generally distributed through the vegetable, and is of a much less fleeting and diffusive nature than that of odour. Tastes have been regarded either as simple or compound; and of each a great diversity is to be found in plants. Tastes differ also in quality, degree, and duration; are more or less fixed or diffusible; and, in some instances, affect variously the different parts of the organ which receives the impression. Of all these, and some other varieties, examples are given by Grew, taken from the savours of the juices found in the wood, bark, and root; or in the leaves, flowers, and fruits of various plants.

In general, however, the roots, and all those parts that are secluded from light, have a taste milder and

Vegetable Physiology. less intense than others: and, as we before remarked, plants, possessing naturally a hot or bitter taste, become mild, or even sweet, by the exclusion of light, and resume again their pungent and acrid qualities if brought into day. Light, therefore, exerts a direct action in the formation of the savours as well as of the odours and colours of plants. The odour and savour are commonly more concentrated in some parts than in others; and when formed in the leaves, they are frequently mixed with the "proper juices," and more or less pervade every part of the plant. Although, therefore, the action of light, in the production of colour, odour, and savour, be, in the first instance, *local*, or confined to those plants, and parts of plants, exposed directly to its influence, yet these properties may afterwards be diffused, by the motions of the fluids, through all parts of the vegetable, including even those buried beneath the soil, and thereby protected from the action of light. From the whole it appears probable, that all the effects, simultaneously produced in plants by the direct agency of light, are, in position, *local*; in operation, *chemical*; and in nature entirely distinct from that series of actions accomplished by the air, and which contribute to their evolution, nutrition, and growth.

4. *Fecundation of Flowers.*—Although in appearance the flower differs so much from the leaf, yet, in structure, it is very similar; and, for the due performance of its proper functions, not only requires the presence of the same agents, but acts in the same manner upon them. The necessity of air to the growth of plants, and the conversion of its pure part into carbonic acid by the leaves, in every stage of that growth, have been already noticed; and Priestley, Scheele, and Ingenhousz, showed that flowers, in like manner, require air, and convert its oxygen into carbonic acid. M. De Saussure has since ascertained that flowers do not develop in atmospheres destitute of oxygen gas; that, in proportion to their bulk, they consume more oxygen than leaves; and that the oxygen that disappears is replaced by an equal volume of carbonic acid gas; so that little or no variation of bulk occurs in the air employed. Unlike leaves, however, flowers do not produce oxygen gas in sunshine. Under such an increase of temperature, they consume even more oxygen than before; but no trace of the production, either of hydrogen or azote, is discoverable in the atmosphere in which flowers have been made to grow.

Connected immediately with the great consumption of oxygen by flowers is the high temperature, which some of them manifest at the period of fecundation. MM. Lamarck and Senebier observed the flower of *Arum cordifolium* to impart the sensation of heat to the touch; and to possess, a little after mid-day, a temperature 12° higher than that of the surrounding atmosphere. In the Isle of Madagascar, M. Hubert found the same plant to raise the thermometer still higher; that the male parts of the flower possessed, in this respect, greater power than the female, so that twelve stamens, placed round the bulb of a thermometer, raised it, at the moment of bursting, from 70° to 121°; that this power resid-

ed in the exterior surface, not within the substance of the organs; and, lastly, that air was necessary to this elevation of temperature, and was rapidly depraved in the process. In confirmation of these facts, M. De Saussure has since found that double or imperfect flowers consume less oxygen than those which are simple and perfect; that the greatest portion of this gas is consumed at the period of fecundation; and that the stamens, adhering by their base to the receptacle, consumed more than other parts. He farther ascertained that the temperature of many flowers rises in proportion to the quantity of oxygen consumed; and, to the rapid combination of oxygen gas with the carbon of the flower, he ascribes, with M. Senebier, the great rise of temperature that occurs, in certain flowers, at the period of fecundation.

This necessity of air to the development of flowers, taken in connection with the chemical changes it suffers, and the high temperature thence arising at the period of fecundation, points to some peculiar action which it exerts in the exercise of the generative function. Not long after the true nature and use of the sexual organs had been made known by Grew, Dr Blair, in a learned essay on the *Generation of Plants*, maintained, that, while the greater part of the ascending sap passed on to the leaf, a portion was also carried to the petals of the flower, and, in its course through them, underwent that change and elaboration which fitted it for forming the pollen, and rendering that matter the proper means of fecundation. A similar opinion of the use of the corolla was held by Du Hamel. The petals, says he, are organs necessary to fructification. They not only protect the stamens and pistils, but perform the office of leaves, in acting on the fluids of the sexual organs, and perhaps effect in them some important preparation. Dr Darwin, too, considered the petals to act, by the agency of the air, in elaborating the juices destined to nourish and develop the sexual organs. These views assign to the less important parts of the flower functions essential to the perfection of the whole, and corresponding in nature with those executed by the leaves, only that "Nature," as Grew observes, "hath lapped up the virtue in leaves as in brown paper, but in the flowers as in leaf-gold."

When the organs of reproduction have attained their perfect state, and a suitable condition of the atmosphere prevails, the process of fecundation is accomplished by various modes in different plants. By the agency of the solar rays, aided probably by that high temperature which, at this period, they derive from the decomposition of the air, the anthers burst and discharge the pollen in the form of a fine dust. This dust, in some instances, falls directly on the stigma of the pistil, previously prepared, by the secretion of a viscid matter on its surface, to receive and detain it. In other instances, the pollen is conveyed to the stigma by insects, or by the wind; and in others, its conveyance is accomplished in different modes. When the pollen has been shed, the stamens and petals soon begin to fade and fall; the filament of the pistil likewise fades; but the ovary at its base augments in size, and the pulpy globules, or vesicles, previously formed within it, enlarge, and as-

Vegetable Physiology.

Vegetable Physiology. some gradually the form and character of the perfect fruit or seed. For an account of the successive appearances exhibited in the formation of the seed, as observed by Malpighi and Grew, we must refer to § 383, 384, &c. of our former article.

The pollen, which occasions these extraordinary changes in the ovarian vesicles, is composed of small particles, which possess a different colour, size, and figure, in different plants. These particles are organized, and, when observed in a bright sunshine with a microscope, may, in some plants, be seen to burst; and then a liquor like saliva escapes, in which, says Du Hamel, small particles are obscurely visible. Of the chemical nature of the pollen little farther is known, than that it yields a peculiar matter, called *pollenin*, which is described as being of a yellow colour, without taste or smell, insoluble in water and alcohol, but highly inflammable, and yielding, by distillation, a good deal of ammonia, which approximates it, in composition, to animal matter; but this knowledge gives us no insight into the nature of its peculiar action.

It is also difficult to determine whether the pollen, after being received on the stigma, is conveyed so as to act directly on the ovarian vesicles, or whether it excites in them its specific action, without being brought into actual contact. In many plants, indeed, the number of pistils corresponds with the number of seeds produced; but in other plants, many seeds are produced, where there is only one pistil. Whatever be the form of the pistil, its opening, says Du Hamel, is often continued to its base, or even into the ovary: in other instances again, this opening is not visible. In the open pistils, a fasciculus of vessels extends probably from each division of the stigma, to each cell of the ovary. In the apple and pear, whose fruits contain five cells, and in which there are as many pistils terminated by their proper stigmata, each style, if dissected, is seen to divide into two below, so that a portion is continued to each seed: and in like manner, he continues, a single style, after entering the ovary, may divide into as many parts as there are cells for seeds. But whether the pollen act directly or indirectly on the ovarian vesicle, there is little doubt but its influence is necessary to the perfection of the seed: for though, as Ray observed, some fruits may be produced without the concurrence of the male parts of the plant, just as some birds will produce eggs without the concurrence of the cock, yet such fruits, like such eggs, are altogether barren and unproductive.

To the impregnation of one species of flower by another of a kindred nature, through the agency of winds and insects, Du Hamel ascribed most of the varieties of fruits denominated new. In some fruits, the species, in the hybrid production, are kept so distinct, that we are able to distinguish one part from another, with which it had been associated at the period of fecundation. Thus, there is a species of orange, which, on the same tree, says he, produces "des bigarades, des citrons, and des balotins séparés, ou même rassemblés par quartiers dans le même fruit." In like manner, a certain species of vine produces, on the same shoot, bunches both of red

and white varieties; or on the same bunch both red and white grapes; or bunches on which the grapes are red and white by halves, or even by quarters. These diversities in fruits he attributed to the impregnation of one species by the pollen of another; and to a similar cause, as we before stated, he ascribed many of those diversities in the colours of flowers, where different varieties grow and blossom together. Others have made many direct experiments on the reproductive function in plants by *crossing* different species with each other; and, by a judicious extension of the same methods, Mr Knight has been able to present us with several new and improved varieties both of seeds and fruits.

#### ART. VI.—*Maturation of Fruits.*

The period that intervenes between fecundation and that in which the ripening of the fruit or seed is completed, varies in different plants, and even in the same plant, is much modified by climate, season, habit, &c. Whatever, to a certain extent, diminishes the vigour of vegetation, favours the production and accelerates the maturation of the fruit. So long as trees continue to shoot and abound in sap, says Du Hamel, their fruits do not arrive at maturity. By stripping them of their leaves, we hasten this period, not so much, however, by exposing the fruit to the sun, as by weakening the flow of the sap. But if the tree be stripped before the fruit has reached its proper size, both its size and quality are bad. As the powers of vegetation decline, the fruit advances towards maturity; and then exposure to the sun, by promoting transpiration and concentrating the juices of the fruit, hastens the ripening process. At an earlier period, however, the same degree of exposure, by exciting too great transpiration, might cause the fruit to languish and wither. When fruits are enclosed in bags to protect them from wasps, transpiration is checked, and the fruit enlarges; but has not so good a flavour as usual. The present taste for what are called "fine fruits," seems directed chiefly to size, and is content to resign the rich and racy flavour, found only in fruits of a moderate bulk, for the pampered and bloated produce of a too luxuriant vegetation.

M. Ingenhousz formerly maintained that fleshy fruits, whether ripe or unripe, and whether growing in sunshine or in shade, always vitiated the air in which they were confined: and in a late *Memoir on the Maturation of Fruits*, M. Berard has adopted the same opinion, and maintained, that green fruits do not decompose carbonic acid and disengage oxygen gas in sunshine, but that, through every period of their growth, they uniformly convert the oxygen of the air into carbonic acid gas. To this *Memoir*, M. De Saussure, who had formerly combated the opinion of Ingenhousz, has replied by new experiments; and has satisfactorily proved, that although, during the night, green fruits convert the oxygen gas of the air into carbonic acid gas, yet that, when exposed to sunshine, they again reconvert this carbonic acid into oxygen gas; so that, if they be placed alternately in sunshine and in obscurity, for two entire days, the air of the vessel undergoes successive changes which nearly counterbalance each other, and at the close of

Vegetable  
physiology.

the experiment no other degree of change exists in it, than may be attributed to errors of observation. Hence it is inferred, that, both in the shade and in sunshine, green fruits act upon the air like green leaves; but this action is carried on to a smaller extent, and diminishes as they approach maturity.

As thus the air, under similar circumstances, suffers the same changes from green fruits as from leaves, it may be presumed that the fruit owes its green colour to the same action of light upon it. Light seems also to act in the production of the other colours which fruits exhibit. M. Bonnet shut up, in cases of white tin, grapes of a black colour, which did not then acquire their natural hue. Pears, says Du Hamel, which grow in the shade are often green, while others, exposed to the sun, are beautifully coloured: and the same things are observed in peaches. Neither peaches, pears, nor cherries, assume their proper colours, if, at the period of ripening, says M. Senebier, they are secluded from light; and if a portion of fruit be covered with tin-foil, that part will continue pale or yellow, while the uncovered portions of the same fruit become perfectly red. If the red juices of fruits be extracted by water or alcohol, they are affected by acids and alkalis like those of flowers; and similar changes are produced by these agents on the coloured infusions obtained from their skins. These facts show that the same chemical actions, which occasion the colour of leaves and flowers, are employed in the coloration of fruits: but in these latter, they are probably much modified by the chemical changes that go on in the fruit itself during the process of maturation.

To discover the chemical changes that take place in the fruit during its maturation, M. Berard analyzed several fleshy fruits at different periods of their growth. With this view, three apricots of the same size were selected, and being plucked in succession, one of them was analyzed at three different stages of growth,—viz. in its green state, in a state more advanced, and in a ripe state.

The several results are given in the following table:

Apricot very Green.	Advanced.	Ripe.
Animal matter... 0,76	0,34	0,17
Green colouring matter } 0,04	0,03	Yellow 0,10
Woody fibre..... 3,61	2,53	1,86
Gum ..... 4,10	4,47	5,12
Sugar ..... traces of	6,64	16,48
Malic acid..... 2,70	2,30	1,80
Lime..... a very small portion in the three.		
Water..... 89,39	84,49	74,87

In the interval between the first and last analysis, the fruit had so much increased in size, as nearly to double its weight. It will be seen that, with the exception of the green colouring matter, which had become yellow, all the ingredients, found in the unripe fruit, were present in the ripe one, but some were in greater proportion. Sugar in particular had greatly increased, and water had diminished. From these

Vegetable  
Physiology.

results it is inferred, that the different flavours of green and ripe fruits are not owing so much to the disappearance of any primary ingredient, or its transformation into another substance, as to the production of new substances, and especially of sugar, made in the progressive stages of growth. Similar analyses of cherries, gooseberries, plums, and peaches, afforded the same results.

There are some fruits, however, as those of apple and pear, which ripen very well after they are detached from the tree; and in these, sugar seems to be formed out of the other ingredients, as it is formed from fecula in the germination of the seed. M. Berard plucked a pear from the tree when firm and green, and shut it up in a close vessel of atmospheric air from the 12th to the 29th of August. Its colour had then become yellow, and it was perfectly ripe. During this period, its total weight had diminished very little, and this was due to the loss of a little water, and a minute portion of carbon; but the proportions of its ingredients were much changed, for the quantity of sugar was nearly doubled, and that of gum, of water, and of woody fibre, had decreased. The united loss of the gum and woody fibre were not, however, equal to more than half the gain of sugar; and, therefore, M. Berard supposes that water may have become fixed, and augmented the proportion of this latter substance. If water be thus held to have contributed to the production of sugar in the pear, we may suppose it to have served a similar purpose in the ripening of the apricot; for the loss of water in the ripe apricot, as compared with the green one, comes near to the gain of sugar; and no change in the relative proportions of the other ingredients can be deemed sufficient to account for the great increase of saccharine matter.

The external agents required to effect these chemical changes in the maturing fruit appear to be heat and air. In the above experiment with the pear, the vessel was kept in a temperature of about 82° Fahrenheit; and the air, as well as the fruit, underwent a change of composition. It remained, indeed, unchanged in volume; but 100 parts of it yielded, on analysis, 13.52 carbonic acid, 7.51 oxygen, and 78.97 azote: so that, as in other cases, the loss of oxygen was supplied by an equal bulk of carbonic acid, since the united volumes of the acid gas and oxygen made together almost exactly the  $\frac{21}{100}$  of oxygen gas which the air at first contained. Hence no oxygen can have combined with the fruit; nor can the azote of the air be deemed to have undergone any necessary change, since the very minute portion of that gas unaccounted for may fairly be set down to error in experiment.

That this conversion of oxygen gas into carbonic acid is necessary to the maturation of fruits, M. Berard inferred from the fact that the process is arrested if fruits be kept in an atmosphere destitute of oxygen; yet, after being kept for some weeks in such an atmosphere, the process recommences if oxygen be supplied. In this production of saccharine matter through the entire substance of the pear, nothing can be attributed to the mere loss of the carbon and water which it gives off, and which to-

gether caused in it only a minute loss of weight; neither can we ascribe it to any combination of oxygen, since all the oxygen that disappears exists, exterior to the fruit, in the form of carbonic gas. Nothing, therefore, remains to explain the use of the air in this process but the liberation of caloric which takes place when its oxygen is converted into carbonic acid gas. To the action, therefore, of this calorific power on the gum or mucilage of the fruit, and perhaps on its water, must we chiefly attribute the change that constitutes maturation.

That caloric, in combination with moisture, will produce saccharine matter in fruits, as well as in seeds, is familiarly known in the ordinary process of baking pears, and was more precisely ascertained by Dr Darwin. He placed some pears, of a very austere taste, in an earthen vessel, and covered them with a few inches of water. The vessel was then placed in an oven. In nine hours, the pears had acquired a sweetish taste, and in twelve more had become nearly as sweet as syrup or treacle.

To this process of maturation, light, though ordinarily present, and acting on the colours of fruits, does not seem necessary; for fruits will ripen in dark places; and, to hasten maturation, it is not uncommon to enclose bunches of grapes in black bags, which must, at the same time, exclude light and accumulate heat. Whether light be actually unfavourable to the formation of sugar in fruits, as it appears to be in seeds, remains to be ascertained; but certainly, though it should retard, it does not prevent maturation; and its presence is ordinarily accompanied with such an increase of temperature as may more than compensate for its supposed injurious operation. Since, also, the vegetating process gradually diminishes as the fruit approaches maturity, and ceases to act upon it when its growth is completed, we cannot ascribe the changes that constitute maturation to vegetation, but must regard it as a chemical change, effected by the reaction of the several ingredients of the fruit on each other, under the operation of those external agents necessary to its occurrence.

#### ART. VII.—*Fecundity of Vegetables.*

The period required for the accomplishment of those changes in the ovarian vesicles, which terminate in the formation of perfect seeds, varies much in different species of plants, and also in the same species, under different circumstances of climate, soil, habit, &c. When they are completed, the ovary or pericarp, in which the seeds were contained, is opened, in various modes, for their discharge: or the fleshy pulp that invested them decays; or the stony covering in which they were imprisoned is rent asunder; so that, in one way or other, they are set free, and by various means are disseminated over the surface of the earth, destined either to reproduce new beings similar to themselves, or to minister to the gratification and sustenance of animal life.

Of the seeds thus produced, the number, size, figure, texture, and other properties, are infinitely diversified. With respect to their number, we have already, in our former article (§ 235), given examples of the productiveness of wheat and barley,

and described the peculiar structure (§ 233) by which, in the family of the grasses, this productive power may be almost indefinitely augmented. M. Dodart prosecuted the same inquiry on trees. He selected an elm, which, in the fifteenth year of its growth, he calculated to produce, in one season, 329,000 seeds. Supposing this tree to live 100 years, and its mean fecundity, for its whole life, to be taken at 329,000, this number, multiplied by 100, will give 32,900,000 as the number of seeds produced, through its whole life, by the single seed of an elm. But suppose farther, says Du Hamel, all these seeds to be planted, and each to produce a tree as fruitful as its parent, and so on from generation to generation,—then, calculating the produce of each of these trees during 100 years, we shall have an increasing geometrical progression, of which the first term will be one—the second, thirty-three millions—the third, the square of that number—the fourth, its cube; and so on to infinity—a fecundity, which, in the revolution of ages, would be sufficient to cover the whole surface of the earth with one species of plant.

But propagation by seeds is not the only mode by which plants are multiplied. With the exception of some trees, as the pine and fir, which do not shoot afresh when they have been lopped, except when very young, most vegetables, continues the same author, contain in all parts of their branches, their trunk, and even roots, germs which do not develope unless rendered necessary by the retrenchment of their boughs. Thus, if an elm be headed, and its smaller branches removed, its trunk and larger branches will, in the following spring, be covered with new productions, which never would have appeared if the first branches had not been removed. At whatever part or height the tree is headed, new shoots spring forth. The whole tree, therefore, from the root to the extremities of the branches, is filled with germs (or rather, we would say, endowed with a capacity of producing them), when the parts, previously existing, receive such injury as to render these new productions necessary to supply the place of the former.

Roots also possess this capacity of producing shoots as well as the branches. If the root of the elm be exposed, with certain precautions, to the air, it puts forth young branches; and many creeping roots, when they come into light and air, produce branches, which, by transplantation, form individual trees. A sprig of willow, when both its ends are thrust into the earth, yields rootlets from both, while the intermediate portion pushes forth leaves into the air; and the leaves of certain vegetables, as those of cotyledon *calycinum*, are capable, in proper circumstances, of producing entire plants. We may therefore say, adds Du Hamel, that there is perhaps no point of the surface either of the branches, the stem, or the root, which does not contain a germ, ready to develope itself when circumstances shall arise wherein this development may be useful to the parent tree.

Nay, more, continues the same author, there is not perhaps any point on the branches, the stem, or the root, from which rootlets may not spring, when the conditions required for their development shall

Vegetable  
Physiology.

be present. If the root of a species of *campanula* be cut into pieces, and these pieces be put into the earth, each piece will produce both roots and stems. Of these concealed germs, dissection indicates no trace, until they become sensible in the progress of their development. From whence do they proceed? From the vessels or the cells? Or are they formed by the sap? Do they exist in a form invisible to us before the tree was headed? This, says he, is pure conjecture, although it is true that, if this operation had not been performed, the sap would have continued its course in the parts already formed, and would not have aided in developing the germs of which we speak. But, not to abandon ourselves to imagination, it is sufficient, he adds, to have shown the immense fertility of vegetables, first, by seeds; and, secondly, by invisible germs, of which but a small number of analogous facts are to be found in the animal kingdom. In these remarks, Du Hamel, the Haller of vegetable physiology, evidently leans to the doctrine of pre-existing germs, which at one time so much occupied the attention of naturalists; but of which he ultimately disposes, with that good sense and real candour, which are not less admirable in all his writings than the talent and information which they every where display.

CHAP. III.

OF THE VITAL POWERS, SECRETIONS, SPONTANEOUS MOTIONS, SLEEP, DECAY, AND DEATH OF PLANTS.

ART. I.—Of the Vital Powers.

Such is a brief outline of those vegetable functions which comprehend the evolution, growth, and reproduction of plants. In the description of these functions, we have endeavoured to keep within the limits of observation and experiment; and, in reasoning from the facts derived from these sources, we have adhered strictly to explanations, which apply only to the *physical* constitution of plants. But we are aware, that, to accomplish these physical changes, not only is a particular structure required, but that structure must be endowed with the property or principle that distinguishes living organized beings from dead and inorganic matter. Without embarrassing ourselves with inquiries into the nature and origin of life, we are content, on the present occasion, to seek it only in its effects; to regard it as a power or property not less essential to the constitution of living matter, than gravitation is to that of dead matter; and, rejecting all speculation about its nature, to study only the physical conditions required for the display of its operations, and, as far as we are able, trace the laws by which those operations are regulated. "It is not," says Dr Franklin, "of much importance to us to know the manner in which Nature executes her laws; it is enough, if we know the laws themselves. It is of real use to us to know that china, left in the air unsupported, will fall and break; but how it comes to fall, and why it breaks, are matters of speculation. It is a pleasure, indeed, to know them, but we can preserve our china without it."

Beside the evidences of a living power in plants derived from the ordinary phenomena of growth

Vegetable  
Physiology.

and reproduction, the function of secretion by which growth is sustained, and various new products formed, deserves more particular notice. Other evidences of this power have been drawn from the various motions exhibited by the roots, leaves, flowers, and fruits of plants; and also from the phenomena of infancy, maturity, and old age, which they exhibit in the successive periods of their existence. To enable them to execute these different functions, and exhibit these phenomena, some physiologists have pushed the analogies between plants and animals to an unwarrantable extent; and, in addition to all the attributes connected with growth and reproduction, have endowed plants not only with irritability but with sensibility, instinct, perception, and volition. In ascribing to them these attributes, more attention seems to have been given to a supposed correspondence in effects, than to a real agreement in the structure and functions of organs. Neither has any very nice distinction been taken between what may be due to physical agents, acting on vegetable organization; and what, from our present inability to explain on *physical* principles, we are too apt at once to attribute to what are called *vital* principles or causes. It is only, however, where physical explanations altogether fail, that it is allowable to resort to the mysterious aid of vital causes: And as the Natural Philosopher, in treating of inanimate matter, assumes gravitation as a fact, and, without investigating its nature, proceeds to describe the laws of its action—so the Physiologist, in studying living bodies, may regard life, and direct his inquiries rather to the laws by which it acts, than to the nature or principle of its action.

ART. II.—Of Secretion.

By secretion is understood the separation of a peculiar matter from the general mass of fluids by some particular structure, and which may either retain its primary condition, or pass into a solid state. Though the mass of fluid from which secretions are produced be one and the same, and the secreting organ, as to external conditions, be often in the same circumstances, yet the matters secreted differ greatly from each other, which difference arises, probably, from a variety of structure in the secreting organs. Thus, an essential oil is found only in the rind of the orange, a fat oil only in the kernel of the almond, and so with regard to other secretions which exist only in particular parts. Besides the acids, alkalis, earths, and metals, which, though of a mineral nature, are more or less constantly found in plants, chemists enumerate about forty products of vegetation, which possess distinct chemical characters; and of many of these products numerous varieties exist. As none of these substances can be detected in the common sap, they must have been elaborated by the specific organs of vegetables, under a process of secretion. By what peculiarity of structure, or of function, these organs are enabled to produce such remarkable chemical changes in the common sap, is quite unknown; neither do we know how much is to be attributed to the action of the organ itself, or to the reaction of the several ingredients on each other, or to the influence of external agents.

Of these secretions, the most important is the *cam-*

*bium*, the fluid employed directly in vegetable nutrition and growth. By the changes which the common sap undergoes in the leaves, the "proper juices" of plants are formed. These juices differ greatly from each other both in their sensible and chemical qualities. It is from them that the cambium is directly formed by a process of secretion, and in all plants is said to possess nearly the same characters. It is a mucilaginous fluid, without colour, odour, or taste; while the "proper juices" themselves exhibit all those properties. The "proper juices" also are contained in the vessels, and flow out when they are divided; but the cambium transudes rather than flows, and that only in places where new parts are to be formed. Thus, in the pine, says Mirbel, while the "proper" or resinous juice flows in the large vessels, the cambium transudes beneath the *liber*; and similar observations on the fig show that the cambium is entirely distinct from the proper juice. The cambium, then, we must regard as a *secretion*, separated from the "proper juice" by the vascular structure of the liber or alburnum, when and where-soever it is required to support nutrition and growth. Hence, in an experiment of Du Hamel, when a piece of the bark of a peach tree was engrafted on the wood of the plum, the new wood, formed beneath the bark, was white like that of the peach, not red like that of the plum. Of the other secretions of plants, which, for reasons already assigned (§ 169), are found chiefly on the *external* parts, as the leaves, flowers, fruits, &c., the number and diversity are very great; they are formed, probably, in each instance, by peculiar and appropriate organs, but in what manner is quite unknown.

#### ART. III.—Of the Spontaneous Motions of Plants.

Although plants, as is well known, possess no locomotive power, yet, in different parts, they often exhibit what are deemed spontaneous movements. In cloudy weather through the day, and always towards evening, many plants, at certain hours, close their leaves and flowers. Bonnet remarked, that the leaves of certain plants approached by their superior surface when the sun shone; but as he declined or set, they fell down, and, even in some instances, approached by their inferior surface. If heat was applied to leaves thus closed, they would open and fold back in a contrary direction: and, on the other hand, if moisture was applied to leaves that had been folded by the sun's heat, they also would open and fold back as from dew. In these examples, the different conditions of heat and moisture seem very much to influence the movements of the leaves. In like manner, the stalks of many fruits change their office under the different conditions, with respect to moisture, that accompany the ripening process: for under the desiccation which then occurs, many of them, says Du Hamel, exercise movements not unlike those of muscular action, and are thereby enabled, in some instances, to scatter their seeds.

We have already described many important effects produced in plants by the direct action of light, and have now to notice the influence it exerts on their movements. If plants be confined in a chamber, where there is but one window, all the younger shoots

will forsake their perpendicular direction and make towards the light. In like manner, a young tree, when growing in the midst of older ones, pushes rapidly upwards, till it reaches the height of those that surround it, when it ceases to grow in height, but augments in size: or, if a young plant be made to grow in an opaque vessel pierced with holes which admit the light, the shoots it puts forth will be directed towards the holes. The sun-flower, and, according to Bonnet, the mallow, clover, and others, follow the sun more or less distinctly in his course from east to west. This motion in the sun-flower is not produced by a twisting of the stem, but by a real nutation, caused, says Du Hamel, by a shortening of the fibres. The smooth upper surfaces of leaves look naturally to the heavens; the lower surfaces regard the earth. M. Bonnet contrived experiments in which these natural positions of the surfaces should be reversed: and nevertheless, under the influence of the solar rays, they soon resumed their ordinary aspects. In these movements, the petiole is turned about so as to bring the reverted face of the leaf to its natural position; and this operation may be repeated many times on the same leaves, but at length the petiole, at the place of torsion, seems to suffer. In these movements, M. Bonnet ascertained that neither heat, nor humidity, nor air, had much influence; so that the sun, says Du Hamel, in causing these motions, acts more by his light than by his heat.

But there are other movements, proper to certain plants, or to particular parts of them, over which light exerts little or no power. Many observations have been made on the motions of the sensitive plant by Hooke, Du Hamel, and others. The latter author remarks, that the movements of this plant do not depend essentially on light or heat: for if kept in a green-house, it closes its leaves early in the evening, before the sun has withdrawn, and while the temperature is yet high; or if placed in perfect obscurity, it still continues to open in the morning, and close in the evening as before. If, during its expansion in the early part of the day, it be gently touched, its leaves partially close, but soon recover their former state. Mere touch, however, without agitation, does not produce motion: for the leaves may be pressed between the fingers, without causing motion, if no agitation be given. With proper address, it is possible, says Du Hamel, to divide the mid-rib of a leaflet, without exciting motion in the other leaflets, or even in its own folioles; nor does motion follow the puncture of a needle, if all agitation be avoided. The time required for a branch, that has been touched, to resume its former state depends on the vigour of the plant, the hour of the day, the season, &c.: and the order in which the parts re-establish themselves likewise varies.

The motions of this plant seem to depend much on peculiarity of structure. From a branch proceed the branchlets that bear the leaves. These leaves are formed of a common petiole, which at its extremity terminates in four conjugate leaflets, each of which has a mid-rib, furnished with a certain number of folioles. In the movements of this plant, the branchlets are so articulated with the branch, that they move on it in the manner of a hinge. The

common petiole of the leaves has a like movement; and lastly, each foliole moves on its proper stalk to apply itself to the opposite foliole. This peculiarity of structure explains why agitation is so necessary to the movements of this plant; and why it bears such great violence without moving, if no agitation be employed to excite motion in its several articulations; so that it is principally in the articulations, says Du Hamel, that the sensibility of this plant resides. He adds, that, when this plant closes, it is not through weakness, but by a sensible contraction, which resists any attempt to replace it in its former state.

In certain flowers also, spontaneous movements take place at the period of fecundation. The stamens of the barberry approach towards the pistil on the slightest irritation, as do those of the sun-flower and other plants. During the night, the petals of many flowers close, and thereby protect the stamens and pistils; but they cease to do so after fecundation is effected. The water-lily is said to bear its flowers on a footstalk under water; and when the flowering season arrives, the stalk rises through the water, till the flowers reach above the surface. The flowers then expand, and the anthers burst and discharge their pollen on the stigma in the usual way. About four o'clock in the afternoon, the expanded flowers close, and the stalk then lies down either upon or under the water. The next day, it rises as before, and continues to do so daily until fecundation is completed, when it sinks beneath the surface, and there remains to ripen its seeds. Other spontaneous movements are exhibited by claspers and tendrils in seeking support from neighbouring bodies, and by roots in the directions they take in search of food.

Unable to assign physical reasons for these and similar phenomena, some naturalists, guided by vague analogies drawn from the animal kingdom, ascribe these movements in vegetables to sensation and perception, by which they not only *feel* their wants, but *perceive* the best mode of gratifying them; and in the performance of the actions necessary to accomplish their objects, they are, according to some, directed by Instinct, and, according to others, by Volition. Such modes of reasoning not only afford no explanation of the phenomena described, but supersede all necessity for it; and are apt, therefore, to beget a conceit of knowledge where ignorance alone prevails. In reference to such attempts at explanation, Du Hamel well observes, that "every peasant has remarked the fact, that the radicle of the seed tends always towards the earth, and that the plume rises in the air. If we ask of them why one part thus strikes into the earth, and the other seeks the air, they give the fact for a reason, by replying that the one part strikes down because it is the root, and the other ascends because it is the stem. And let not us, he adds, smile too complacently at these modes of expression; for we ourselves use them every day when we raise questions about things which are unknown to us. Do we not say that a stone falls because of its gravity? And those who give for a reason that it is attracted by the earth do not satisfy the real philosopher, who never is content with simple terms void of meaning.

To me it seems both more simple and more honest to make at once a confession of our ignorance."

#### ART. IV.—*Of the supposed Sleep of Plants.*

Some writers, deeming plants to possess voluntary power, have from thence inferred that they require sleep. We have no proof, however, that they possess any such power; nor that, in the exercise of their ordinary functions, they experience that fatigue and exhaustion which renders sleep necessary to their restoration. All the spontaneous movements of vegetables previously described, seem to arise from the operation of physical agents, conjoined with those inherent properties which belong to them as living beings. These agents act variously on different plants; and hence some close their leaves and flowers from the abstraction of heat or moisture, and others from the exclusion of light; and this at various periods of the day, as well as through the night. Other plants exhibit spontaneous movements only in the flower, and at the season of fecundation, when suitable conditions of the atmosphere prevail: and though, in some instances, these motions continue for a time after the conditions required for their display may have been withdrawn, yet we must ascribe such motions rather to habit than to any thing that partakes of the nature of volition.

The diminution or suspension of action that occurs, through the night, to plants that inhabit temperate climes, cannot be received as a proof of sleep, induced by exhaustion of the vegetative powers; for even in such climes, vegetation, in favourable seasons, proceeds often by night as well as by day. In climates still more favourable, the same plants which produce fruits only once a-year with us, yield two or more crops; and in Norway and Lapland, where the sun, at certain periods, continues almost constantly above the horizon, the whole period between seed-time and harvest sometimes occupies only about fifty days. In such cases, little or no suspension of the vegetative functions can have taken place; nor have we the smallest reason to believe that the continued exercise of them is followed by fatigue or exhaustion sufficient to require sleep. What, therefore, has commonly been denominated the "sleep of plants," we can regard only as a diminution or suspension of the vegetative functions, arising from the abstraction, more or less complete, of those external agents, whose presence is essential to their full operation and display.

#### ART. V.—*Of the Decay and Death of Plants.*

But whether the functions of vegetables unceasingly continue, or be occasionally suspended by the abstraction of the conditions necessary to their exercise, all plants submit at length to the same general law, and die, either in whole or in part, when the great purposes of their existence—those, namely, of growth and reproduction—have been accomplished. Some plants speedily arrive at maturity, and, having produced their seeds, die altogether: others flourish for one or two seasons, and then decay and perish; and others again die only in part, after having produced their seeds, and also a new series of buds to carry

Vegetable  
Physiology.

on their continued growth and fructification. In the progress of our inquiry, we have seen that, in every stage of vegetation, certain organs fall into decay after having fulfilled their allotted functions. Thus the tunics of the seed perish beneath the soil, after having yielded their nutrient matter to carry on the evolution of the embryo; and those cotyledons, which rise into the air, decay also, when the radicle has taken its proper hold of the soil, and the leaves are sufficiently developed to execute their appropriate functions. So likewise the petals, the stamens, and pistils of the flower, rapidly fade and fall as soon as the important function of fecundation is effected; the fruits next drop when they have reached maturity; and lastly, the leaves, even of perennials, when their allotted functions have ceased, decay and fall like those of annual plants.

To account for this *fall* of the leaves, many hypotheses have been proposed. Some have ascribed it to defective transpiration, and consequent accumulation of juices in the vessels; others to an inequality of growth between the stem and petiole of the leaf, during the progress of vegetation; others to the desiccation of cellular tissue, supposed to exist at the insertion of the petiole with the stem; others to a simple sloughing of worn-out parts; and by others, the fall of the old leaf has been attributed to the growth of the new bud. In all the examples enumerated above, of the decay and fall of cotyledons, flowers, and fruits, the organs ceased to execute their functions, when the purposes of their existence were accomplished; and such we must regard as the general law that determines the death of the leaves. In some instances, the death of parts seems to be hastened by the diversion of nutrient matter from the older organs to the new parts which are subsequently developed, as is exemplified in the decline and fall of the stamens and pistils from the growth of the ovary after fecundation; but, in other instances, as in the death of annual plants, no such acting cause is apparent; and nothing remains to account for the event that occurs, save the character of duration, more or less extended, which was impressed on the plant at the era of its formation.

But from whatever cause the deciduous organs of plants cease to perform their functions, the immediate cause of their fall seems to vary in different vegetables; and to depend often on accidental circumstances of climate, &c. In some instances, the growth of the young bud seems to occasion the fall of the leaf. Thus, though the leaves of the oak die and become dry in autumn, they do not, says Du Hamel, fall till spring, when the buds begin to open, and the new leaves to appear. In other instances, the fall of the leaf seems to be connected with the exercise of the transpiratory function; for plants which transpire largely soonest lose their leaves, and hence evergreens, which transpire little, retain their leaves longest. Even if an evergreen be engrafted on a deciduous tree, it still retains its leaves after those of the stock have fallen. Sudden changes of temperature and humidity in the atmosphere, fre-

quently promote the fall of leaves; thus, in autumn, when rain succeeds to a white frost, the leaves sometimes rapidly fall. So, likewise, it sometimes happens, that the too great heats of summer dry up the leaves; and then also, if warm rains follow, the dried leaves fall and new ones succeed, which continue longer than those of spring. On the other hand, leaves equally fall, though not so speedily, when the winter is mild; and in conservatories, where a regular temperature is kept up, deciduous plants lose their leaves in spring, when the new ones shoot forth. Certain accidents or diseases, however, as lightning, or the eruption of the proper juice from its vessels, or a peculiar disease which separates the bark from the wood, sometimes kill a tree suddenly; and then, says Du Hamel, though the leaves become dry, they adhere strongly to the branches. These facts show, that, while the natural *death* of the leaf is to be sought in the specific nature and constitution of the plant to which it belongs, its *fall* depends sometimes on the growth of new buds; or on variations in the motion of its fluids; or on sudden changes in the temperature and humidity of the atmosphere; and sometimes, probably, the period of the fall is determined by a difference of texture in the fibre of the plant itself.

The duration of the stem or trunk, after the leaves have fallen, is very different in different plants. In many herbs the stem dies at the same time, or shortly after the leaf; but in some trees, the life of the trunk is prolonged through many ages. The *Gentleman's Magazine* for 1762 contains an account of the age of a chesnut tree, then growing at Tamworth in Staffordshire. This tree, it is said, was, at that period, probably the oldest, if not the largest, in England, being 52 feet in circumference. Its period of rising from the nut may be fixed at the year 800, in the reign of King Egbert. From that date to the reign of Stephen is 335 years, at which time it was fixed on as a boundary or landmark, and called, by way of distinction, the *Great Chesnut Tree of Tamworth*. From the first year of Stephen, *anno* 1135, to 1762, is 627 years; so that its entire age, at that period, was 962 years. It bore nuts in 1759, from which young trees were raised. In this tree, therefore, the faculty of producing seeds remained at the age of more than 950 years; but whether this faculty continues through the entire life of such trees is not known. In annuals, we know that life ceases in the whole plant soon after reproduction has been accomplished; but the observations of Mr Knight seem to show that, in certain trees, as those of the apple and pear, the reproductive powers cease before those of vegetation terminate. The death of plants at such various ages, yet occurring at the same age in plants of the same species, suggests the belief that a period, beyond which life cannot extend, was assigned to each species at the era of its creation, and that this character of duration, like the others peculiar to the species, is transmitted through all succeeding generations. (q.)

## W A K

Wakefield.

WAGES. See TAXATION, page 620.

WAKEFIELD (GILBERT), a commentator and critic of some celebrity, born at Nottingham, 22d February 1756, was the son of the Reverend George Wakefield, Rector of the parish of St Nicolas.

He was observed in his earliest infancy to be of a serious turn of mind, and he made a rapid progress in the first elements of literature. At the age of seven, he was sent to a free school at Nottingham, and remained there two years, chiefly under the tuition of Mr Beardmore, afterwards master of the Charterhouse: he was then sent to a school kept by the Reverend S. Pickthall, at Wilford, an institution which seems to have been only distinguished by the regular imprisonment of the boys for no less than eleven hours a day. After this, when his father obtained the vicarage of Kingston in Surry, with the chapelry of Richmond, he was placed under the care of his curate, who kept a school at Richmond; he was, however, removed in 1769 to a better conducted establishment in the same neighbourhood, kept by the Reverend R. Wooddeson, of whom he speaks in his Memoirs with high approbation.

At sixteen he went to Jesus College, Cambridge, where his classical studies still continued to be the principal object of his attention, although he was so fortunate as to obtain the rank of second wrangler at the termination of his academical studies in 1776. He has, indeed, the candour to observe, that the year was below mediocrity, with regard to the performances of the candidates in general; and that, when he obtained the second classical medal, on the Duke of Newcastle's foundation, he had only one competitor; still, it must not be denied, that to be both second wrangler and second medallist, in any year, implies no ordinary portion of application, as well as some considerable talent. Mr Wakefield was however distinguished, throughout his life, by a singular mixture of opposite habits; and, in the midst of his studies, he confesses, that "he sometimes felt himself almost incapable of reading a single page for months together," and in summer especially, he could only wander about the fields in a state of perfect inactivity. On the other hand, he says, that, "for five years, he rose, almost without exception, by five o'clock, winter and summer, but never breakfasted, drank tea, or *supt* [supped]," or of course dined, "alone, half a dozen times during all that space, enjoying society, from the first, beyond measure."

He became a Fellow of Jesus College in 1776, and he gained, in two successive years, the second Bachelor's prizes given by the Chancellor: in 1778, he was ordained, by the Bishop of Peterborough, though he did not subscribe the Articles without great reluctance. He obtained a curacy first at Stockport in Cheshire, and then at Liverpool. The year after, he married Miss Watson, a niece of the Rector of Stockport, and thus vacated his fellowship:

his domestic life appears to have been happy and harmonious, though the only merit of his wife, that he has left upon record, is the singular hereditary qualification, that her great grandfather and great grandmother had lived together as man and wife for seventy five years.

Soon after his marriage, he became classical tutor in the dissenting Academy at Warrington, though he did not professedly unite with any specific community of dissenters as adopting all their opinions; but he soon began openly to attack those of the established church in a multitude of controversial writings, and especially in the notes accompanying his new translations of some parts of the Scriptures; a work for which he had diligently laboured to prepare himself by the study of various dialects of the Oriental languages.

After the dissolution of the Academy of Warrington, he lived at Bramcote in Nottinghamshire, at Richmond, and at Nottingham; partly occupied in the instruction of a few pupils, and partly in pursuing his own studies and illustrations of antiquity. In 1786, and for two or three years after, he suffered greatly from an acute pain in his shoulder, which interfered materially with the prosecution of his theological investigations.

In the year 1790, he accepted the classical professorship at Hackney; here his lectures and instructions were generally approved and admired, but he carried his dissent from the articles of faith of any established society of Christians so much further than any of his colleagues, that he was thought too independent to continue in his situation, and he consequently left the institution in 1791; and for a similar reason he failed of obtaining the charge of two private pupils whom he expected to have been placed with him.

He continued to reside at Hackney, employing himself partly as an author and editor, and partly in the education of his own children. Among his original productions were several polemical and political pamphlets, relating to the war with France, and to the various controversies of the day; of these, the most remarkable for its consequences to himself was his *Reply to the Bishop of Landaff's Address*, which occasioned a prosecution to be brought by the Attorney General against his publisher first, and then against himself; and he was sentenced to be confined for two years in Dorchester jail; a punishment which was probably intended to be somewhat severe, but which was most fortunate in its operation on his subsequent comfort, since it was the cause of his obtaining, by the exertions of his friends and his partisans at large, a subscription of about L. 5000; a sum which not only alleviated the rigour of his imprisonment, but also enabled him to leave his family in a state of comparative affluence.

He was principally occupied during his confinement in continuing his literary labours for the press, and in preparing a series of classical lectures, begin-

Wakefield.

Wakefield. ning with the illustration of the second book of Virgil's *Eneid*, the first course of which he delivered in London immediately after his liberation in May 1801. The effect of unusual exertions of body and mind, after so long a cessation of exercise, and in hot summer weather, appears to have predisposed his constitution to a typhous fever, of which he died, after a fortnight's illness, the 9th of September 1801, leaving a widow and six children, four sons and two daughters. His brother, the Rev. Thomas Wakefield of Richmond, also survived him, and died in 1806. The catalogue of his literary offspring is so multitudinous, that it partly tells its own story by its length, and admits of very few particular remarks.

1. *Poemata: quibus accedunt quædam in Horatium Observationes.* 4. Camb. 1776.
2. *A Plain and Short Account of the Nature of Baptism.* 12. Warr. 1781.
3. *An Essay on Inspiration.* 8. Warr. 1781.
4. *A new Translation of the First Epistle to the Thessalonians.* 8. Warr. 1781.
5. *A new Translation of the Gospel of St Matthew.* 4. Warr. 1782.
6. *Directions for the Student in Theology.* 12. Lond. 1784.
7. *A Sermon Preached at Richmond on the Peace.* 8. Lond. 1784.
8. *An Inquiry concerning the Person of Jesus Christ.* 8. Lond. 1784.
9. *On the Origin of Alphabetical Characters.* Manch. Mem. I. 1785. *Life*, II. Attempting to cut the knot of their invention by referring it to inspiration.
10. Several Letters signed Nepiodidascalos, in the *Theological Repository.* Lond. 1785.
11. *The Poems of Mr Gray, with Notes.* 8. Lond. 1786.
12. *Virgilii Georgica.* 8. Camb. 1788.
13. *Remarks on Dr Horsley's Ordination Sermon.* 12. Lond. 1788.
14. *Four Marks of Antichrist.* 8. Lond. 1788.
15. *A new Translation of Parts of the New Testament wrongly translated.* 8. Lond. 1789.
16. *An Address to the Inhabitants of Nottingham.* 8. Lond. 1789.
17. *Remarks on the Internal Evidence of the Christian Religion.* 8. Lond. 1789.
18. *Silva Critica.* I. 8. Camb. 1789. II. 1790. III. 1792. IV. Lond. 1793. V. 1795. Intended for the illustration of the Scriptures from the Greek and Roman writers. The last two parts were printed at the expense of the Rev. R. Tyrwhitt.
19. *An Address to the Bishop of St David's.* 8. Birm. 1790. On the Liturgy.
20. *Cursory Reflections.* 8. Birm. 1790. On the Corporation and Test Acts.
21. *An Inquiry into the Expediency and Propriety of Public or Social Worship.* 8. Lond. 1791. Ed. 3. 1792.
22. *Memoirs of his Life.* 8. Lond. 1792. 2 Ed. 2 v. 8. 1804. Continued by Mr Rutt and Mr Wainewright.
23. *A Translation of the New Testament.* 3 v. 8. Lond. 1792. 2d ed. 2 v. 8. 1795.
24. *Strictures on Dr Priestley's Letter concerning Public Worship.* 8. Lond. 1792.
25. *Reply to the Arguments against the Inquiry.* 8. Lond. 1792.
26. *Evidences of Christianity.* 8. Lond. 1793.

But few of the characters that have ever employed the pen of a biographer, have exhibited more remarkable contrasts, either in a moral or in a literary

Wakefield. point of view, than that of Gilbert Wakefield: and he has accordingly been depicted, by critics and historians of various sentiments, in colours the most opposite and the most discordant. "Of his particular modes of thinking on religious and political subjects," says Mr Lindsay, "different men will form different opinions: concerning the integrity of his heart, and the consistency of his character, there can be but one opinion amongst those who enjoyed the happiness of his acquaintance." It would, indeed, be difficult to find out a more splendid example of high honour and self denial, and of magnificent liberality, even under actual pecuniary embarrassment, than Mr Wakefield displayed, at a time when he had to support himself, with a wife and six or seven children, on about L. 150 a year, in voluntarily paying the expenses of Mr Cuthell on his prosecution for publishing the *Reply to the Bishop of Landaff's Address*, which exceeded the whole yearly amount of his income. "His devotedness to study," says his friend Dr Aikin, "was by no means attended with a reserved or unsocial disposition; for no one could delight more in free conversation, or bear his part in it with a more truly social spirit: and if, in controversial and critical writings, he was apt to indulge in the contemptuous and severe expressions which he found too much sanctioned by polemical use, in disputation by word of mouth he was singularly calm and gentle, patient in hearing, and placid in replying. To conclude the topic of [his] moral character, it was marked by an openness, a simplicity, a good faith, an affectionate ardour, a noble elevation of soul, which made way to the hearts of all who nearly approached him, and rendered him the object of their warmest attachment." But "he wanted time or patience," says Dr Parr very justly, "for that discrimination which would have made his conjectures fewer indeed, but more probable, and his principles more exact: [yet] I shall ever think of him as one of the best scholars produced by my own country in my own age." The compliments of Heyne, and of his pupil Jacobs, are still more elaborate: but it is well known that when Porson was one day asked for a toast, with a sentiment from Shakespear, he gave "Gilbert Wakefield, *What's HECUBA to him, or he to HECUBA?*" and there was quite as much of truth as there was of neatness in the application. A reviewer of his *Life* in the *British Critic*, by no means favourably disposed towards him, readily admits, that "he was strictly and enthusiastically honest, and seems to have acquired even a passion for privations: these feelings, added to his pride of independent thinking, led him, we doubt not," he says, "to abstain from wine; to have relinquished in part, and to be tending entirely to give up the use of animal food, with various other instances of peculiarity. Knowing his own assiduity, and giving himself ample credit for sagacity, he thought that he was equal to the decision of every possible question: and thus he became bigotted to almost every paradox which had once possessed his very eccentric understanding. He was as violent against Greek accents as he was against the Trinity, and anathematized the final *N* as strongly as Episcopacy. Whatever coincided not with his

ideas of rectitude, justice, elegance, or whatever else it might be, was to give way at once, and to be rescinded at his pleasure, on pain of the most violent reprehension to all opponents; whether it were an article of faith, a principle of policy, a doctrine of morality, or a reading in an ancient author, away it must go, *κύνεσσι δῖανόθεῖ τε πᾶσι*, to the dogs and the vultures. These exterminating sentences were also given with such precipitancy, as not to allow even a minute for consideration. To the paper, to the press, to the [public], all was given at once, frequently to the incurring of the most palpable absurdity. Thus the simple elegance of *O beatē Sexti*, in Horace, was proposed, in an edition of that author, to be changed to *O bea Tē Sexti*, though the alteration, besides being most bald and tasteless, produced a blunder in quantity so gross, that no boy, even in the middle part of a public school, would have been thought pardonable in committing it. By faults [either] original or habitual, his sincerity became offensive, his honesty haughty and uncharitable, his intrepidity factious, his acuteness delusive, and his memory, assisted by much diligence, a vast weapon which his judgment was totally unable to wield."

It is not impossible that Mr Wakefield might have been more successful in his studies, if he could have found sufficient motives for directing them rather to scientific than to philological pursuits: for he seems to have been fully impressed with the superior dignity of science to that of any department of philology. "Compared with the noble theories of mathematical philosophy," he says, "our classical lucubrations are as the glimmering of a taper to the meridian splendour of an equatorial sun." He would, however, scarcely have had perseverance enough to distinguish himself in that solitary labour which is required for the minute investigation of natural phenomena: and it is seldom that any collateral encouragement is held out, in this country, for the continued cultivation of abstract science; while the classical scholar, though he is supposed to be principally occupied with nouns, and verbs, and particles, is, in fact, unconsciously, and, therefore, most effectually, learning the arts of poetry, and rhetoric, and logic, which have furnished, in all ages, the spur and the reins for urging on and directing the mighty bulk of the body politic, in church and in state, at the will of its leaders. The young man, on the other hand, who commences the pursuit of science with ardour, obtains, if he is most successful, and untormented by unnecessary scruples, a quiet fellowship, a comfortable apartment, and an excellent plain dinner for the remainder of his life: and if he fails of these, he may chance to be made an exciseman; or, in the improved arrangements of the present auspicious days, a computer or an assistant astronomer: but with respect to any influence that his pursuits might be supposed to have on the elevation of his rank in life, or in the independent provision for a family, he must lay no such flattering unctions to his soul, but must at all times place his pride and his happiness in the reflection that *AT MIHI PLAUDO IPSE DOMI*, which is, in truth, the best sublunary support of the wise and the good in every circumstance of human life.

(A. L.)

New South  
Wales.

WALES (NEW SOUTH). In the *Encyclopædia*, under the head HOLLAND, NEW, is given an account of this colony, including a history of its first settlement by a party of convicts conducted there by Governor Philip; a description of the country, and of the natives, and such few slight notices on its internal geography, and animal and vegetable productions, as the narrow limits which then bounded the excursions of the settlers had enabled them to make. In this *Supplement*, under the Article AUSTRALASIA, the accounts of the settlement are brought down to the year 1814, and copious details given of the results of several expeditions undertaken for the purpose of internal discovery. Considerable discussions having been excited in Parliament, and carried on in the diurnal and other periodical publications, respecting the government of the distant settlements in the southern hemisphere, it was resolved by the Government to send a Commissioner with powers to examine every part of the administration; to report on the condition of the inhabitants in general, on their pursuits, their habits, their property, and their conduct; and to suggest, for the consideration of his Majesty's Ministers, such laws and regulations as might tend to make those settlements less burdensome to Great Britain, and more conducive to the improvement of those persons whose violations of law had created a necessity for their removal from Europe.

From the *Reports* of Commissioner Bigge, whose labours were closed in 1821, and from other papers laid before Parliament, the following accounts of the present state of New South Wales are chiefly extracted, and presented to our readers in a condensed form.

Present state  
of the Popu-  
lation.

The increase of inhabitants by births, owing to the great disproportion between the males and females, has been very small since the commencement of the settlement, and must continue to be so till the sexes approach nearer to an equality than they do at present. The whole number of convicts exported to New South Wales and to Van Dieman's Land, from the year 1787 to 1820, was 22,217 males, and 3661 females; and the present population of all the settlements in the latter year amounted only to 29,407 persons. The inhabitants of New South Wales, amounting to 23,939, are classed in the following manner, viz. 1307 are persons who came to the colony as free settlers; 1409 are persons born in the settlement; 3255 were become free by the expiry of the terms for which they had been sentenced; 159 had received absolute pardons; 962 had received conditional pardons; 1422 were convicts, but with tickets of leave, which enabled them to work on their own account; 220 were serving on board colonial vessels; 9451 were convicts in a state of servitude; and the remainder, 5668, consisted of children of both sexes. The whole number of females, of all classes and ages, in 1820, were 6310, viz. 3707 women, and 2603 female children. It appears that in thirty-three years, from 1787 to 1820, during which the whole numbers transported have been 25,878 persons, the number of the convicts who have died, who have lawfully returned to Great Britain, or who have made their escape, amounts together to 7080. The

greater part of the inhabitants reside either in the town of Sidney (the capital), or in its immediate vicinity. The returns from that place make the inhabitants to be 12,079, of whom 4457 are convicts.

New South  
Wales.

Whilst this colony has been increasing in numbers, there is reason to hope it has been instrumental in somewhat improving the moral character of the persons transported to it, or, at least, that their progeny is placed in circumstances less exposed to temptation than it would have been under the tuition of such parents in Europe. There has been a gradual, but general improvement in the moral condition of the society, by the children of convicts arriving at maturity; thus forming, with the free settlers, a nearer proportion to the convicts than was the case at the more early periods of the settlement. The remitted convicts, and those whose time has expired, seem, in some instances, to become useful members of society. Mr Bigge relates, that out of 4376 remitted convicts, including those whose time has expired, 369 may be considered as respectable in conduct and character.

The proportion of landed property acquired by those classes of inhabitants, may be considered as evidence of some improvement in their condition and character. The whole quantity of land granted was, in 1820, 389,288 acres. Of this portion, 20,317 belonged to remitted convicts, and 54,693 to convicts whose time has expired. Thus those classes seem to have a fair proportion of the landed property of the settlement; and we think it may be inferred from the Commissioner's *Reports*, that they possess a large share of the moveable property likewise, as they seem to be the principal persons who own vessels and carry on distant trade.

Adjustment  
of Property  
among the  
Classes.

Mr Bigge remarks, that "though the free settlers have not, as a body, been the most successful improvers, either of their own condition or that of the colony, yet the best cultivated estates, and the greatest quantity of cattle, belong to them, though they have not lately engaged in mercantile operations." The large grants that have been recently made have rendered the quantity of land, held by classes of individuals, a less accurate criterion of property than it was before those grants were made. In the year 1810, the land cleared was to the land granted as 1½ to 4; but in the year 1820, when the land granted was 389,000 acres, the portions returned as cleared were 54,898 acres, or as 1½ to 7. Of the cleared land, in 1820, 16,706 acres were cultivated to yield wheat, 11,270 maize, 1230 barley, 379 rye and oats, 213 pease and beans, 504 potatoes, and 1094 in orchards and garden ground.

The future progress of this colony must depend mainly on the productions raised from the soil, and hence the condition of its agriculture, including the breeding of cattle, becomes a most interesting subject. The first land settled near Sydney, though then moderately fertile, has been exhausted by overcropping, so that a considerable expenditure in manure, or in labour for fallowing, or in both, is indispensable to renew its productive powers. It has hence become necessary to pay attention to the production and proper application of manure, as well as to the cultivation of artificial food for the cattle.

Agriculture.

New South  
Wales.

Lucerne, sanfoin, and burnet, as well as rye-grass and meadow fescue, have been introduced and gradually assimilated to the climate. It has been remarked of the grass seeds imported from Europe, that their first and second flowering is in conformity with the season in Europe, but that the next time they flower according to the season of New South Wales. The cost of reclaiming an acre of forest land, of converting it into tillage, and of sowing it with wheat, is calculated to amount to L. 6, 10s. The cost of the same operation to fit it for maize would be L. 5, 8s. 6d. Mr Cox, the surveyor, has estimated, that on a farm of 50 acres, when the government supplied subsistence for six months, the expence would exceed the produce L. 5, 19s. the first year; that in the second year the produce would exceed the expenditure L. 49, 10s., and in the third year L. 36, 10s.; after which, recourse must be had to the renovating power of manure. Maize and wheat are grown on the same land in one year; the former when hoed well, and twice hilled up, being found a good preparation for the latter. Wheat is sowed in March or April, and harvested in November. Maize is sowed in November and gathered in April. The produce of wheat on the Hawksbury settlement, from 1804 to 1814, was from 21 to 25 bushels to the acre, and since the last of those periods from 15 to 20 bushels. The land on the rising ground is inferior to that on the borders of the river, but the wheat grown on it, though yielding less in quantity, is of a superior quality. Mr Oxley, the Surveyor-General, thinks the average produce of wheat on the colony does not exceed 10 bushels to the acre; whilst, on land of similar quality, the produce of maize is from 30 to 60 bushels. The price of wheat has been from 11s. to 12s. 6d.; of maize from 3s. to 7s. *per* bushel.

Besides the grains, attempts have been directed to several articles whose cultivation appears suitable to the climate. Flax has been grown with success, but has not been extended from the very limited demand for it in the settlement. Tobacco has been well produced, but from want of sufficient practice in curing the leaves, the tobacco of Brazil has been so generally preferred, as to leave but little inducement to grow it in the colony; though of late, some improvements in drying offer a prospect of more success. Vines have not yet been prosperous, owing to blights which probably have arisen from improper exposure to prevailing winds. As this is an object of great importance, Mr J. Macarthur has paid much attention to rectify any errors, and hopes are entertained of more favourable results in future, than have hitherto been produced. The same gentleman, one of the earliest settlers, with his characteristic spirit, has been at pains to introduce the olive, and as far as can be judged from the trees, which are yet but in their infancy, with the greatest earnest of success. All the finer fruits of Europe are most profusely brought forth, and in some gardens, the choicer kinds of the tropics are successfully cultivated.

Cattle and  
Wool.

The breeding of cattle must, however, be the most sure road to the prosperity of the colony for some years to come. The numbers of horned cattle have quintupled between the years 1810 and 1820. In the latter year they amounted to 54,103; besides

New South  
Wales.

those tame cattle, a race have grown up wild in the woods, derived from some stock which early strayed from the settlement, and which were supposed to have perished, till their offspring were discovered in large herds in the interior. The sheep have been tripled in ten years. In 1820, they amounted to 99,487. Mr Macarthur has a flock of 6800, of which about 300 are pure Merinos, and yield wool of excellent fineness. As the duty on wool from New South Wales has been reduced to 3d. *per* lib. in Great Britain, eager hopes are entertained of success, which will naturally tend to increase the numbers, and to improve the quality of the wool. The average weight of the fleeces of the New South Wales Merinos is about 2 lb. 7 oz. Some few bales of that wool have been sold in England at 5s. 6d. *per* lb., and one at 10s. 4d.; but the far greater part have hitherto sold at about 2s. The importation into Great Britain has been, in 1819, 71,299 lbs.; 1820, 112,616 lbs.; 1821, 175,433 lbs. The increase of horses has been in nearly the same ratio as the sheep. In 1810, they were 1114, and in 1820, 3639. They are generally of the European breed, with a mixture of the Arabian brought from India. Pigs and poultry have increased in nearly the same proportion as other stock. The mineral productions of this settlement are yet but slightly ascertained. Iron has been found about eight miles from Port-Dalrymple, which is said to be equal in quality to that of Sweden. The mines have not yet been worked. There is abundance of coal at Hunter's River, about 50 miles north of Port-Jackson. The vein is three feet thick, was worked by a passage from the river, but is now by a shaft 112 feet deep, and the labour of twenty-seven men can extract twenty tons *per* day. In this labour, the criminals from Sydney are destined to be employed. Lime, for building, has hitherto been burnt from oyster-shells, as no limestone has been discovered near the settled ports. Common salt has been extracted from sea-water, but from the bitter not being accurately separated, the culinary salt of England, notwithstanding its price, is generally preferred.

The circumstances of the colony are not favourable to manufactories; but some hats, blankets, woolen stockings, and coarse cloths, have been made from the native wool. Pottery wares, of different kinds, have also been made, but they have not yet acquired the art of glazing them. The most advantageous operation of manufacture is tanning; but, from want of sufficient practical knowledge, it has been hitherto badly performed. The bark of the mimosa, a tree that abounds in the interior, is found to contain the requisite properties for tanning hides. With a little more experience, and with some regulations to prevent damage to the hides on flaying them, the colony might supply itself with leather from the cattle bred and slaughtered at home.

The foreign trade of the colony consists of the importations of sugar, spirits, soap, and cotton goods, from Bengal; of tea, sugar-candy, silks, and some clothing, made of English cloth, from China; of iron and hardware, cottons, millinery, wines, porter, cheese, and salted provisions, from England; and of sugar, tobacco, and spirits, from Brazil. The exportations

Commerece.

New South  
Wales  
||  
War.

have hitherto been but trifling. Wool has been already noticed: seal skins and fish oil might have formed returns but for their being charged with higher duty in England, if taken by a colonial than by a British vessel. Exportations to China have been made of sandal-wood, and pearl shells, previously collected at the Islands. Some attempts have been made to export flour to the Cape of Good Hope, and horses to Batavia; some coals have also been shipped for Bengal and for Batavia. The shipping of the colony consists of twenty-seven vessels, from 15 to 184 tons burden. This branch of industry is much retarded in its growth by the restrictions which are found necessary to prevent the escape of convicts by sea.

The external trade has been assisted by the establishment of a bank; but the institution has been injured by having suffered its cashier to defraud it of nearly L. 10,000, being half the capital. The principal circulating medium is the bills of the Government, or receipts for stores received by the Commissary, which amount to about L. 40,000. The smaller operations are performed by means of the notes of the bank, which are issued for 2s. 6d., 5s., 10s., 20s., and five pounds. The legal interest of money in the colony was 8, and is now raised to 10 *per cent.*

By the accounts of the treasurer for seven years,

ending September 1821, it appears that the taxes collected in that period amounted to L. 174,310, 10s. and the expenditure to L. 163,790, 8s. The income is derived chiefly from port dues, import duties, licences, and tolls. The chief expenditure has been on the establishments for male and female orphans, and for public schools—for public buildings and works—for salaries to officers—and for public and judicial charges.

In all the grants, reservations of land have been made for the support of the clergy, and for the maintenance of schools. The clergy are under the inspection of one of their number, denominated senior chaplain. Some Roman Catholic chapels are building, and one for the Wesleyan Methodists. The public services of religion are reported to be attentively observed. The administration of justice is executed in a court established by special act of Parliament, in which the Chief is an English Barrister; and recently an Attorney-General has been appointed, who is to be the general prosecutor of all offences.

See Wentworth's *New South Wales; Parliamentary Papers* ordered, by the House, to be printed at the following dates—19th June 1822, 19th April 1821, 13th March 1823, 9th March 1821. (w. w.)

## W A R.

THE present state of military science presents an inquiry of very considerable extent. To take a luminous view of every branch, would require a compass of theoretical knowledge and practical experience, possessed by very few in any service. Even to attempt a satisfactory essay on any one of the principal branches would be a task of considerable difficulty; if recent authors, of known ability and experience, had not discussed many of the most important questions, and demonstrated the mutual dependence between theory and practice, in all their essential bearings.

Objects of  
this Article.

In the body of the work, the science is considered under the articles FORTIFICATION, GUNNERY, and WAR. The two former take a sufficient view of their respective subjects; but the latter, including likewise naval war, is contracted to the mechanism of columns of movement and formation in armies; the operations of detachments; and a short account of strategy, position, and field service. But, as no particular notice is taken of the great principles of war, the knowledge of which is of primary importance to the soldier and the politician, and indeed to the general observer, as the only safe guides in the judgment of operations; and as the improvements in this essential branch constitute the most valuable feature in the late eventful wars, we shall endeavour to give as complete a view of its principal combinations as our limits will allow; and by referring to the most signal events in modern times, afford them that illustration,

which the reader, if not previously acquainted with the details of the subject, will immediately obtain by referring to any authentic author, in which they are more circumstantially described: reserving for the conclusion, a few observations on minor subjects, of present or future applicability, and a list of the authorities consulted, or whose works are of acknowledged utility in the study of the theory, or in judging the practice of war in military history.

Jomini has demonstrated that the art of war re-Theory of  
poses upon one governing principle, or what may be War.  
termed the *Fundamental Maxim*; by the applica-  
tion of which all the combinations are good, and  
without which they are all faulty. This maxim con-  
sists in

*Effecting, with the greatest mass of forces, a com-  
bined operation upon the decisive point.*

To illustrate the subject, it may be observed, that the decisive point in war, or what has been termed the primitive objective point, is obviously that in which resides the principle of strength in an enemy; and it follows, that to be able to destroy it in the shortest and most effectual manner, must be the fundamental principle adopted by his antagonist. The mode of effecting this purpose is, however, the difficult part of the question, because of the infinite variety of circumstances to which it is subjected. But the theory of war may nevertheless be divided into three primitive combinations; because the practice is composed of as many branches, each of which de-

War. pend upon particular principles: therefore, a great operation, to be perfect, ought to combine the three primitive combinations; because, then, they produce the complete application of the fundamental maxim.

The first of these relates to what is commonly termed forming the plan of a campaign, and consists, either in an offensive or defensive view, in the art of embracing the lines of operations in the most advantageous manner.

The second is the art of moving the mass of forces, in the most rapid manner possible, upon the objective point of the primitive or accidental line of operations. This is the method of execution, or strategy.

The third is the art of combining the simultaneous application of the mass of forces on the most important point of a field of battle. This branch is usually designated by the term Tactics.\*

#### I.—Plan of Campaign.

A plan of a campaign depends upon six essential considerations: 1st, The political situation of both parties; 2d, The situation of the moment; 3d, The relative force and military means; 4th, The location and distribution of the armies; 5th, The natural line of operations; 6th, The most advantageous line of operations. In forming the plan, it is not necessary to have regard solely to the exact balance of the relative means of war between the parties, but to view them only as they are important. Territorial and manœuvring lines of operations are the principal object; and though they are subject to many accessory considerations, the rules of the art must nevertheless form their basis. Originality and great boldness are not incompatible with their application: such, for instance, as the plan which Napoleon, in 1800, executed in Italy. No enterprise could be more daring, none more rich in great and decisive combinations, or more prudent and cautious; since, while it menaced the enemy with ruin, no greater misfortune could occur, in case of check, than the sacrifice of the extreme rear-guard.

Before we proceed, it may be useful to fix, by definitions, several terms, upon the comprehension of which the most important military reasoning depends.

By a *base* or *basis of operations* is meant a frontier, the course of a river, a coast, a range of mountains or fortresses, or any topographical or political extent of country, upon the imaginary line of which the corps of an army assemble, offensively,—to take their departure from thence into the enemy's country, and towards which, in case of failure, it is intended to retreat; defensively,—to counteract all the measures which an invading force may pursue.

*Lines of Operations* are divided into territorial and manœuvring lines. By *Territorial Lines* are understood those which nature or art has traced for the defence or invasion of states. Frontiers covered by fortresses, or defended by nature, with chains of

War. mountains, great rivers, or other obstacles, form their constituents. *Manœuvring Lines* are the dispositions of the general to traverse them offensively, or cover them defensively. Both these lines of operations are intimately connected. In offensive war, the line is an imaginary perpendicular upon the base, along which an army operates against the enemy; in defensive war, it is often the same, but still oftener parallel to the territorial line. A *Line of Communication* is either the same as that of operations, or any other by which the army receives its supplies, and communicates with the base.

Some examples will render the definitions more evident. France and Austria have three great lines of operations against each other—by Italy on one side; Switzerland and Tyrol in the centre; and by Germany on the other. In these the Po, the Meyn, the Danube, or a principal road, constitute the *material* of lines; which are amenable to only a few rules prescribed by their nature. Between Prussia and Austria again are three lines—through Moravia, Lusatia, and Saxony. Lines of operations are divisible into collateral or separate points. Frederick entered Bohemia by his central line, upon four points. The French invaded Germany in 1796 and 1799 upon two subdivided lines. Napoleon always operated upon one principal line, as did the Duke of Wellington in Spain.

Thus far no great variety of combinations seem to perplex the view; but in the selection of the particular line, the problem becomes difficult; because a great multiplicity of circumstances, many of them, not purely military, interpose. The political situation of the belligerents; their relative resources; character and situation of the fortresses; accidental strength of their forces; distance by sea; course of a considerable river; direction of a chain of mountains; nature of the country; political state of either party; jealousy of a neutral, or apprehensions of an ally; all in their turn claim consideration. In general, however, the initial application of military masses should be, when the belligerents are neighbours, upon some part of the frontier, which projects into the hostile state; such as Bohemia with regard to Prussia, or *vice versa*, Silesia with regard to Austria. But it is a maxim that lines of operations have their key as well as fields of battle; in the former, the great strategical points are decisive; as in the latter, the points which command the weak part of a position constitute the key. Where there exists a vast superiority of force on one side, the key, or great strategical point, may be sought at a considerable depth in the line of operations; but where the masses are nearly balanced, it is necessarily reduced to a relative proportion with the breadth of the base. Thus, for instance, the destruction of a French army on the frontier of the Netherlands, would not immediately produce the consequence of the victors marching to the capital, unless they had sufficient

\* For the sake of perspicuity, when this term is applied to the instruction of troops, it should be distinguished by the qualifying adjective, *Elementary Tactics*. Thus also the phrases, science and art of war, are used as synonymous, while we should understand by the science of war, the knowledge of the theory of all its elements; and by the art of war, the skilful application of that knowledge.

War.

superiority to mask the principal fortresses which cover her line of defence in that quarter, or some other accidental circumstance rendered such a measure practicable. As farther proofs of the relative proportion between the depth and base of a line of operations, that of Napoleon in Russia failed on both its pivots, before the summit was defeated; and those in Spain, although they were supported by intermediate fortresses, immediately contracted, when the battle of Salamanca produced consequences which endangered the western communication with the base.

Although it is absolutely necessary to move with a mass of force near the enemy, it is more advantageous to march in separate corps while still at a distance from him, if he has not a concentrated mass ready to act, and there be several roads leading concentrically towards the point intended to be occupied. It is evident, that five corps, of twenty thousand men each, will move forward more rapidly towards any point, than a hundred thousand men, marching on the same road, who can only advance with the tardiness inherent in large bodies, and besides are encumbered with the immense train of their subsistence. Celerity of movement, multiplying the force of an army by enabling the mass to be carried alternately upon every point of the line, is an advantage of invaluable consequence; but this is not the only reason for recommending this method. There are two others, viz. the increased facility of subsistence, and the uncertainty into which it throws the enemy.

An army of 20,000 men can find subsistence, in central Europe, on every part of their march, by merely causing the country, within some leagues, to contribute to their wants; and if they convey with them biscuit for eight or ten days, that is, during the first period while corps are in position, or manœuvring in a contracted area with other columns, they will be enabled to subsist till the magazines are formed. Thus, military operations are, in a great degree, emancipated from the necessity of pre-arranged magazines, and the regular encumbrance of field ovens.

The army which commences offensive operations takes the lead in all the movements, and those of the enemy are necessarily subordinate to them. If, therefore, it occupies with a corps, each of the great avenues leading to the enemy, he will be in a state of uncertainty along his whole line of defence or operations, and remain in suspense as to the point upon which he ought to collect his masses to oppose them. Upon these facts, the following series of maxims are founded:

1. When an army undertakes an invasion, or acts offensively, it takes the lead (or, as the French term it, *l'initiative*) in the movements.
2. This advantage precludes the necessity of marching in mass, until near the point where the enemy is to be found and attacked; until then, it is preferable to move in several strong corps, in proportion to the collective strength of the army, and to direct them upon the communications which lead concentrically to the point.
3. The general direction can only be upon the

4

War.

centre, one of the extremities, or the rear of the hostile line. An extremity will usually be found most eligible, because, from that point, the rear is easily attained; the centre, only in the case where the enemy's line is scattered, and his corps separated by great intervals.

4. In this case, the greater number of the corps should advance upon one of the isolated parts, and endeavour to surround it, while the remainder should occupy a central point to keep the rest of the hostile army in check.

5. When the principal mass of these corps is directed into the rear of an enemy, by passing one of the extremities of his line, one corps should remain upon that extremity, in order to keep open the communication with the line of operations, while the opponent is cut off from his. This corps serves likewise to attack him in flank, and to prevent him from withdrawing out of a faulty position by a secret movement.

6. These operations are most advantageous when the enemy is at a great distance from his own base. The principle may, however, be applied to positions less distant (two or three marches); provided the different corps have no greater distance to traverse to the point of reunion, than that which separates them from those of their own advanced posts who face the enemy. But this rule should not be understood as applying to isolated divisions upon an extended front of ninety or a hundred miles, unable to unite on a day of action, and whose movements cannot be simultaneous upon the decisive point. The difference is easily perceived between such operations and those of several corps concentrated in a position, the depth of which equals the extent of front, and whose simultaneous co-operation is certain before the enemy can make an attempt upon their line.

7. By means of this system, the army occupying a greater space marches more rapidly, and is enabled to subsist on the roads. Cattle and biscuit alone will be required to follow each corps, in sufficient quantity to subsist it when in the vicinity of the enemy, where the other corps having likewise arrived, they are obliged to live within a smaller periphery. The stock of provision will be sufficient, if equal to the time required for collecting another.

8. Magazines are then formed in the rear as the army advances. They are collected by means of regular requisitions made on the neighbouring provinces, and enforced by a few troops; contracts are entered into with the local administrations, and precautionary convoys follow from the frontiers. Cattle, rice, and biscuit, are the most useful provisions; the easiest to be transported.

In this view of the theory of initial operations, such as Jomini, and other authorities, consider them, no great regard is paid to the waste of human life, by the frequent want or irregularity of the issue of provisions, or notice taken of the indiscipline which naturally arises when famine drives the soldier to marauding. A relentless conscription system may, indeed, supply recruits; but they are a very inadequate instrument when compared to formed soldiers.

It remains to examine the art of forming a plan of campaign or operations in reference to insular

War. expeditions. In the application of masses on the base line of operations by sea, or by an insular force, much difficulty occurs; especially if that base is to be obtained by force on a hostile coast; because the line of communication from the port whence an expeditionary army proceeds to the point where debarkation takes place is lengthened, uncertain, and broken. The point of debarkation becomes a secondary base; and unless a friendly fortress, or a naturally advantageous point, left unguarded by the enemy, can be occupied, the difficulties are nearly insurmountable. It is again difficult to despatch a large force in one fleet; it is dangerous to keep it together, and dangerous to allow great intervals; the elements affect the time, connection, and order of the convoy; an independent and separate service (the navy) influences the primary organization and execution; debarkation absorbs much invaluable time, particularly that of the artillery, horses, and stores. From these causes, a practice has arisen of fitting out expeditions not sufficiently formidable, with a view of ascertaining the practicability of an object, but which, by that very system, is often rendered impossible; for the first landing having been effected, the enemy's attention is no longer divided; he assembles his means of defence, while the second convoy is expected, and the delay becomes decisive of the event. Yet if, in any military operation, the effect of masses simultaneously employed be of consequence, it is in those which commence on the sea shore; for the troops have not only to debark and act offensively, but also to construct their means of security and retreat, in case of failure. If we examine the primary operations of this class from the wars of King William to the present period, we shall find that, with the exception of such as were favoured by chance or particular circumstances, the success or failure was dependent upon one or more of the following maxims, especially as applied to continental expeditions:

1. When an army is directed to make a descent upon an enemy's coast, with the object of penetrating into the country, a point of debarkation should be selected, where the enemy possesses no local means to arrest the progress, such as a fortified city or a defensible peninsula. If, however, circumstances compel the descent near or upon such a spot, immediate measures should be taken to mask or capture it, and secure the success of ulterior operations.

2. If the expedition is intended to be confined solely to the coast, the point of debarkation should possess the indispensable qualifications of facility of communication with the fleet; security of retreat; and reembarkation. A point possessed of these advantages is a fit spot for a temporary base of operations.

3. An expedition intended to operate ulteriorly, should be *ab initio* superior to the probable immediate force of the enemy, so that the success of the landing and march into the country be not problematical.

4. No combinations of invasion should be made depending on the co-operation of corps expected from distant or opposite quarters. It is important to have them collected, as much as possible, on or

War. near one point of embarkation, to proceed from thence in mass to execute the enterprise.

5. In the plan of an expedition, no combinations should be admitted which include two or more lines of operations from separate bases. Armies transported by sea are, from that circumstance, not numerous; division renders them still weaker, and if on one point a misfortune occurs, the other must reembark.

6. In colonial and insular expeditions, it is only necessary to combine the means in proportion to the strength of the object, and with attention to the season and climate. But on all occasions where the reduction of a fortress is in contemplation, the engineer department should possess an adequate *materiel* as well as the artillery.

All these maxims are in unison with the leading principles of the art of war, or constitute mere modifications to adapt them to maritime affairs. As examples of the importance of the first rule may be quoted, the landing of the Emigrants at Quiberon: being confined to a narrow peninsula, they were immediately blocked in by the enemy. The Helder expedition, though victorious in two battles, could not penetrate beyond the neck of the Haerlemmer Meer, which makes a peninsula of North Holland. At Aboukir, again, a peninsula, similar results would have ensued, but for the circumstance, that a communication could be opened on the side of Rosetta, which rendered the position central against the two exterior lines of the enemy; namely, those of Cairo and Alexandria; and enabled the British to carry their mass alternately upon each, and ultimately with inferior numbers to reconquer that province.

In the second maxim, the causes are pointed out which allowed the expedition to Cherbourg, in 1758, to reembark in safety, although no regular precautions insured the measure; and those which produced the disaster at St Cast under General Bligh, notwithstanding every precaution. The Ostend expedition had the same defects, though, perhaps, on this occasion the object was considered of sufficient magnitude to allow a disregard of the consequences.

Inattention to the third, had a preponderating influence at the Helder. The first division having landed, was obliged to wait behind the intrenchments of the Zyp for the arrival of the main body. Meantime the enemy, now certain of the point in danger, collected his means, and arranged the plan of defence. After three battles, he was only thrown back upon stronger ground, in a position where he could neither be turned nor attacked in front with probability of success. In Egypt, the expeditionary force was likewise inferior to the enemy, and if the hostile commander had sacrificed the establishments and *Institut* at Cairo, to collect his forces on one line, he could have resisted the invasion with success. The Walcheren expedition, considered in its primary combinations and preparatory measures, was a model; as also that of the French for the invasion of Egypt. Both were wrong in the choice of the point of debarkation; but the results were different, and, from an unconquerable propensity in man, by the results they have been judged.

The expedition to the Helder again furnishes the

War.

proofs of the fourth maxim. Had the two British and the Russian divisions arrived in time to act in mass, within a few hours after the first landing, the enemy could not have matured an effectual plan of defence. But the combinations required easterly winds for the Russians and westerly for the British reinforcements, and both were, nevertheless, to arrive, if possible, simultaneously on the same spot. The Egyptian expedition was to be sustained by a corps from India and the Cape, by the Red Sea, which could scarcely, by any chance, arrive in proper time. At Copenhagen, indeed, the two divisions from Rugen (an island in the Baltic, where a British corps lay in transports) and from England did arrive without accident; but the successive divisions sent to the river Plate, to be successively defeated, are a farther corroboration.

The fifth maxim is sufficiently obvious. Sir John Moore's division was off the coast of Portugal when the battle of Vimiera was fought; had it sailed conjointly with Sir Arthur Wellesley's, the result of that battle would have brought the British into Lisbon *without* a convention. If the division engaged had been defeated, a corps on board of ships could not have rendered the least assistance. In the next campaign, Sir John operated on several lines from Portugal, and Sir David Baird from a different base (Corunna), with the view of uniting at the distance of more than 200 miles on a point in possession of a formidable enemy. Such combinations produced their natural consequences, the hard pressed retreat of the army to Corunna ensued; and, as if another proof were wanting, no sooner were the troops compelled to fight an action, than another division appeared to witness the conflict from the ships, and return to England.

To the deficiency of a proper establishment of sappers and miners, with the *materiel* required to enable the engineers to act with effect, many delays and failures may be ascribed. It has necessitated the severe system of bombardment, and repeatedly rendered the British arms odious, without thereby insuring success. Carcasses and rockets ruin the defenceless inhabitants, but have no decisive influence upon the defence of a regular fortress.

If we examine the wars in America by the rules of art, we find Lord Amherst operating by the line of Lake Champlain upon Montreal, and Wolfe by the St Laurence upon Quebec, both successful, and yet two years without connection. Next appear isolated expeditions traversing a vast continent, deficient in numbers, and therefore always inferior to the local militias on the spot, terminating their career in defeat or capture; or else dispersed along the coast, occupied in landings for trivial purposes, and when re-embarked, leaving the enemy to boast of successful resistance. In the Canadas we behold the key of defensive operations left without a fortress; true, indeed, that a fortress does not defend a state—that an army must be looked to for that purpose; but an army is a frail instrument, and if armies defend nations, fortresses defend armies.

Reflecting on the miscarriages produced by dispersing the forces, it appears, that in British military combinations it should be a maxim, *never to act*

*offensively on more than one point at a time.* This rule, a fundamental principle of the Roman policy in her best days, should have been acted upon in the wars of the Spanish succession, when that question ought to have been decided in the Netherlands. The consequence of pursuing a multiplicity of offensive combinations at the same time, was never better exemplified than in the failures of the simultaneous expeditions to Buenos Ayres, Constantinople, Alexandria, and Rugen. It follows that small expeditions, hovering along hostile coasts, produce no beneficial effects. The local garrisons and militia of the country are generally superior, and a momentary debarkation produces in the mind of the enemy not only national union, but also the ideas of victory. The debarkations at St Malo and St Cast; that under Sir James Pulteney at Corunna; most of those in America, were fraught with risks, not counterbalanced by any prospects of real advantage. Those on the east of Spain were of a different character; they had a political object of importance, and served as a diversion which fixed a whole hostile army in that quarter.

It is a general rule, liable, indeed, to occasional exceptions, *that the operations of the land forces should be confined to fixed important points, where the object is not only to land, but to conquer and maintain themselves.* There is no instance in the history of the nation where a British mass of forces met with disaster, when that mass acted by itself, or with sufficient preponderance among its allies. From the nature of the sea line of operations, expeditions, like other military enterprises, must be liable to miscarriage; but a right use of the forces will at least increase the chances of success. In the selection of the points, much must be left to the circumstances of the case, but their importance should always be in relation to the risk, expence, and time.

As these observations apply to great operations only, it is unnecessary to advert to flying corps, or such expeditions as are merely intended to alarm a coast or distract an enemy; because these, in most cases of problematical utility, should be very sparingly resorted to; and, at all events, never consist of more than a few frigates, with troops on board. The geographical extent and insular position of Great Britain afford equal facilities for defence and attack. Defence, however, when passive, is allowed to be the very worst that can be adopted in the military policy of a state; but when the national superiority at sea is considered, it becomes evident that British operations ought to be offensive. With a great number of garrisons stationed in every quarter of the world, the land forces form no where a considerable body; those in England being scarcely adequate to the local duties, and the relief of such as return from abroad. At the commencement of a war, although the militia is called out, the reinforcements required to place distant garrisons, on the war establishment, absorb nearly all the infantry, and leave not only no disposable force, but even no sufficient elements to create new corps in an efficient manner. Hence, three or four years of war pass by in preparations on one side, and in conquests on the other. Millions are spent, and vast sacrifices made, to arrest the progress of the enemy; humiliated

War.

War. ing offers are made, which the opponent, blinded by success, has the imprudence to reject. Then, forced to still greater expence, other campaigns follow, to recover what was lost in the first. By a rational system of preparation wars might be terminated in a short period, or altogether prevented; and yet long wars, the real cause of the prodigious national debt, are brought about by an ill-judged prejudice against a standing army, backed by still weaker ideas of economy. Since regular armies have been maintained in Europe, the obvious utility of having at least some disposable force to give weight to negotiations, requires scarcely an argument. Instead of three battalions, the only applicable troops in 1792-3, which were sent to Willemstadt, had Great Britain possessed 25,000 disposable troops, the National Convention would have paused before it declared war; or this force would immediately have influenced the reconquest of Belgium. Even a year later, such a national force could have averted the consequences of the action of Hooghlede, the retreat from Dunkirk, and the final evacuation of the Netherlands. In the late war, the inability of Great Britain to act from the first with vigour compelled her to fight twenty-one years, with incalculable waste of blood and treasure, merely to restore the balance of power; and the nation, which at first had only three battalions for service, ended, in 1814, with a mass of more than a million of men in arms.\*

In a military point of view, the economical system has been productive of immense losses to the nation; but if, under given circumstances, in time of peace, the army must be very generally reduced, care should be taken not to destroy the elements of regeneration. On a war breaking out, all the troops in the kingdom should be brigaded, with their generals, staff, field train of artillery, commissariat, and medical officers, and concentrated as much as possible, for the purpose of rapidity of execution, and creating habits of duty in large bodies, which the staff and commissariat generally begin to learn when before the enemy,—at a period when all parties should be fully acquainted with them, and when mistakes may be fatal. The orders of Government are thus executed as soon as issued, and that species of confusion is obviated which all who served in the beginning of the late war must have witnessed.

Till the beginning of the present century, plans of operations were usually arranged in the Cabinet, by superannuated officers, on obsolete principles; or by Ministers without professional knowledge, upon combinations entirely political. The Austrian Government was particularly unfortunate in this system. Plans, calculated with the precision of summer manœuvres, where every march, battalion, and detachment were prescribed, without adverting to the measures of the enemy, tied the hands of the generals, who were never successful against a formidable enemy but when they disobeyed their instructions, as Eugene did at Zenta. But when Fre-

derick traced his own plans of campaign, although even he was not fully sensible of the laws which should regulate territorial and manœuvring lines of operations, still circumstances and superior *tact* soon led him into the true system. Jomini blames, with sagacity, some of his initial operations; but he does not sufficiently consider his circumstances and his era; he compares the operations of Napoleon, with all the resources, fortresses, population, and revolutionary excitation of France, together with the adventurous gambling of his hero, to the conduct of a sovereign who had his native throne to defend; without a military frontier, with a scanty population, a barren soil, and no pecuniary means but such as arose from his economy; and yet he rose superior to all the difficulties of his situation, though under circumstances more unpromising than those which ultimately hurled Napoleon from his throne.

## II.—Manœuvring Lines of Operations.

The connection between manœuvring lines and those which nature has marked out, and the views of the general-in-chief, form separate classes, each named after the nature of that connection.

1. *Simple lines of operations* are those when an army operates in a single direction from a frontier, without forming detached corps.

2. *Double and multiplied lines*, when an army acts upon the same frontier with two or three isolated corps, towards one or several objects.

3. *Interior lines of operations* are formed to oppose several hostile lines, and are so directed as to possess internal connection, and enabled to move and approach each other, without allowing the enemy to oppose a superior mass to them.

4. *Exterior lines*, on the contrary, possess the opposite qualities; they are such as an army may form, at the same time, upon the two extremities of one or several hostile lines.

5. *Lines upon an extended front* are those which are arranged upon a great contiguous development by isolated divisions; but still belonging to the same mass of forces, and operating upon the same object. Under this head are comprehended, likewise, lines formed by two separate corps upon one given extent; they are then double lines upon a great front.

6. *Deep or lengthened lines* are those which, commencing at their base, pass over a great extent of country before they can attain their object.

7. *Concentric lines of operations* are either several or a single line subdivided, moving from distant points in order to arrive at the same object, in front or in rear of their base.

8. *Eccentric lines* designate a single mass starting from one point, and dividing itself in order to form several diverging lines upon isolated objects.

9. *Secondary lines* are those in the great combinations of two armies, which designate their relative connection while operating upon the development of the same frontier.

\* According to authentic documents, this mass amounted to 1,116,813, including navy, East India, and local militia force, but exclusive of yeomanry and volunteers.

War.

10. *Accidental lines* are produced in the original plan of campaign, when unexpected events necessitate a new direction for the operations. They are of the highest importance, and rarely adopted but by generals of the first abilities.

Formerly, lines of operations were considered only as they effected the *materiel* of armies; it was even advanced, that armies encamped near their magazines had no lines of operations; but an example will prove the fallacy of this opinion. Supposing two French armies encamped, one on the Upper Rhine in front of Brisac, and the other on the Lower Rhine in front of Dusseldorf, with both their magazines in the safest place, that is, behind the river. These armies must have either an offensive or defensive object, and therefore have territorial, as well as manœuvring lines of operations. 1st, The territorial defensive line will extend from the point of their position to the point which they are to cover; therefore they would both be cut off if the enemy occupied that point before them. If Melas, with his army, could have subsisted near Alexandria in Lombardy, after the battle of Marengo, he was no less cut off from his line of operations as long as his victorious opponents occupied the line of the Po. 2d, Their manœuvring lines would be a double against a simple one, if the enemy concentrated his masses to crush one of the armies; it would be a double external line against a double internal, if the enemy formed also two corps, but so directed that they could be united most readily.

The article in the *Edinburgh Review*, on the work of Jomini, makes the following able remarks on lines of operations: "Among all these lines, the simple and interior are the best, particularly when combined, as being most congenial to the great principle of carrying a mass of troops upon the decisive point. A few remarks will make the truth of this apparent. If an army advances from its base of operations upon one line, it is clear that the general commanding will have but two important dangers to provide against; first, that of his troops being attacked unawares; and, secondly, that of being turned and cut off from his communications with his base. The most effectual method of guarding against either is, to attack the opposing enemy first, or, as the author calls it, *prendre l'initiative*; and if, in so doing, the assailants can place themselves in such a position, that a victory will give them the means of utterly destroying their adversary, while a defeat will not be of material detriment to themselves, the manœuvre must be considered as a perfect one. Now, a single and interior line has a manifest advantage over every other in aiding such an operation. An army which moves upon double, exterior, or multiplied lines, must be weakened in proportion to the number of its divisions. The general has many combinations to attend, and many dangers to guard against; his columns being on many roads and unconnected, must also be dependant upon many persons and many orders. Obstacles will be multiplied at every step; and errors cannot be known or corrected without much loss of time. The success of his plan must depend upon the exactness and concert between the different divisions; a misfortune attending any one vitiates or destroys the whole project, and yet each column, se-

parately, will be too weak to strike an important blow, if a favourable opportunity should occur. They will suffer severely from mishaps, and they cannot well take advantage of misfortunes.

"An army that manœuvres upon simple and interior lines gets rid of all these incumbrances; the troops will be together and well in hand, with the general upon the spot, ready to rectify errors, and to superintend every movement; and upon whichever road he marches against an enemy acting upon double or multiplied lines, his combinations must be more simple, and his numbers must be superior; he will have the power of overwhelming whatever division of his adversary he may meet with, and, by thus disorganizing his opponent's plan of campaign, enable himself to cut off their communications, or to attack their columns in detail. We will suppose, however, that, finding their line penetrated, they might, by great exertions, unite the remainder of their scattered corps by a retrograde movement; but they will hardly be able to cover their communications, which must be nearly as numerous as their divisions, and the attacking army will give battle in the execution of a preconceived plan, while they will be in the confusion of a baffled one. If the great principle, however, of carrying a mass upon the decisive point has governed the general who advances upon the simple line, he will, by a victory, deprive his foe of retreat, and utterly destroy him; while, if he fail, his communications are still open, and, from want of a plan, the pursuit cannot be very vigorous."

These remarks upon manœuvring lines are well illustrated in modern military history. In the Seven Years' War, Frederick had the choice of attacking Austria, on his left, by Silesia into Moravia, in the centre through Lusatia, and on the right by Saxony, both into Bohemia. His natural territorial line was, undoubtedly, the first of these three; because, while his own flank was covered by the fortresses of Silesia, he could penetrate at once into the vitals of the Austrian dominions, and masking Olmutz, threaten Vienna. He did not feel the advantage of this line until the third campaign, when he was every where outnumbered by the enemy, and yet even then he might have had signal success, if his besieging train, &c. had been in more efficient order and better applied. From this period he became sensible of the superior utility of central lines, and from 1758 he operated successively with his principal mass in Saxony, Silesia, and Brandenburg: the same troops were victorious in all these quarters, by alternately reinforcing each corps so as to attain a superiority. Having missed the opportunity in 1757 of deciding the war by a successful invasion, he at last gloriously saved his kingdom by this new system. All these successes belong to the three first classes of simple, double, and interior lines of operations. Those of his adversaries, on the contrary, were always of the fourth and fifth, exterior lines, and lines upon an extended front. For, on looking at the map of the seat of war, it will be readily observed, that he operated within the triangle formed by Dresden, Breslaw, and Custrin, while the enemy manœuvred outside of that figure. After the battle of Hochkirch,

War.

War.

indeed, when this area was broken in, he made a master stroke, by uniting his three armies in Saxony, and thus wresting from Daun the advantages of his victory. The operations of that crisis belong to the tenth, or accidental lines, in which Frederick has never been surpassed. To this class belong, likewise, his invasion of Bohemia, after raising the siege of Olmutz; his march into Silesia and manœuvres before and after the battle of Liegnitz, in 1760; and his central position at Buntzelwitz, by which he kept the enemy divided, in 1762.

The French operations in Hanover were not more successful. In 1758, they formed two lines of operations, in Hessa and on the Wezer, upon a development of 300 miles. Prince Ferdinand manœuvring upon their extreme left, had only isolated corps to contend with, and drove them across the Rhine. Marshal Contades, after the battle of Crevelt, felt the advantage of the line of the Rhine, all the fortresses being in his hands; but while he acted without vivacity on his right, Prince Ferdinand took a central direction, and broke the concert between the two hostile armies, who, at the end of the campaign, lost nearly all they had gained, having spent their time in disjointed marches, and in writing *projets* and counter *projets*. After the battle of Bergen, in 1759, the French, grown wiser, united all their forces in Hessa; they made conquests, which even the defeat of Minden did not wholly repair. In 1760, Marshal Broglie persisting in operations in mass, made a respectable campaign, but the next two, armies were again formed at a great distance; Prince Ferdinand again was beforehand with them every where; at length they approached each other to attack, but, for want of concert, were defeated at Fellinghausen.

In comparing the constant difference of the lines of operations which the Austrians, Russians, and French adopted, with those of the Prussians and Hanoverians, their opposite results are at once discovered.

During the wars of the Revolution, the Duke of Brunswick's march into Champaign was a simple line, but wanted corps to cover the flanks and activity in the execution. The recovery of Belgium by the Austrians was also effected by operating in mass; but on the French frontier they wasted their time in sieges, and acted upon exterior and eccentric lines. The French operated in a similar manner, but having a line of fortresses and numerical superiority, they were at last successful, and expelled the allies from Belgium. This worthless system was then cried up, and denominated Carnots. Accordingly, in 1795, the French persisted in acting on double lines. They manœuvred on the Rhine, by Dusseldorf and Mannheim: Clerfait operating centrally, carried his masses alternately from right to left; gained the decisive victories of Mannheim and the lines of Mayence, and threw the French army of the Sambre and Meuse back across the Rhine to cover the Mozelle, and Pichegru under the cannon of Landau.

In 1796, the French in their lines of operations on the Rhine, still copying Frederick's faulty system of 1757, and their own of 1794 and 1795, were not more successful than the preceding campaign. The armies of

War.

the Rhine, and of the Sambre and Meuse, moved from the extremities of their base to take a concentric direction on the Danube. As in 1794, they formed two exterior lines. The Archduke Charles opposed his own in an interior direction to be more readily concentrated, and seized the critical moment, while the corps of Count Latour was covered by the Danube, to steal some marches unperceived by Moreau, and to throw his mass upon Jourdan, who was routed at Wurtzburg. This decided the fortune of the campaign in Germany, and compelled Moreau's deep lines to retreat into France.

Meanwhile Napoleon commenced his extraordinary career in Italy, as Frederick had recommended half a century before: his system was to divide the enemy, and force the Austrians and Piedmontese to take two exterior lines. They fell into the snare, and he defeated them separately at Mondovi and Lodi. An army had assembled in the Tyrol to relieve Mantua; it was led on in two lines separated by a lake (Guarda). The French general raising the siege, hurried with the mass of his forces to meet the first column at Brescia, and routed it; the second column arrived soon after on the same ground, and was likewise driven back upon the Tyrol. Wurmsier determined to cover the two lines of Roveredo and Vicenza; Napoleon, after defeating the first and driving it into the Lawis, changed his direction to the right, passed through the gorges of the Brenta, upon the left line of the enemy, and forced the wrecks of this fine army into Mantua, where it ultimately capitulated.

In 1799, the system of Carnot again prevailed. France, twice punished for operating with two exterior lines, now adopted three. An army on the left observed the Lower Rhine, one in the centre was on the Danube, and a third occupied Switzerland. These armies could not unite till they reached the valley of the Inn, eighty leagues from their base. The Archduke uniting his forces in the centre, gained the victory of Stockach, and the Helvetian army was constrained to evacuate the Grisons and Eastern Switzerland. In their turn the allies committed the same fault; instead of pursuing the conquest of this central bulwark of Europe, they formed a double line in Switzerland and on the Lower Rhine. The army in the former country was ruined at Zurich, while that in the latter was trifling about Mannheim. In Italy a double line was formed by the French; one towards Naples, where 32,000 men were employed to no purpose; while the other, on the Adige, was too weak, and suffered severe loss. At length, when the army of Naples returned towards the north, it committed the fault of taking a direction from that of Moreau. Suworow took an able central position, marched against the first of these armies, and defeated it within a few leagues of the other.

In 1800 the scene changed again. Napoleon, having returned from Egypt, displayed a new combination of the lines of operations: 150,000 men filed off on the flanks of Switzerland, opening, on one side, on the Danube, and on the other upon the Po. This masterly combination secured immense advantages. Modern Europe had not as yet presented such operations. The French armies, forming two

interior lines, which reciprocally sustained each other, forced the Austrians to take a contrary or exterior direction, which disabled them from communicating together. By this arrangement, the reserve army cut off the communications of Melas with the base, while it preserved all its own, with the army of the Rhine,\* which constituted its secondary line. A reference to the map of that seat of war will show Moreau posted at Stockach and Zurich, and Kray facing him on the north side of the Danube. In Italy, Napoleon on the Po, at Pavia, and Tortona, with a corps at Verceil, completely insulating Melas at Alexandria; while the French commander, in case of check, had all the gorges of Switzerland, the St Bernard, Simplon, St Gothard, and Splügen open. The events of that period offer convincing proofs of the decisive effect of a proper choice of lines of operations.

In a subsequent campaign, Napoleon, breaking up from Boulogne, and directing several corps through central Germany to approach the Danube, suddenly turned the position of Mack at Ulm, and, placing himself upon his communication, forced him to surrender. But in this campaign his fortune began to blind him. Forgetting that he had no base of operations nearer than the Rhine, he hurried forward to Vienna, and thence to meet the Russians in Moravia. Prussia was in arms; an English corps had reached the west of Germany; Bohemia had risen in mass; the Tyroleans made a successful resistance; and the Archduke Charles, after crippling the French army of Italy, had advanced to the vicinity of Vienna. At this moment, with only a small reserve at Frankfort, the Austro-Russians, who had every interest to temporize, hazarded the battle of Austerlitz; and his good fortune, and the imprudence of the allies, saved him from a dilemma from which that victory would not have relieved him, but for the pusillanimous feelings which signed the peace.

Similar manœuvres towards the sources of the Saala produced the disasters of the Prussians at Jena and Auerstadt. But in this war, Napoleon became still more enamoured of deep and baseless lines of operations; the baneful effect of which he was not destined to feel till the campaign of 1812, when he invaded Russia without a true base nearer than the Rhine. His secondary base on the Vistula bore no relation to the depth of his line of operations, intersected by the Niemen, the Dwina, and a solitary waste of endless woods and heaths. Although he operated on a simple line, the immense distance from his base left him without communications. The extremes or pivots of the secondary base were already turned and broken, when Kutusoff moved to the rear of his flank upon Kaluga, towards the Berezina, and destroyed the greatest army recorded in modern history. The next year, though his lines were shorter, circumstances were totally altered; he operated with ability in mass; but being greatly inferior in horse, and the allies manœuvring likewise in mass, the first

battles were indecisive, till his adversaries, operating upon double exterior lines,—on this occasion applicable from their great superiority in numbers and in cavalry,—moved again round the flank, and decided the question at Leipsig.

Meantime, the Duke of Wellington, in the Peninsula, *cunctando restituit rem*. Opposing a single line against a single line, he saved Portugal by his masterly position of Torres Vedras, without a battle. Next, he drove the enemy from the frontier fortresses, by alternately carrying his masses across the Tagus. His line was shorter from north to south than that of the enemy, and he caused them to increase theirs by the destruction of the bridge of Almeras. Thus he forced his opponents to operate exteriorly. After the victory of Salamanca, his march into Spain was by two interior lines; and though this operation has been blamed, because it ended in a retreat, we forget that the enemy was obliged to abandon the south, or one half of Spain, to produce it. The next operation was upon a single and decisive line. The enemy was encountered at Vittoria before he could concentrate his forces, cut off from his base, and driven headlong into Pampluna.

This comparison of the combinations and results of the most celebrated campaigns shows, that all the lines of operations that have been crowned with success depended on general principles, of which the following are the principal heads.

1. A double line of operations is advantageous, if the enemy has, likewise, a double line; provided theirs be exterior, and at a greater distance than yours, and unable to unite without first risking a battle.

2. An army possessing interior lines, more connected than those of the enemy, can, by strategical movements, destroy them successively, by carrying the mass of forces alternately upon each point, as exemplified in the campaign of 1758, and subsequently at Manheim and the lines of Mayence; at Wurzburg and Emmendingen; at Lonato and Castiglione; Trente and Bassano; at Stockach and Zurich; Abendsberg and Eckmuhl, &c.

3. In order to effect this movement, a corps should be left before the army which it is intended to keep in check, with orders not to engage, but merely to retard the march, by taking posts behind defiles or rivers, and retreating towards the army.

4. From the above premises, it follows that a double line of operations against an enemy, whose corps are in closer connection, will always be unfortunate with equal numbers, if the enemy profits by the advantages of his situation, and manœuvres with rapidity within it.

5. A double line of operations becomes still more dangerous, when its parts are separated by several days' march.

6. Simple and interior lines, on the contrary, are always most safe; because they admit the action of

\* Army of the Rhine, of the Sambre and Meuse, were names given to French armies, although they were not always on these rivers.

War. the mass of forces against the isolated divisions of the enemy, if he be so imprudent as to venture an action.

7. A double line of operations, however, may be adopted with success, if the forces employed are so much greater, that superior masses can be presented to the opponents on both its parts.

8. Two interior lines, mutually sustaining each other, and facing two exterior lines at a certain distance, must avoid being compressed into a small area; for the exterior hostile lines might thereby act simultaneously.

9. Again, they should not operate at too great intervals; for the enemy might have time to crush one of these divisions, while it is weakened by detaching to the other, and thus gain a decisive advantage.

10. It being the interest of a commander to divide and isolate the opponent's forces, his manœuvring lines should never have the object of drawing the whole hostile forces upon him; as Tempelhoff boasts Frederick to have done in the campaign of 1760.

By reference to the preceding sketch of the operations in late wars, the value of these rules is everywhere observable. When the details in history are examined, such as they are presented by authors acquainted with the art of war, they form a key, which opens an unerring way into all the causes of success and misfortune. Thus, in what has been said on accidental lines of operation, it might have been added, that Napoleon did not know how to avail himself of them, when he was advised to operate by the right bank of the Elbe, and change his direction upon the pivot of Magdeburg, instead of risking the battle of Leipsig, and suffering, in violation of the eighth rule, the enemy to place him between two fires. Nor, in Champaign, in 1814, when he operated at too great a distance, overlooking the ninth rule, which gave the allies time to force the gates of Paris, thus employing the just system of throwing the mass of their forces upon the most important point. The Duke of Wellington's defensive campaign in Portugal hinged upon a prudent application of the second rule; and Napoleon, in 1814, could not have resisted so long as he did in France, but by the same system; although the allies, at that moment, conducted their operations on the seventh rule, perfectly applicable under the then existing circumstances, yet the vast superiority of internal lines remained evident. But when his eccentric movement placed him out of the sphere of real operations, the allies applied the third rule with perfect success, and effected his fall.

In order to complete the view of territorial and manœuvring lines, it is requisite to consider them as they are affected by the configuration of frontiers.

1. In order to operate with advantage, there should not be two different armies upon the same frontier: because,

2. Double lines will always fail, with equal chances, against a single line, as has already been shown.

3. Interior lines resist with advantage against exterior lines, either upon the same, or upon two dif-

ferent frontiers. The objection that Pichegru proved successful in 1794 is not valid; because Prince Coburg did not avail himself of his interior line, but acted by detachments, while he remained inactive with his mass, inferior in strength, and unsupported by fortresses on the flanks.

4. When the hostile fortresses are scattered upon a line of great extent, the most advantageous manœuvring line is upon their centre; as the Russians experienced to their cost, in the beginning of the campaign of 1812: but on all other occasions, the best direction is upon one of the extremities, and from thence on the rear; as exemplified in 1800, in Italy; in 1805, in Bavaria, and the next year at the sources of the Mein and Saala, &c. When central masses are moved with ability against scattered corps, all other things being equal, they must always be successful, often even without a battle: as when Moreau making demonstrations against the left of Kray, near Huningen, moved rapidly into Switzerland, whereby the greater part of Swabia fell into his hands without an action. The march of the Duke of Wellington upon Madrid and Burgos produced the immediate evacuation of the south of Spain; and the movement of Kutusoff upon Kaluga, forced the French from Moscow and out of Russia.

5. The configuration of a frontier may have important influence on the direction of lines of operation. Central positions, forming salient angles towards the enemy, such as before observed, Bohemia forms towards Prussia, Switzerland towards Austria or Saxony, as it was circumstanced in 1813, are the most advantageous; because they are naturally interior, and lead to the flanks and rear of the opponent's defensive line. The sides of these salient angles are therefore so important, that all the resources of art should be added to those of nature to render them impregnable. Switzerland and Bohemia are sufficiently proved to possess these natural advantages; but Saxony appears more doubtful, because Napoleon was at length defeated at Leipsig. Yet, it was his conviction of these central advantages that made him neglect to change the line of his operations upon the pivot of Magdeburg: and if we examine the character of the operations, though the allies were numerically, and especially in excellent cavalry, superior, we discover that when his defensive manœuvres were confined to a moderate distance from the Elbe, and the ridge of the mountains of Bohemia, no impression could be made upon him; but his system was solely that of attack, and his impatience sought the Prussians deep in Silesia, the grand army beyond the defiles of Bohemia, and the northern army in the sands of Berlin; not successively, but all at the same moment. He was thus on all sides inferior, but not dislodged, till, by his own indecision, he allowed the enemy to turn both his flanks simultaneously, and to bring him to action between two fires at Leipsig. We may take occasion to revert once more to the double exterior lines of the allies, here, and in 1814, in Champagne. When each of the armies operating exteriorly amounts to 120,000 or 150,000 men, they possess a consistency which obviates all need of co-operation: for, admitting the enemy to be even stronger, there is not a great dis-

War.

parity of force between the parties, which can be deployed and brought into action on the same field of battle: hence the weaker army can decline a battle, and in both these cases, where the allies had great superiority of cavalry, they could begin and break off a battle at their pleasure; as they proved at the first battle of Leipsig or Lutzen, and at Bautsen.

6. Where no such central position or territorial projection exists, the same effect may be produced by the relative direction of the manœuvring lines, as exemplified in Plate CXXI. fig. 1. *CD*, manœuvring on the right flank of the army *AB*, and *HI*, moving upon the left flank of *FG*, form two interior lines, *CK* and *IK*, upon the extremities of each of the exterior lines, *AB* and *FG*; both of which may be destroyed by carrying the mass of forces alternately upon them. This combination presents the effect of the French campaigns of 1800 and 1809. It is also the spirit of the Duke of Wellington's defence of Portugal; for by his bridges on the Tagus, he had a direct and interior communication on both his lines north and south of the river, while the enemy, being placed on the segment of a circle, had only the precarious connection by the bridge of Almeras, which being destroyed, he could not advance from either Andalusia or Salamanca, without immediately placing himself in the disadvantageous position here described.

7. The configuration of the theatre of war may possess the same importance as that of a frontier; for, in fact, every theatre of war may be considered as a quadrilateral figure. To elucidate this idea, the scene of operations of the French army from 1757 to 1762, and the operations of Napoleon in 1806, may be cited. In Plate CXXI. fig. 2, the side *AB* being inclosed by the North Sea; the side *BD* by the river Wezer,—base of the army of Prince Ferdinand; *CD* representing the river Mein,—base of the French, and *AC* the Rhine, likewise in possession of the French; their armies operating offensively on the sides *AC* and *CD*, had the third *AB* or North Sea in their favour, and therefore *BD* was the only side, which they were to gain by their manœuvres, to have possession of the four sides, and consequently of the base of all the communications of their adversary.

This is more clearly exemplified in fig. 3. The French army *E*, proceeding from the base *CD*, to gain the position *FGH*, cuts off the allied army *J*, from the side *BD*, its only communication and base. It would thus be driven into the angle *LAM*, which is formed near Embden by the line of the Rhine, the Ems, and the Sea; while the army *E* could always communicate with *CD* or the Mein.

The manœuvre of Napoleon, on the Saala, in 1806, was combined on the same principles. He moved upon Jena and Naumburg in the position *FGH*; and then advancing by Halle and Dessau, he threw the Prussian army *J* upon the side *AB*, formed by the sea. The fate which attended that army at Erfurth, Magdeburg, Lubeck, and Prentzlow, is well known. The great art, therefore, consists in combining the marches, so as to arrive upon the communications of the enemy, without sacrificing

one's own. Now the lines *FGH*, by means of the prolonged position, and the angle formed towards the extremity of the enemy, always preserves the communication with the base *CD*. This constitutes the application of the manœuvres of Marengo and Jena.

When the theatre of hostilities is not near the sea, it will be still circumscribed by some great neutral power which guards the frontier, and incloses one side of the quadrangle. No doubt this barrier is inferior to the sea, but, in a general view, it must nevertheless be considered as an obstacle, upon which it is dangerous to be driven after a defeat, and advantageous to push an enemy. A state with 200,000 men will not suffer its neutrality to be violated with impunity; and if a beaten army ventured so to do, still it would be cut off from its base. But if an inferior power forms the limit of the theatre of war, the square of operations may then be considered as extending over it to the next great neutral power, or the sea.

To give a still more convincing proof of the justness of the preceding ideas, let us examine the scene of the campaign of 1806-7, in Poland. The Baltic and the frontier of Austrian Galicia formed the two sides *AB* and *CD* of the above square. It was of great consequence to both parties to avoid being driven upon either of these obstacles. The configuration of the frontiers may modify the sides of the square, and convert them into a parallelogram, or a trapezium, as in the 4th figure, Plate CXXI.

In this case, the army *GH* being in possession of the sides *AC* and *CD*, would be still more favourably situated, because the base of the opponent being contracted at *BD*, would be more difficult to keep open. The front of the base *BD* having less extent, offers fewer resources for manœuvring, and affords to the army *GH* the means of operating with more success; because the direction of the line *CD* naturally leads upon the communications of the enemy, and because the space to be occupied in order to cut him off, is shorter, and therefore more easily held with concentrated forces.

The theatre of war in Prussia and Poland, previously mentioned, was precisely of this figure. The frontiers of Austrian Galicia extending to the Narew, formed by the line of the Vistula, the contracted side *BD*; and the manner in which Napoleon embraced that line at Pultusk and Eylau was similar to the figure here shown. This operation had, however, its unfavourable chances. The first depending upon the doubtful trust to be reposed in the neutrality of Austria, and the second upon the great distance from the base of operations, which exposed the communications of the armies with the Oder to the mercy of the Cabinet of Vienna. It depended even then upon Austria (as, indeed, it had the year before depended on Prussia) to put a stop to these endless invasions. The manœuvre of the French general was good, but the operation of the statesman was only daring. These examples are sufficient to demonstrate, that the manner of embracing a theatre of war is amenable to the two following principles.

1. To direct the masses upon the decisive points of the line of operations, that is, upon the centre, if

War. the enemy has been so imprudent as to scatter his forces, or upon an extremity, if he is in a contiguous line.

2. To make the great effort in the latter case upon that extremity, which has its back against an insurmountable obstacle, or which leads upon the communications of the enemy without sacrificing our own.

Defensive Operations.

Defensive operations, in a great measure already examined in the preceding discussions, require, nevertheless, some further remarks. Passive defence offers no security to a state, nor fortresses without an army; it is confiding in a shield without a sword. Reason and experience alike prove, that defensive system to be the best, which embraces the greatest number of offensive facilities; for these we refer, in particular, to interior and simple lines; and those directions of lines which best anticipate or counteract the most effectual offensive ones. But as defensive measures imply inferiority of forces, they must in a considerable degree depend upon local means to counterbalance the superiority of the enemy. Rivers and chains of mountains are the natural obstacles; fortresses, intrenched camps, and well selected positions upon the most advantageous lines of defence, the artificial means in a territorial front. Fortresses, with *letes de pont* upon a river parallel to the frontier, are very advantageous; but upon a river perpendicular to the frontier, they are still more useful; particularly if fortified upon both banks, as Prague on the Mulda, or Maestricht on the Meuse. In the former case, an offensive army must cross the river only once; but in the latter, it must cross as often as the adversary thinks proper: for, placing his camp under protection of one of these fortresses, the enemy cannot pass him, without being taken in flank or rear; nor besiege the place without dislodging the enemy. Hence, intrenched camps, covering and covered by a fortress, add considerably to the defence of a state. The Austrians felt severely the want of these precautions on the Danube in the late wars. Thus the operation of Mack upon Ulm would have been good had he moved in time to attack from thence either on the right or left of the river; but to have rendered it secure, there should have been fortified positions on the Schellenberg at Donauwerth, Ingolstadt, and Ratisbon: for then he could always place the river between him and the enemy; and if the latter operated on both banks, he could attack, with his whole mass, that part which was most convenient, before the other could cross to assist it. Fortifications are also eminently useful in the defence of passes in chains of mountains. The insignificant fort of Bard, with 600 men, arrested the progress of the principal column of Napoleon, when descending the Great St Bernard into the valley of Aoste, in 1800; and if the fort had been better secured, the whole plan of campaign would have failed; for Melas would have had time to arrive and defeat the enemy in detail. Again, the French Emperor having constructed the fine roads into Italy, neglected to secure them by any fortifications, and the first military use that was made of them was by the Austrians, in the two successful invasions of France, where the old fort of L'Ecluse, near Gene-

va, was the only point that could, and actually did; retard them some days.

War. Fortresses likewise secure the magazines, stores, and hospitals of an army, and save the *materiel* and broken troops after a defeat. Pampeluna saved what did escape of the French after the battle of Vittoria, as Prague did the Austrians in 1757. But, in order to make them capable of producing the share of security to a state which reason can expect from them, fortresses should not be too numerous, because they absorb too great a proportion of troops for garrisons, and cost immense sums; nor small, for then they are easily embraced and overpowered by artillery; nor all on the frontiers, for if the enemy penetrate beyond them, the great arsenals, depots, founderies, &c. of the nation are no longer within reach of the defensive army, which is also deprived of the *appui* for a position to cover the capital, and turn the flank of the invader. In the last campaigns, France felt the want of intermediate fortresses. If such had existed about Soissons, on the Marne, and about the junction of the Seine and Aube, the avenues to Paris would have been more easily defended. Intrenched positions are often eminently useful, provided they intersect or flank the most direct lines of operations; but as they do not contain arsenals, &c. they are less so than fortresses, and the selection of their site is extremely difficult. Those of the Russians at Drissa, upon the line of Moscow, were abandoned. The intrenchments of the French on the frontiers of Spain, and at Toulouse, were forced; but those on the Isla near Cadiz, and at Torres Vedras, both saved kingdoms. A position ably chosen has sometimes the same effect. That of Dumouriez, near the wood of Argonne, arrested the advance of the Duke of Brunswick in 1792; and that of Kutusoff at Malojarslaf near Tula, forced the French to retire by the road they came. Both were on the flank, and menaced the rear of the enemy. Dumouriez, in the north-east corner of the French frontier, presented a salient angle, upon a simple line of operations towards the German and the Netherland fronts of defence, and was near the fortresses of Lorraine. Napoleon, in 1814, endeavoured to recover a similar line after the battle of Brienne; but it was then beyond the sphere of operations, and his march cost him the loss of his empire. To conclude, defensive war does not consist in covering every part of a state, but in preventing an enemy from obtaining any advantage, which may enable him to accomplish his main object.

### III.—Battles.

Between a battle won and a battle lost there is an immense distance, said Napoleon, the day before the conflict at Leipsig—empires lie between them; and, indeed, the plan of campaign, and the strategical movements, are only so many preparatory dispositions to arrive at the great crisis of a battle. The rules applicable to battles, therefore, form the most important branch of the science of war; because, unless they are well understood, all other knowledge will be comparatively useless. In many respects, this branch is less capable of being reduced to fixed principles than the others. There are,

however, certain general rules, which should govern the dispositions, and the chance of success will be increased or diminished in the ratio of their due application. Among these, the first is that of operating with a superior mass upon the decisive point, because the physical force of organized numbers in arms furnishes the unerring means of victory, when the moral qualities in both armies are equal. The means of bringing this force to bear in the most advantageous manner is the art of fighting; consequently, courage and fortune being nearly balanced, that general who can operate with the largest mass upon the most decisive point must be successful. But to effect this purpose, the combinations must be such as to produce a unity of movements, conducting simultaneously to the same object.

The following maxims are of general application :

1. No opportunity should be left till the morrow.
2. No battle should be given, but for an important object, unless the position should render it unavoidable.
3. After a victory, the enemy should not be allowed to recover—the pursuit should be incessant.

As in lines of operations, so on fields of battle, it is necessary to avoid dispositions, which have generally proved fatal; such as, 1st, forming isolated divisions; 2d, ordering extended movements, which deprive the army of a part of its strength, and enable the enemy to ruin either the main body or the detachment; 3d, positions with too great an extent of front; 4th, allowing obstacles to separate the wings, or obstacles which prevent the connection of columns, and expose them to separate defeats.

The finest combinations are those which produce an oblique order of battle; those with a wing reinforced; those which out-flank the enemy; and those which form a perpendicular upon a hostile extremity, or upon a scattered centre. These are almost always successful, because they present a whole line to an extremity; and, therefore, a greater mass than the enemy. Thus the fundamental principle of all military combinations; namely, *to effect with the greatest mass of forces, a combined attack upon the decisive point*, is applied; and it is easy to understand how a general of ability, with 60,000 men, may be able to defeat 100,000, if he can bring 50,000 into action, upon a single part of his enemy's line. For battles are decided, not by troops upon the muster rolls, nor even by those present, but by those alone who are simultaneously engaged. Numerical superiority of troops not engaged, so far from being useful, only increases the disorder, as was fully exemplified at Leuthen.

There are not a great variety of measures applicable to this maxim.

I. The first is evidently that of taking the lead in the movements. The general who is enabled to have this advantage, can employ his forces wherever he thinks them applicable; while, on the contrary, he who is obliged to await the enemy, is no longer master of a single combination; because his movements must be subordinate to those of his adversary, and it is too late to arrest them, when they are already executing. The general who takes the lead

knows what he intends to perform; he conceals his march, surprises or overpowers an extremity or a weak part of the hostile line; while the waiting army is defeated on one of its points, before the knowledge of the attack has reached its commander. Hence the following are corollaries.

1. An army taking the lead in a movement can conceal it until in full execution; therefore, when the manœuvre takes place in the interior of its own line of operations, the commander may gain several marches of the enemy.

2. To judge soundly of military operations, it is highly important to banish all calculations which suppose that the hostile general will be informed of a movement, and will oppose it by the best possible manœuvre, from the instant that the movement is begun.

3. When two armies combine to place the enemy between two fires, from the distance of several marches, they must ground the disposition upon a double line of operations against a simple one, and expose themselves to be defeated separately, if the enemy takes advantage of his central position. Such a manœuvre is similar to a movement made at a distance against the flanks; and should be ranged among those which cannot produce a simultaneous effect at the moment required.

II. The second consists in directing the movements against a weak point of the enemy, when that point offers the greatest advantages.

An attack to the front is always to be avoided, if a concentrated effort can possibly be made upon the extremity of an enemy's line, for which simple demonstrations on the front are sufficient.

Against double and scattered lines of operations, it is preferable to direct the attacks upon the central points; for the mass of forces having ruined a central division, the corps to the right and left can no longer operate in unison, and are forced to retreat eccentrically; as was proved in the disasters of Wurmser, Mack, and the Duke of Brunswick. Against simple lines of operations and contiguous lines of battle, the weak points are the flanks, because they are liable to be crushed before they can be sustained. Albuera offers, perhaps, the only positive example to the contrary in modern history. For here, the right wing of the allies was turned and routed, and yet the battle gained, by the centre forming an echelon to the rear.

A deep column being attacked on the head, is in a similar condition as an extremity of a line; both the one and the other are engaged in succession and defeated, or what is termed rolled up. This was proved at Rosbach and Auerstadt. It is, however, more practicable to make a fresh disposition from a column, than with the extremity of a line, when attacked by the enemy.

In executing a general strategical movement against an extremity of an enemy's line of operations or of position, a mass is not only brought to bear against a weak point, but also, from that extremity, it becomes easy to gain the rear and communications, either of the base or of the secondary line of the opponent. Napoleon's manœuvre in 1805 by Donauwerth and the line of the Lech, turned the

War. line of communication of Mack with Vienna, which was his base ; and it intercepted his connection with Bohemia, which was his most important secondary line, by which he expected the assistance of the Russians. Such were also the views of Soult when he turned the allies at Albuera, and of Junot in his attack upon the flank and rear of the British at Vimiera. Napoleon performed the same manœuvre against the Prussians in 1806 by Saalfeld and Gera ; Kutusoff in 1812, by Kaluga and Krasnoi ; the grand allied army in 1813, when it debouched from Bohemia upon Dresden and Leipsig ; and Napoleon finally attempted it in 1815 by Wavre.

1. But if it be intended to remedy the deficiency of numbers by acting with all the forces upon a single point of the enemy's line ; that line being contiguous, the point selected should be as far as possible from the centre, because the centre can be sustained immediately from both the wings ; while, on the contrary, an extremity can only receive succours by degrees from the divisions nearest at hand.

2. An attack upon the centre is never advisable excepting when the hostile line is very extensive, and scattered into separate divisions ; then, indeed, the result must be successful from the same causes, and the consequences even more brilliant, because the enemy's corps will thereby be totally separated and disabled from re-uniting ; whereas an attack upon the flank can produce similar success only under particular circumstances.

III. The result of the preceding truths leads to the maxim, that as it is better to attack the extremity of a line, yet that both the extremities should not be attacked at the same time, unless there be a very great superiority on the part of the assailant. An army of 60,000 men forming two corps of 30,000 each, for the purpose of attacking an enemy equally numerous, is deprived of the power of striking a decisive blow ; because it enables the adversary to take equal measures, or even, if the movement be extended and unconnected, to assemble his mass against one of the divisions, and destroy it, by his momentary superiority. Multiplied attacks by means of a greater number of columns are still more dangerous,—more repugnant to the best principles of war ; particularly when they cannot commence acting at the same moment, and upon the same point. But when there is a very great superiority of force on the side of the assailant, then indeed both the extremities of the hostile line should be attacked, because thus a greater number of troops is brought into action on both his wings ; whereas if this great superiority were kept in one mass upon a single point, the adversary might deploy as many as the other party could bring into action, and thus engage with equal numbers. In this case it is only requisite to collect the greatest mass upon that wing where the greatest success is expected. Daun manœuvred in this way at Hochkirch, and the whole allied forces at Leipsig.

To illustrate this maxim more fully, it is necessary to enter into some detail, and fix a few particular principles. If 50,000 men, intending to attack 60,000, should form two corps of nearly equal force, and with a view to embrace both the extremities of their line,

War. should extend and isolate the attacks, it is clear that the 60,000 will have the facility of moving more rapidly within the interior of their line, than the assailant's corps with such a mass between them ; as Plate CXXI. fig. 5, demonstrates. The two corps B and C might gain momentarily some ground, but the enemy A, leaving a corps to check C upon the most advantageous ground for defence which its position might offer, could throw the remaining mass of forces on the front, flank, and rear of B, which must consequently be destroyed. If B and C should have a third detachment on the centre, the result would be still more disastrous, for then separate corps would attack without union, a force everywhere imposing, which could not fail to overpower them. This took place at Kollin, from inattention to the orders of the King ; at Neerwinden in 1793 ; and at Stockach in 1799, where Dumouriez and Jourdan were defeated by Prince Coburg and Archduke Charles. At Krevelt, a similar result would have occurred if the French army had been ably commanded, and exercised in great manœuvres. At Blenheim all Eugene's efforts were unavailing, even when he had gained the flank, until Marlborough's success decided the victory.

The truth of these observations is so manifest, that it may be applied to an army superior in numbers : 50,000 attacking in this manner an army of 40,000, would still incur all the same risks ; and if the inferior force, after leaving a corps to mask one attack, should take a rapid offensive measure, and overtake the enemy in his preparatory dispositions, which would necessarily be calculated upon the principle of finding the opponent in his position, the heads of his columns might be turned, and completely routed. But if the two hostile attacks should have between them some difficult object, a wood or river, they might each in their turn be destroyed. Examples of this kind occurred at Lonato, Castiglione, Abendsberg, Eckmuhl, and Ratisbonne.

When, however, the attacking army is double the force of the enemy, the principle no longer holds as stated in the cases of Hochkirch and Leipsig ; but, to avoid the danger of divided forces, it is requisite to have the lead, and to conceal it in such a manner that both attacks may commence nearly at the same moment. Thus two maxims, in appearance contradictory, are derived from the same principle.

1. An army intending to attack another of equal or superior force, cannot insure success but by a concentrated effort upon a single point of a weakened line, which is not in a condition to be timely supported.

2. But when a superior army attacks one much weaker, two or three divisions should be formed, in order to bring all its masses into action against the inferior masses opposed ; for if the attack were confined to a single point, the whole of the forces could not be brought into line, and the enemy might deploy an equal number ; but it is necessary that the whole combinations centre on the same ground, and at the same instant, to produce unity of execution, and avoid partial and successive defeat.

3. As every front of operations and each position

War.

of battle contains a decisive point, it is important that the repartition of forces insure not only a general superiority over the enemy, but also that a strong reserve be appropriated to support the attack upon that principal point.

These maxims are more especially applicable to battles than to strategical operations; for, with these, no necessity demands that corps, acting at the distance of several marches from each other, should engage exactly at the same hour—and it would be impossible so to do on the same ground. But if the principle is to be enforced differently, it is still of full efficacy. It may appear that in these ideas, the main stress of the argument rests upon the local superiority of numbers; but it is nevertheless true, that their combination is the chief object; for 30,000 men may be defeated by half their numbers, if, in the disposition, and in the choice of the ground, some vicious arrangement take place, which produces a real disadvantage;—such as La Motte experienced from Webb, at Wynendael and Chevert, from Imhoff, at Meer; and the Austrians from Moreau, in the defiles of Hohenlinden.

IV. In the strategical movement of a great mass in a combined effort upon one point, it is advisable to keep the forces concentrated, within a space approaching to square, so as to have them perfectly disposable; or, in other words, that the depth of the disposition be nearly equal to the front, enabling the battalions to arrive with promptitude from all quarters towards the point attacked. Extensive fronts militate as much against good principles, as great detachments and isolated divisions deprived of the means of being sustained. The inattention of Napoleon and Ney to this maxim gave Benningsen the advantage at Eylau; and the care of the allies in 1815, notwithstanding the difficulty of guarding an open frontier, enabled them to concentrate their masses at Waterloo.

V. One of the most efficacious means of applying the above general principles, is to induce the enemy to take contrary measures. By means of small corps of light troops, jealousies may be created for some important points of his communications. If he can be persuaded that they are formidable, he will be tempted to detach strong divisions against them, and scattering his forces, be disabled from acting with vigour himself, and be exposed to an attack from superior forces. Operations by detachments have, nevertheless, been in fashion. To divide and subdivide, till the main army was reduced to the secondary character of mere observing, was considered as the very summit of strategical science. In the Hanoverian campaigns, the French, with two great armies, acted upon this system; nor could they ever be undeceived, although Prince Ferdinand, with less than half their force, contrived not only to reconquer the country, but afterwards to keep them constantly at bay, and even to attack them with superior numbers. The Austrians, and the army of the empire, operated similarly in Saxony, and reaped similar fruits. But Mack, trained in the Turkish wars, was the great patron of cordons and scattered posts, with inert positions to sustain them. The Austrians have, however, little reason to exult in

the success of their system. The least mischief which they have derived from it was, that they fought on accessory points, while the main armies, reduced in strength, were unable to do more than menace the principal objects of the campaign, wasting their time until they were attacked by superior forces.

Nor are hostile armies destroyed by merely taking positions upon their communications, and remaining inactive within them. Had Napoleon halted upon the Lech in 1805, or on the Saala in 1806, he could neither have prevented the escape of Mack, by Donauwerth, nor the retreat of the Duke of Brunswick to the Elbe. The art of war does not consist in incursions upon communications, but in placing the mass upon them, in order to attack the enemy with decided advantage. Detachments upon the communications of the adversary are only accessories of secondary utility.

VI. When the lead is taken in a decisive movement against the enemy, great importance is attached to an exact knowledge of the positions and movements which he may undertake. Spies are then of the utmost consequence; but the use of partisans, thoroughly versed in watching the enemy, is of still greater utility. For this purpose, the general should scatter small parties in all directions, and multiply them with as much care as he would show to restrain them in great operations. Some divisions of light cavalry, expressly organized for this service, and not included in the order of battle, are the most efficient. To operate without such precautions is to walk in the dark, and to be exposed to the disastrous consequences which may be produced by a secret march of the enemy. Generally speaking, these measures are too much neglected. The *Espionnage* is not sufficiently organized beforehand; and the officers of light troops have not always the requisite experience to conduct their detachments.

The Cossacks under Platoff, Chernicheff, Tetenborn, &c. in Russia and Poland; these, with the Prussians under Lutzow in Germany and France; and the Guerillas of Mina, the Empecinado, and others in Spain and Portugal, have shown the immense advantages to be derived from their services. While they were few in number, their real importance was not fully understood; but when 15,000 or 20,000 of them appeared in the field, especially in a friendly country, they became the most formidable enemy, with respect to the combinations, which a general could encounter; because those were always liable to be disjointed, by the uncertainty of the timely arrival of orders. Every convoy demanded a numerous and well-conducted escort, and every march was endangered by the want of real information, relative to the hostile positions. The duties, greatly multiplied, exhausted a great part of the army; and the regular cavalry was soon rendered unserviceable by their excessive fatigue.

VII. It is not sufficient for a good operation of war to convey with ability the mass of forces upon the most important points; they require, moreover, to be brought into action. If they remain inactive when arrived upon those points, the principle is forgotten; for the enemy may make counter-movements

War.

War. to defeat the project; and it is therefore indispensable that, from the moment his communications or his flank are gained, the mass of forces must march up to him and attack. This is the moment when a simultaneous employment of the troops must take place. Masses of troops present do not decide battles, but the acting masses alone have effect; the former, indeed, produce that consequence in strategical movements, but the latter determine the success of the action.

To insure this result, a general of ability will seize the proper moment to force the decisive point of the field of battle, and combine the attack in such a manner that all his forces will be brought into action, with the exception always of the reserve. But if the efforts emanating from this principle fail of the desired success, no other combination remains than a simultaneous general onset, in which the reserve is then to be brought forward, to make a last and decisive effort.

VIII. We now come to battles proper, all the combinations of which are reducible to three systems.

The first includes defensive battles, where the enemy is expected in a strong position, with the simple object of maintaining the ground. Such were the positions of Tallard at Blenheim, Villeroy at Ramillies, Marsin at Turin, Daun at Torgau; and the events are sufficient to show their general disadvantage.

The second is the opposite system, wholly offensive. It consists in manœuvres of attack wherever the enemy may be found, such as those of Marlborough at Blenheim, Ramillies, and Oudenaerde; Frederick at Leuthen, Zorndorff, and Torgau; Napoleon at Jena and Ratisbonne; Wellington at Vittoria, and the Allies at Leipsig.

The third offers, in some measure, the middle term between the other two. It consists in selecting a field of battle, carefully reconnoitred beforehand in its strategical applicabilities and advantages of ground; then to wait the enemy's attack, and to fix upon the proper moment of passing from the defensive into offensive measures with the best chances of success. In this class must be reckoned the combinations of Napoleon at Rivoli and Austerlitz; of Blucher at the Katsbach and Laon; and of Wellington at Salamanca and Waterloo.

It is difficult to prescribe fixed rules by which the choice of any of these systems should be guided. The circumstances of the moment, the moral character of the troops, considered as affecting their courage, discipline, and inclinations, their national temper, and the conformation of the ground, must be taken into account.

1. Under these general considerations, it may be fixed, that the best mode is to act offensively on all occasions, when the troops are inured to war, and the ground presents no extraordinary features.

2. Where the topography of the field of battle is difficult of access, either from natural or artificial causes, and the troops of different nations not having the same unity of feeling and of discipline, it will be preferable to receive the attack in a position previously selected, with the determination of assuming the offensive when the enemy shall be exhausted by the first efforts.

3. When the strategical circumstances of the parties are such, that one is obliged to attack the other without considering localities; as, for instance, to prevent the junction of two hostile armies, or to crush an isolated corps, &c.

4. When particular circumstances, as extreme inferiority of numbers, forbid any other than strictly defensive measures; such as Eugene took at Chiari, Abercromby on the Zyp, and Moore at Corunna.

Battles in general, whether offensive or defensive, notwithstanding all the varieties of ground and changes of position, may be classed into three systems of disposition, or what are termed *orders*, each subject to some modifications.

First, the simple parallel order, or that in which hostile armies are drawn up in parallel lines, to advance or receive the attack. Jomini justly observes, that accident or superior valour alone decide the contest in this class of orders, and that the soldier is entitled to all the credit; because such a disposition being the fruit of ignorance and incapacity, the general can have no part in it. Notwithstanding this censure, it is somewhat singular that the only battle in which a considerable British corps was severely handled was of this description, when Berwick defeated Lord Galway at Almanza.\*

The second order is the parallel, reinforced upon one or several parts of the line. In this class, especially if dispositions with an angle to the front or rear are included, most of the great victories of ancient and modern times may be reckoned. For although it is not the most perfect in theory, it is the most constantly applicable in practice; under almost every possible character of ground, or counter disposition of the enemy.

The oblique order of battle is the third and the best class of tactical dispositions; but in the application, great simplicity of combination is necessary, and great prudence in the execution. Against a manœuvring army ably commanded, it will always be very difficult to apply it; but when produced, the effect is instantaneous and decisive: it is the triumph of discipline and of grand manœuvre.

IX. Orders of battle, or the most appropriate disposition for leading troops into action, should possess the inherent qualities of mobility and solidity. To attain these two objects, troops which are to remain on the defensive should be partly deployed and partly in columns, as the allied army was at Waterloo, or the Russians at Eylau; but the corps destined to attack a decisive point should be disposed into

\* Accident, it must be owned, had a great share in this battle; for it is asserted that the statue of St Antonio, the nominal commander-in-chief, was shattered by a cannon ball, which instantly caused the Portuguese to retreat, and leave the British and Dutch to their fate.

War.

two lines of battalions, formed into columns of more or less density. Jomini proposes columns of grand divisions (according to the French formation of a battalion of six companies, making three grand divisions):

6	5	4	3	2	1	Battalion.
—	—	—	—	—	—	
—	—	—	—	—	—	
—	—	—	—	—	—	
12	11	10	9	8	7	Battalion.
—	—	—	—	—	—	
—	—	—	—	—	—	
—	—	—	—	—	—	

Three grand divisions would thus form three lines, and the second line three more. This order, according to his view, offers much more solidity than a deployed line, which waves too much, retards the impulse necessary for attack, and prevents the officers from managing their men. In order to facilitate the march, obviate the great density of the mass, and procure a greater front, the divisions should be formed only two deep; for thus the battalions will be more moveable. The march in front, three deep, is always fatiguing to the centre rank, which, being pressed between the first and third, produces fluctuation, and consequent faintness in the onset. In this manner, all the desired strength will be produced; the three grand divisions giving a depth of six ranks, which is more than sufficient; and the front being one-third longer, augments the quantity of fire, if it should become necessary to use it. The enemy, likewise, will be awed by a display of greater numbers, and the artillery will have less effect than upon more solid masses.

If the proposal of Jomini were applied to the British system of battalion, the same effect would be obtained by fronts of wings of battalion, each three deep. What is said of fluctuation in the march is, indeed, true; but the lock-step is never, and cannot be, observed in a charge or rapid advance to the front in action. The ranks open in those cases sufficiently to allow freedom of step. Firing three deep, though practised at drill, is, in truth, when applied in battle, not more efficient, perhaps less than in two ranks. If, therefore, the expedient of forming battalions only on two ranks be resorted to, still the fronts of wings covering each other, and producing only a depth of four men, would be sufficient for troops so eminently qualified for battle as the British. This proposal of Jomini is an avowal of the inefficiency of dense columns, as they are usually formed by the French and other continental armies, in attacks and charges. If that General had been engaged against the British, he would have been still more convinced of this. During the

late wars, not an instance occurred where a hostile column, *au pas de charge*, broke through a British line. And the charge at Maida, by a brigade of light infantry; at Barossa, by the 87th, and three companies of the guards; at Vimiera, by the 50th; and at Waterloo, by the whole line—all in deployed order, two deep only, against lines or columns, demonstrate the error of supposing, that a mass of human beings, possessed of individual will and feelings, can be subjected to the laws of mechanical action.

Rogniat, General of Engineers, in the dispositions of the legion which he proposes, instead of battalions, contends for three ranks deployed, and the second line in columns, at quarter distance, ready to form squares when required: but both he and Jomini agree in the unprofitableness of fire from a third rank; in which they only maintain opinions that were long ago held by Folard, Saxe, and Lloyd.

Another system may be suggested, which would obviate many inconveniences under which the present labours. The present system of the infantry might be left, such as habit, founded on experience, has framed it; with the exception of arming a third rank with rifled fusils and spears, about ten feet six inches in length. The fusil, when not used, to be slung on the shoulder in the manner of riflemen; and the spear, with a spike, to fix in the ground; and a hook, about four and a half feet from the bottom, to serve for a rest in firing.\* As light infantry now form nearly one-third of the foot in armies, this species of troops should perform all their duties, and be exercised accordingly. When scattered in front, their fire from a rest would be more destructive; the spear would give them more confidence and security against light cavalry. When called back into line, they would give it solidity; and in a charge, their spears, reaching beyond the bayonets of the first rank, would render it doubly formidable. Being drilled to form in front or rear, they would be the first rank, when the battalion forms square, to resist cavalry. In pursuits, they alone should be let loose upon the enemy. By their institution, every battalion, every detachment, would have its proportion of light infantry; intrenchments would be more obstinately defended, and breaches more easily stormed. If a rivulet were to be forded, their spears would sound for a passage on a whole line in a moment. On the outposts, three spears and two great-coats would form a tent. The idea is not new, for the Austrian militia in Hungary have a corps (Granitzer Schutzen) thus armed. Should the cuirassiers in the armies again resume the lance,—an event of some probability, since it is asserted that the Polish lancers of the guard of Napoleon, now in the Russian service, changed their small Ukraian horses for a larger breed about two years ago, with the in-

\* As these troops would have no bayonet, they might be furnished with Pontoneer swords, and saws and hatchets; both instruments of great utility in securing posts, clearing obstacles, and opening roads, and a thousand other daily wants. It is not meant, that they should not have a drill of their own, and modes of formation independent of the battalion; but merely that, in giving or receiving charges in line or square, they should then constitute a third rank.

War.

War.

tention of being converted into cuirassier lancers,— it may be foreseen, that the spear will again be resumed in the infantry.

X. On the extensive subject of position, we can only give some particulars.

1. The best military positions cannot cover a state merely by being occupied and maintained.

2. Every position has its key or decisive point, as before observed: but this point is not difficult to find. In a scattered line, it is in the centre; in a contiguous line, it will be found on that point where the nearest connection lies with the base of operations.

3. When an army occupies a position upon a height, or any other ground fit for a field of battle, it is important to have the front and flanks most carefully reconnoitred and watched, to prevent the enemy gaining either extremity of the line by a secret movement.

4. But as it is admitted, that to employ strong corps for that purpose, causes a useless waste of force, attracts the attention of the enemy, and does not, after all, secure the army from surprise, it is preferable to place small posts of observation in all the sinuosities of the ground, with orders to communicate with each other and with the army, or the nearest intermediate corps. These two latter rules were demonstrated by the surprise and attack of the Prussian army at Hochkirchen, of Korsakoff at Zurich, and Murat at Tarutina; but especially on the first-mentioned occasion; for, next to the battle of Leuthen, no instance produces more ample proof of the terrible effects of an army being surprised and taken in flank. The whole mass of Daun's forces was actually upon both flanks before they were discovered.

5. On ground of difficult access, such as vineyards, inclosures, gardens, steep heights, &c. the defensive order of battle should be in lines deployed two deep, covered by swarms of skirmishers. But the corps destined for attacks, and the reserves, are best in columns, formed on their centres, in the manner above described (IX.); for the reserves, being destined to fall upon the enemy at the critical moment, must advance with resolution and rapidity, that is, in column. If, however, it be desired to awe the enemy by a greater display of forces, the reserve may be deployed until the moment of attack.

6. A superior army should never wait to be attacked, still less wholly deploy into line, if compelled by circumstances to remain in its post. In this case, no more troops should form line than are necessary to check the enemy. The remainder, formed into three or four heavy columns, should be placed ready to strike a decisive blow upon the most important point. A great army wholly deployed can no longer manœuvre with the same facility as columns; and to render troops not engaged immoveable, is repugnant to the best principles of tactics.

7. An army posted behind villages should cover the front with them, by occupying the inclosures, &c. with some battalions of infantry, and the outlets with cannon. The first line should be sufficiently

near to sustain and be sustained by them, and also to provide the means of securing the evacuation of the place, in case the enemy should have gained so much ground on other points as to be able to mask them. Villages, being liable to be turned, should not be held by considerable corps of infantry, unless their topographical situation should constitute them the key of the position, as was the case at Vimiera. The battle of Blenheim deserves attention on account of the consequences produced by the neglect of the principles applicable to villages.

8. When an army occupies a position perpendicularly to a river, with a wing resting on the border, that wing should not be attacked, because, if the enemy changed front in mass towards the river, the attacking corps might be driven into it. On the contrary, if the onset is directed against the other wing with the principal mass of forces, that chance is in favour of the assailants; because the wing being turned, the whole line will be pressed towards the stream, and incur the risk of being destroyed. This would have been the case with Hiller's corps at Wagram, if a prompt retreat had not saved it. Similar would have been the fate of the united French armies at Talavera de la Reyna, had they persisted in an attack upon the Spaniards; and they acted with great judgment in directing their efforts solely towards Lord Wellington's left.

9. In the successful defence of a position, a repulsed attack should not be pursued, unless that attack had been decisive; because it might have been combined by the enemy for the purpose of drawing the defensive force out of its advantageous ground. An untimely pursuit by the Austrian right lost the battle of Prague; and by the Saxons that of Kesselsdorff; and again by the Austrian centre that of Jemappes.

10. Positions may, sometimes, be so arranged, that although they be scattered, they still possess the faculty of timely re-union. Several are indicated in Frederick's secret strategical instructions, and one occurs when he besieged Olmutz. Being greatly inferior to the enemy, who menaced him from several quarters, he posted a corps at Littau, while he remained in person with the covering army at Prosnitz; and in order to connect the two masses at will, a small corps occupied the hill of Hrad, between Namiest and Laskow, to serve as an intermediate point. Orders were given to the corps at Littau, in case of attack, to retreat towards him, and if a superior attack were made upon the covering army, he would retire towards the other; but if timely information were received, all were to unite in the position of Gross Jenitz.

11. As it is a maxim to operate against a weak part of the enemy's line, no position should be attacked upon its strongest point, as the Austrians did at Breslaw; but if the hostile position be prolonged by a detached corps, the principal effort should be directed against it; because, if that be defeated, the main body is turned, and thereby worsted.

12. Armies may sometimes be posted behind a ridge of hills with defensive points upon their summits. These should not be attacked without an exact knowledge of the position behind, and precau-

War.

War. tions to resist a counter movement. The events of Austerlitz and on the Katsbach prove the necessity of this precaution.

13. No position or disposition of attack should be made where the line is intersected perpendicularly by a difficult obstacle, such as a river or morass; because the enemy may act defensively on one side, and throw his whole mass on the other; as happened at Dresden, where the left wing of the allies was separated from the main body by the ravine of Plauen, and severely handled.

14. When an army remains immovable in its position, both its flanks are liable to be turned. To obviate such manœuvres, others of a similar character should be opposed to them; as was done at Albuera. These counter manœuvres are not difficult to execute, because the army turning a flank moves upon the arc, while the opponent takes the chord; consequently he is enabled to move a greater mass in less time, even when both parties are equal in forces. Rosbach, Vimiera, and Salamanca, are decisive examples, where the enemy moved in open day (which it is both difficult and dangerous to do in the night), and thereby rendered the counter offensive both prompt and decisive.

15. There are positions which cannot be turned nor attacked obliquely. If the stratagem to draw the enemy out of them does not take effect, a parallel attack with the centre reinforced is likely to be the best adapted to such circumstances. The dispositions of Marlborough at Blenheim were of this class, and deserve the study of military men.

On Angles  
or Forma-  
tion en Po-  
tence.

1. Between two armies equally capable of manœuvring, the defensive one may form an angle with advantage to secure a flank from attack; but to render this precaution efficacious, the angle alone is not sufficient, because its utility is only momentary; the mass, therefore, should change front in the same direction, and present a whole line to the enemy.

2. If the army be sufficiently strong to assume the offensive against the assailant, a change of front, which is merely defensive, should be followed as soon as the angle is formed and the enemy checked; by placing the line in columns of divisions to the flank, and prolonging the direction from the position first occupied to gain the hostile flank. Thus taken in front by the angle, and in flank and rear by the new direction, the enemy will be defeated. See Plate CXXI. fig. 6. A the army endeavouring to turn the left flank of B, which forms the angle C, and under the protection of this corps, prolongs its line in the direction EE, by means of which the extremity of the hostile flank is gained. A cannot well oppose the execution of this movement in the presence of the angle C, and of the line E, which, though it be in column, can form in an instant; hence A must fall back and change front also.

3. An angle to the front of the line or *potence*, such as the Austrians formed at Prague and Kollin, is not so serviceable as one thrown back to the rear; because the enemy can readily outflank its extremity from his position, while that extremity can be sustained but by slow degrees. Thus at Kollin, the Prussian cavalry turned it at the beginning of the action;

and at Eylau, Benningsen repulsed the corps of Davoust on his left, and Ney on his right.

4. If a defensive position has an angle to the rear, the front will be weakened in proportion as that angle becomes more acute: but, if there be a considerable interval on the summit, where the two lines should meet, the danger will be still greater; for if the enemy can establish himself on the point A, it is clear that the two wings, A C and A B, will be enfiladed and forced to retreat; if not rolled up in confusion by an actual charge on either or both of these extremities: this caused the defeat of the Austrians at Prague, and of the Prussians at Breslaw. (Plate CXXI. fig. 7.)

5. If two allied armies or great corps take up positions, forming a re-entering angle with a space between them, and some considerable obstacle masks that space, they expose themselves to be attacked and defeated separately: this danger increases with the increase of the distance between them. The corps A D being separated from B E, by a wood, lake, or other considerable obstacle, at G; the enemy F H, being covered by that obstacle, may attack and defeat one before the other can arrive to sustain it. (Fig. 8.) This principle results from the maxims of interior against exterior lines of operations. Such positions as these were occupied by Prince Henry and Hulsen, at Freyberg and Katzenhausen, with the Tharand forest, and what was worse (at the distance of more than six leagues), with the Mulde between them. Yet the army of the empire, superior in force, remained three months before them, until Prince Henry moved and defeated it at Freyberg.

1. To insure the success of an attack, properly combined and reinforced on the essential point, it is necessary to refuse the weaker wing. This precaution is obvious, not only for the purpose of keeping a weaker part out of reach, but also because reinforcements are readily drawn from it, to the point where the effort is making. Thus, instead of exposing it to be repulsed by superior forces, there is a real advantage in keeping it reserved to secure the victory. Leuthen affords a proof of the wisdom of such a disposition; Kollin and Jægerndorff of the consequence, when disregarded.

2. If it be admitted, that the most advantageous attacks are those which emanate from a concentrated effort, upon an extremity of the hostile line; it becomes indispensable to gain that extremity, by measures which mask the movement. For, by neglecting this precaution, the enemy may follow the march of the columns in their endeavours to turn him; present constantly a front, or even anticipate, and take them in flank, as happened at Rosbach.

3. The march may be concealed by the darkness of the night, by the conformation of the ground, or by means of a false attack on the front of the enemy. The two last mentioned are to be preferred; because night marches are uncertain and even dangerous, slower, and always more irregular than those by day. For this purpose, it is not necessary to march by lines, if the movement be masked by an attack of the advanced guard, while the mass advances towards the extremity desired, in columns of battalions at half

Oblique  
Attack.  
General  
Observa-  
tions.

War.

distances. This will render it difficult to be discovered by the enemy, in time to be counteracted.

4. In order to molest a greater space of front, instead of an advanced guard making a regular attack, it is preferable to employ a corps of light troops, formed in parties; having points for re-assembling light cavalry and some artillery to sustain them. This method is sure to distract the enemy's attention, and keep his whole line in check.

An oblique attack, according to Guibert and the *Journal Topographique*, is a disposition by which a part, or the choice of the forces, are advanced towards the enemy, and the other kept out of his reach. This definition is not quite correct, as Plate CXXI. figs. 9, 10, 11, and 12 demonstrate. An army may be out of reach of the enemy, and therefore refused in a line nearly parallel, and strongly reinforced on a wing, without being oblique. (Fig. 9.) It may also be in an inclined line on the head of the attacks, and form a positive diagonal, without being reinforced (fig. 10); or perpendicular upon a flank, as at Kunersdorff, with a wing reinforced (fig. 11); or horizontal upon the head of the columns without being oblique. (Fig. 12.) There are several modifications of these four orders (among others fig. 11); as, for example, a perpendicular angle to the front, as formed by the Austrians at Prague, Kollin, and Hochkirchen (Plate CXXI. fig. 13); the angle A C being perpendicular to the army D E, reinforces the right wing of the line A B without being oblique: so also an angle to the rear would reinforce the line without obliquity.

A parallel line, considerably reinforced upon the most important point, is no doubt good, and even very generally applicable; for it is conformable to the principle which forms the basis of all operations: but it has several inconveniences. The weak part of the line being near the enemy, may be engaged contrary to the intention, and be defeated; which event would balance and arrest the advantages gained on the other wing; as happened to both armies at Wagram. The reinforced wing having defeated its opponent, cannot take it in flank and rear without a considerable movement, which would separate it from the other, if already engaged. But admitting the weaker wing not to be engaged, the other cannot even then turn the flank without drawing it circularly along the hostile front, which the enemy must necessarily anticipate by being on the chord of the movement; and consequently give him the advantage of the offensive by reaching the decisive point first with the mass of his forces.

With the oblique order of Frederick, as applied at Leuthen, the effect is quite different; the extremity of the wing attacked is not only overpowered by a whole line, but the end of that wing is constantly outflanked, and the line turned, without manœuvre, or prolongation of direction, simply by a direct advance of the oblique line. The distance of the divisions which are not intended for the principal attack, places them out of the danger of being engaged by a superior force, and yet sustains the wing in action. These effects of the open oblique attack, although known, cannot be too often presented to the reflections of military men. They offer,

War.

besides, another advantage still more decisive, in bringing the half of the army constantly into action against the extremity, probably of only two brigades, of the hostile army, which has no counter manœuvre to stop its progress. What troops can stand against such odds, when besides they are constantly outflanked and taken in reverse? Is it possible that confusion and dismay should not follow in a whole line, whose flank is overthrown, and menaced with total destruction, by the progressive advance in a direction upon the rear?

Yet such must be the infallible result of an oblique attack when once it has reached the flank of the opponent undiscovered; as indicated in the preceding maxims; and when the lines are rapidly formed, according to the method of Frederick; as will be seen in the observations on marches. Plate CXXI. fig. 14, demonstrates the mechanism more clearly. The left wing, B C, of the army, A C, will receive the fire of the second brigade of the army, D K L, whilst the first brigade, or extreme right, formed in column of divisions, will turn it and decide the first attack with rapidity. The second brigade, in the oblique direction of its march, will soon be seconded by the third; and when that has passed the extremity, which must constantly recoil before a contiguous front, the fourth brigade opens its fire; and in this manner, supposing the army, D F, K L, arrived at the dotted line, H I, the whole will have been engaged in succession with a fourth or a third of the enemy's line, the battalions of which, being crushed one after another, will be nearly surrounded.

This demonstration is sufficient to show the great advantage of an open oblique order of attack. It is called open, because the disposition, such as that of Leuthen, was nearly at right angles with the line of the Austrians, and different in every respect from a parallel order. All these advantages are equally applicable to masses concentrated upon the extremity, which it is intended to crush. The army A B, fig. 15, instead of forming two lines, as in the former figure, may draw up the first line only, and keep the second in columns at half distances behind the right, centre, and left, prepared to manœuvre or strike the decisive blow. These columns will be more moveable, and not being intended for the first attack, they will nevertheless cover it against counter-movements of the enemy. The battle of Salamanca offers a memorable lesson of this description, where the troops were concealed by the ground, and then suddenly brought in mass upon the enemy's left wing. That of the Katsbach, almost the counter part, was equally grounded upon these principles; both, however, with the difference, that the lead of the manœuvres was on the side of the adversary. Jomini, habituated to the lively national character of France, lays too much stress on the value of the lead in manœuvres, and therefore does not fully appreciate the powers of well conducted counter-maneuvres, which the cool firmness of British and German soldiers can develop.

The battle of Leuthen furnishes another maxim equally important; namely, that an army with the flank resting upon an obstacle, such as the great

War.

pond of Gohlau, which covered the angle of Nadasti, may still be outflanked by an oblique attack. For this purpose, it is only necessary to mask the first brigade of the enemy by the nearest of the attacking corps, and move obliquely with the next, so as to press the principal effort upon the second. For the line being broken, the obstacle is no longer of any use; and the masked brigade is even in danger of being taken if not promptly withdrawn. But the manœuvre is not so advantageous as when the flank is ill supported and easily turned.

Of Marches.

Marches in columns to the front, flank, or rear, which must be followed by deployment or echelon formations, are useful as parts of elementary tactics; but never safely applicable near the enemy on a great scale, if they are at all complicated in the construction of the columns, or in the nature of the ground. Guibert devoted several volumes to their mechanism; but Tempelhoff alone has described the nature of Frederick's columns, by means of which his dispositions were executed with so much simplicity and precision. Although the present system of moving by corps has, in a great measure, superseded the old method of organization by lines, and consequently rendered the march manœuvres, which triumphed at Rosbach, Leuthen, and Zorndorf, less applicable; they are still the best for such corps as are obliged to manœuvre in the presence of the enemy, whether it be to engage in front or to turn his flank.

On examining the mechanism of his columns at Kollin, Leuthen, &c., it will be perceived, that his army having broken into open columns, each line forming one by a mere wheel of divisions, right or left in front, by this method the army could,

1. Execute all the movements united without danger of being attacked in detail; because the columns of lines were at no further distance than was required for actual engagement.

2. The enemy could neither cut them off, nor penetrate between them.

3. In taking the direction of the intended line, the army, when moved to the ground, is formed in a few minutes,—that is, in the space of time required for the word of command to pass down the column to wheel into line. In this method, the only precaution required was to send an advanced guard to protect the march, and at the same time to keep the enemy in suspense.

4. As the army requires only two or three hundred paces between the columns, and the divisions no more than their respective distances to form into two lines, the manœuvre is easily executed with precision.

5. The army having reached the flank of the enemy by concealing the movement, as before noticed, and wheeling into line, will not allow the enemy time to form an angle, or to change front; consequently, he will be overpowered in succession along his line.

6. To conclude, if two columns, of the length of the line of battle, are not immediately desired, or the ground requires a modification, four columns may be formed, by doubling up the lines, or by

War. marching by wings, without increasing the difficulty of forming. The four columns being constructed of the two lines doubled, when arrived near the point where they are to form, the second and fourth halt until the first and third have proceeded so far as to disengage from each other. While halted, they protect the march of the others, and when cleared by them, they follow in their rear, and thus are prepared to wheel into line with them.

If the columns are formed by wings, they will again fall into two lines by a simple change of direction, executed by all the heads of columns of each line at the same time to the right or left, and then leading into the rear of the preceding. But this transition of columns of wings into columns of line should take place at some distance from the enemy. At Leuthen, this manœuvre introduced the battle: Plate CXXII. fig. 16, A, the advanced guard masking the march of the army in four columns; B B B B, the heads of the four columns forming the first line; and C C C C, the heads of the second line (now in rear of the first), all changing direction by a wheel to the right at the same instant, and consequently forming two open columns ready to wheel into line. The advance meantime either halts in position to alarm the enemy on another point, or continues to open the march by preceding and covering it.

It is, however, evident, that these kinds of marches must be made on open ground; for in countries deeply intersected, great movements are impracticable; and it thus becomes necessary to arrive by the openings which are known, and engage more or less in columns. By Guibert's and the regulation systems the army being broken into several columns, they move with their heads often out of sight of each other at the distance of more than a mile, and yet they are expected to keep their alignments and relative distances. When ordered to form, they either close and deploy, or march by echellons to fit into an exact alignment. All this is evidently impossible before the enemy, who must discover the tedious manœuvre, and have time to act as he pleases, while the numerous errors are rectifying; and if the centre divisions should be chosen for the points of deployment, half the columns must turn their backs upon his fire to perform it! Frederick, during the whole Seven Years' War, attempted these movements only twice; first in a combination with Bevern to attack Loudohn, which failed by the premature arrival of one column; and, secondly, at Torgau, which, as far as that manœuvre was concerned, failed also; for Zieten's column came too late, and was isolated. At Minden the French manœvred in the same manner, and were a great part of the night and the next morning employed in rectifying the errors, which gave Prince Ferdinand time to arrive. It is true, he moved likewise in columns, but he had previously sent all the generals to reconnoitre their routes and points of formation, and cut openings and fixed marks to insure the exact direction. Such precautions surpass even the underhand tricks to help the manœuvres in a camp of instruction; and the very precautions prove the impossibility of applying them in ordinary cases. During the Revolutionary wars of France, all the Belligerents met with fail-

ures from vain endeavours to apply them ; notwithstanding that the new organization of corps and the use of swarms of skirmishers greatly facilitated their execution.

Lehwald's manœuvre at Jøgerndorff is worthy of notice, as particularly applicable in intersected ground. His infantry advanced in a double column from the centre, and formed to right and left without risk of confusion ; the cavalry moving at some distance, easily took up the alignment.

The order of march on Frederick's system must, however, be considered only as a manœuvre, and not be applied to marches in great operations.

As this order of march is best calculated for attacks against lines, so is it also upon columns in march. An attack upon an army while on the march is advantageous, for the same reasons as an attack upon an extremity of a line ; because the army attacked on the heads of its columns is precisely in the same situation, relatively to the enemy, as one assailed in flank. The battle of Rosbach furnishes an illustration. AB, Plate CXXII. fig. 17, represents the army of the King, CD that of the French. Supposing them both in line, CD would still be attacked perpendicularly, and outflanked on one of its wings, exactly as it was on the head of its columns. The advantage of both these manœuvres lies in the necessity to which the enemy is reduced of bringing his battalions in succession to the front, while the opponent, acting with vigour, defeats them, one after another, by the superior pressure of his mass, provided its march be onward in an appropriate direction. Horizontally, if the column moves perpendicularly, and perpendicularly, if the march is horizontal. The object for producing, as nearly as possible, an opposite direction, is to present a whole line to a head of a column, or to an extremity of a line ; because, if both moved in a direction to meet with the heads of their columns, both would be obliged to deploy, and a parallel order would be the consequence, without tactical advantage to either army. Fig. 18, the columns AB meeting those of the enemy CD in the same order, both fearing to be attacked, will immediately deploy ; AB will therefore form the line FG, and CD the line HI, which gives no advantage to either party.

The battle of Rosbach offers a further illustration. As an angle must necessarily be formed when the heads of columns are attacked, to check the first efforts of the enemy, the advanced guard or leading brigade should deploy, while the rest of the army should take a new direction of march clear of the enemy's flank, in order to protect the retreat of the advance already engaged, and to gain a station for acting offensively. See fig. 19. If the advanced guard or leading brigades AB of the columns HI be attacked, a deployment must take place according to the direction of the attack CD. This manœuvre having checked the enemy FG, the army in the rear being thus momentarily protected, should immediately change direction exteriorly, by filing the divisions into a new alignment, IL ; or by altering the direction of the columns in a similar manner, so as to produce a prolongation beyond the enemy's flank, KK. It is, however, clear, that if the columns are

left in front, the operation is according to rule ; but if the right be in front, a direction to the left would present the reverse flanks to the enemy. There would be no time for a countermarch, and still less for wheeling up in succession. It therefore appears that the columns should change the pivots of divisions, and wheel to the right into line ; for though this manœuvre would be against the letter of the regulations, no disorder would ensue, and it is actually practised, at least by cavalry, in some of the continental armies. There is no want of proofs of the occasional necessity of this manœuvre in every campaign ; but the battle of Laswaree will suffice for an illustration. The British infantry advanced in a single column by the right, and after crossing the Mahnus Nye, a deep sunken rivulet, found itself opposite the enemy's right. To have prolonged the movement, was to produce a parallel order of battle ; advantage was therefore taken of a ravine which led to the hostile right flank, and could conceal the movement. The head of the column, therefore, turned to the left, and gained the flank ; but when ordered to wheel into line, the pivots being reversed, some of the Sepoy troops adhering to the letter of the rules and regulations, wheeled with their backs to the enemy.

This method of converting a probable defeat into an offensive movement and oblique attack, will probably intimidate the enemy, and check his pursuit of AB, from the moment he perceives the menaced attack against his own flank. As a manœuvre it is also more rapid and simple than a change of front which would only tend to a parallel formation. Although the existing modifications in the structure of armies, as already observed, renders this kind of attack more rare, and the organization by corps and divisions is advantageous to prevent them, it is nevertheless true, that the Prussians lost the battle of Auerstadt, and the French were placed in the most critical situations at Marengo, Eylau, and Lutzen, because they were attacked on the march before they expected a general action.

The battle of Waterloo, unquestionably the most decisive event of the late awful contest, offers so many instructive circumstances, and so much matter for deep meditation, in the position and manœuvres, and in the exhibition of the soundest maxims of war, that it may be considered as a general illustration of the advanced state of the art of war at the present period. Without entering into details, the minutiae of which are apt to confuse, we shall content ourselves with merely pointing out the principal distinctive features which it displays. As there are many plans more or less correct, and the ground is generally known, the remarks we are about to offer will be readily understood by those who have any elementary knowledge of war. After Blücher's retreat from Ligny, and the Duke of Wellington had fallen back from Quatre Bras, he occupied the position of Mont St Jean, determined to risk a battle with the forces he could collect on that point. Exclusive of the Prussians, whose severe loss in killed, wounded, and stragglers, could not immediately be reorganized or replaced, but by the expected

War.

arrival of the corps of Bulow, the Anglo-Netherlands army consisted of about 81 battalions and 87 squadrons; which, with the artillery, may have amounted to 66,700 men. Of these, upwards of 30 battalions and as many squadrons had never been in action. This mass of forces was posted with the centre diagonally across and in front of the forking of the two causeways from Brussels to Charleroy and to Nivelles; the right centre behind the chateau of Goumont, and the left considerably refused, passed in rear of La Haie Sainte, along the cross road in the direction of Ohain. Behind the right centre, Lord Hill placed his corps, *en potence*, in columns, prepared to manoeuvre to his right, on the small plain of Braine la Leud; or to his left, to sustain the centre. In and about Braine la Leud was a Netherland division, with the right thrown forward, and covered by the rivulet Hain, and leaving the small plain open; a kind of gorge to tempt the enemy between the two sides of the re-entering angle of the right wing. The Prussians were expected to debouche through the woods of Lasne towards Planchenois, which would form the left into another gorge, or re-entering angle. Thus the position formed a kind of open W (BB, Plate CXXII. AAA. BB), with the chateau of Goumont at the summit of the salient angle, covered by a plantation of wood and inclosures, occupied by six or eight battalions; so that the enemy could not enfilade from behind that plantation, either of the faces of the centre, nor approach on either of the causeways which passed through the centre, without presenting his flank. Besides this point, La Haie Sainte, a stone farm close to the chaussé of Charleroy, and further on the left, the farm of Papelotte and chateau of Frichermont were occupied; the whole front offered a gentle slope towards the enemy, and in the rear the cavalry was distributed in brigades, each in two lines, covered by the rising ground; and the artillery, all the field-pieces of which were nine-pounders or twelves, formed a line of almost contiguous batteries along the front, interspersed with howitzers and rockets.

By the returns found after the battle, it appears that the enemy had debouched from Charleroy with 122,000 men,\* exclusive of the reinforcements that joined after the 15th of June. Of these he produced on the field of battle, about 80,000 men, formed in concentrated masses on both sides of the chaussé of Charleroy, and gradually advancing the right parallel to the British left (CCCC); but as he was jealous of the woods on the right, he formed an angle to the rear, and kept his reserves far back. He had made a demonstration with a corps of cavalry beyond the British right towards Hal, where he found the corps of General Colville, and Prince Frederick of Orange, with two divisions posted at Tubise, Clabbeck, and Braine le Chateau, to cover that avenue to Brussels: another corps, 42,000 strong, under Grouchy, was detached to his right upon Wavre, to turn the allies, pursue, or arrest the Prussians, and prevent the timely

War.

junction of Bulow. Thus the dispositions of both the commanders were combined with consummate ability; Napoleon operating on the system of throwing two-thirds of his masses alternately on either side, and the allies, in combining manoeuvres, to bring a superior mass on the decisive point. On the field, however, the problem was difficult to solve. The communication with France was open only by the roads of Charleroy and Nivelles; hence the enemy could not quit them in the attack; nor could he gain Brussels by any other avenue than that of Waterloo: therefore, to possess the chateau of Goumont, without which he could not arrive at the position, was the natural object of the attack. As this was sustained by the mass of the allied army, and could not be enfiladed, his attacks failed. All those directed on the road of Charleroy to the left centre, were necessarily oblique, and exposed to the fire in flank before they could reach their opponents. To have risked a general onset of all his masses, before the British were thinned and exhausted, he knew, under the circumstances of the moment, to be too hazardous. The plain of Braine la Leud appeared open. He could arrive by it; but that very circumstance proved that the enemy was prepared on that side. To have turned the force thither would, in the first place, have caused the loss of the communication by Charleroy; and next, facilitated the junction of the Prussians; and, besides, the corps on the other side of the Hain flanked the advance, and could, in a short time, be sustained by the two divisions in its rear, and which he knew to be at hand. He would, therefore, have been placed between two fires, and have lost his point of retreat upon Charleroy; and the road by Nivelles might, meantime, be cut off by the troops left behind at Mons. Again, if he threw his masses towards the left, he only went to meet the Prussians, and left the British masters of the road of Nivelles; and possibly, if he advanced far, of that of Charleroy. He entangled himself in woods and defiles, where his superior cavalry could not act. The character of his opponent bespoke immediate offensive movements from the moment his right would be at liberty; therefore the chances were again in favour of the enemy; yet this was the only advantageous side, because it brought him nearer Grouchy; and in case of defeat, he could take a new line of retreat by Namur. He, however, preferred the experiment which the enthusiastic valour of his troops might enable him to make; and this committed him so deeply, that, when at length the Prussians appeared, a retreat was no longer possible.

These observations disprove the ignorant assertion, that little skill was displayed on either side. The Generals and the soldiers equally did their duty: the veteran Blucher behaved with just prudence, in keeping so long back from the dangerous manoeuvre which was assigned him; and when he saw the hostile cavalry destroyed, he acted with vigour and skill. As for Grouchy, who wasted his time

\* The return was dated the 13th, according to the assertion of a Prussian officer of the staff. The whole force brought over the frontier must, therefore, have amounted to nearly 150,000 men.

War.

in forcing the position of Wavre across the Dyle, everywhere fordable, his manœuvres show, that he felt the danger of his movement, and he wisely remained on the banks. Much might be added upon the judgment which posted the corps at Wavre and another at Hal; on the several lines of retreat which the allies could take in case of defeat; on the dispositions of the artillery; the squares and lines formed and reduced repeatedly; the disposition and effect of the charges of cavalry; the counter offensive of the Prussians; the general charge to the front, and fate of the enemy's squares: but sufficient is advanced to excite to the study of a battle, where three of the greatest commanders, and the best manœuvring armies in Europe, gloriously struggled for victory; and, let it be added, notwithstanding the assertions to the contrary,—where none committed a positive fault; and where Napoleon, in particular, who has been condemned by some of his own partisans, operated with all the skill and vigour which the circumstances of the moment allowed.

appears that none of them were the consequence of a defeat, and especially such defeats as the modern system of attack inflicts; they were merely armies manœuvring back towards their base upon their own lines of operations, watching a favourable opportunity to resume the offensive; or retreats after battles where both parties had claims to the victory, as Benningsen's after Eylau, and Kutusoff's after Borodino. The difference between Lloyd and Jomini is merely in words; for the former points out the facility of uniting two corps, which, if he meant the eccentricity applied by Bulow, would be impossible.

But an army completely defeated is no longer in the hands of the general, whether he be the Duke of Brunswick or Napoleon. A check, such as the Austrians suffered at Fleurus, and the Allies at Lutzen, Bautzen, and Dresden, does not prevent the commander from executing the best measures that circumstances will allow. Thus, in the three former, the armies retired in mass; in the latter, they divided into several columns, and thereby not only covered themselves by the mountains of Bohemia, but also applied Lloyd's maxim, in uniting two corps to destroy one of the pursuers at Kulm. Hence, circumstances must govern the measure; and if, after a real defeat, a broad river, chain of mountains, or range of fortresses, can be gained in two or three marches, the division of a routed army may be applied as a safe rule.

A retiring army is not always obliged to fall back upon its own frontier; it may sometimes change the direction of its operations, as Frederick did after the siege of Olmutz in 1758; when, instead of returning into Silesia, he changed his line, and marched into Bohemia. This measure was also proposed to Napoleon before the battle of Leipsig. He was advised to approach the Elbe, call in the corps of St Cyr from Dresden, cross the river about Wittenberg, and descend by the right bank towards Magdeburg. The Prussian and Northern armies, being on the left of the Elbe, could not have prevented the destruction of Berlin, Potsdam, and Brandenburg. And from Magdeburg, reinforced with its vast garrison, and connected with the Danes and the corps of Davoust at Hamburg, he could have operated by a new line, having his communications open by Wesel, Cassel, and all the fortresses of Holland; the sterile country to which the allies must have followed him could not have subsisted their vast cavalry; and the sandy roads would hardly have allowed sufficient transport of provision to maintain the troops. There were, however, many, and probably superior reasons, which made him reject the proposal.

If the art of war consists in applying the superior Pursuits. force of a mass upon a weak point of the enemy, it follows that a defeated army should be pursued with the utmost vivacity. Never delay till to-morrow, is an ancient military maxim, applicable especially in pursuit; for the strength of an army consists in its organization, in the unity resulting from the connection of all its parts with the main-spring which makes it move. After a defeat, this unity no longer exists. The harmony between the head, which combines, and the body, which executes, is broken; their connection is suspended, often destroyed. To

War.

Of Retreats.

This unpleasant operation in war requires as great a display of skill and firmness as any. The Austrians have often conducted their's with sagacity, and it is perhaps owing to the preserving spirit of their retreats, that after twenty unfortunate campaigns, the monarchy was as formidable as in the commencement. Their Generals are not then controlled by cabinet orders, and, therefore, always operate with precision. Among the retreats which deserve the study of the soldier, are that of Schulemburgh, with the Saxons; the Duke of York's out of Belgium; the two retreats of the Archduke Charles; that of Moreau from Bavaria to the Rhine; the Russian retreat upon Moscow and Tula; and, lastly, the fine movement of Prince Eugene Beauharnois, in Italy.

In the choice of a position, it is not sufficient to have a strong front and secure flanks; the means of retreating must also be considered in case of defeat. Lloyd, in his *Reflections on the battle of Kollin*, observes, that a defeated army retires with greater facility by dividing itself into as many corps as the nature of the country will allow; because, 1st, if the enemy forms an equal number of divisions, he cannot operate vigorously upon any, and the retiring army having the facility of *reuniting*, may totally defeat one of the hostile corps; 2d, if the enemy operates *en masse*, it can be only towards one, and the others fall back unmolested: that division, however, covered by a strong rear guard, avoids serious actions, and having the faculty of moving more rapidly, because it is less numerous, can escape likewise without great loss. Bulow, taking up this question mathematically, advances the opinion that the columns should move outwards, or eccentrically, from a point towards the periphery; but Jomini combats both so far victoriously. He observes, that Lloyd admits that the division of the pursuing forces exposes them to defeat; why, then, recommend such a manœuvre to a retreating army, which must be already inferior to the enemy? He quotes the fine concentric retreat of the Archduke Charles, and might have added the Russian, and both Lord Wellington's. But in examining the mechanism of these movements, it

War.

pursue and attack is to march to a certain triumph. All the late campaigns offer signal examples of this truth. Generals of mediocrity often neglect this maxim, and their victories are scarcely more than a forcible removal of troops. The direction of the pursuit, though guided by circumstances, should always, however, aim at gaining the hostile line of communications, and cutting off the enemy from his base; because, by so doing, he may be thrown upon such obstacles as to force him to surrender.

**Sieges.** Sieges, according to Lloyd, should never be undertaken but with the following views: 1st, When fortresses are situate upon the passages which lead to the enemy, so as to render it impossible to penetrate without capturing them. 2d, When they intercept the communications, and the country is unable to furnish the necessary subsistence. 3d, When they are wanted to cover magazines formed in the country, and thereby to facilitate the operations. 4th, When the enemy has considerable depots within the fortress, of which he is absolutely in want. 5th, When the capture of a fortress produces the conquest of a considerable tract of country, and enables the besieger to winter in that vicinity. To these may be added, 6th, The recapture of a fortress essential in the defence of a frontier.

Covering Sieges.

1. As victory is best secured by taking the lead in an operation, an army covering a siege should never wait to be attacked by the enemy, but endeavour to anticipate him; for, by defeating the forces which aim at raising the siege, the place is sure to fall.

2. If the enemy approach the covering army with an imposing mass, the siege should be raised, all the forces united, and an attack in force directed against him.

3. When the relieving army is defeated, the siege should be resumed, while the pursuit continues, and the enemy is not in a condition to return before the capture of the place.

4. When an army besieges a place, in consequence of offensive movements and anterior success, the covering army should not remain in a position near the place, but drive the enemy as far as possible forward; for the relieving army will find the difficulty of raising the siege, increased with the distance it is removed from the place: but, if at length that army should arrive so near as to furnish a probability of raising the siege, the besieging corps should then rapidly join the covering army, and make a united effort to defeat it.

Concluding Remarks on Innovations and Improvements.

Among the late innovations in war three are of immense influence; but before they can be considered as permanent improvements, they will require to be subjected to some regulations. The first of these is the Conscription System; a salutary measure under proper restrictions; but a scourge, if carried beyond the principle of defence. The next is that of Requisitions; which requires to be placed under the con-

War. trol of public law. The third is the formation of a Militia, or Landwehr. This measure, incontestably proved to be efficient, will always be resorted to in moments of real danger: and it is one calculated to bridle the projects of ambition, because it makes every state strong in defence, but not therefore strong in aggression.

In examining the new inventions which may become instruments of moment in the science of war, that of Vessels impelled by Steam will probably figure as the most important among maritime nations; whose coasts, rivers, and harbours, will probably be assailed and defended by them. The terrific Rockets may in time acquire a precision of direction equal to that of shells and carcasses. They are, in their present state, an excellent substitute for horse artillery, particularly in pursuits, vanguards, and false attacks. At the battle of Leipsig, a British battery of rockets compelled a column of four battalions to surrender on the first fire.\*

The present method of forming divisions with artillery, a proportion of light cavalry, and light infantry, commissariat and staff, approaches so nearly to the Roman Legion, and is, in reality, so advantageous, that it may be foreseen, should one great continental state permanently model its army upon that principle, the others will immediately adopt it. Should the heavy-armed cavalry or cuirassiers resume the Lance, the infantry would soon be obliged, as before observed, to be partly armed with a similar weapon. Field Fortification has been too much neglected, and the troops are not sufficiently provided with implements for that purpose; but as the influence of militia systems will bring large bodies of troops together, in a state of inferior discipline to veterans, field works will recover their proper estimation.

It is not the solid immoveable system of Daun that is here in view, but merely such works as can be completed in a few hours; provided a greater quantity of light implements, as hatchets, hand-saws, pick-axes, and shovels, be furnished the troops, and the proportion of battalion pioneers be augmented and rendered more respectable. Rogniat extols the advantages which the French army derived from this practice being introduced among the artillery sappers and miners under his orders; each of whom carried an implement of this kind during the campaign of 1813. It was by their means that the *Palankas*† were so speedily constructed before Dresden, upon which the formidable artillery of the allies scarce made an impression. This sort of field work is unquestionably of great importance where the materials can be procured; as appeared again in 1814 at Tournay, in the fruitless attack which, owing to its application by the Saxon engineers, the French, under Maison, made upon that place. The *Spanish* Redoubts, which the same ingenious officer recommends, appear likewise to possess great advantages; because they can be raised in a few hours, and are there-

\* Of this fact, the author was assured, by the late General Bulow, who stated that he rode up alone to receive their submission.

† So named from their Turkish origin.—Redoubts fenced with trunks of trees closely planted and pierced for musketry.

fore applicable in a defensive position, if a single night intervenes before the attack. It is somewhat singular, that in the systems of permanent defence, it should not have occurred that positions, intended for intrenched camps, might be pitched upon; and that by planting, along the lines of the *tracé*, rows of such trees as will thrive close together, a cheap, simple, and strong preparatory defence might be raised; which, on the breaking out of a war, might easily be completed by the neighbouring militia.

(v. v. v.)

Boundaries,  
Extent, and  
Divisions.

WARWICKSHIRE, an inland county of England, and nearly in the centre of the kingdom. It is bounded on the western side, from north to south, by Staffordshire, Worcestershire, and Gloucestershire; and on the eastern side by Leicestershire, Northamptonshire, and Oxfordshire. Its greatest length, from north to south, is about forty-eight, and its breadth across the middle thirty-two miles. It contains 902 square miles, or 577,280 statute acres. It is divided into four hundreds, besides the city of Coventry, which, with its liberties, extends over about 18,000 acres. These hundreds are subdivided into eighteen portions, for convenience in the execution of the laws.

Population.

By the census of 1821, it appeared that the number of inhabited houses was 55,082, occupied by 60,123 families: of these 16,779 were chiefly employed in agriculture; 39,189 in trade, manufactures, or handicraft; and 4,155 were comprised in neither of those classes. The whole number of persons was 274,392; of whom 133,827 were males, and 140,565 females. The increase of population between the years 1811 and 1821 appears to be about 20 per cent.

Face of the  
Country and  
Agriculture.

Although Warwickshire is an elevated district, it is in general level; the rivers are of languid course, and the undulations of the surface are rare and gentle. It is generally inclosed, and the fields are of moderate extent. The fences are for the most part high and umbrageous, being thickly planted with forest trees, so that, though woods are rare, the face of the country seems, at a distance, to be one continued track of woodland. There are but few common fields, and very little waste or barren land. The extent of pasture land is greater than in most parts of England, and is estimated to be more than half of the whole. The pasture land, calculated at 300,000 acres, may be said wholly to be appropriated to the sustenance of the different species of animals. 100,000 acres are annually mowed for hay, and the other two-thirds are used for feeding. The agriculture of the county is well conducted. The cultivation of turnips is practised to a great extent, with much skill, and with very productive effects. The crops of wheat, barley, oats, pease, beans, and tares, are

quite as luxuriant as in any portion of England. The cows are generally of the long-horned kind, but there are amongst them many varieties. The ancient race of Warwickshire sheep has been crossed with the Leicester breed, and this mixture has produced a kind adapted to the land, and equal to any race in the kingdom.

The streams of this county are numerous, but, with the exception of the Avon, are inconsiderable; though, by the means of irrigation which they furnish, they are of great value to its rural economy. The whole of them run directly or indirectly to the Severn. The Avon alone is navigable for barges from Stratford to its junction with that river near Tewkesbury. The intercourse of the county is much facilitated by the numerous canals that intersect and connect it with every part of England; supply every part with cheap fuel; and serve to convey its heavy productions to the exporting towns, London, Liverpool, and Bristol. These canals are the Birmingham Old Canal, the Birmingham and Fazeley, the Warwick and Birmingham, the Worcester and Birmingham, the Coventry, the Warwick and Napton, the Stratford, the Ashby de la Zouch, and, above all, the Grand Junction.

The minerals and fossils of this county are coal, iron, limestone, and freestone. At Leamington Priors are mineral springs, whose celebrity have made that place one of the resorts of fashionable company as well as invalids. The waters contain neutral and sulphureous salts, with carbonate of iron. At Newham Regis is a chalybeate bath, whose renown was formerly much greater than it is at present.

This county possesses considerable manufactories; of these, the greatest are those in metals of all kinds, conducted upon a stupendous scale at Birmingham, and the towns and villages in its vicinity. The minute divisions and subdivisions of labour, the various mechanical inventions, the discoveries in chemistry, and the industrious and economical habits of the people, have rendered this part of the country the principal reservoir from whence the world is supplied with domestic utensils, ornaments, and a thousand minute articles which add much to the comfort of civilized life.

Warwick-  
shire  
||  
Waterford.

The city of Coventry has long been celebrated for its manufactures of ribbons, and other goods of silk, which now give occupation, in that place and its vicinity, to more than 15,000 persons. There are also at Coventry large undertakings for making watches; a trade that has of late been much extended. Mills for spinning cotton and wool have been erected at Warwick, and to them is attributed a great increase, which has lately taken place in the population of that town. At Tamworth, very large works are constructed for printing calicoes. At Alcester, several hundred persons are employed in making needles. In several parts of the county much linen yarn is spun.

The most remarkable objects in the county are Kenilworth Castle, now in a dilapidated state; Maxstoke Castle, a most extensive pile; Comb Abbey, a Cistercian Convent; the school-house at Rugby; and the house at Stratford in which Shakespeare was born.

The titles derived from this county are,—Earls of Coventry and Warwick, and Baron Arden. Two members are returned to Parliament for the county, and two each for Coventry and Warwick. Two are also returned for Tamworth, a part only of which borough is in this county.

The largest places and their population are as follows:—Birmingham, 106,722; Coventry, 29,380; Warwick, 8235; Nuneaton, 6610; Sutton Coldfield, 3466; Atherstone, 3434; and Stratford, 3069.

The most remarkable, among a great number of noblemen and gentlemen's seats, are Warwick Castle, Earl of Warwick; Ragley Hall, Marquis of Hertford; Walton Hall, Sir C. Mordaunt; Compton Verney, Lord Willoughby; Guys Cliff, B. Greathead; Great Packington, Lord Aylesford; Compton Wyngate, Marquis of Northampton; Astley Castle; Newdigate; Hewill Grange, Earl of Plymouth; and Merevale, D. S. Dugdale.

See Dugdale's *Antiquities of Warwickshire*; Marshall's *Rural Economy*; Hutton's *History of Birmingham*; *Beauties of England and Wales.* (w. w.)

**Boundaries.** WATERFORD, a maritime county in the province of Munster in Ireland, bounded by the river Suir, which separates it from Kilkenny and Tipperary, on the north; by the harbour of its own name, an arm of the sea running up between this county and Wexford, on the east; by the sea on the south; and by the county of Cork on the west, the river Blackwater here flowing along part of its boundary.

**Extent.** It is about 51 miles in length, and 29 in breadth, and contains 710 English square miles, or 454,400 English acres, divided into the liberties of the city of Waterford, and 7 baronies, and including 74 parishes belonging to the Sees of Waterford and Lismore.

**Surface.** Very little of this district is level, the far greater part being hilly, and much of it mountainous. It is only on the south and east that it is rich and productive; on the west and north, which are occupied by the high grounds, the proportion of fertile land is inconsiderable. Yet the wooded banks of the Suir and the Blackwater, and of the streams that join them, present many delightful and romantic views, diversified by ancient castles and the modern seats of the proprietors. The Suir, which has its

source in Tipperary, on the north, after entering this county, flows almost due east, till it joins the Barrow and the Nore, beyond the city of Waterford, and then, taking a southern direction, these united streams enter the sea at the harbour of Waterford; forming an estuary nine Irish miles long and two broad. At the city of Waterford, the Suir is about a mile broad, with a depth sufficient for vessels of considerable burden. The Blackwater rises on the confines of Kerry, and, after traversing the county of Cork, comes into Waterford a little to the east of Fermoy. At Cappoquin, beyond Lismore, where it suddenly bends to the south, it becomes navigable for small vessels, and pursuing its course southwards, falls into the sea at Youghall Bay. The climate of this and the other districts on the south coast of Ireland is exceedingly mild. Frost and snow are never of any duration, and cattle continue to graze all the year round.

In this county there are some very large estates, of which the most extensive belongs to the Duke of Devonshire. Leases are commonly for twenty-one years and a life; and on the banks of the rivers, where the land is most valuable, farms are small. According to Mr Wakefield's information, "in this county, when the eldest daughter of a farmer marries, the father, instead of giving her a portion, divides his farm between himself and son-in-law; the next daughter gets one-half of the remainder, and this division and subdivision continues as long as there are daughters to be disposed of. In regard to the male children; they are turned out into the world, and left to shift for themselves the best way they can." (Wakefield, Vol. I. p. 280.) Mountain land included, the rent in 1808 was computed to be about a guinea and a half the Irish acre, and this is chiefly paid from the produce of the dairy, which is conducted on a greater or smaller scale over all the county, and from the pigs, which are partly fed upon its offals. Some of the dairy farmers, most of whom are in easy circumstances, at that time paid L. 1000 a-year of rent; and a great deal of butter is made even among the mountains, where small cows, suited to the nature of the pastures, form the principal stock. In the neighbourhood of Waterford, cows were let for L. 16, L. 18, and even L. 20 for the season. There are very few sheep, and those of a bad description; and comparatively but a small portion is in tillage. Where lime is used as a manure, it must be brought from a distance, as there is no limestone to the east of the Blackwater, and it costs upwards of L. 5 for an acre. Orchards are numerous on the banks of this river, and extensive plantations of timber trees have been formed in various parts. Furze is so much used as fuel, that whole fields are kept under this shrub for the purpose.

The towns are Waterford, Dungarvon, Tallagh, and Lismore, all except the first, places of no great importance. Waterford, situated on the south bank of the Suir, near the harbour which bears its name, and having an inland water communication northwards by the Barrow and Nore, and westward to Clonmell by the Suir, has a population of 26,787, and carries on a considerable trade with the interior and with England, and other countries; and within these few years, it employed 70 vessels in the Newfoundland

Waterford  
||  
Watson.

Watson.

land trade. Packet boats are established between this port and Milford-haven. It has a noble quay a mile long, with a wooden bridge across the Suir, which affords an easy communication with the counties of Wexford and Kilkenny. Hogs form so important a branch of trade, that the number brought to this town in 1809 was estimated to be worth about L. 1,000,000 Sterling. They are cut up for bacon and hams, which are salted and sent to London, where they are cured by fires made from different kinds of wood, which communicate a corresponding difference of flavour. The principal manufactures are glass and salt; with linen, cotton, and coarse woollens, in other parts of the county. Beef, pork, butter, grain, and linen, are the principal exports: of agricultural produce alone, the export has been estimated at L. 3,000,000 Sterling yearly. By means of the Suir, a great part of the goods imported by Waterford harbour are carried forward to Clonmell for the supply of the interior of Ireland. Part of the provision trade is also carried on at Youghall, situated at the mouth of the Blackwater; the country around it furnishing abundance of pork and grain, but it is not so considerable as formerly. Dungarvon, on the bay of that name, is a fishing town, and this place, and the village of Tramore, a few miles south from Waterford, particularly the latter, are noted for being the residence of the gentry during the bathing season.

ter. He had made it a constant practice in his mathematical pursuits, to think over the demonstration of every proposition that he studied, in his solitary walks; a habit which must certainly have been very conducive to the improvement of geometrical talent, though it could scarcely be adopted without great labour by those who follow the algebraical mode of analysis in all their investigations. After this period he passed many hours daily, for a considerable portion of his life, in the occupation of instructing others, without much enlarging the scale of his own information, though certainly not without adding to the solidity and precision of his knowledge of the most important elementary truths of science; and when he graduated in 1759, he was classed as the second wrangler, which he seems to have considered, not without reason, as the place of honour for the year, the senior wrangler, who was a Johnian, having, as it was generally believed, been unfairly preferred to him. In October 1760, he became a fellow of Trinity, and in November, assistant tutor of the college. Having taken his degree of M. A. in 1762, he was soon afterwards made moderator of the scholastic exercises of the university, an arduous and honourable office, which he also filled in several subsequent years.

Representa-  
tion.

The county, and the city of Waterford, which is a county within itself, with the boroughs of Lismore, Tallagh, and Dungarvon, returned ten members to the Irish Parliament; the number of its representatives is now four, two for the county, one for the city, and one for the borough of Dungarvon. In 1791, the population was computed to be 110,000, and by the census of 1821, it was found to be 127,679. The Protestants, according to Mr Wakefield, bear a very small proportion to the Catholics over the county; and even in the city of Waterford, where the disproportion is not so great as in the country, the latter are increasing in a greater proportion than the former. Most of the landed and personal property is in the hands of the Catholics. The celebrated philosopher Boyle was born in the Castle of Lismore, and also Congreve, the dramatic writer, whose father was agent to the Boyle family, the maternal ancestors of the Duke of Devonshire.

In 1764, he undertook a journey to Paris, though without being able to speak the language, in order to take charge of his young friend and pupil, Mr Luther, who returned to England with him soon after. He was elected in the same year Professor of Chemistry, though he had never devoted any portion of his attention to that science; but he soon rendered himself sufficiently master of all that was then known of the science, to give a very popular course of lectures on the subject about a year after his election, with the assistance of an operator whom he had brought from Paris, and to become the author of a series of essays, which served for many years as the most agreeable introduction to the elementary doctrines and the ordinary processes of chemistry. He obtained from the Government, by proper representations, a salary of L. 100 a year for himself, and for all future professors: he paid also some attention to theoretical and practical anatomy, as having some relation to the science of chemistry. In 1767, he became one of the principal tutors of Trinity College; in 1769, he was elected a Fellow of the Royal Society, and in October 1771, he unexpectedly obtained the important and lucrative appointment of Regius Professor of Divinity, upon the premature death of Dr Rutherford, and in that capacity he held the rectory of Somersham in Huntingdonshire. He had been little accustomed to the study of the divinity of the schools, or even of the fathers; but his eloquence and ingenuity supplied the want of theological learning, though he gave some offence to his more orthodox colleagues, by confining his arguments more strictly to the text of the scripture than they thought perfectly consistent with the duty of a champion of the Church of England, which they considered to be the description of a professor of divinity in an English university. He attracted, however, as long as he officiated in person, audiences as numerous, to the exercises in the schools at which he presided, as had attended his chemical lectures.

Population.

See the works of Young, Beaufort, Newenham, and Wakefield, quoted under the other Irish counties; Curwen's *Observations on the State of Ireland* (1818), and the *Statistical Accounts of Ireland*. (A.)

WATSON (RICHARD, BISHOP OF LANDAFF), celebrated as an able Theologian, and a Professor of Chemistry, was born in August 1737, at Heversham near Kendal, in Westmorland. His ancestors had been farmers of their own estates for several generations; and his father had for forty years been master of the free school at Heversham, but was become infirm, and had resigned it a little before his birth. He was, however, educated at this school, and continued there till 1754, when he was sent as a sizer to Trinity College, Cambridge. He applied without intermission to his studies, and in 1757 he obtained a scholarship, with particular expressions of approbation from Dr Smith, who was then mas-

Watson.

He married, in December 1773, Miss Wilson, of Dallam Tower in Westmorland; their union continued uninterrupted for more than forty years. In 1774 he obtained a prebend of Ely, in exchange for a rectory in Wales, which the Duke of Grafton had procured for him: and he became Archdeacon of Ely in January 1780; in the same year Bishop Keene presented him with the rectory of Northwold in Norfolk; and, in 1782, his pupil, the Duke of Rutland, gave him the rectory of Knaptoft in Leicestershire: the same interest obtained him also from Lord Shelburne the Bishoprick of Landaff. Here his episcopal preferment rested: he generally joined the politics of the Opposition, and especially on the question of the unlimited regency: but he was too independent in his sentiments to become a very useful member of any administration; and he retired, before the end of the year 1789, without books, and with somewhat more of disgust than he ought in justice to have felt, to an estate which he had bought, at Calgarth, on the banks of Winandermere, and occupied himself entirely, besides the education of his family, in agricultural improvements, especially in planting, for which he received a medal from the Society of Arts in 1789. His pupil Mr Luther, of Ongar in Essex, had died in 1786, and left him an estate, which he afterwards sold for something more than L. 20,000.

He considered as one of the best practical results of his chemical studies the suggestion which he made to the Duke of Richmond, then Master of the Ordnance, respecting the preparation of charcoal for gunpowder, by burning the wood in close vessels, which, it seems, very materially improved the quality of the powder.

He had the liberality to confer, in 1804, a small living, as a reward for literary merit only, on Mr Davies, the author of the *Celtic Researches*. The next year, he applied with success to the Duke of York for the promotion of his son, who had then the rank of a Major, and his Royal Highness speedily complied with his solicitation, as a personal favour only, without waiting for any Ministerial influence.

His health had been seriously impaired by an illness which attacked him in 1781, and which his friends attributed, though perhaps without sufficient reason, to excessive study: in October 1809, he had a slight paralytic affection, and another in 1811; but it was in 1813, that his last illness might be said to begin, and he sunk gradually till the 4th of July 1816. The elder of his two sons was in the army, the younger in the church: he left also several daughters. His writings are as miscellaneous as they are numerous; but none of them are bulky.

1. *Institutionum Chemicarum pars Metallurgica*. 8. Camb. 1768. Repr. Ess. Vol. V.
2. *Experiments and Observations on the Solution of Salts*. *Phil. Trans.* 1770. P. 325. Ess. V. Especially on the specific gravities of salts and their solutions.
3. *Remarks on the Effects of Cold in February* 1771. *Phil. Trans.* 1771. P. 213. Ess. V. With some experiments on congelation.
4. *Experiment with a Thermometer having its bulb blackened*. *Phil. Trans.* 1773. P. 40. Ess. V. Raised 10°.
5. *Chemical Experiments and Observations on Lead Ore*. *Phil. Trans.* 1778. P. 863. Ess. V.
6. *Observations on the Sulphur Wells*

at Harrowgate. *Phil. Trans.* 1786. P. 171. Ess. Watson. V.

7. *Essay on the Subjects of Chemistry, and their General Division*.

8. *Assize Sermon, preached at Cambridge*. 4. 1769.

9. *Letters to the Members of the House of Commons by a Christian Whig*, 1772.

10, 11. *Two Sermons*. 4. Camb. 1776. On the Revolution, and on the King's Accession.

12. *A Brief State of the Principles of Church Authority*, 1773. Reprinted in 1813 as a charge.

13. *A Fast Sermon*, Feb. 1780.

14. *A Sermon addressed to the Clergy of Ely*, 1780. Recommending Oriental Literature.

15. *Apology for Christianity, in a Series of Letters addressed to Edward Gibbon, Esq.* 12. 1776. Often reprinted, and considered as very satisfactory, though the author confesses, with more of the courtier than of the orthodox divine, in a letter to Mr Gibbon, that the *Essay* "derives its chief merit from the elegance and importance of the work it attempts to oppose."

16. *Chemical Essays*, 5 v. 12. 1781-7. Addressed to his pupil the Duke of Rutland. The work was intended for general information, and became extremely popular as a first introduction. The first volume relates to salts, sulphurs, vitriols, and gunpowder; the second to common salt, distillation, lime, clay, and pit coal; the third to bitumens, charcoal, evaporation, lead, and lead ores; and the fourth to zinc, gum, metal, tin, copper, iron, and stones; the fifth is a republication of the author's earlier chemical tracts. After the completion of these volumes, he had the resolution to burn all his chemical papers.

17. *A Letter to Archbishop Cornwallis on the Church Revenues*, 1782. A plan for equalising the bishoprics.

18. *A Sermon preached the 30th Jan. before the Lords*. 4. 1784.

19. *Visitation Articles, for the Diocese of Landaff*.

20. *Theological Tracts*. 6 v. 8. 1785. Collected from various authors, not excluding many works of dissenters from the church.

21. *A Sermon on the Wisdom and Goodness of God, in having made Rich and Poor*, 1785, 1793. Adapted to allay the discontents which were then prevalent among the lower classes.

22. *Sermons and Tracts*. 8. 1788. Chiefly republications.

23. *An Address to Young Persons after Confirmation*. 12. 1789.

24. *Considerations on the Expediency of Revising the Liturgy*. 8. 1790. Anonymous.

25. *A Sermon preached for the Westminster Dispensary in 1785, with an Appendix*. 1792.

26. *A Charge to the Clergy of his Diocese*. 4. 1792.

27. *Two Sermons and a Charge*. 4. 1795. The first sermon is entitled *Atheism Refuted*; the second, *The Christian Religion no Imposture*.

28. *Apology for the Bible, in a series of Letters addressed to Thomas Paine*. 12. 1796. An able and judicious answer to the contemptible work of a mischievous incendiary: it seems to have been singularly successful in producing clear and rapid conviction: thanks were returned to the author from

Ireland and from America, and he gained L. 1000 by the sale of the book, besides allowing it to be often reprinted gratuitously.

29. *An Address to the People of Great Britain*. 8. 1798. Enforcing the necessity of submission to the exigencies of the times. It went through fourteen editions, besides several piracies; and it was reprinted in Ireland by order of Lord Camden, then Lord Lieutenant. Mr Wakefield answered it somewhat intemperately, and the Bishop attempted ineffectually, out of respect for his classical acquirements, to lighten the punishment which was allotted to him.

30. *Charge to the Clergy of Landaff*. 31. *Second Charge*, 1802. On similar subjects.

32. *A Charge relating to Ecclesiastical Reform*, 1802.

33. *A Sermon preached at the London Hospital*, 1802. Against the principles of Paine.

34. *Thoughts on the intended Invasion*. 8.

35. *Substance of a Speech intended to have been delivered*, 1804. In favour of Catholic Emancipation.

36. *Sermon preached before the Society for the Suppression of Vice*, 1804.

37. *A Charge to the Clergy*, 1805. 38. *Another Charge, on the Catholic Question*, 1808.

39. *Two Apologies, Two Sermons, and a Charge*, 8. 1806. Reprinted.

40. *A Second Defence of Revealed Religion*, 1807. In two sermons, preached in the Chapel Royal.

41. *A Paper on Planting and on Waste Land*. Communications to the Board of Agriculture, Vol. VII. 4. 1808. 42. He had also written some *Preliminary Observations in the Agricultural Report of Westmorland*.

43. *Miscellaneous Tracts*. 2 v. 8. 1815. Religious, political, and agricultural. "His discourse on the first and second Adam, and the nature of death as affected by each, is almost unequalled in originality of thought, and vigour of expression." *Quarterly Review*.

(44). It has been said that he published some papers in the *Manchester Memoirs*; but they do not appear in the Indices.

45. *Anecdotes of his Life*; revised in 1814, and published by his son Richard Watson, LL. B. Prebendary of Landaff and Wells. 4. Lond. 1817. *Quarterly Review*, XVIII. P. 229. Treated with great ability, but with too much severity. His chief mistake, indeed, seems to have been, that he expected his literary merits alone to secure him political advancement; further than this, there is nothing disgusting, to a candid reader, in the sincerity with which he displays the consciousness of his own merits. The praises of the reviewer himself are at least as energetic as those of the friends whose language he has occasionally copied; his censures are not less impressive; but for an author's censure of himself, it would be idle to look in a work of autobiography.

Though somewhat reserved, Dr Watson is said to have been remarkable for the simplicity of his manners and the equality of his temper. With respect to his conduct in the school of divinity, the Reviewer confesses that "he ascended the chair with many eminent qualifications for his difficult and distinguished functions. The exercise of four years, as moder-

ator of the philosophical schools, had rendered his faculty of speaking Latin perfectly easy; by great assiduity the vices of his early education had been so far corrected, that a false quantity was never heard to escape him; all the tricks and shifts of school logic were familiar to his mind; in addition to which, his acuteness and ingenuity were admirable. His majestic and commanding figure, his terrific countenance, his deep sonorous voice, the uninterrupted tenor of his sentences, which, though far from classical, were never either barbarous or soloecistic, and above all, the boldness and originality of his sentiments seldom left the under graduates' places unoccupied in the theological school. It was sport to see how the grave professor would glide over the surface of the subject with every appearance of profundity, or when pinned, as his opponent hoped, into a corner, would wind himself out with all the lubricity of an eel. Still he had a large mind; he endured, he encouraged, he delighted in the opposition of able men; he never flinched from the strokes of those who had more information than himself; secure in the consciousness of his own ability to encounter learning by invention. The same tolerance of contradiction, the same dexterity in parrying attacks, he brought with him into private conversation, which rendered him, when the poison of politics did not operate on his constitution, a most agreeable and amusing debater. In these happier hours, and they were not few, he would even smile at the pomp and magnificence of his own manner, and relax into all the playfulness and pleasantry which are almost inseparable from *real genius*."

Our critic appears, however, to have exceeded the limits of candour and of charity, when he asserts that "he was governed through life by the two leading principles of interest and ambition, both of which were thwarted, in his political conduct, by a temper so wayward, and a presumption so overweening, that the disappointment produced by their collision embittered his mind, and exasperated his latter days to a very high degree of malignity. Accomplished as he was in academical learning, he had no ingenuous or disinterested love of knowledge: he read only that he might teach, and he taught only that he might rise."

"When he felt himself neglected, he avowedly and professedly abandoned all study, because, says he, "eagerness in the pursuit of knowledge was a part of my temper till," and only till, "the acquisition of knowledge was attended with nothing but the neglect of the King and his Ministers." Disgusted, therefore, and disappointed, as much as broken in constitution, he withdrew into the wilds of Westmorland without a library, and to this privation he voluntarily submitted almost thirty years. From taste he derived neither amusement nor occupation, for of taste he never had a tincture: placed amidst the most delicious scenes of England, he thought of nothing but turning his own portion of them to emolument!" Thus "this violent declaimer against sinecures and nonresidence was the first who converted the regius professorship of divinity into a sinecure: this enemy of pluralities held at least fourteen places of preferment; this man of moderation in his wishes, and calm contentment, under the shade of retirement, spent

Watson  
||  
Watt.

the last twenty nine years of his life in 'execrating' [complaining of] those, who, for his factious obstinacy, had left him to that retirement, while he was occupied in nursing up a fortune, till, according to his own boast, with the poorest bishopric in the kingdom, he became the richest bishop upon the bench."

With respect to the merits of the question between him and the administration of his early friend Mr Pitt, there will probably be as many different opinions as there are readers of different political parties; but he had surely no right to expect that a ministry determined to support every minute article of the established constitution of the country, both in church and in state, should voluntarily add to the power and authority of a person who had repeatedly declared himself rather hostile than indifferent to many points which they thought essential to both; or even of one who felt so decided a conviction of the importance of every single opinion which he had himself adopted, as to refuse his concurrence in such measures of legislation, as they might deem of vital importance to the good of the country, and such as had been sanctioned by the concurrent determination of the majority of a cabinet taking on themselves the whole responsibility of their proceedings. He must have been aware that a house divided against itself cannot stand, and that the members of every administration, in a country not despotic, must consent to give up something to each other's feelings, and to make a small sacrifice of private conviction for the great objects of public energy and unanimity.

(A. L.)

WATT (JAMES), a philosopher, mechanician, and civil engineer, whose inventive talents, extensive knowledge of the sciences and arts, and practical application of them to the purposes of life, place him in the foremost rank of those illustrious men, whose discoveries have influenced the state of society, and conferred distinction upon their country and age.

His great-grandfather farmed his own small estate in the county of Aberdeen, but engaging in the civil wars, was killed in one of Montrose's battles, and his property lost to his family. His son, Thomas Watt, left an infant, was brought up by relations, and having a turn for the mathematical sciences, made such proficiency by his own exertions, under very untoward circumstances, occasioned by the persecutions of the times, as to enable him at a later and quieter period to establish himself at Greenock, as a teacher of these sciences, and of the dependent arts of surveying and navigation. There he acquired reputation, and dying in 1734, at the advanced age of 91, left a brief record of his partiality to his profession in the inscription upon his tomb in the West Churchyard.\*

He had two sons, John and James; the former brought up as a mathematician, settled first at Ayr, and afterwards at Glasgow, where he was much employed in surveying and directing the improvement of estates; was an able man, and drew neatly and accurately, which was not very common in those days. He died in 1737, at an early age, leaving a *Survey of the River Clyde, from Glasgow to the Point*

*of Toward*, which was published by his brother several years afterwards. James, his younger brother, of an active, ingenious, and enterprising mind, became a merchant in Greenock, and was for upwards of twenty years a member of the Town-Council, a magistrate, and a zealous promoter of the improvements of the town. By his wife, Agnes Muirheid, he had two sons, James, the subject of the present article, and John, a youth of promising abilities, who was lost at sea soon after he became of age. Misfortunes in trade, and the decay of the faculties of his mind, occasioned his retirement from business some years before his death, which happened in 1782, in his eighty-fourth year.

Watt.

James Watt, his eldest son, and only surviving child, was born at Greenock, the 19th January 1736. He received the rudiments of his education in the public schools of his native town; but from the extreme delicacy of his constitution, was with difficulty enabled to attend the classes, and owed much of his acquirements to his studious habits at home. Little more is known of his early years, than that, from the first, he manifested a partiality for mechanical contrivances and operations, and frequently employed himself in that way. The desire of improvement in an art then little practised in Scotland, induced him to go to London in his eighteenth year, and there to place himself under the tuition of a mathematical instrument-maker; but he remained little more than a twelvemonth, the infirm state of his health compelling his return to the paternal roof.

In that short period, he appears to have made great proficiency, and continued, after his return to Scotland, to perfect himself in this art, both at home and on his visits to his mother's relations at Glasgow, where it was his wish to establish himself. But some opposition being made by the corporations, who considered him as an intruder upon their privileges, the Professors of the College took him under their protection, and accommodated him with an apartment and premises for carrying on his business within their precincts, with the title and office of *Mathematical Instrument-maker to the University*. This took place in 1757, when he was twenty-one years of age, and it must be inferred, that he had already given satisfactory proofs of talent to the eminent men who then adorned that seat of learning; of whom it is sufficient to mention the names of Robert Simpson, Adam Smith, Dr Black, and of Dr Dick, the Professor of Natural Philosophy. There Mr Watt applied sedulously to business, and in the few intervals which its concerns, and ill health allowed, cultivated those various talents which distinguished him in after life; and there a lasting friendship was formed with the kindred minds of Dr Black, and of Mr, afterwards Dr John, Robison, then a student at the University, and nearly of his own age.

He remained in the College until some time in the year 1763, when he removed into the town previous to his marriage with his cousin, Miss Miller, which took place in the summer of the following year.

The Steam-Engine had been a frequent subject of conversation between Mr Robison and himself, and

\* He is there styled, Professor of the Mathematics.

Watt.

the former had suggested the possibility of its application to the moving of wheel carriages. About the year 1761 or 1762, Mr Watt had tried some experiments on the force of steam in a Papin's digester, and had constructed and worked with strong steam a small model, consisting of an inverted syringe; the bottom of the rod of which was loaded with a weight, alternately admitting the steam below the piston, and letting it off to the atmosphere. Observing the imperfections of this construction, he soon abandoned it; but the attention necessary to be bestowed upon his business prevented his reconsidering it, until the winter of 1763-4, when he was employed by the Professor of Natural Philosophy to put in order a working model of a steam-engine upon Newcomen's construction. When he had repaired it and set it to work, he found that the boiler, though large in proportion to the cylinder, was barely able to supply it with steam for a few strokes *per* minute, and that a great quantity of injection water was required, though it was but lightly loaded by the pump attached to it. It soon occurred, that the cause lay in the little cylinder (two inches diameter, six inches stroke), exposing a greater surface to condense the steam than the cylinders of larger engines did, in proportion to their respective contents. By shortening the column of water in the pump, less steam and less injection water were required, and the model worked at a proper speed. Thus the purpose for which it was put into his hands was accomplished; and with this mode of accounting for the defect and this result, most artists would have been satisfied. Not so Mr Watt. He had now become aware of a great consumption of steam, and his curiosity was excited to a more accurate investigation of the causes, in which he proceeded in a truly philosophical manner. The cylinder of his small model being of brass, he conceived that less steam would be condensed by substituting cylinders of some material which would transmit heat more slowly. He made a larger model with a cylinder (six inches diameter, and one foot stroke) of wood, soaked in oil, and baked to dryness. He ascertained, from experiments made with boilers of various constructions, that the evaporation of boiling water is neither in proportion to the evaporating surface, nor to the quantity of water, as had been supposed, but to the heat that enters it; and that the latter depended chiefly on the quantity of surface exposed to the action of the fire. He likewise determined the weight of coal required for the evaporation of any given quantity of water. Being convinced that there existed a great error in the statement which had been previously given of the bulk of water when converted into steam, he proceeded to examine that point by experiment; and discovered, that water, converted into steam of the heat of boiling water, was expanded to 1800 times its bulk: or, as a rule for ready calculation, that a cubic inch of water produced a cubic foot of steam. He constructed a boiler to be applied to his model, which should show, by inspection, the quantity of water evaporated, and, consequently, would enable him to calculate the quantity of steam used in every stroke of the engine. This he now proved to be several times the full of the cylinder. He also observed, that all attempts to improve the vacuum, by throwing in more injection

Watt.

water, caused a disproportionate waste of steam: and it occurred to him, that the cause of this was the boiling of water in vacuo at very low heats (recently determined, by Dr Cullen, to be under 100°); consequently, at greater heats, the injection water was converted into steam in the cylinder, and resisted the descent of the piston. He now perceived clearly, that the great waste of steam proceeded from its being chilled, and condensed by the coldness of the cylinder before it was sufficiently heated to retain it in an elastic state; and that, to derive the greatest advantage, the cylinder should always be kept as hot as the steam that entered it, and that, when the steam was condensed, it should be cooled down to 100°, or lower, in order to make the vacuum complete. Early in 1765, the fortunate thought occurred to him of accomplishing this, by condensing the steam in a separate vessel, exhausted of air, and kept cool by injection, between which and the cylinder a communication was to be opened every time steam was to be condensed, while the cylinder itself was to be kept constantly hot. No sooner had this occurred to him, than the means of effecting it presented themselves in rapid succession. These have been in a great measure already described in the *Encyclopædia*. A model was constructed, and the experiments made with it, placed the correctness of the theory, and the advantages of the invention, beyond the reach of doubt.

In the course of these trials, he was much struck by the great heat communicated to the injection water by a small quantity of steam, and proceeded by a very simple experiment to satisfy himself upon that subject, when he discovered that water converted into steam will heat about six times its own weight of water at 47° or 48° to 212°. He mentioned this extraordinary fact to Dr Black, who then explained to him his doctrine of latent heat, to the support of which, Mr Watt had afterwards the satisfaction of contributing his experiments. From some of these he was led to suppose the latent heat of steam to be above 1000°, but he afterwards considered 960° a more accurate determination. From others, he deduced the important conclusion, that the sum of the latent and sensible heat of steam, at different temperatures, is a constant quantity, the latent heat increasing as the sensible heat diminishes; or, in other words, that a given weight of water in the state of steam contains nearly the same quantity of heat, whatever may be the bulk or density of the steam.

He also, at this time, made experiments upon the capacities of different bodies for heat, and upon the heats at which water boils under various pressures; from which he ascertained, that where the heats proceeded in an arithmetical, the elasticities proceeded in a geometrical ratio, the curve of which he laid down. These he repeated some years after with more accuracy.

We have been thus minute in our details of the successive steps by which Mr Watt proceeded to his great improvement upon the principle of the steam-engine, in order to convey some idea of the sagacity, ingenuity, and science, with which he conducted the investigation. Our limits will oblige us to be more brief in our narrative of his subsequent improvements.

From this period (the early part of 1765), his mind

Watt.

became very much engaged in contriving the machinery for executing his improvement upon a large scale; but the want of funds prevented his attempting it, until he was induced to address himself to Dr Roebuck, who had a short time before completed his establishment of the Carron Ironworks, and who, in addition to his known qualities of ingenuity and enterprise, was considered to be possessed of ample means of introducing the invention to the public. He agreed to enter into the plan, upon having the proceeds of two-thirds of the invention assigned to him; and an engine upon a large scale was then constructed by Mr Watt, at Kinneil, near Borrowstounness, where the Doctor then resided; the trials made with which gave satisfaction. But the introduction of the invention to the public was retarded, on the one hand, by the pecuniary difficulties in which the Doctor became involved, by the failure of several of his multifarious undertakings; and on the other, by the employment, which the rising reputation of Mr Watt, for knowledge and skill in the line of a civil engineer, procured him.

He was employed, in 1767, to make a survey for a canal of junction between the rivers Forth and Clyde, by what was called the Lomond passage, and attended Parliament on the part of the subscribers, where the bill was lost. An offer was then made to him of undertaking the survey and estimate of an intended canal from the Monkland Collieries to Glasgow; and these proving satisfactory, the superintendence of the execution was confided to him. This was quickly followed by his being employed by the *Trustees for Fisheries and Manufactures in Scotland*, to make a survey of a canal from Perth to Forfar, through Strathmore; and soon afterwards, by the *Commissioners of the Annexed Estates*, to furnish a report and estimate of the relative advantages of opening a communication between the Firth of Clyde and the Western Ocean, by means of a navigable canal across the isthmus of Crinan,\* or that of Tarbert. Business of this description now crowded upon him; and surveys, plans, and estimates, were successively undertaken by him for the harbours of Ayr, Port-Glasgow, and Greenock; the deepening of the river Clyde; the rendering navigable the rivers Forth and Devon, and the water of Leven; the making of a canal from Machrihanish bay to Campbelltown, and of another between the Grand Canal and the harbour of Borrowstounness; the building of bridges at Hamilton and at Rutherglen, &c. &c. In these surveys he made use of a new micrometer, and a machine for drawing in perspective, which he had invented to facilitate his operations. Our limits do not allow us to go into the details of his *Reports*, which are remarkable for their perspicuity and accuracy, although the work of a self-taught engineer. The last and greatest work upon which he was employed was the survey and estimate of the line of a canal between Fort-William and Inverness, since executed by Mr Telford, upon a larger scale than was at that time proposed, under the name of the Caledonian Canal.

\* The Crinan Canal was executed several years afterwards, under the direction of his friend Mr Rennie, with some variations.

+ Mr Watt had originally intended to derive the rotary motion from the working beam by means of a connecting rod and crank; but the workman employed to make the model communicated it to a neighbour-

Watt.

Whilst engaged upon this survey, in the latter part of the year 1773, Mr Watt received the account of the death of his affectionate wife, leaving him a daughter and a son. He appears soon after to have made up his mind to adopt the advice of his friend Dr Small of Birmingham, and the invitation of Mr Boulton, to settle in England. He had secured his title to his *Improvements for saving Steam and Fuel in Fire Engines*, by patent, in the year 1769; but all hopes of carrying them into effect, by the assistance of Dr Roebuck, being at an end, he had induced that gentleman to agree, for certain considerations, to transfer his share of the patent to Mr Boulton of Soho, near Birmingham—a gentleman equally distinguished by his knowledge of the arts, and his enterprising spirit, who had some years before established his manufactory upon a scale as unrivalled for extent and elegance, as for the variety and perfection of the processes carried on.

In conjunction with him an application was made to Parliament for an extension of the term of the patent, and an act prolonging it for twenty-five years was obtained in the year 1775, when the business of making steam-engines was commenced by the firm of Boulton and Watt.

Mr Watt now married for his second wife Miss Macgrigor, the daughter of an old friend, at Glasgow, and devoted himself to the improvement of the details of the engine with a degree of application and exertion not to be expected from his delicate and infirm state of health; and he found in his partner a zealous and able coadjutor.

Some engines for pumping water were soon made upon a large scale, and the savings in fuel were demonstrated by repeated comparative trials to amount to three-fourths of the quantity consumed by those of the best construction before in use. A deputation from the mining interest of Cornwall was sent to ascertain the fact, and their report led to the introduction of the improved engines into that county, to which they have proved of such vast utility.

The immediate application of the powers of steam to giving a rotary motion to mills had formed an early object of Mr Watt's attention, and he had deeply considered the various means of effecting this. One method of producing a continued movement in one direction was by a steam wheel, described in his patent of 1769. Various others of a similar kind suggested themselves to him, of some of which drawings and models were made; but the difficulty of rendering them steam and air-tight, and the loss of power by friction, induced him to turn his thoughts to the adaptation of the reciprocating motion to the production of a continued regular rotary one. This he accomplished by a series of improvements, the exclusive property of which he secured by successive patents in the years 1781, 1782, 1784, and 1785; including, among other inventions, the rotary motion of the sun and planet wheels, † the expansive principle, the double engine, the parallel motion, and the

Watt. smokeless furnace. The application of the centrifugal regulating force of *the governer* gave the finishing stroke to the machine.

The invention of the separate condenser, and the contrivances necessary to give it full effect, would alone have established the fame of Mr Watt; but when to these are added the various inventions called forth to perfect his rotative engines, we are impressed by a union of philosophical research, of physical skill, and of mechanical ingenuity, which has, we believe, no parallel in modern times.

The perfection thus given to the rotative engine soon led to its general application for imparting motion to almost every species of mill-work and machinery; and gave an impulse, unexampled in the history of inventions, to the extension of our manufactures, population, and wealth.

Nor were Mr Watt's inventive powers confined to the steam-engine. The necessity of preserving accurate copies of his various drawings and of his letters, containing long and important calculations; and the desire of avoiding that labour himself, which he did not think it right to entrust to others, led him, in the year 1780, to contrive a copying apparatus, the exclusive property in which he secured by Letters Patent, and commenced the manufactory of them in partnership with Mr Boulton, and his friend, Mr Keir, under the firm of James Watt and Company;—a contrivance of great simplicity, and of which he reaped an ample benefit in the time, labour, and expence it saved to himself, to say nothing of its advantages to the public.

In the winter of 1784-5, he put up an apparatus for heating the room in which he drew and wrote by means of steam. The possibility of doing this we find suggested by Colonel Cooke in the *Philosophical Transactions* for 1745; but we know not whether this was known to Mr Watt when he made this first practical attempt, from which he deduced proportions of surface, &c., which afterwards served to guide his firm in the introduction of the process in larger buildings.

Chemical studies engaged much of his attention during his busiest time, and at the very period when he was most engaged in perfecting his rotative engines, and in managing a business become considerable, and, from its novelty, requiring close attention, he entered deeply into the investigations then in progress relative to the constitution and properties of the different gases. Early in 1783, he was led, by the experiments of his friend and neighbour, Dr Priestley, to the important conclusion, that water is a compound of dephlogisticated and inflammable airs (as they were then called) deprived of their latent or elementary heat, and he was the first to make known

Watt. this theory. This was done in a letter to Dr Priestley, dated the 28th April 1783, in which he states the Doctor's experiments to have come in aid of some prior notions of his own, and supports his conclusions by original experiments. That letter Dr Priestley received in London; and, after showing it to several members of the Royal Society, he delivered it to Sir Joseph Banks, with a request that it might be read at some of the public meetings of the Society; but before that could be complied with, Mr Watt, having heard of some new experiments made by Dr Priestley, begged that the reading might be delayed. Those new experiments soon afterwards proved to have been delusive, and Mr Watt sent a revised edition of his letter to Mr De Luc on the 26th November of the same year, which was not read to the Society until the 29th April 1784, and appears in the *Philosophical Transactions* for that year, under the title of *Thoughts on the Constituent Parts of Water and of Dephlogisticated Air, with an Account of some Experiments upon that Subject*. In the interim, on the 15th January 1784, a paper by Mr Cavendish had been read, containing his *Experiments on the Combustion of the Dephlogisticated and Inflammable Airs*, and drawing the same inference as Mr Watt; with this difference only, that he did not admit elementary heat into his explanation. He refers in it to his knowledge of Mr Watt's paper, and states his own experiments to have been made in 1781, and mentioned to Dr Priestley; but he does not say at what period he formed his conclusions; he only mentions that a friend of his had given some account of his experiments in the summer of 1783 to Mr Lavoisier, as well as of the conclusion drawn from them. It is quite certain, that Mr Watt had never heard of them; and Dr Blagden has stated, that he mentioned at Paris the opinions of both the English philosophers, which were not admitted without hesitation, nor until the French chemists had satisfied themselves by experiments of their own.\*

Mr Watt also has the merit of being the first person to introduce into this country, and to carry into effect, on a practical scale, in any country, the bleaching of linens and cottons by oxymuriatic acid, the invention of his friend, Mr Berthollet. That gentleman had communicated his invention to Mr Watt at Paris in the winter of 1786-7, whither he had proceeded with Mr Boulton at the instance of the French government, to suggest improvements in the mode of raising water at Marly, and his mind was instantly alive to the extensive application of which it admitted. He advised Mr Berthollet to secure the property by an English patent; but that he declined, and left his friend to make such use of it

ing manufacturer, who took out a patent for it. This stimulated Mr Watt to the invention of other means of effecting the same object, of which five are described in his patent of 1781. He afterwards used the crank, which was indeed his own, when he saw occasion, in defiance of the patentee, who never troubled him.

\* There is a confusion of dates in the accounts of this affair. Mr Watt's letter to Mr De Luc in the *Philosophical Transactions* appears dated 26th November 1784, which is evidently an error of the press. Mr Cavendish, in his letter, read 15th January 1784, speaks of Mr Watt's paper "as lately read before the Society," whereas the paper itself purports to have been read on the 29th April 1784. This we cannot explain.

Watt.

as he thought proper. He, in consequence, communicated it to his father-in-law, Mr Macgrigor, and gave directions for the construction of the proper vessels and machinery; and soon after himself superintended the first trials at his bleachfield near Glasgow, which proved eminently successful.

Some years after this, Mr Watt was led, by the illness of the daughter, and some apprehensions entertained for the son, who were the issue of his second marriage, to consider the subject of the medical application of the factitious airs, and to contrive various apparatuses for that purpose, which were described by himself, in his friend Dr Beddoes's publications on *Pneumatic Medicine*.

We have not space to particularize other improvements introduced by Mr Watt, or at his suggestion, into various arts; for there were few arts with the details of which he was not intimately acquainted, and to the practical professors of which he was not able and willing to impart information. We shall only mention, that, before he left Glasgow to settle in England, he had assisted some of his friends in the establishment of a pottery there, to the success of which his experiments and advice had greatly contributed, and in which he afterwards continued a partner. At a later period, he occupied himself much upon a composition, having the transparency, and nearly the hardness of marble, from which he made many casts. This promoted, if it did not create a taste for sculpture and statuary, and led to his employing himself, during the last years of his life, in the contrivance of a machine for multiplying busts and other carved work, which he left in a very forward state.

Mr Watt did not escape the common lot of eminent men, that of meeting with pirates of his inventions, and detractors from his merit. The latter, indeed, were but few, and their efforts transitory; but the former were numerous, and in proportion to the benefits expected to arise from an evasion of the patent dues claimed by Boulton and Watt; though these were established upon the liberal footing of receiving only one-third of the savings of fuel compared with the best steam-engines previously in use. In consequence, the attention both of Mr Watt and of Mr Boulton was greatly occupied, from the year 1792 to the year 1799, in defending their patent rights against numerous invaders, the principal of whom were supported by a portion of the mining interest of Cornwall, although the respectable part of it refused to concur in their measures. The admission of their respective sons into the partnership, in 1794, infused vigour into their proceedings; and, after repeated verdicts, establishing the novelty and utility of Mr Watt's inventions, the validity of his claim was finally confirmed in the year 1799 by the unanimous decision of all the Judges of the Court of King's Bench.

In 1800, upon the expiration of the act of Parliament passed in his favour, he withdrew from business, resigning his shares to his two sons; of whom the youngest, Mr Gregory Watt, died soon after, having given splendid proofs of literary and philosophical talents, and left a durable record of the latter, in his paper *On Basalt* in the *Philosophical Transactions*. Mr Watt continued to the close of life

Watt.

to interest himself in the pursuits of his former associates, and to maintain an uninterrupted friendship with Mr Boulton, whom he survived several years.

On two occasions afterwards, in 1811 and 1812, he gave proofs of the undiminished powers of his mind in his former profession. In the one instance, he was induced, by his grateful recollections of his residence in Glasgow, to assist the proprietors of the water-works there with a plan for supplying the town with better water, by means of a suction pipe, with flexible joints, laid across the bottom of the Clyde, accompanied with instructions for insuring the supply of water on the opposite side; a plan which answered completely, and for which the proprietors presented him with a handsome memorial of their gratitude. In the other instance, he was prevailed upon by the earnest solicitation of the Lords Commissioners of the Admiralty, to attend a deputation of the Navy Board, and to give with his friend, Captain Huddart, and Mr J. Jessop, an opinion upon the works then carrying on at Sheerness Dockyard, and the farther ones projected by Messrs Rennie and Whidby; on which occasion, he no less gratified the gentlemen associated with him, by the clearness of his general views, than by his knowledge of the details, and received the thanks of the Admiralty.

Mr Watt, also, at a still later period, in 1814, yielded to the wishes of his friends in undertaking a revision of Professor Robison's articles on STEAM and STEAM-ENGINES in the *Encyclopædia Britannica*; and enriched them with valuable notes, containing his own experiments upon steam, and a short history of his principal improvements upon the engine itself.

His originally infirm health had been subjected to severe trials by the great exertions of his mind, during the period of carrying into execution his improvements on the steam-engine, and had with difficulty resisted the cares and anxieties attending upon business, and those created by the subtleties of the law, during the protracted proceedings of seven long years. There appears to have been an organic defect in his digestion, and its effects were intensely severe sick headaches; but, by continual temperance and good management of his constitution, which he treated with much medical skill, it improved as he advanced in years; and with faculties little impaired he reached his 84th year, when, after a short illness, rather of debility than of pain, he expired in the bosom of his family at his house at Heathfield, in the county of Stafford, on the 25th August 1819.

His remains are deposited in the chancel of the adjoining parochial church of Handsworth, near those of Mr Boulton. An excellent bust had been made of him, some years before his death, by Mr Chantry, and a statue is now nearly finished by the same great artist; intended by filial piety to be placed upon his tomb, and to convey to distant ages a faithful representation of those features in which the lines of intense thought were blended with the mild expression of benevolence.

Mr Watt was elected a member of the Royal Society of Edinburgh in 1784; of the Royal Society of London in 1785; and a corresponding member of the Batavian Society in 1787. In 1806, the hono-

Watt. rary degree of Doctor of Laws was conferred upon him by the spontaneous and unanimous vote of the Senate of the University of Glasgow; and in 1808, he was elected first a corresponding, and afterwards a foreign member of the Institute of France.

In this brief narrative of his long, busy, and useful life, we have endeavoured to confine ourselves to a statement of the principal facts, and shall now add the Character drawn up, soon after his death, by a distinguished writer, who knew him well, and enjoyed a large portion of his esteem.

“It is with pain that we find ourselves called upon, so soon after the loss of Mr Playfair, to record the decease of another of our illustrious countrymen, and one to whom mankind has been still more largely indebted.—Mr James Watt, the great improver of the steam-engine.

“This name fortunately needs no commemoration of ours; for he that bore it survived to see it crowned with undisputed and unenvied honours; and many generations will probably pass away before it shall have ‘gathered all its fame.’ We have said that Mr Watt was the great *improver* of the steam-engine; but, in truth, as to all that is admirable in its structure, or vast in its utility, he should rather be described as its *inventor*. It was by his inventions that its action was so regulated as to make it capable of being applied to the finest and most delicate manufactures, and its power so increased as to set weight and solidity at defiance. By his admirable contrivances, it has become a thing stupendous alike for its force and its flexibility,—for the prodigious power which it can exert, and the ease, and precision, and ductility, with which it can be varied, distributed, and applied. The trunk of an elephant that can pick up a pin or rend an oak is as nothing to it. It can engrave a seal, and crush masses of obdurate metal like wax before it,—draw out, without breaking, a thread as fine as gossamer, and lift a ship of war like a bauble in the air. It can embroider muslin and forge anchors,—cut steel into ribbands, and impel loaded vessels against the fury of the winds and waves.

“It would be difficult to estimate the value of the benefits which these inventions have conferred upon the country. There is no branch of industry that has not been indebted to them; and in all the most material, they have not only widened most magnificently the field of its exertions, but multiplied a thousandfold the amount of its productions. It is our improved steam-engine that has fought the battles of Europe, and exalted and sustained, through the late tremendous contest, the political greatness of our land. It is the same great power which now enables us to pay the interest of our debt, and to maintain the arduous struggle in which we are still engaged, with the skill and capital of countries less oppressed with taxation. But these are poor and narrow views of its importance. It has increased indefinitely the mass of human comforts and enjoyments, and rendered cheap and accessible all over the world the materials of wealth and prosperity. It has armed the feeble hand of man, in short, with a

power to which no limits can be assigned, completed the dominion of mind over the most refractory qualities of matter, and laid a sure foundation for all those future miracles of mechanic power which are to aid and reward the labours of after generations. It is to the genius of one man, too, that all this is mainly owing; and certainly no man ever before bestowed such a gift on his kind. The blessing is not only universal, but unbounded; and the fabled inventors of the plough and the loom, who were deified by the erring gratitude of their rude contemporaries, conferred less important benefits on mankind than the inventor of our present steam-engine.

“This will be the fame of Watt with future generations; and it is sufficient for his race and his country. But to those to whom he more immediately belonged, who lived in his society, and enjoyed his conversation, it is not perhaps the character in which he will be most frequently recalled—most deeply lamented—or even most highly admired. Independently of his great attainments in mechanics, Mr Watt was an extraordinary, and in many respects a wonderful man. Perhaps no individual in his age possessed so much and such varied and exact information,—had read so much, or remembered what he had read so accurately and well. He had infinite quickness of apprehension, a prodigious memory, and a certain rectifying and methodising power of understanding, which extracted something precious out of all that was presented to it. His stores of miscellaneous knowledge were immense,—and yet less astonishing than the command he had at all times over them. It seemed as if every subject that was casually started in conversation with him, had been that which he had been last occupied in studying and exhausting;—such was the copiousness, the precision, and the admirable clearness of the information which he poured out upon it without effort or hesitation. Nor was this promptitude and compass of knowledge confined in any degree to the studies connected with his ordinary pursuits. That he should have been minutely and extensively skilled in chemistry and the arts, and in most of the branches of physical science, might perhaps have been conjectured; but it could not have been inferred from his usual occupations, and probably is not generally known, that he was curiously learned in many branches of antiquity, metaphysics, medicine, and etymology, and perfectly at home in all the details of architecture, music, and law. He was well acquainted, too, with most of the modern languages—and familiar with their most recent literature. Nor was it at all extraordinary to hear the great mechanic and engineer detailing and expounding, for hours together, the metaphysical theories of the German logicians, or criticising the measures or the matter of the German poetry.

“His astonishing memory was aided, no doubt, in a great measure, by a still higher and rarer faculty—by his power of digesting and arranging in its proper place all the information he received, and of casting aside and rejecting, as it were instinctively, whatever was worthless or immaterial. Every conception that was suggested to his mind seemed instantly to take

its place among its other rich furniture, and to be condensed into the smallest and most convenient form. He never appeared, therefore, to be at all encumbered or perplexed with the *verbiage* of the dull books he perused, or the idle talk to which he listened; but to have at once extracted, by a kind of intellectual alchemy, all that was worthy of attention, and to have reduced it for his own use, to its true value and to its simplest form. And thus it often happened that a great deal more was learned from his brief and vigorous account of the theories and arguments of tedious writers, than an ordinary student could ever have derived from the most faithful study of the originals,—and that errors and absurdities became manifest from the mere clearness and plainness of his statement of them, which might have deluded and perplexed most of his hearers without that invaluable assistance.

“It is needless to say, that, with those vast resources, his conversation was at all times rich and instructive in no ordinary degree; but it was, if possible, still more pleasing than wise, and had all the charms of familiarity, with all the substantial treasures of knowledge. No man could be more social in his spirit, less assuming or fastidious in his manners, or more kind and indulgent towards all who approached him. He rather liked to talk,—at least in his later years; but though he took a considerable share of the conversation, he rarely suggested the topics on which it was to turn, but readily and quietly took up whatever was presented by those around him, and astonished the idle and barren propounders of an ordinary theme, by the treasures which he drew from the mine they had unconsciously opened. He generally seemed, indeed, to have no choice or predilection for one subject of discourse rather than another; but allowed his mind, like a great cyclopædia, to be opened at any letter his associates might choose to turn up, and only endeavoured to select from his inexhaustible stores what might be best adapted to the taste of his present hearers. As to their capacity he gave himself no trouble; and, indeed, such was his singular talent for making all things plain, clear, and intelligible, that scarcely any one could be aware of such a deficiency in his presence. His talk, too, though overflowing with information, had no resemblance to lecturing or solemn discoursing, but, on the contrary, was full of colloquial spirit and pleasantry. He had a certain quiet and grave humour, which ran through most of his conversation, and a vein of temperate jocularly, which gave infinite zest and effect to the condensed and inexhaustible information, which formed its main staple and characteristic. There was a little air of affected testiness, and a tone of pretended rebuke and contradiction, with which he used to address his younger friends, that was always felt by them as an endearing mark of his kindness and familiarity,—and prized accordingly, far beyond all the solemn compliments that ever proceeded from the lips of authority. His voice was deep and powerful,—though he commonly spoke in a low and somewhat monotonous tone, which harmonised admirably with the weight and brevity of his observations, and set off to the greatest advantage the pleasant anecdotes which

he delivered with the same grave brow and the same calm smile playing soberly on his lips. There was nothing of effort, indeed, or impatience, any more than of pride or levity, in his demeanour; and there was a finer expression of reposing strength, and mild self-possession in his manner, than we ever recollect to have met with in any other person. He had in his character the utmost abhorrence for all sorts of forwardness, parade, and pretension; and, indeed, never failed to put all such impostors out of countenance, by the manly plainness and honest intrepidity of his language and deportment.

“In his temper and dispositions he was not only kind and affectionate, but generous, and considerate of the feelings of all around him, and gave the most liberal assistance and encouragement to all young persons who showed any indications of talent, or applied to him for patronage or advice. His health, which was delicate from his youth upwards, seemed to become firmer as he advanced in years; and he preserved, up almost to the last moment of his existence, not only the full command of his extraordinary intellect, but all the alacrity of spirit, and the social gaiety which had illuminated his happiest days. His friends in this part of the country never saw him more full of intellectual vigour and colloquial animation,—never more delightful or more instructive than in his last visit to Scotland in autumn 1817. Indeed, it was after that time that he applied himself, with all the ardour of early life, to the invention of a machine for mechanically copying all sorts of sculpture and statuary,—and distributed among his friends some of its earliest performances, as the productions of a young artist just entering on his 83d year.

“This happy and useful life came at last to a gentle close. He had suffered some inconvenience through the summer; but was not seriously indisposed till within a few weeks from his death. He then became perfectly aware of the event which was approaching; and with his usual tranquillity and benevolence of nature, seemed only anxious to point out to the friends around him the many sources of consolation which were afforded by the circumstances under which it was about to take place. He expressed his sincere gratitude to Providence for the length of days with which he had been blessed, and his exemption from most of the infirmities of age, as well as for the calm and cheerful evening of life that he had been permitted to enjoy, after the honourable labours of the day had been concluded. And thus, full of years and honours, in all calmness and tranquillity, he yielded up his soul, without pang or struggle,—and passed from the bosom of his family to that of his God!

“He was twice married, but has left no issue but one son, long associated with him in his business and studies, and two grandchildren by a daughter who predeceased him. He was a Fellow of the Royal Societies both of London and Edinburgh, and one of the few Englishmen who were elected members of the National Institute of France. All men of learning and science were his cordial friends; and such was the influence of his mild character and perfect fairness and liberality, even upon the pretenders to

these accomplishments, that he lived to disarm even envy itself, and died, we verily believe, without a single enemy.\*"

WEAVING BY POWER. See the Article *Weights and Cotton-Manufacture*, in this *Supplement*, Vol. III. p. 400. *Measures.*

## WEIGHTS AND MEASURES.

THE bill for ascertaining and establishing UNIFORMITY of WEIGHTS and MEASURES, which passed the Imperial House of Commons in the Session of 1823, not having been carried through the House of Lords, the subject has less immediate interest at the present moment than there has been every reason to suppose, for a few years past, that it would by this time have acquired. But there is little doubt that the discussion will be revived either in the Upper or the Lower House of Parliament before many more months have elapsed; and it seems to be highly improbable that any insuperable difficulties should stand in the way of its ultimate success. This presumption is founded on no hasty view of the subject in question, but upon a laborious and somewhat painful examination of the historical progress of the measures which have been taken respecting it, and especially of the laws of England respecting uniformity of practice in different parts of the country; a uniformity which, though generally esteemed by all governments a thing to be encouraged and enforced, has often proved to be no more subjected to the controul of legislative enactment, than the introduction of a uniformity of language and a grammatical accuracy of speech would be found in every part of an extensive empire.

Augustus is said to have endeavoured in vain to force a new Latin word into the language of ancient Rome; the French, on the other hand, after all their labours to recommend a uniform system of measures, have ended in such a complication, that for the most simple purposes of practical mechanics and civil life, it is become usual to carry in the pocket a little ruler, in the form of a triangular prism, one of the sides containing the old established lines and inches of the royal foot, a second the millimetres, centimetres, and decimetres of the revolutionary school, and the third the new ultraroyal combination of the Jacobin measure, with the royal division, the inches consisting each of the 36th part of a metre, or the four millionth of a degree of the meridian of the earth. If such occurrences as these be calmly considered, they will make us more disposed to diminish than to increase the number of penal statutes intended to compel the inhabitants of the different parts of a country to study their own convenience conjointly with that of their neighbours, and to spare themselves the necessity of a few arithmetical operations in the course of every market day; and we shall feel that it is more incumbent on a wise government to endeavour to facilitate both the attainment of correct and uniform standards of legal existing measures of all kinds, and the ready understanding of all the provincial and local terms

applied to measures, either regular or irregular, by the multiplication of glossaries and tables for the correct definition and comparison of such terms.

Measures have apparently always been derived, in the first instance, from some part of the human person; a foot, a pace, a fathom, the orgyia or stretch of the arms, a cubit, a palm, and a finger; these have probably all been used in the earlier states of society by each individual from the magnitude of his own person; and afterwards a standard measure has been established by authority from the real or supposed magnitude of the person of some king or hero, in order for the attainment of more perfect uniformity in practice; though it is said, that in some parts of the East the Arabs still measure the cubits of their cloth by the fore arm, with the addition of the breadth of the other hand, which serves to mark the end of the measure, as the thumb which was formerly added at the end of the yard by the English clothiers. It ought not, however, to be forgotten, that any one of these terms possesses an advantage, for popular use and for the convenience of future ages and of remote countries, which would be lost by the introduction of any more arbitrary measurement; thus a hand's breadth, or a foot, is always sufficiently understood, without any definition, to enable us to form to ourselves a tolerable accurate picture of the magnitude intended to be described; and there is scarcely an instance of the caprice of denomination having ever extended so far as to make the measure called a foot in any country so small as half a natural foot, or so great as two feet of an ordinary person, and certainly not of its amounting to three ordinary feet; while a metre, even to those who know that the word implies a measure, might as well have meant a mile, or an inch, or a quart, as a length somewhat greater than a yard.

The idea of accurately verifying the standard of a country by any other means, than that of a comparison with some actually existing original, can scarcely have occurred, except in a very advanced period of the progress of civilisation. It was indeed enacted, in the time of our Henry the Third, that an ounce should be the weight of 640 dry grains of wheat taken from the middle of the ear, that a pound should be twelve ounces, a gallon of wine eight pounds, and eight gallons of wine a bushel of London; but this seems rather a direction for making a single standard than a mode intended for the continual verification of the standard in case of any minute uncertainty. Again, in a statute of Henry the Seventh, a gallon of corn was mentioned as containing eight pounds of wheat: and this may, perhaps,

\* The Editor has received this article from a quarter which entitles him to state, with the utmost confidence, that it contains an accurate and faithful account of Mr Watt. The brilliant eulogium with which it so properly concludes is known to have been written by Mr Jeffrey.

Weights and Measures.

serve to explain the origin of the two different gallons. But the substitution of an original standard, derived from an object of definite magnitude, exterior to the human person, seems to have been reserved for the days of the French Revolution, though it has since been adopted, in an improved form, by the introduction of a foot equal to  $\frac{3}{8}$  of the pendulum vibrating seconds as a representative of the customary foot of the kingdom of Denmark. (*Journal R. I.* 1821, *Astr. Coll. N. V.*)

The Royal Society, under the presidency of Mr Folkes, made some very accurate comparisons of the English, and French, and old Roman standards, which are recorded in the *Philosophical Transactions* for 1736, 1742, and 1743; and George Graham, the watchmaker, determined, at the same time, the correct length of the pendulum vibrating seconds to be 39.130 inches, but the standard, with which he compared it, requiring some reduction, it was afterwards ascertained, that the length, as derived from these experiments, ought to have been more nearly 39.14 inches.

A Committee of the House of Commons was appointed in 1758, of which Lord Carysfort was chairman; their Report contains some important information respecting the standards then in use. They found that the customary ale and beer gallon of the Excise was estimated at 282 cubical inches, while the legal wine gallon of the Exchequer was computed at only 231, though the only existing standard of the wine gallon, in 1688, which was kept at Guildhall, contained no more than 224 cubical inches; they suggested the adoption of this smaller gallon for the legal standard, perhaps as being more favourable to the revenue, though the gallon of 231 inches had been previously legalised by the act of the fifth of Queen Anne; and they employed the well known Mr Bird to prepare two standards, which were to be exact copies of that which was made by Graham for the Royal Society in 1742, from a very careful comparison of the various yards and ells of Henry the Seventh and Elizabeth, which were kept in the Exchequer. One of these copies was marked "Standard Yard, 1758," and was presented by the Committee to the House with the intention that it should be adopted as the legal standard; the other was made "with cheeks," for common use, and proposed to be kept in the Exchequer.

A subsequent Report of a Committee, appointed in 1759, consists principally of proposals for some legislative regulations, tending to facilitate the equalisation of weights and measures by the establishment of proper methods of checking and authorising the standards to be employed. In 1765, two bills were brought into the House of Commons by Lord Carysfort, in conformity with the reports of the Committees; but, from some accidental circumstances, they were not passed into laws.

Another Committee was appointed in 1790; but no minutes of their proceedings have been recorded. In 1814, however, a very important Report was presented to the House by a new Committee, who had called upon Dr W. Hyde Wollaston and Professor Playfair for their opinions on the subject; and it was principally in consequence of these examinations that the Committee stated that the length of the pen-

Weights and Measures.

dulum vibrating seconds had been ascertained to be 39.13047 inches, and that the metre of platina measured, at the temperature of 55°, 39.3828 English inches, representing, at 32°, the ten millionth part of the quadrant of the meridian; they remarked, with great truth, that, although in theory, the original standard of weight is best derived from the measure of capacity, yet, in common practice, it will generally be found more convenient to reverse this order; and they recommended, upon the suggestion of Dr Wollaston, that a gallon, containing ten pounds of pure water, should be adopted as a substitute for the ale and corn gallons, which had become different rather from accident than from any direct legislative authority, containing the one a little more than ten pounds, the other a little less, though the standards of the latter were extremely discordant among themselves. It seems to have been intended to abolish the wine gallon, which is also that of the apothecaries; though it was recommended to retain the use of the Troy Weight of the goldsmiths employed also by the apothecaries. It had before been observed, that twelve wine gallons of distilled water weighed exactly 100 pounds Avoirdupois; but Dr Wollaston's proposal, to make an ale gallon of exactly ten pounds, afforded a greater facility in the operation of adjusting the measure, since it is not very easy to divide 100 pounds into twelve equal parts, with the weights in common use.

Some very important experiments on weights and measures had been made, a little before the date of this Committee, by Sir George Shuckburgh Evelyn, who had published an elaborate paper on the subject in the *Philosophical Transactions* for 1798; and by the ingenious Mr Whitehurst, who obtained the length of the pendulum by measuring the difference of two lengths affording vibrations of different frequency. There were still some minute discordancies between the various measurements which appeared to be of the highest authority; and some particulars in the Report of the Committee of 1814 are manifestly erroneous; thus the weight of a cubic foot of water is stated, from a mistake in computation, to be 1000 ounces at 56½° of Fahrenheit, while, in fact, it is less than this even at 39°, the maximum of density; and again, the customary length of the English foot, which has always been adjusted at the ordinary temperature of the atmosphere, and rather at that of the summer than of the winter, as, for example, in the great trigonometrical operations of General Roy and his successors, at 62° of Fahrenheit, was, in the experiments, copied by the Committee from Pictet, compared with the French standard, which was intended to be employed at the freezing point of water, without any correction for this diversity; though Dr Young had long before pointed out the omission both in the *Journals of the Royal Institution* and elsewhere, and had computed the true length of the metre according to these operations of Professor Pictet, confirmed by some earlier ones of Bird, Maskelyne, and Lalande, to be 39.3710 English inches, instead of 39.3828.

In order, therefore, to remove any doubt which might still be reasonably entertained on the subject, Mr Davies Gilbert moved the House of Commons, in the year 1816, to present an humble address to

Weights and Measures. the Prince Regent, praying that he would give direction, that proper measures should be taken for ascertaining the length of the pendulum vibrating seconds, and for comparing the French and English standards with each other. In consequence of this address, the Astronomer Royal was in the first instance directed to perform the necessary operations; and, upon his asking for some further assistance, the President and Council of the Royal Society were requested to appoint a Committee to cooperate with him. This Committee consisted, besides the President and Secretaries, of the late Sir Charles Blagden, Mr Gilbert, Dr Wollaston, Dr Young, Captain Kater, General Mudge, Mr Brown, Mr Rennie, and Mr Troughton. They began by discussing the several modes of making the requisite experiments which occurred to the different members, and it was resolved, that as many of these methods, as were preferred by each of them, should be separately carried into execution, in order to obtain collateral determinations of the required length. Mr Pond pursued the method of the French astronomers, and obtained some very satisfactory results, with an apparatus such as they had employed; Dr Young proposed a method derived from that of Whitehurst, and very perfect in theory, but somewhat complicated, and which has never yet been practically executed; Captain Kater invented, with great ingenuity, and employed, with great mechanical skill, an apparatus which does as much credit to his talents in the arrangement as to his perseverance in the experiments which he performed with it, and the accuracy of his determinations has been fully appreciated by mathematicians and practical astronomers throughout the world; and his operations have been and are still about to be repeated by many observers in different countries. Captain Kater's apparatus has been fully described in the Article PENDULUM of this *Supplement*; it owes no inconsiderable part of its advantage to the property subsequently demonstrated by Laplace, that, even if the opposite knife edges were considerably blunted and rounded off, supposing them to be equally affected, the distance between them would still afford the true measure of the length of the pendulum, without any further correction for the change of the axis of motion. It has also been demonstrated in this country, by means of the experiments of Chladni on the elasticity of metals, that the temporary change of form, depending on the compression of the steel edge, would be too inconsiderable to produce any sensible alteration of the length in question.

The object of Dr Young's apparatus was, to obtain two or more fine lines, traced at different parts of a scale, which should exhibit between them a certain determinate portion of the length of a pendulum vibrating seconds. He apprehended that the accurate determination of the form and direction of the knife edges, and the measurement of the distance between any such edges, which was necessary in the method proposed by Prony, as well as in that which was subsequently invented by Captain Kater, would require more skill and delicacy in the execution and the observation, than could be expected from any common workman or experimenter; and though

Weights and Measures. Captain Kater, by his extreme care in combating every source of error, has, in point of fact, apparently obviated all these difficulties, yet it cannot be expected that so rare a combination of qualifications should again be found, in case of a repetition of the experiments, and Dr Young's apparatus may still, at some future time, be employed with advantage, at least for a collateral check upon the results.

The obstacles which prevented the completion of the observations which were made for some time with this apparatus at Greenwich, was the difficulty of obtaining a scapement so delicate as to count the number of vibrations, without sensibly interfering with their frequency. A very ingenious clockmaker was employed to furnish a scapement, of which the intention was to strike the pendulum slightly and instantaneously at the lowest point of its vibration, and then to recoil from it, so that even a considerable impulse might have little or no effect in altering the rate of the pendulum; but it was in fact observed, upon comparison with the clocks of the observatory, that the vibrations in larger arcs were more frequent than those which were performed in smaller; so that the scapement must have exerted a very considerable influence on the time of every vibration. It was therefore found necessary to abandon this method of making the experiment; but there would be no difficulty in conducting it very satisfactorily by means of a journeyman clock, with a wooden or brass pendulum, capable of having its length altered, so as to become comparable with the vibrations of Dr Young's pendulum in its different states; and it might even be found sufficient to observe the pendulum, with the same scapement, so altered as not to give any impulse whatever, but merely to reckon the vibrations by means of the detent, during the spontaneous vibrations of the pendulum, which, on account of its great weight, would be continued for a considerable time in consequence of the first impulse, taking care that the detent should be struck exactly at the middle of the vibration, and that it should rebound in some measure from the pendulum at the moment of contact.

Before any attempt was made to introduce any legislative regulations upon the foundation of the various scientific experiments, which had been so accurately and satisfactorily conducted, it was thought advisable by his Majesty's Ministers that the subject at large should be submitted to the deliberate consideration of some competent persons, who might discuss it more minutely than could be done with convenience before a Committee of either House of Parliament; and that a commission should be appointed for this purpose by a writ of the Privy Seal. The commissioners thus nominated in 1818 were the late Sir Joseph Banks, Sir George Clerk, Mr Davies Gilbert, Dr W. Hyde Wollaston, Dr Thomas Young, and Captain Henry Kater. Some further operations for the comparison of the existing standards of length were undertaken by Captain Kater; Dr Wollaston examined some of the authorised measures of capacity, and Dr Young offered his services as secretary to the committee, with the assistance of a clerk who had studied the law, while Sir George Clerk and Mr Gilbert were employed in

Weights and Measures.

preparations for carrying into effect, in their legislative capacity, such regulations as the commissioners at large might agree to propose. The first occupation of the clerk was to make copious extracts from the statutes at large, by means of which Dr Young drew up an abstract of the present state of the laws relating to weights and measures, and afterwards to select from the *Agricultural Reports* of the different counties such materials, as afforded a glossary of all the terms employed in any part of Great Britain for denominating the irregular weights or measures, which have acquired a local currency in agricultural or other commercial transactions.

After this sketch of the previous history of the subject, we may now proceed to extract from the *Reports of the Commissioners*, and from the bills founded on them, such statements as may either serve in the place of canons for the regulation of weights and measures in general, or as documents respecting the actual value of the various standards possessing the highest degree of authenticity; and this article cannot be more properly concluded than by subjoining some further comparative tables of the standards of measures and weights adopted by different countries and at different periods.

*First Report.*—“ I. Upon a deliberate consideration of the whole of the system at present existing, we are impressed with a sense of the great difficulty of effecting any radical changes, to so considerable an extent as might in some respects be desirable; and we, therefore, wish to proceed with great caution, in the suggestions which we shall venture to propose.

“ II. With respect to the actual magnitude of the standards of length, it does not appear to us, that there can be any sufficient reason for altering those which are at present generally employed. There is no practical advantage in having a quantity commensurable to any original quantity existing, or which may be imagined to exist, in nature, except as affording some little encouragement to its common adoption by neighbouring nations. But it is scarcely possible that the departure from a standard, once universally established in a great country, should not produce much more labour and inconvenience in its internal relations, than it could ever be expected to save in the operations of foreign commerce and correspondence, which always are, and always must be, conducted by persons to whom the difficulty of calculation is comparatively inconsiderable, and who are also remunerated for their trouble, either by the profits of their commercial concerns, or by the credit of their scientific acquirements.

“ III. The subdivisions of weights and measures at present employed in this country, appear to be far more convenient for practical purposes than the decimal scale, which might perhaps be preferred by some persons for making calculations with quantities already determined. But the power of expressing a third, a fourth, and a sixth of a foot in inches, without a fraction, is a peculiar advantage in the duodecimal scale; and, for the operation of weighing and measuring capacities, the continual division by two renders it practicable to make up any given quantity,

with the smallest possible number of standard weights or measures, and is far preferable in this respect to any decimal scale. We would therefore recommend, that all the multiples and subdivisions of the standard to be adopted should retain the same relative proportions to each other as are at present in general use.

“ IV. The most authentic standards of length which are now in existence being found, upon a minute examination, to vary in a very slight degree from each other, although either of them might be preferred, without any difference that would become sensible in common cases; we beg leave to recommend, for the legal determination of the standard yard, that ‘which was employed by General Roy, in the measurement of a base on Hounslow Heath, as a foundation for the trigonometrical operations that have been carried on by the Ordnance throughout the country, and a duplicate of which will probably be laid down on a standard scale, by the Committee of the Royal Society appointed for assisting the Astronomer Royal in the determination of the length of the pendulum;’ the temperature being supposed to be 62 degrees of Fahrenheit, when the scale is employed.

“ V. We propose also, upon the authority of the experiments made by the Committee of the Royal Society, that it should be declared, for the purpose of identifying or recovering the length of this standard, in case that it should ever be lost or impaired, that the length of a pendulum vibrating seconds of mean solar time in London, on the level of the sea, and in a vacuum, is ‘39.1372’ inches of this scale; and that the length of the metre employed in France, as the 10,000,000th part of the quadrantal arc of the meridian, has been found equal to ‘39.3694’ inches.

“ VI. The definitions of measures of capacity are obviously capable of being immediately deduced from their relations to measures of length; but since the readiest practical method of ascertaining the magnitude of any measure of capacity is to weigh the quantity of water which it is capable of containing, it would, in our opinion, be advisable in this instance to invert the more natural order of proceeding, and to define the measures of capacity rather from the weight of the water they are capable of containing, than from their solid content in space. It will therefore be convenient to begin with the definition of the standard of weight, by declaring that ‘nineteen cubic inches of distilled water, at the temperature of 50°, must weigh exactly ten ounces Troy, or 4.800 grains; and that 7000 such grains make a pound avoirdupois; supposing, however, the cubic inches to relate to the measure of a portion of brass, adjusted by a standard scale of brass. This definition is deduced from some very accurate experiments of the late Sir George Shuckburgh on the weights and measures of Great Britain; but we propose at a future period to repeat such of them as appear to be the most important.

“ VII. The definitions thus established are not calculated to introduce any variation from the existing standards of length and of weight, which may be considered as already sufficiently well ascertained.

Weights and Measures.

Weights and Measures.

Weights and Measures.

But, with respect to the measure of capacity, it appears, from the *Report* contained in the Appendix (A), that the legal standards of the highest authority are considerably at variance with each other: the standard gallon, quart, and pint of Queen Elizabeth, which are kept in the Exchequer, having been also apparently employed, almost indiscriminately, for adjusting the measures both of corn and of beer; between which, however, a difference has gradually, and, as it may be supposed, unintentionally crept into the practice of the Excise; the ale gallon being understood to contain about four and a half *per cent.* more than the corn gallon, though we do not find any particular act of Parliament in which this excess is expressly recognised. We think it right to propose, that these measures should again be reduced to their original equality; and at the same time, on account of the great convenience which would be derived from the facility of determining a gallon and its parts, by the operation of weighing a certain quantity of water, amounting to an entire number of pounds and ounces without fractions, we venture strongly to recommend, that the standard ale and corn gallon should contain exactly ten pounds avoirdupois of distilled water, at 62° of Fahrenheit, being nearly equal to '277.2' cubic inches, and agreeing with the standard pint in the Exchequer, which is found to contain exactly twenty ounces of water.

"VIII. We presume that very little inconvenience would be felt by the public from the introduction of this gallon, in the place of the customary ale gallon of 282 cubic inches, and of the Winchester corn gallon, directed by a statute of King William to contain 269, and by some later statutes estimated at 272 $\frac{1}{4}$  cubic inches; especially when it is considered that the standards, by which the quart and pint beer measures used in London are habitually adjusted, do not at present differ in a sensible degree from the standard proposed to be rendered general. We apprehend, also, that the slight excess of the new bushel above the common corn measure would be of the less importance, as the customary measures, employed in different parts of Great Britain are almost universally larger than the legal Winchester bushel.

"IX. Upon the question of the propriety of abolishing altogether the use of the wine gallon, and establishing the new gallon of ten pounds, as the only standard for all purposes, we have not yet been able to obtain sufficient grounds for coming to a conclusive determination; we can only suggest, that there would be a manifest advantage in the identification of all measures of the same name, provided that the change could be made without practical inconvenience; but how far the inconvenience might be more felt than the advantage, we must leave to the wisdom of his Majesty's Government to decide."

Dated "24th June 1819."

"Appendix (A).

The standards kept at the Exchequer, for the adjustment both of CORN and BEER measures, are a bushel, a gallon, and a quart, dated 1601, and a pint, dated 1602, all marked with an E and a Crown. They were examined by Sir George Clerk and Dr Wollaston, and the weight of Thames water which they held, at the temperature of 52°, was found as in the

subjoined table. Now, since, according to Sir George Shuckburgh's experiments, a cubic inch of distilled water, at 60°, weighs 252 $\frac{1}{2}$  grains, the specific gravity of the water being to that of distilled water as 1.00060 to 1, and the apparent specific gravity of distilled water, in a vessel of brass at 52°, being to that of water at 62° as 1.00046 to 1, it follows that the apparent specific gravity of the water employed was 1.00106, and that an ounce avoirdupois corresponded to 1.731 cubic inches. Hence we obtain the contents of the measures in cubic inches, which are compared, in the table, with the more direct measurement of Mr Bird and Mr Harris, reported to the House of Commons in 1758.

	Oz. Avoir.	Cub. In.		Gallon.	Rep. 1758.
Pint	20.00	34.6	( $\times 8 =$ )	276.9	34.8
Quart	40.35	69.8	( $\times 4 =$ )	279.3	70.0
Gallon	156.25	270.4	( $=$ )	270.4	271.0
Bushel	1229.85	2128.9	( $\times \frac{1}{8} =$ )	266.1	2124.0

"The Exchequer standard WINE gallon is dated 1707, and was found to contain 133.4 ounces, answering to 230.9 cubic inches. An experiment of Dr Wollaston and Mr Carr, in 1814, gave 230.8, the mean being 230.85; while the measurement of 1758 made it 231.2. A duplicate of this measure, and of the same date, is kept at Guildhall.

"Dr Wollaston and Mr Carr examined also the three other WINE gallons at Guildhall. The oldest of these seems to be the same that was measured by Halley and Flamsteed in 1688, and was said to contain 224 cubic inches; its actual capacity is 224.4. The wine gallon of 1773, which is in daily use for adjusting other measures, was probably in the first instance a correct copy of the Exchequer gallon, but has been reduced by a bruise, and by the wear of the brim, to 230.0 cubic inches, having lost  $\frac{4}{5}$  of a cubic inch, or  $\frac{1}{55}$  of its whole capacity. The wine gallon of 1798 contains 230.8 cubic inches.

"The Excise WINE gallon was found, by a similar experiment, to contain 230.1 cubic inches, having partaken of the progressive deficiency of the Guildhall gallon, from which it was derived."

*Second Report.* "We have examined, since our last *Report*, the relation of the best authenticated standards of length at present in existence, to the instruments employed for measuring the base on Hounslow Heath, and in the late trigonometrical operations. But we have very unexpectedly discovered that an error has been committed in the construction of some of those instruments: We are therefore obliged to recur to the originals which they were intended to represent, and we have found reason to prefer the Parliamentary standard executed by Bird in 1760, which we had not before received, both as being laid down in the most accurate manner, and as the best agreeing with the most extensive comparisons which have been hitherto executed by various observers, and circulated throughout Europe; and, in particular, with the scale employed by the late Sir George Shuckburgh.

"We have therefore now to propose, that this standard be considered as the foundation of all legal weights and measures, and that it be declared, that

Weights and Measures.

the length of a pendulum vibrating seconds in a vacuum, on the level of the sea, in London, is 39.13929 inches, and that of the French metre 39.37079 inches, the English standard being employed at 62° of Fahrenheit."

Dated "13th July 1820."

*Third Report.* "The measurements which we have lately performed, upon the apparatus employed by the late Sir George Shuckburgh Evelyn, have enabled us to determine, with sufficient precision, the weight of a given bulk of water, with a view to the fixing the magnitude of the standard of weight; that of length being already determined by the experiments related in our former *Reports*: and we have found by the computations, which will be detailed in the Appendix, that the weight of a cubic inch of distilled water, at 62° of Fahrenheit, is '252.72' grains of the Parliamentary standard pound of 1758, supposing it to be weighed in a vacuum."

*Appendix.* The Commissioners having been furnished, by the kindness of the Honourable C. C. C. Jenkinson, with the apparatus employed by the late Sir George Shuckburgh Evelyn in the determination of the magnitude of the standard weights, and there being some doubt of the perfect accuracy of his method of measuring the capacity of the bodies employed, it was judged necessary to repeat that measurement with greater precautions; and the results of Captain Kater's experiments have afforded some slight corrections of the capacities in question.

"The sides of Sir George Shuckburgh's cube were found by Captain Kater equal to 4.98911, 4.98934, and 4.98935 inches, the diameter of the cylinder 3.99713, and its length 5.99600 inches; and the diameter of the sphere 6.00759 inches. Hence the content of the cube appears to be 124.1969 inches; that of the cylinder 75.2398; and that of the sphere 113.5264 inches of Bird's Parliamentary standard of 1760, recommended in the last *Report* of the Commissioners, or of the standard made by Troughton for Sir George Shuckburgh.

"The difference of the weight of the cube in the air at 62°, with the barometer at 29.0, and in water at 60.2°, was 31381.79 grains; and adding to this the weight of an equal bulk of the air at 62°, which is

$\frac{1}{834} \cdot \frac{29}{30}$  of that of the water, or 36.26 grains, and

subtracting from it  $\frac{1}{8.5}$  of this, or 4.26 grains, the

buoyancy of the brass weights, we obtain 31413.79 grains for the weight of the cube of water in a vacuum at 60.2°. Now this cube is less than the supposed measure, at the standard temperature of 62°, in the ratio of 1 to 1.0000567, on account of the contraction of the brass, and the water is denser than at the standard temperature, according to Mr Gilpin's experiments, in the ratio of .99998 to .99981, or of 1.00017 to 1; the whole correction, for the difference of 1.8°, being .0001133, or 3.55 grains, making

31410.24 for the weight of the cube of water in a vacuum at 62°; which, divided by 124.1969, gives 252.907 for the weight of a cubic inch, in Sir George Shuckburgh's grains.

"In the same manner, we obtain for the cylinder, which was weighed in air under the same circumstances, and in water at 60.5°, the difference being

19006.83 grains, the correction  $\frac{1}{834} \cdot \frac{29}{30} \cdot \frac{7.5}{8.5}$  for the

effect of buoyancy, amounting to 19.43 grains; and for the difference of temperature of the water and brass conjointly, the densities being .999955 and .999810, the correction .000145—0.00047=0.000095, or 1.80 grains, leaving +17.63 grains for the whole correction of the weight, as reduced to a vacuum at 62°, and making it 19024.46, which, divided by 75.2398, the content of the cylinder, affords us 252.851 for the cubic inch in a vacuum at 62°.

"The sphere was weighed in air at 67°, the barometer standing at 29.74; the correction for the buoy-

ancy is here  $\frac{7.5}{8.5} \cdot \frac{29.74}{30} \cdot \frac{1}{843}$ , or, for 28673.51 grains,

29.72; while the temperature of 66° requires, for the difference between the expansion of brass and water, the addition of .00042—0.000126, or .000294 of the whole, that is +8.43 grains, making the whole correction 38.15, and the weight in a vacuum 28711.66; which, divided by 113.5264, gives us 252.907, for the cubic inch in a vacuum.

"The mean of these three measures is 252.888, giving for the three errors, +.019,—.037, and +.019; and this mean, reduced to the Parliamentary standard, makes '252.722' grains, for the cubic inch of distilled water at 62°, weighed in a vacuum, or 252.456 in air, under the common circumstances of the atmosphere, when weights of brass are employed. In a vacuum, at the maximum of density, that is, at 39°, the weight of a true cubic inch will be 253 grains, and of a cubic decimetre 15440.\* The proposed imperial gallon, of ten pounds, or 70000 grains of water, will contain very nearly 277.3 cubic inches, under common circumstances."

In conformity with these *Reports*, a bill was brought into the House of Commons, in 1822, by Sir George Clerk, and again, with a few alterations, in 1823, which appears to be drawn up with great care and judgment, and which comprehends a statement of the true ground of the proposed measures, and of the determinations which are intended for their bases.

"Whereas notwithstanding it is provided by the Great Charter, that there shall be but one Measure and one Weight throughout the realm, and by the Treaty of Union between England and Scotland, that the same weights and measures should be used throughout Great Britain as were then established in England, yet different weights and measures, some larger and some less, are still in use in various places throughout the United Kingdom of Great Britain and Ireland, and the true measure of the present

\* It appears, however, from an official *Report* obligingly communicated to us by Dr Kelly, that the actual standard chiliogramme has been found to contain only 15433 English grains.

Weights and Measures.

standards is not verily known, which is the cause of great confusion and of manifest frauds: Be it therefore enacted, THAT from and after the 1st January 1824, the straight line or distance between the centre of the two points in the gold studs in the straight brass rod, now in the custody of the Clerk of the House of Commons, whereon the words and figures 'Standard Yard, 1760,' are engraved, shall be, and the same is hereby declared to be, the original and genuine standard of that measure of length or linear extension called a yard; and that the same straight line or distance between the centres of the said two points in the said gold studs in the said brass rod, the brass being at the temperature of sixty two degrees by Fahrenheit's thermometer, shall be, and is hereby denominated the 'Imperial Standard Yard,' and shall be, and is hereby declared to be, the unit or only standard measure of extension wherefrom or whereby all other measures of extension whatsoever, whether the same be linear, superficial or solid, shall be derived, computed, and ascertained; and that all measures of length shall be taken in parts or multiples, or certain proportions of the said standard yard; and that one third part of the said standard yard shall be a foot, and the twelfth part of such foot shall be an inch; and that the pole or perch shall contain five such yards and a half, the furlong 220 such yards, and the mile 1760 such yards. . .

" And whereas it is expedient that the said standard yard, if lost, destroyed, defaced, or otherwise injured, should be restored of the same length by reference to some invariable natural standard: and whereas it has been ascertained, by the Commissioners appointed by his Majesty to inquire into the subject of weights and measures, that the said yard hereby declared to be the imperial standard yard, when compared with a pendulum vibrating seconds of mean time in the latitude of London, in a vacuum at the level of the sea, . . . is in the proportion of thirty six inches to 39.1393; BE it therefore enacted and declared, That if at any time hereafter the said imperial standard yard shall be lost, or shall be in any manner destroyed, defaced, or otherwise injured, it shall and may be restored by making, under the direction of the Lord High Treasurer . . . for the time being, a new standard yard, bearing the same proportion to such pendulum as aforesaid, as the said imperial standard yard bears to such pendulum.

" And ' whereas the Commissioners appointed by his Majesty to inquire into the subject of weights and measures have recommended that the standard brass weight of two pounds troy weight, made in the year 1758, and now in the custody of the Clerk of the House of Commons, shall be considered as authentic; be it enacted, That a brass weight equal to one half of the said brass weight of two pounds, gravitating in air (the barometer being at thirty inches, and the thermometer being at 62° by Fahrenheit's scale) 1822 [1823, be it further enacted, That from and after the 1st January 1824, the standard brass weight of one pound troy weight, made in the year 1758, now in the custody of the Clerk of the House of Commons], shall be, and the same is hereby declared to be, the original and genuine standard measure of weight; and that such brass weight . . . shall be and

Weights and Measures.

is hereby denominated the Imperial Standard Troy Pound, and shall be, and the same is hereby declared to be, the unit or only standard measure of weight, from which all other weights shall be derived, computed, and ascertained; and that  $\frac{1}{2}$  of the said troy pound shall be an ounce; and that  $\frac{1}{20}$  of such ounce shall be a penny weight; and that  $\frac{1}{4}$  of such penny weight shall be a grain; so that 5760 such grains shall be a troy pound; and that 7000 such grains shall be, and are hereby declared to be, a pound avoirdupois; and that  $\frac{1}{8}$  of the said pound avoirdupois shall be an ounce avoirdupois; and that  $\frac{1}{16}$  of such ounce shall be a dram.

" And whereas it is expedient, that the said standard troy pound, if lost, destroyed, defaced, or otherwise injured, should be restored of the same weight, by reference to some invariable natural standard; and whereas it has been ascertained, by the Commissioners appointed by his Majesty to inquire into the subject of weights and measures, that a cubic inch of distilled water in a vacuum, weighed by brass weights, also in a vacuum, at the temperature of 62° of Fahrenheit's thermometer, is equal to '252.72,' 1822 [1823, 252.724], grains, of which as aforesaid, the imperial standard troy pound contains 5760; BE it therefore enacted, That if at any time hereafter the said imperial standard troy pound shall be lost . . . it shall and may be restored, . . . by making, under the directions of the Lord High Treasurer . . . a new standard . . . determined according to this proportion.

" And be it further enacted, That the standard measure of capacity, as well for liquids as for dry goods not measured by heaped measure, shall be the gallon, containing ten pounds avoirdupois weight of distilled water, weighed in air, at the temperature of sixty two degrees of Fahrenheit's thermometer, the barometer being at thirty inches; and that a measure shall be forthwith made of brass, of such contents as aforesaid, . . . and such brass measures shall be, and is hereby declared to be, the imperial standard gallon, and shall be, and is hereby declared to be, the unit and only standard measure of capacity, from which all other measures of capacity to be used, as well for wine, beer, ale, spirits, and all sorts of liquids, as for dry goods not measured by heaped measure, shall be derived, computed, and ascertained; and that all measures shall be taken in parts or multiples, or certain proportions of the said imperial standard gallon; and that the quart shall be the fourth part of such standard gallon, and the pint shall be one eighth of such standard gallon; and that two such gallons shall be a peck, and eight such gallons shall be a bushel, and eight such bushels a quarter of corn or other dry goods, not measured by heaped measure.

" And be it further enacted, That the standard measure of capacity for coals, culm, lime, fish, potatoes, or fruit, and all other goods and things commonly sold by heaped measure, shall be the aforesaid bushel, containing eighty pounds avoirdupois of water as aforesaid, the same being made round with a plain and even bottom, and being 19 $\frac{1}{2}$  inches from outside to outside of such standard measure as aforesaid.

" And be it further enacted, That in making use of such bushel, all coals, and other goods and things commonly sold by heaped measure, shall be duly

**Weights and Measures.** heaped up in such bushel in the form of a cone, such cone to be of the height of at least six inches, and the outside of the bushel to be the extremity of the base of such cone; and that three such bushels shall be a sack, and that twelve such sacks shall be a chaldron."

" Provided always, and be it enacted, That in all cases of dispute respecting the correctness of any measure of capacity, arising in a place where recourse cannot conveniently be had to any of the aforesaid verified copies or models of the standard measures of capacity, it shall and may be lawful to and for any Justice of the Peace or Magistrate having jurisdiction in such place, to ascertain the content of such measure of capacity by direct reference to the weight of pure or rain water which such measure is capable of containing; ten pounds avoirdupois weight of such water, at the temperature of 62° by Fahrenheit's thermometer, being the standard gallon ascertained by this act, the same being in bulk equal to '277.276' 1822 [1823, 277.274] cubic inches, and so in proportion for all parts or multiples of a gallon."

The slight discordance between the numbers of the two successive years depends merely on the adoption of a standard troy pound, better authenticated than the two pound weight particularly employed by Sir George Shuckburgh, which was finally preferred both as representing a unit, and as being more simple in its form than the two pound weight.

(A. L.)

Boundaries.

WESTMEATH, an inland county in the province of Leinster in Ireland, bounded on the north by Cavan, on the east by Meath or Eastmeath, on the south by King's County, on the north-west by Longford, and on the west by the river Shannon, which separates it from Roscommon. It extends from north to south 25 miles, and from east to west 24, and contains 592 English square miles, or 378,880 English acres. It is divided into 12 baronies and 62 parishes, the latter belonging to the Sees of Meath and Ardagh.

Extent.

Surface.

The surface of this district is exceedingly diversified with wood, lakes, and streams, bogs, and rich grazing lands ; in no part mountainous nor flat, but gently undulating or rising into hills of no great elevation, some of which are cultivated to their summits, and others covered with wood, presenting in several parts some of the finest scenery in Ireland. The

rivers are the Shannon on the western boundary, which here expands into the noble lake called Lough Ree, full of wooded islands ; the Inny, which has its source among some lakes on the north, and flowing south and south-west joins the Shannon, at Lough Ree, is a considerable stream which also spreads out into lakes in its course ; and the Brosna, which rising in Lough Owel, passes into King's County. From this lake another stream also takes it rise, and flows in a direction opposite to that of the Brosna. The principal lakes are Loughs Leign, Iron, Derveragh, Hoyle or Owel, and Ennel, some of them surrounded by low wooded hills, and others by fertile and well cultivated fields. Most of the soil, lying upon limestone, yields very fine pastures.

Westmeath contains few large estates, but it abounds with gentlemen of moderate fortunes from L. 2000 to L. 3000 a year, most of whom are resi-

Rivers.

Lakes.

Estates.

**Westmeath** || **Westmoreland.**  
 dent. The leases are commonly for 21 years and a life, though in some instances for 31 years and three lives. A great many fine long-horned cattle and long-woolled sheep occupy the grazing grounds, which extend over much of the best part of the district. Tillage is accordingly upon a limited scale, though more corn is raised than the inhabitants consume; and besides the crops common in other places, flax, hemp, and rape, are cultivated, with clover and turnips, the two latter, however, not generally.

**Towns.** There are few towns here, and none of them large. The most considerable is Athlone, seated on both sides of the Shannon; so that part of it is in the county of Roscommon. Mullingar, the county town, is noted for its great fairs for horses and for wool. Mool-grenoguer, Kilbiggan and a few others, are very small places. Before the Union, the county, with the boroughs of Mullingar, Athlone, Kilbiggan, and the now miserable village of Fowre, sent ten members to Parliament; the number now is two for the county, and one for the town of Athlone. Notwithstanding its inland and central situation, Westmeath enjoys the benefit of extensive water communication by the Shannon on the west, and the Royal Canal from Dublin, which crosses it from east to west by Mullingar; the Grand Canal also passes near its northern boundary. Yet, as the linen manufacture is the only one which affords a surplus for exportation, its trade consists chiefly in the exchange of live stock and the raw produce of the land, for the commodities required for the consumption of its inhabitants. The land-owners here are almost all Protestants, but the rest of the population is chiefly Catholic. In 1791, the number of inhabitants was computed to be 69,000; by the census of 1821, it was 128,042. The condition of the lower classes is better than in Meath, and some of the contiguous counties; they are not addicted to drinking, but industrious and provident. The women, who work a good deal out of doors, are singularly hardy. Mr Wakefield saw them four days after they had lain in, carrying into the fields their husbands' dinner. The people are nevertheless very superstitious, and under great subjection to their priests, who sometimes beat them, which they submit to without grumbling. The same author was informed that indulgences were sold in 1809, at a friary at Multifarnham in this county.

See the general works quoted under the former Irish counties. (A.)

**Boundaries and Extent.** WESTMORELAND, one of the most northern English counties. It is separated from the sea shore by a narrow strip of the county of Lancaster, which bounds it on the south and south-west, as do Cumberland on the north and north-west, and Yorkshire on the east. It is of a very irregular shape. Its greatest length is 40, and its greatest breadth 35 miles; containing, by the best estimate, 763 square miles, or 490,320 British statute acres. It is divided into four wards, distinguished by the prefixes of East, Kendal, Lonsdale, and West, which are again divided into thirty parishes.

**Population.** The population, according to the returns of 1821, amounted to 51,359, of whom 25,513 were males, and 25,846 females. The families were 10,438; of whom 5096 were chiefly employed in agriculture,

3801 in trade, manufactures, or handicraft, and 1541 were comprised in neither of those classes. The increase of inhabitants in the preceding ten years had been only 12 per cent. The density of population is much less than in any other county, being but one individual to nine acres and a half of land.

The greater part of the county consists of bleak and barren moors, and groups of lofty and naked mountains. The vallies between these mountains through which the rivers wind are of moderate fertility, and when well cultivated yield good crops of oats, and in some few instances of wheat and barley. The better parts of these vallies are appropriated to feed cattle or produce hay. The acreable value of the land, in the whole of this county, is much lower than that in any other part of England. According to the returns under the income-tax, the average annual rent and tithes together did not exceed 8s. 7d. per acre, being about half the average value of the rest of the kingdom. The romantic prospects, however, which are afforded by the contrast between the mountains and the lakes, more than repay the traveller for rambling at his leisure through the fine scenery. The lakes of Winandermere and Ulleswater are partly in this county, and those of Grasmere and Hause Water, with several smaller lakes, provincially called Tarrs, wholly so. Besides the char (a fish almost peculiar to those lakes), trouts, pikes, perch, and eels, are taken abundantly in these waters.

The cattle of Westmoreland are of the long-horned kind, and attain a large size when well fed; the butter they afford is highly valued, and supplies to some extent the markets of the metropolis. Large flocks of sheep are fed on the mountains, which yield a coarse wool; but by crossing the breed, the wool of late years has been much improved. Numbers of geese are fed on the moors, and these, with hams, form a part of the exports of the county. Westmoreland is nearly destitute of coals, and the metallic ores lie so deep, or are in such remote situations, that they are none of them worked. Slates, of the finest quality, are abundant, and large quantities of them are exported. Limestone is also very plentiful.

The principal manufactures of the county are chiefly carried on at Kendal, a place early celebrated for woollen cloth, which bore its name. This manufacture, and that of linsey woolsey, as well as of coarse worsted stockings, is still continued, and recently considerable progress has been made in introducing the making of cotton goods.

The principal rivers are the Eden, the Lune, the Ken or Kent, and the Lowther, which are more remarkable for the beauties displayed on their borders, and for the abundance of fish they contain, than for any facilities they afford to intercourse. None of them are navigable, nor are there any artificial canals.

This county gives titles to two noble families, the Earls of Westmoreland and Lonsdale. Two members are returned to the House of Commons by the county, and two by the borough of Appleby, which, though small, is the capital of the county, and the place where the assizes and elections are held.

Westmore-  
land  
||  
Wexford.

The most remarkable seats of noblemen and gentlemen are the following: Lowther Castle, Lord Lonsdale; Appleby Castle, Lord Thanet; Abbot Hall, Christopher Wilson, Esq.; Mint House, J. H. Long, Esq.; Netherdale Hall, John Mounsey, Esq.; Brougham Hall, Henry Brougham, Esq.; Carlton Hall, Right Hon. Thomas Wallace.

The town of Kendal contains 8984 inhabitants, and Kirby Lonsdale 1643; no other town in the county has a population of 1500.

See Britton's *Beauties of England*; *England Delineated*; *Parliamentary Population Returns*.

(w. w.)

Boundaries.

WEXFORD, a county in the province of Leinster in Ireland, having the county of Wicklow on the north, the sea on the east and south, and Waterford, Kilkenny, and Carlow, on the south-west and west; extends about 56 miles from north to south, and 32 from east to west, and contains 934 English square miles, or 597,760 English acres. It is divided into eight baronies, exclusive of the liberties of the town of Wexford, and 142 parishes, 140 of which belong to the diocese of Ferns, and two to that of Dublin. There are some inconsiderable islets on the south coast belonging to the county; the two Salters are the largest, neither of them having an area of a square mile.

Divisions.

Surface.

On the north and north-west, on the confines of Wicklow and Carlow, this district is mountainous, and the same character applies generally to its western side. On the east, in the baronies of Forth and Bargie, it becomes less elevated, and here the soil, though light, is well cultivated and productive. In the other parts a cold stiff clay prevails, which, from the want of limestone, there being none in this county, has made little advance towards improvement. The Slaney, which flows through the middle of the district, from Newton Barry to Wexford, affords a perpetual variety of picturesque and romantic views among its wooded and winding banks; the stream here struggling through rocks, by which its channel is greatly contracted, and there expanding into broad and still lakes. The scenery around the bay of Wexford has been also much celebrated. Besides the Slaney, which is navigable to Enniscorthy, near the middle of the county, it has the Barrow, which separates it from Kilkenny on the west, by which large vessels reach the town of New Ross, situated near the junction of that river with the Nore. A great variety of fine timber trees, and some large myrtles, are found here, and the woodlands altogether are of considerable extent and value.

Estates and  
Farms.

Wexford is divided into estates worth from L. 2000 to L. 10,000 a-year, and into farms of various sizes; but there is little of that minute division which is common in other parts of Ireland; nor are there any rich grazing farms. The rent, in 1808, was estimated at from 20s. to 25s. an Irish acre over all the county. Dairies, at which the principal article is butter, are numerous, but generally under bad management. The cows themselves are of a very inferior description; and the same character belongs to their sheep, which form a very inconsiderable part of the live stock. In their modes of cultivation, however, the

farmers here are more advanced than in many other parts of the island. The baronies of Forth and Bargie have been long noted for their great crops of barley; beans too are cultivated with success, as well as clover and turnips; the drill system is common for potatoes, and preferred to every other method; and lime, though brought from a distance at a great expence, and also marl, are very extensively employed as manure. The tenantry, even including the cottars, are accordingly in a much better condition, industrious, provident, and many of them comparatively wealthy. Here, as in Cork and Waterford, whole fields are kept under furze, which, in this mild climate, is pretty much used as fuel. The bakers employ it for heating their ovens, of which a considerable number are employed, as a good deal of wheat bread is consumed in these counties.

The towns are Wexford, the county town; Enniscorthy on the Slaney; New Ross on the Barrow; Gorey; and Newton Barry, the latter one of the pleasantest villages in Ireland. Wexford is a considerable town, situated on the large and beautiful harbour of the same name, but which is too shallow to admit vessels of great burden, and the passage into it is continually changing, owing to the sand brought down by the Slaney, which flows into it. Here there is a wooden bridge over an arm of the sea 2100 feet broad. The trade of this town, however, is not inconsiderable. It exports corn, chiefly to Liverpool; provisions which are brought down the Slaney from Enniscorthy; and also live stock. Enniscorthy and New Ross are also places of some trade, supplying the consumption of the surrounding country with their imports, and affording outlets for its raw produce. The linen manufacture, so general in Ireland, is almost unknown in Wexford; but that of cotton is carried on at Enniscorthy, where a good deal of coarse woollens are also made. Before the Union no fewer than eighteen members were returned to Parliament for this district; the county and the boroughs of Wexford, Enniscorthy, Gorey, New Ross, Fetherd, Bannow, Clonmines, and Taghmore, sending two each. Wexford and New Ross have now each one representative, and the county two. "This county," says Mr Wakefield, "is the only one in Ireland where the tenants have displayed the courage to act in opposition to their landlords" in voting for candidates; "but it is merely from a religious principle, as they have no other political system to support, than that which promotes the interest and success of the Catholic faith." The Catholic population, according to the same writer, is to the Protestant as ten to one, and most of the personal property, and part of the landed, is in the hands of the former. In 1791 the whole was computed to amount to 115,000, and by the census of 1821 it was 169,304. The baronies of Bargie and Forth are peopled by a distinct race, who are said to be descended from the adventurers who accompanied Strongbow to Ireland, and their manners and habits, which are different from those of the Irish around them, bear a strong resemblance to those of their Saxon forefathers.

There are friaries of the order of St Augustine at New Ross, Clonmines, and Wexford, the members

Wexford  
||  
Whitaker.

of which are supported by contributions levied upon the tenantry. This county took an active part in the Rebellion of 1798, and was the scene of some acts of savage cruelty perpetrated by both parties.

See the general works quoted under the Irish counties, and Frazer's *Statistical Survey of Wexford*.

(A.)

WHITAKER (JOHN), was born at Manchester about the year 1735. Of his parentage, and of his first steps in learning, we find no memorials; but he was sent at an early age to the University of Oxford, and in due time was elected a fellow of Corpus Christi College. He took the degree of M. A. in 1759, and that of B. D. in 1767. Here, we are informed, "his uncommon vigour of intellect at once displayed itself among his acquaintance; but, whilst his animated conversation drew many around him, a few were repelled from the circle by his impatience of contradiction (a failing which almost ever accompanies powers like his), and by the consciousness, it should seem, of their own inferiority." That his conversation must have displayed sufficient vivacity, and his temper sufficient warmth, may very easily be conceived; but through these lines of panegyric, it is impossible not to discern a strong ray of truth; namely, that, from the earliest period of his literary career, he was distinguished by a bold and dogmatical spirit, which could ill endure dissent or opposition. This may indeed be considered as his first and last characteristic; and although the zeal of a friend has, with some degree of dexterity, endeavoured to convert it into a topic of praise, by representing it as the ordinary mark of a superior mind, we are not very much inclined to regard it in the same light. The doctrine seems, indeed, to be of a somewhat dangerous tendency; to be calculated for misleading young candidates for literary honours, who may thus be induced to supply, by arrogance and dogmatism, what is wanting in sound learning and solid judgment. It may be asserted without much hazard of confutation, that this overweening and dogmatical spirit is at least as frequently the characteristic of those who possess but a very moderate stock of real merit; who have perhaps made no uncommon progress in any branch of science or literature, and yet consider themselves as entitled to decide all controversies, and to adjust all claims to intellectual distinction.

While Mr Whitaker was still a fellow of his college, he gave the first conspicuous proof of his abilities by the publication of *The History of Manchester*. Lond. 1771, 4to. The second volume followed in the year 1775; but although four books were originally promised, only two are thus completed; they embrace the Roman, British, and Saxon periods of the history. This work, which is perhaps the most remarkable of his publications, was immediately regarded as the production of no ordinary writer, but as more conspicuous for bold and ingenious speculation, than for cool and judicious discussion. Like the other works of the same author, it is written in a lively and rambling manner. His impatience and vivacity rendered him incapable of selecting his topics, and condensing his thoughts; and by adhering

to his usual method of writing, a large book may be produced on almost any subject.

Whitaker.

Before he had brought this work to a close, he published *The Genuine History of the Britons asserted*. Lond. 1772, 8vo. This volume is chiefly directed against the historical work of Mr Macpherson, better known as the foster-father of *Ossian*; and both publications have been considered by competent judges as adding very little to the real stock of information.

In the course of the following year we find him residing in the metropolis, and officiating as the morning preacher of Berkeley Chapel. For this appointment he was indebted to a Mr Hughes; but their connection was of a very short duration, for he was removed from his situation in less than two months. He thought proper to communicate his grievances to the public, in *The State of the Case between Mr Whitaker and Mr Hughes, relative to the Morning Preachership of Berkeley Chapel*. Lond. 1774, 4to. His resentment was so strong, and his discretion so weak, that he thus subjected himself to the vexation of a lawsuit, and the Court of King's Bench held his printed Case to be a libel.

About the year 1778 he resigned his fellowship, on being presented by his college to the rectory of Ruan-Lanyhorne, one of the most valuable livings in the gift of that society. He now withdrew into Cornwall, and took possession of his benefice; and he afterwards married Miss Tregenna, a lady of an ancient Cornish family. For a long time his retirement was not attended with peace and studious ease. His restless and domineering disposition soon involved him in a long train of contentions with his parishioners: he proposed a tithe-composition, which his friends represent as by no means unreasonable, but of which his parishioners appear to have entertained a different opinion; they refused to accede to his proposal, and he demanded the tithes in kind. "Disputes," we are informed, "arose upon disputes; animosities were kindled; and litigations took place. That Mr Whitaker was finally victorious, afforded pleasure to the friends of the rector, and to the friends of justice and truth; yet it was long before harmony was restored to Ruan-Lanyhorne." Let us here remark in passing, that this mode of confounding the cause of religion with the cause of tithes is a pretty ancient device. It is not certainly to be considered as wonderful, if, after all these contentions, and litigations, Mr Whitaker was subjected to the mortification of observing that his parishioners manifested an aversion to his preaching, an indifference to his admonitions, and a repugnance to his authority. This is indeed the natural consequence of the measures to which he resorted; they have an obvious tendency to excite or continue animosities, and to circumscribe the utility of a clergyman, by rendering him obnoxious to almost every man in his parish who has property enough to bring him within the circle of such litigations. It may perhaps be regarded as extremely doubtful whether any clergyman, possessing a portion of the primitive spirit of Christianity, would be tempted to engage, more especially with his own flock, in quarrels, disputes, and lawsuits, which there

Whitaker. might be any decent means of avoiding. We are informed, that after the lapse of a few years, Mr Whitaker had the satisfaction of perceiving a visible alteration in the behaviour of his principal parishioners, and that a good understanding was at length established between the pastor and his flock. His manner was hearty and familiar; and notwithstanding the rabid spirit that sometimes animates his writings, he was possessed of many virtues, though meekness and humility were certainly not of their number.

His next publication was of a professional kind, namely, *Sermons upon Death, Judgment, Heaven, and Hell*. Lond. 1783, 12mo. He afterwards engaged in the famous controversy respecting the character of Queen Mary, and produced an immense work under the title of *Mary Queen of Scots vindicated*. Lond. 1787, 3 vols. 8vo. He published an enlarged edition in the year 1790; and he seems to have been not a little mortified that neither Lord Hailes nor Dr Robertson could be induced to print a single page against him. This production, which is by no means eminent for coolness of reasoning, or sobriety of manner, has probably convinced very few competent judges of historical evidence, who have submitted to the labour of a patient investigation. If Mary's innocence is so apparent as some of her advocates aver, is it not remarkable that so many bulky volumes should be required to display that innocence? Besides, if we suppose her to be innocent, we must at the same time suppose all the most distinguished of those who opposed her after the murder of her husband, to be covered with an enormous load of infamy. And we will only venture to add, that the uncontroverted history of her proceedings, from a short period preceding the murder, till her indecent nuptials with Bothwell, furnishes a degree of moral evidence which seems to be ineffectually opposed by all the persevering sophistry of her defenders.

Having again recurred to his theological studies, Mr Whitaker published a large volume, entitled *The Origin of Arianism disclosed*. Lond. 1791, 8vo. Whatever might be the opinion of others, it is clear that the author himself entertained a favourable enough opinion of this production; which he represents as "a train of historical argumentation, at once novel in its direction, comprehensive in its scope, and decisive in its efficacy." If he could not discuss a point of history without heat and violence, it is easy to conceive how he would be disposed to discuss a point of heresy. As a proof of his zeal for orthodoxy, an anonymous friend presents us with the following anecdote: "That the feeble Deist should have shrunk from his indignant eye, may well be conceived, when we see his Christian principle and his manly spirit uniting in the rejection of a living of considerable value, which was at this time offered him by an Unitarian patron. He spurned at the temptation, and pitied the seducer." But in order to render this anecdote altogether intelligible, some further information seems to be required. Were his principles so pure and rigid that he could only accept of preferment from a patron of confirmed and approved orthodoxy? Or did this nameless

patron offer him the living under the condition, express or implied, that he should become a convert to the Unitarian creed? With respect to the first question, it is quite evident that many pious divines have accepted of preferment from patrons who, to all human appearance, had no religion whatsoever; and with respect to the second, it is equally evident, that no patron, if he possessed common sense, could expect a beneficed clergyman to make an open avowal of opinions which the church has formally condemned as heretical.

Mr Whitaker had contributed to the *English Review* a series of articles on Gibbon's history, which were now reprinted in a separate form, under the title of *Gibbon's History of the Decline and Fall of the Roman Empire*, in Vols. IV. V. and VI. quarto, reviewed. Lond. 1791, 8vo. This work, which extends to a considerable volume, is written in his usual vein—with sufficient acuteness and animation, but with little suavity of manner, or elegance of style. He certainly detects errors and exposes inconsistencies; but it may readily be supposed that a writer of his cast of mind was not very likely to form an impartial estimate of Gibbon's real merits, which, after all the fair and necessary deductions are made, must still be allowed to be very great. Mr Whitaker is always an intrepid writer; he is never afraid to deliver a decided opinion; and whether the subject is very familiar or quite new to him, his tone of decision is commonly the same. Thus, for example, in his animadversions on Gibbon's admirable chapter relating to the Roman jurisprudence, he is pleased to declare, that "nothing can subdue the native barrenness of such a field as this." His censure refers to a subject of which he may be considered as in a state of almost total ignorance: he seems to have been alike unacquainted with this science, and incapable of appreciating the masterly manner in which it is here discussed. It may, indeed, be affirmed that there is no portion of Gibbon's work more remarkable than this very chapter: although his early studies had not prepared him for such a task, he has yet exhibited a rapid and powerful sketch of the Roman jurisprudence, to which it might be difficult to find a parallel in the writings of the professed civilians. And it has accordingly been stamped with the approbation of some of the most distinguished civilians of the present age. It has been illustrated by Hugo and Warnkoenig, the former having published it in German, and the latter in French.

After an interval of three years, Mr Whitaker produced a copious work on a subject which is certainly curious and interesting. This work he entitles, in his usual form, *The Course of Hannibal over the Alps ascertained*. Lond. 1794, 2 vols. 8vo. Like some of his former publications, it attracted a considerable degree of attention, and, like them, was thought to contain many hasty and erroneous opinions. On this ground he was encountered by the late Lord Woodhouselee, who published, but without his name, *A Critical Examination of Mr Whitaker's Course of Hannibal over the Alps ascertained*. Lond. 1795, 8vo.

In the year 1795, he endeavoured to enlighten

Whitaker. the public by an octavo tract on *The real Origin of Government*, which we have never had the pleasure of seeing, but which his friend, formerly quoted, describes as a very singular pamphlet. This information may, without scruple, be received as authentic; for it is not difficult to conjecture how the subject of civil government would be treated by such a writer at such a period.

The last work which Mr Whitaker lived to communicate to the public is *The Ancient Cathedral of Cornwall historically surveyed*. Lond. 1804, 2 vols. 4to. His vigour was still undiminished, and he had formed the plan of many other works, particularly a history of Oxford, and a history of London: the former he intended to comprise in an octavo volume, the latter he contemplated as "quite new and original, and fit to make a quarto." While he was prosecuting his ardent researches into the antiquities of the metropolis, his friends remarked the first indications of declining health. He had originally possessed a robust constitution, but his mind was restless, and his temper ardent; and during his last visit to London, his great exertions in procuring materials for his work, and his great efforts in supporting his usual tone of conversation in the literary circles, left him in a state of debility which was not at first considered as alarming. It was, however, followed by a stroke of palsy, from which his recovery was never so complete as to allow him to resume his occupations with his former vigour. During the last year of his life, he lingered in a state of gradual decay; and he is said to have contemplated his approaching dissolution with the cheerful resignation of a Christian. On Sunday the 30th of October 1808, he sank as into a quiet slumber, without any indication of suffering, and with a smile on his countenance. He died at Ruan-Lanyhorne, at the age of about seventy-three, and left a widow and two daughters.

He had recently sent to the press an antiquarian volume, which was soon afterwards published under the title of *The Life of Saint Neot, the oldest of all the Brothers of King Alfred*. Lond. 1809, 8vo. The preface is written by his publisher, Mr Stockdale. All his principal works have now been enumerated, but a few supplementary notices are still necessary. He wrote an introduction to Flindell's *Bible*, and a supplement to Polwhele's *Antiquities of Cornwall*, and was a contributor to *The Cornwall and Devon Poets*. His connection with the *English Review* has already been mentioned; but he likewise appears to have lent his aid to the *British Critic* and the *Antijacobin Review*; and his eulogist informs us, in a very solemn style, that "the strength of his principles is no where more apparent than in those articles where he comes forward, armed with the panoply of truth, in defence of our civil and ecclesiastical constitution. It was there he struck his adversaries with consternation, and we beheld the host of Jacobins shrinking away from before his face, and creeping into their caverns of darkness." The same tasteful and judicious writer avers, that at Whitaker's lucubrations "a Gibbon trembled;" but this panegyric is somewhat abated by another piece of information, namely, that Gibbon was a "feeble Deist."

With what torrents of fiery indignation this worthy divine must, in his fugitive and anonymous writings, have overwhelmed Jacobins and heretics, may very easily be imagined by those who have inspected his more elaborate works, bearing his name and addition, and intended for the benefit of posterity. Some persons of cooler tempers, and of more habitual candour, when they are fairly enveloped in the cover of a review, may now and then be tempted to speak in a very high and arrogant tone to men greatly elevated above their own standard, and of subjects of which they only possess a very casual and superficial knowledge.

This anonymous writer, whom we strongly suspect to be Mr Polwhele, has, in the following passage, discussed the character of Mr Whitaker with more sobriety and discrimination. "It is true, to the same warmth of temper, together with a sense of good intentions, we must attribute an irritability at times destructive of social comfort, an impetuosity that brooked not opposition, and bore down all before it. This precipitation was in part also to be traced to his ignorance of the world; to his simplicity in believing others like himself—precisely what they seemed to be; and, on the detection of his error, his anger at dissimulation or hypocrisy. But his general good humour, his hospitality, and his convivial pleasantry, were surely enough to atone for those sudden bursts of passion, those flashes which betrayed his 'human frailty,' but still argued genius. And they who knew how 'fearfully and wonderfully he was made,' could bear from a Whitaker what they could not so well have tolerated in another. In his family, Mr Whitaker was uniformly regular; nor did he suffer at any time his literary cares to trench on his domestic duties. The loss of such a man must be deemed, as it were, a chasm both in public and private life. But, for the latter, we may truly say, that if ever wife had cause to lament the kind and faithful husband, or children the affectionate parent, or servants the indulgent master, the family at Ruan-Lanyhorne must feel their loss irreparable." (*Gentleman's Magazine*, vol. lxxviii. p. 1037. See likewise Nichols's *Literary Anecdotes of the Eighteenth Century*, vol. iii. p. 105.) (w. w. w.)

WICKLOW is a county in the province of Leinster in Ireland, bounded by Dublin and Kildare on the north; by Wexford on the south; by St George's Channel on the east; and by Kildare, Dublin, and Carlow on the west. It extends about 40 English miles from north to south, and 33 from east to west, containing 781 square miles, or nearly 500,000 English acres, and is divided into six baronies and half baronies, and 58 parishes. Of these parishes, 49 are situated in the archbishopric of Dublin, six in the diocese of Leighlin, and three in that of Ferns.

The outline of this county is rendered very irregular by a district on the south-west, the barony of Shillelagh, being almost detached from the rest of it, projecting between the counties of Carlow and Wexford. On the east, the sea-coast stretches almost in an unbroken line, except a little to the south of the town of Wicklow, where there is a promontory called Wicklow Head. Bray Head, another point, is on the northern extremity. Mountains and bogs oc-

Wicklow.

cupy a great part of the interior, from the north along the centre of the district, to the barony of Shillelagh. Much of this tract is without inhabitants. To the north and west these mountains are bold and abrupt; but on the east they are penetrated by several beautiful glens, of which the Dargle, the glen of the Downs, the vale of Imalee, and Glendalough, are the most celebrated. Some of these are of considerable extent, finely wooded and watered, and, with the mountains which inclose them, exhibit a great variety of romantic scenery. In these glens much of the wood is oak, but not of a large size. Detached hills also abound on either side of this range, though on the east, south, and west, the country is in general low and fertile. It has been compared, not inaptly, to a frieze cloak with a laced border. In the central range, the prevailing rock is granite, and argillaceous schist in the less elevated hills on the east and south. On the north, near the confines of Dublin county, is a remarkable chasm, called the Scalp, in a ridge of granite. Calcareous strata occur on the west, and also on the east, from Wicklow to Bray; but no limestone has been found in continuous rocks. In these quarters, it is in the form of pebbles or gravel.

Minerals.

Wicklow is thought to be rich in metallic substances, particularly on the south, from the Croughan Mountain to the hill of Cronebane, about ten miles to the north-east. In this tract copper has been wrought at Cronebane and Ballymurtagh to a considerable extent. In 1809, the Cronebane mines produced about 3000 tons of ore annually, at an expense of L. 8000; but at both places the works were soon after discontinued. Native gold has been found on the north-east side of the mountains Croughan Kinshela, on the summit of which this county meets with that of Wexford, in a stream which falls into the Ovoca, and also on the south side of these mountains. In 1796, gold was obtained to the value of L. 10,000, sometimes in pieces of considerable weight; one of them weighed nine, a second eighteen, and a third even twenty-two ounces. The search was then undertaken by Government, both in the mountains themselves and the streams which flow from them; but no veins were discovered, and the works have been long since abandoned. Lead has been worked at Glenmaher and in Glendalough, or the Seven Churches. At the latter place, in 1809, there were three smelting houses, and about 180 bars, weighing one hundred weight each, were made *per week*.

Rivers.

The rivers are the Liffey, which has its rise on the north-west quarter of this county, and passes into that of Dublin; the Ovoca, which flows into the sea at Arklow; and the Slaney, which, rising in the south-west, proceeds southward into the county of Carlow. None of these rivers are navigable in their course through this district. There are no extensive lakes; the most considerable are Lough Bray, Lough Tay, Lough Dan, and the loughs of the Seven Churches. Some of the streams precipitate themselves from considerable heights, forming beautiful cascades; the most remarkable one is at Powerscourt, where the water falls from a height of 360 feet.

Climate.

The climate of this county is remarkably mild.

Myrtle flourishes in such profusion as to have been sometimes used for making stable-brooms. The common laurel, Portugal laurel, and arbutus, attain a great size, and can scarcely be recognized to be the same shrubs. Dublin is supplied with early potatoes and house-lamb from the sea-coast of Wicklow, the climate of which, according to Mr Wakefield, is decidedly different from that of the rest of Ireland. This is the only part of that country where he ever saw grapes growing out of doors.

Estates and Farms.

There are several large estates in Wicklow. That of Earl Fitzwilliam extends to 66,000 Irish acres. The centre of the county, which consists of bogs and mountains, and is uninhabited, belongs chiefly to the see of Dublin. The district of the sea-coast, however, is much divided, and abounds with villas, the temporary residence of the wealthy citizens of Dublin. "It appears to me," says Mr Wakefield, "to contain more gentlemen's seats than the same space in the vicinity of London." The common period of leases is twenty-one years and a life. On the sea-coast, land lets at from L. 3 to L. 5 *per* Irish acre, or about 47s. the English acre, and on the north-east, near Dublin, it is considerably higher. Potatoes, and all the usual kinds of corn, are cultivated; but turnips, clover, and other ameliorating crops, only partially. Marl and limestone gravel are the principal manures. Irrigation is practised according to the method common in England. A breed of fine-woolled sheep, peculiar to the mountains of this county, exhibit the only traces of a distinct race of short-woolled sheep in Ireland.

Manufactures.

Besides the manufacture of coarse woollens for domestic use, flannel is made to a considerable amount for sale; there is a Flannel Hall at Rathdrum, at which, before 1808, from 5000 to 7000 pieces were sold annually. The cotton trade was, at that period, in a flourishing condition at Stratford on the western side of the county. But the linen manufacture, so general in other parts of Ireland, is carried on here only to a small extent. There are no good harbours, nor any canal or navigable river, in this district. Wicklow harbour has only from seven to eight feet of water on its bar at high tides. Wicklow, the county town, with Baltinglass, Blessington, and Carysfort, were Parliamentary boroughs before the Union, though, excepting the first, none of them contained, at that time, 1000 inhabitants, and Wicklow itself not many more. The villages are Bray, Rathdrum, Arklow, Stratford-upon-Slaney, and a few others. Of these Arklow, the most considerable, contained about 2600 inhabitants. A battle was fought there 9th June 1798, in which the rebels, computed to be about 31,000, were defeated, by General Needham, with a mixed force, said not to have exceeded 1500. The herring-fishery, in the Herring-bay of Arklow, which, next to that of Galway, is considered the best in Ireland, employed, in 1816, from 100 to 150 boats, and has sometimes produced about L. 25,000 yearly.

Herring-Fishery.

The population of this county, in 1790, was about 58,000. According to the census taken in 1821, it was 115,162. Mr Wakefield computes the proportion of the Catholics to the Protestants to be as ten to one. In the parish of Arklow, according

shire.  
Representa-  
tion.

to the writer of that Article in the *Parochial Survey*, the proportion is only as three to one. The county sends two members to Parliament, both of whom may be returned by the influence of Earl Fitzwilliam. The wages of labour and the prices of provisions being affected by the vicinity of Dublin, are higher than in most parts of Ireland, and the condition of the lower classes is said to be more comfortable.

See Frazer's *General View of the Agriculture, &c. of the County of Wicklow*, and the works of Beaufort and Wakefield, as quoted under the former Irish counties.

Situation  
and Bounda-  
ries.

(A.) WIGTOWNSHIRE, a maritime county on the south-west extremity of Scotland, situated between 54° 38' and 55° 4' north latitude, and between 4° 16' and 5° 6' west longitude. This, with the stewardry of Kirkcudbright, now forms the province of Galloway, which was once more extensive. It is bounded by the stewardry of Kirkcudbright on the east; by the Irish Sea on the south and west, and by Ayrshire on the north, containing 485 square miles, or about 310,000 English acres, and is divided into seventeen parishes. About a third of the land is productive or cultivated, and the rest is in its natural state, and comparatively of little value.

Extent.

The district is of a very irregular form, the western side being almost cut off from the rest by two arms of the sea, Luce Bay on the south, and Lochryan on the north; while Wigtown Bay, which separates it from Kirkcudbright, penetrates it on the east. It is popularly divided into the *Rhinns*, the *Machers*, and the *Moors*. The *Rhinns*, which signifies points or promontories, consists principally of the peninsula lying west of Lochryan and the bay of Luce, being the nearest land in Britain to Ireland, and terminating on the south in the Mull of Galloway, the most southerly land in Scotland; from whence may be seen, in a fine day, the Isle of Man and the shores of England and Ireland. It is connected with the rest of Wigtownshire by an isthmus about six miles broad, which seems to have been at one time overflowed by the sea. The *Machers* is a large promontory, none of it much elevated, which runs out to the south-east between the bays of Wigtown and Luce; and the *Moors* are spread over the rest of the county, but chiefly on its northern side, where it is bounded by Ayrshire.

Divisions.

The surface of this county, except in the northern quarter, where the hills rise to 1000 feet and upwards, is very little elevated above the sea; but, exclusive of a narrow tract of alluvial land near the bottom of the bay of Wigtown, there is very little that is flat or level. It consists, for the most part, of a great many low hills and gently undulating grounds, often broken by detached rocks which rise a few feet above the surface, and interspersed with considerable tracts of mossy and moorish soils, even in the lower and more cultivated parts; being similar in this respect to the stewardry of Kirkcudbright, the other division of Galloway. (See KIRKCUDBRIGHT in this Supplement.)

Surface.

The climate, though moist, is mild and salubrious, especially in the low grounds, the prevailing winds being from the south-west. In the *Rhinns* rains are more frequent than in the *Machers* on the south-east; but

Climate.

Wigtown-  
shire.

the winters on this coast are every where milder than on the eastern coast of Scotland; and no part of the county is more than ten or twelve miles from the sea. In summer, however, there is also less sunshine, and, for this reason, the crops of wheat and barley, particularly the former, are commonly inferior in quality to those raised on the eastern side of the island.

The soil of the arable land is, for the most part, Soil. of a hazel colour and shallow, but dry and not unfer- tile, and well adapted to turnip husbandry. On the bay of Wigtown, there is a tract of rich alluvial land, fit for the growth of wheat and beans; similar to the Carse lands of Gowrie, and other tracts on the Forth and Tay; but this and every other description of clay land forms but a very small proportion of the whole. On the western side, between the bay of Luce and Lochryan, the soil is chiefly a deposition of sea sand, interspersed with considerable tracts of flow moss. In this quarter, near Glenluce, there is an extensive rabbit-warren, said to yield about L.400 a-year. Much of the higher grounds, or the *Moors*, is wet, spongy, and sterile, producing herbage very inferior to that of the hills on the south-east of Scotland, and depastured by a small kind of coarse-woolled heath-sheep, and an inferior variety of the native cattle.

The rivers are, the Cree, the Bladenoch, and the Rivers. Luce, with a number of smaller streams. The Cree, which rises among the mountains of Carrick in Ayrshire, enters this county from the north, and, flowing along the boundary with Kirkcudbright, falls into the bay of Wigtown a little above the town of that name; and it is navigable upwards to the Carty a little below Newton-Stewart. The Bladenoch, after a circuitous course of about twenty-four miles, also enters the bay of Wigtown, and, by means of the tide, admits small vessels a little above its mouth. The Luce, the only other stream of any size, after a northern course, falls into Luce Bay at the town of Glenluce. These streams are frequented by salmon, of which there are one or two considerable fisheries on the bay of Wigtown. There are several lakes, but none of them worthy of particular notice. Lochryan, though it has all the appearance of a lake, is an arm of the sea, and is of great importance as affording a safe and commodious harbour, with an inland navigation for eight or ten miles, and occasionally a productive herring-fishery.

The valued rent of Wigtownshire, as taken in Valuation 1642, is L. 67,641, 17s. Scots, and the real rent of and Rental. the lands and houses, in 1812, was L. 131,778, 12s. 10d. Sterling; the land rent being about 8s. an English acre. This is divided among a few great proprietors, one of whom has a rental of upwards of L.30,000, and several others have from L. 5000 to L. 10,000 and upwards. More than half the county is held under entail. The territory is further divided into farms Farms. of a moderate size, on the arable lands seldom exceeding 200 or 300 acres, which are held on leases for 19 or 21 years, as in other parts of Scotland. It was formerly the practice to add the life of the tenant; and some of these leases still subsist, but few are now granted but for a term of years certain. In no part Rents and of Scotland, perhaps, have rents risen more than in Agriculture. this quarter. "A variety of instances," says the

Wigtown-  
shire.

author of the *Agricultural Survey*, "might be adduced where the present rents of farms are equal to the prices paid for them in the memory of persons still living." Yet an improved system of agriculture has not kept pace with this advance of rent, which has been chiefly occasioned by the increased demand of the English markets for their cattle, which are much esteemed in every part of the island. (See AGRICULTURE in this *Supplement*.) The management of the arable land, though improved within these few years, is still very much inferior to that which prevails in the eastern and other lowland counties of Scotland. The principal corn crops are oats and barley, or rather bear; the potatoe, which occupies a considerable portion of every farm, is still a much greater favourite than the turnip; and where turnips are raised they are, with few exceptions, carried off the ground, instead of being consumed on it by sheep, according to the practice of the eastern counties. It is, therefore, to their cattle principally that the farmers trust for payment of their rents, and a great portion of even the best arable land is still appropriated to grazing. On the western side, the dairy has been introduced within these few years by farmers from Ayrshire, and found to answer better, it is said, than the system common in other parts of the county. One of the largest dairies in Scotland is in this quarter. Almost all the land, even the higher grounds, is enclosed chiefly with stone fences, well known by the name of *Galloway dykes*; and of late, a considerable improvement has taken place in the farm-houses and offices, many of which have been constructed in a substantial manner. There is very little natural wood; but considerable plantations have been formed by some of the principal proprietors. Among the trees found most able to endure the sea spray, and resist the westerly winds, are the pinaster and the Huntington willow, which thrive almost on the sea beach. On many parts of the coast large banks of shells have been formed, which are used as manure, in place of lime, and in others sea-weeds are used for the same purpose; lime as well as coal must be imported from Cumberland and the west of Scotland, there being none of either in the county. From the want of coal, the principal article of fuel used in the interior is peat and turf.

Towns.

Wigtownshire has three royal burghs; Wigtown, the county town, situated at the bottom of the bay of that name; Whithorn, near the south-eastern point of the Machers division; and Stranraer, at the bottom of Lochryan. In the elections for the Scottish burghs, these, with New Galloway in the stewartry of Kirkcudbright, send one member to Parliament; the county, in which there are about sixty freeholders, being also represented by one. None of these towns, however, are extensive or populous. The villages are Newton Stewart on the Cree, Garlieston, a small sea-port on the bay of Wigtown, New Luce, an inland village a few miles east from Stranraer, Glenluce, at the bottom of Luce Bay, and Portpatrick, on the west side of the Rhinns division, on the great thoroughfare between Britain and Ireland; the Channel, between Portpatrick and Donaghadee on the Irish coast, being only about twenty miles broad. There are no manufactures of any consequence, and no other

Representa-  
tion.

trade but what is carried on in small vessels with the nearest ports of England and Ireland and the west of Scotland, for the export of their raw produce, and the import of coal, lime, and other articles required for consumption. In the weights and measures used here, there is now less variety than in most other parts of Scotland, the Winchester bushel and the avoirdupois weight being in general use. By the former, all the corn, potatoes, &c. are measured, and the prices stated; the weight of the corn, however, being attended to, in estimating its value, as well as the measure. Thus, a bushel of wheat weighing 60 lbs. is worth more than the same measure, of which the weight is only 56 lbs. It is to be wished that this practice were general in other parts of Scotland, where the great diversity of weights and measures, sometimes even in the same county, occasions so much inconvenience.

Wigtown-  
shire

Trade.  
Weights and  
Measures.

Wigtownshire is not rich in antiquities. The most noted ruins are those of Dunskey Castle, situated on the verge of a precipice, a little to the south of Portpatrick; Castle Kennedy, the ancient seat of the family of Cassillis, in the parish of Inch; and the abbey of Glenluce. But the most interesting remains of this kind, perhaps, are what are called the Standing Stones of Torrhouse, in the parish of Wigtown; consisting of 19 erect pieces of granite, within a circle of 218 feet, and several large stones standing singly at a little distance to the south and east. There are also two cairns or barrows in the same quarter.

The population, according to the census of 1801, was 22,918; in 1811 it had increased to 26,891; and in 1821 to 33,240; of which 15,837 were males, and 17,403 were females. The families employed in agriculture were 3525; in trade and manufactures 2089, in all other occupations 1160. The increase of population from 1811 to 1821 was 6349.

See Smith's *Survey of Galloway*, and the general works quoted under the former Scottish counties.

(A.)

WILTSHIRE, an inland county of England, in the western judicial circuit. It is bounded on the north-west and west by the county of Gloucestershire; on the west by Somersetshire; on the south by Dorset and Hants; and on the east and north-east by the latter county and Berkshire. The length is about 50 miles, and the breadth about 34. It is of an elliptical form, with very irregular indentations on the borders. The area is 1379 square miles, or 882,560 statute acres. The county is divided into twenty-nine hundreds, comprising one city, 23 market towns, and 295 parishes. The whole of the county, with the exception of the parish of Kingswood, is in the diocese of Salisbury, and is ecclesiastically divided into two archdeaconries, which are subdivided into ten deaneries.

By the census of 1821, Wiltshire appeared to contain 43,125 houses, inhabited by 47,684 families; of whom 24,972 were employed chiefly in agriculture; 16,982 in trade, manufactures, or handicraft; and 5730 were not comprised in either of these classes. The whole number of persons was 222,157, of whom 108,213 were males, and 113,944 females. The increase of population between the census of

Wiltshire. 1811 and that of 1821 was at the rate of 15 *per cent.*

Face of the Country and Cultivation.

The southern division of Wiltshire is chiefly that extensive tract of unwooded land usually denominated Salisbury Plain. It is an uninclosed country, and from thence has an appearance of desolateness; but bottoms are frequent, and having generally streams of water running through them, the houses and villages are, for the most part, erected in them, and the district is much more populous than a traveller passing over the plain would suspect. The land, though chiefly used for feeding sheep, is, when brought under the plough, highly productive in turnips, barley, and wheat. There is a tract of rich land between Salisbury Plain and Marlborough Downs; and to the north of these downs the country is well inclosed, and abounds in rich pasture, on which are fed the cows that produce the excellent cheese known by the name of North Wiltshire. The peculiar breed of sheep of this county, and which are universally called by its name, are all horned, afford heavy fleeces of moderately fine wool, and are very numerous; on Salisbury Plain they are said to be more than 500,000. The produce of wheat and other grain is estimated to be less *per acre* than the general average of the contiguous counties. There were anciently several extensive forests in this county, and, though the districts still retain the name either of *Forest* or *Chace*, they are, with the exception of Savernake or Marlborough Forest, and Cranbourn Chace, almost wholly now either in pasture or under the plough.

Rivers and Canals.

Wiltshire being an elevated district, many rivers have their sources in it, or water the lands of it soon after their rise. The most important of these are the Thames, the Lower Avon, and the Kennet, all of which are navigable. Besides these are the tributary streams, the Upper Avon, the Willey, the Nadder, the Bourne, the Stour, and the Brue. The canals which pass from or through this county are the Thames and Severn, connecting those two rivers with each other; the Kennet and Avon, which also unites those rivers. Both of these canals have been most expensive, and, hitherto, unproductive undertakings, designed to facilitate the intercourse between London and Bristol. The Wilts and Berks Canal, designed to connect the Severn with the Thames, has been especially an unfortunate concern. The Salisbury and Southampton Canal has been found of some benefit, by supplying the former place with coals, but has been little productive to the proprietors.

Manufac- tures.

This county has long been one of the chief districts for the manufacture of fine cloths. That branch of industry is now, however, confined to the western part of it. The populous towns of Bradford, Trowbridge, Devizes, Warminster, Chippenham, Westbury, Melksham, Calne, and the villages surrounding them, are chiefly maintained by making cloths and casimeres of fine quality, the wool for which used to be imported from Spain to Bristol, but of late years the fine wools of Saxony have in a great measure supplanted those of Spain in this country. Salisbury is distinguished by its manufactory of fine flannels, and by cutlery and steel articles of superior quality. Wilton makes carpets and fine cloths. At Mere and in its vicinity linen goods, chiefly dowlass

and bed ticks, are made. At Swindon are many manufacturers of gloves. Wiltshire.

Antiquities.

Few counties present so many objects of antiquarian research as Wiltshire. Among those of British origin are the Wansdike, a fortification of earth traversing the whole county; the druidical masses of stone at Stonehenge and Avebury; the numerous barrows, or *tumuli*, which are to be seen on a great number of spots on the Downs; and the earthen ramparts supposed to have formerly inclosed the towns of the ancient Britons. Among the Roman antiquities are many of the roads constructed by that people, their fortified encampments, and the ruins of several of their castles, especially those of Marlborough, Devizes, Malmesbury, and Old Sarum. The monastic remains, especially at Malmesbury, present very interesting subjects of study to the antiquarian. Besides these vestiges of antiquity, tessellated pavements, coins, urns, fragments of sculpture, daggers, shields and ornaments of British, Roman, Saxon, and Norman fashion, have been discovered. The cathedral of Salisbury, though not of such an age as to be classed among antiquities, is an object of great admiration on account of the elegant design and scientific execution of the structure. The beautiful spire is much admired for its height and its proportions, and though in a valley, may be seen at a great distance rising above the surrounding hills. It is said to be the loftiest in England, rising from the floor of the church to the height of 400 feet.

The following Peers derive their titles from this county: Duke of Marlborough, Marquises of Lansdowne and Salisbury, Earl of Malmesbury, Viscount Bolingbroke, Baron Arundel. Two members are returned to the House of Commons by the county, and two each from Salisbury, Chippenham, Calne, Cricklade, Downton, Devizes, Heytesbury, Hindon, Great Bedwin, Marlborough, Malmesbury, Ludgershall, Westbury, Wilton, Wotton Bassett, and Old Sarum.

Titles and Representation.

The chief places and their population are as follows: Salisbury, 8763; Trowbridge, 9545; Warminster, 5612; Melksham, 4765; Calne, 4549; Devizes, 4208; Bradford, 3760; Chippenham, 3201; Downton, 3114; and Marlborough, 3038. Towns.

Among a great number of seats belonging to noblemen and gentlemen, the most remarkable are Longleat, the Marquis of Bath; Bowood, Marquis of Lansdowne; Tottenham Park, Lord Aylesbury; Wardour Castle, Lord Arundel; Fonthill Abbey, late Mr Beckford; Wilton, Earl of Pembroke; Stourhead, Sir R. C. Hoare; Longford Castle, Earl of Radnor; New Park, Thomas Estcourt, Esq.; Dinton House, William Wyndham, Esq.; Corsham House, P. C. Methuen; Wilbury House, Sir C. W. Malet; Charlton Park, Earl of Suffolk; Stoke Park, Joshua Smith, Esq.; Bradley, Duke of Somerset; and Ramsbury, Sir Francis Burdett. Chief Seats.

(w. w.)

## WINE-MAKING.

Wine-Making.

THE history of wines is both curious and amusing; and their topography is not less so, if we may apply this term to the several kinds, to their enumeration, and to that of the countries where they grow, and to the variations followed in their manufacture. This is a subject which would occupy a volume; and we must therefore pass it over, that we may dwell on what is of more moment, the general mode of making this important article, and the several chemical circumstances connected with it. France is the only nation which has bestowed much attention on the philosophy of this subject, as it is that which excels all others in the variety and the goodness of its produce.

Fruits, their Nature.

Vinous liquors, resembling wine, may be made from every fruit, as well as from every vegetable which contains acids united to its extractive matter. The term wine is thus applied to the produce of currants, gooseberries, and many others; while that of cyder is especially reserved for the liquor to be obtained from apples. That term would be a fitter one for many of the vinous liquors in question, and we shall here restrict the term *wine* to the produce of the vine.

All fruits consist of the following principles: water, sugar, a peculiar combination of sugar and extract, called the sweet principle by the French, supertartrate of potash, malat of potash, and malic acid, superoxalate of potash, extractive matter analogous to mucilage, and vegetable gelatin, tannin, a principle of flavour, and a colouring principle. These, however, are not all found in any one fruit, and they also vary in their proportion in different ones. The essential ones to the making of wine are the tartarous acid, sugar, or the sweet principle, extract, and water; and those which are useful, without being indispensable, are flavour, tannin, or astringency, and colour. And it is by possessing these in right proportions that the grape excels all other fruits for the purpose of making wine.

Effects of the Principles of Fruits.

Tartarous acid, or its combinations, is especially indispensable: and hence it is that the grape, which contains it in large quantity, produces wine; when the apple, and other fruits which contain the malic acid, produce cyder. It is essential to the fermentation, as well as to the quality of the produce; and it is decomposed in the process so as to increase the quantity of alcohol, which the sugar would otherwise yield. Where malic acid is also present, the quality of the wine is bad. Sugar must be considered the fundamental element, and as that from which the alcohol is chiefly derived. Thus the most saccharine grapes produce the strongest wine. But it seldom exists in a pure state in the grape, or in any other vegetable. It appears to be most pure in the sugar cane; but even there it is combined with the extractive matter, and also with some acid, forming the sweet principle of the French. Pure sugar does not ferment in water, it crystallizes; and whenever fer-

Wine-Making.

mentation occurs, some other vegetable matter is present. When sugar, again, has crystallized from a solution of the sweet principle, what remains runs still more readily into fermentation. In the produce of the cane, this is molasses. It is very important to keep this distinction in view, because the fabrication of sweet wines depends materially upon it. It explains many circumstances in the process of fermentation, and some that are often overlooked. It explains, among other things, why wine ferments in a cask when it will not ferment in bottles; because the sugar derives the necessary extractive matter from the wood. The chemical nature of the extractive matter is not known; but it is supposed to contain azote, as this is the produce of fermentation. Yeast, or leaven, contains the extractive principle in great abundance, and hence its power in inducing fermentation in a solution of pure sugar. All vegetables contain it; and it is most abundant in those juices which gelatinate in boiling. It is found in the grape, and it is thus the natural leaven of wine, whether existing in a separate state or united to sugar in the form of the sweet principle. Water is a much more essential ingredient than would at first be suspected. If over abundant, it is difficult to prevent the produce from running to the acetous stage. Hence weak wines become sour. If deficient, it is difficult to establish the fermentation; and hence sweet wines. Thus, also, sweet wines are insured by drying the grapes, or evaporating their juice, both common practices in the wine countries. Colour must be looked on in the light of an ornament, and is found in the husk of the grape. So is the tannin principle, which occasions astringency in Port wine. Of the principle of flavour chemistry knows nothing; it seems often the produce of fermentation, as in Claret and Burgundy wines: in those of Frontignan and Muscat it is the natural flavour of the fruit.

When the process is complete, the wine is dry, or contains no sugar, so that sweet wines, which are compounds of wine and sugar, are the produce of an incomplete fermentation. When all the elements above described are in due proportion, the product is perfect, a dry wine; and the elements that require particularly to be balanced for this result are the extract, or leaven, and the sugar. If the former is in excess, the wine tends to vinegar, unless means are used to stop the fermentation by abstracting the leaven; if in defect, the process is imperfect, a sweet wine. Hence the perfection and management of the leaven are among the most important circumstances in the manufacture. It is coagulable partially by heat; and hence also it is, as well as by evaporating the water, that boiled *must* produces sweet wine. It is also abstracted by precipitation, and by the action of sulphurous acids; whence other processes in use in wine-making.

In fermentation, the superfluous extract or leaven is separated in two forms, that of yeast and lees;

Wine-Making.

and these will excite that process in fresh solutions of sugar, or renew it, or continue it, in the mixture whence it was separated; whence racking and fining. There is, however, one important difference between the natural or original, and this artificial or secondary leaven. The latter is soluble in hot water, and not in cold; and hence it is separated in fermentation. By restoring this separated matter to wine in the course of fabrication, the fermenting process is prolonged, or the wine rendered drier; by skimming, and fining, and racking, the process is checked: and hence the application of these practices to sweet wines. The *rolling* of wine, or returning on its lees to *feed*, is hence understood; and hence also the improvement which certain wines experience in long voyages. But the same principle and process which improves Madeira destroys Burgundy, and the reason must now be obvious. The theory of racking, fining, and sulphuring, is hence also apparent; and, of the sulphurous acid, it is a property to combine with the leaven, and form an insoluble separable compound. It is thus that it checks fermentation. Hence, also, it is that sweet wines do not turn sour: their leaven has been expended. Thus also we may see that the process of fermentation is not an unmanageable and a precarious one; but that the essential ingredients are in our power, and that we can modify them to the desired result. If it has been stopped prematurely, it may be renewed by fresh leaven; if in excess, it may be checked or suspended. And thus it is too, that dry wines, and fined wines, and wines in bottles, are durable, when they would perish in the cask.

The acid was shown to be also essential to the produce of wine. Mere extract, or leaven, and sugar, produce beer, not wine. Tartarous acid cannot well be in excess in that compound in which it exists, viz. the supertartrate of potash; because it is a salt of difficult solution, and the superfluity is precipitated; hence the tartar of wine-casks; hence, also, the crystals which are seen, in cold weather, to float in Madeira wine. We noticed that it was decomposed in the fermentation, and was thought to contribute to the quantity of alcohol. The French chemists also assert that a part of it is converted into the malic; hence the peculiar properties of some wines; hence also the practice of liming the vats, or of sprinkling the grapes with lime in the manufacture of Sherry wines; whence they acquire that peculiar dry and hard taste which distinguishes them from the wines of Madeira. As the tartarous salt adds to the fermenting power of the fluid, hence we explain the facility with which the juice of green grapes runs into fermentation when compared with ripe ones; the immature fruit containing a much larger proportion of this salt than the mature. Thus also those wines continue to ferment longer, or to retain the power of fermenting; and hence the vivacity of Champagne wines, the most effervescent kinds of which are made from half ripened fruit.

The temperature of 54° Fahrenheit is considered the most favourable to this process. In extreme heat it fails, as in extreme cold. Hence the difficulty of making wine in India, and the West Indian islands. Hence also, in the temperate climates, we have it in our power to regulate fermentation by the use of

heat or of cold. Hence, also, it is that wines which had ceased to ferment, recommence in spring; and hence, one of the processes essential to the manufactures of Champagne wines; namely, that of watching the spring fermentation, and bottling the wines in this stage.

Air is necessary to fermentation, rather than essential. The operation does not cease in closed vessels, but is retarded. Air is not absorbed in the vinous fermentation; although its oxygen is in the acetous. The wine is stronger in close vessels, if the process is slower, because a portion of the alcohol escapes from the vats; and this is now understood in our malt distilleries. That alcohol is held in solution in the carbonic acid which is generated; and thus, it appears, to intoxicate more rapidly; as is well known in Champagne wines. Under pressure, this compound is united to the fluid; and, being disengaged, produces the well known effervescence. The practice of fermentation is partly regulated by this consideration. The violent stage of that process in wine-making is allowed to take place in an open vat: the next is partially checked by an occasional bung, and, in the last of all, the vessel is completely closed. In strong still wines, the whole process may be conducted in open vessels: but, in light and brisk ones, it is absolutely necessary that the last part should take place in closed ones. Champagne wines are managed so as to ferment even in their bottles.

The volume of the fermenting fluid has a considerable effect on the process; a few days are sufficient to complete it when the quantity is large. When small, it is difficult to establish, and tedious in the progress, and the results are also different: wines of different qualities being thus produced from the very same materials. It is the same in the ultimate fermentation or ripening of wines. Champagne would be destroyed in a large cask: porter, an extreme case, is ripened in enormous masses, as are many of the stronger wines. Bulk is peculiarly required for the strong and sweet wines; Champagne may be made in a gallon measure.

The first appearance is the production of air bubbles, terminating at length in a general ebullition. The liquor then becomes turbid, a variety of solid matters are disengaged, some falling to the bottom, and others rising to the top of the fluid. The leaven, before mentioned, is thus separated among other matters, while the bulk of the fluid is materially increased. It is in this stage that we have the power of regulating the extent of the fermentation; by separating the floating leaven, or allowing it to return into the liquor. Hence, the process of fermenting in a full cask, ejecting that substance by the bung-hole.

The disengaged gas is carbonic acid chiefly: but holding, as first remarked, some alcohol in solution. It appears, by analysis, that this is the produce of part of the carbon of the sugar and of its oxygen; and this is the great change which leads to the production of the alcohol. But it also contains some obscure vegetable matter in suspension; because, if passed through water, it not only converts it into vinegar, but deposits that mucilage, which, in vinegar, is called the *mother*. It is possible, however, that this may itself be a new compound: and it is

Wine-Making.

Phenomena of Fermentation.

Circumstances of Fermentation.

Wine-  
Making.

one which, in certain cases, contains azote. That substance, which exists in yeast, has also been found in the disengaged gas, partly, it is said, in the form of ammonia: and hence, possibly a nauseous ammoniacal taste, well known in bad wines, and very remarkable in those of the Cape of Good Hope.

The generation of heat is one of the most remarkable phenomena in fermentation, and it bears a proportion to the bulk of the fluid. It is sometimes so great as to render it necessary to reduce it by art; its cause is obscure. The colour of wines is also produced during the fermentation; the red appears to be a substance analogous to resin, soluble in alcohol; and thus its production is accounted for. Hence, white wines may be made from red grapes, by excluding the husks; hence also, red wines are often astringent; because the tannin also lies in the husk. Thus also, in Champagne wines, the red are generally inferior; because, the species of fermentation required to extract the colour dissipates part of the flavour.

The formation of alcohol is the last, and the essential phenomenon; and it is now plain, how this must depend on the quantity of sugar, on the goodness of the fruit, on the due apportioning of the leaven, and on the management of the process.

Thus, when all the necessary circumstances are present, the process goes on till the produce is pure wine, or a compound of alcohol, water, acid, colour, vegetable extract, and sugar. For although the two latter are said to be destroyed, there is almost always a minute portion of both remaining; the former rendered very sensible, in some wines, by the skinny matter which they deposit on the sides of the bottles. In a similar manner, it happens, that a portion of sugar continues attached to the wine for a long time, though it is not always sensible except to a fine taste. Thus, it is perceptible in Claret, and even in Madeira, which are among the driest of our wines. It is often very sensible in Port; and, when in excess, is commonly the mark of a bad wine. In the first stages of the fermentation, the sugar is never thoroughly decomposed. If that were the case, indeed, the process would stop, or it would proceed to vinegar. Farther fermentation, that slower species which takes place in the casks, tends farther to diminish it; but, still a portion remains, even when it has been bottled.

It is the gradual conversion of this sugar, the chief operation that goes on in bottled wines, which is the cause of the change which these undergo. This process often requires many years for its completion: that is the case in the Clarets of Chateau Margaux, and other Bourdeaux wines; and the same process indeed takes place, to a greater or less degree, in Madeira and the other strong wines. In these cases, it is a cause of improvement; the wine becoming more perfect under this last tedious fermentation; in others, however, it is mischievous: and hence the destruction of many wines. Thus, Champagne is destroyed, and often very quickly: thus, Burgundy also is easily ruined; and thus, even our Port is not a very durable wine, though the destruction is here accelerated by the intermixture of brandy used in this particular manufacture. Age,

which thus meliorates one wine, destroys another, independently of that loss of flavour which occurs in some of the more delicate; though this also is the result of the slow fermentation under review. In the sweet wines, the same process tends constantly to diminish that sweetness: and hence, the comparatively dry qualities of ancient Malmsey and of Paxaret under the same circumstances. In this class of wines also, the flavour is injured by the same process, or by age: and hence, though age may confer merit as well as honour on Malmsey and Malaga, and generally on the sweet Spanish and Greek wines which have little flavour, by diminishing their lusciousness: it destroys or injures the highly perfumed wines of Frontignan, which can scarcely be drunk too new.

By the same considerations we can account for the benefit which Madeira wines receive in a hot climate, or in a hot cellar. The effect of the heat, and, in the case of a sea voyage, united to the agitation, whose action was considered before, is that of accelerating the imperceptible fermentation, and thus ripening the wine sooner than would have happened in a low temperature and at rest. But it is a mistake to imagine, that this is peculiar to Madeira, or that it is the only wine which can be benefited by this treatment. It is the same for all the Spanish wines, for Sherry and for Port, and it is also true of the better and safer wines of France, of those of Hermitage and the Bordelais. Claret becomes drinkable in a much shorter time in a warm than in a cold cellar; and that is equally true of many more of these wines. But that which some will bear, others will not; and thus many of the wines of France, so far from admitting a high temperature, can scarcely be preserved even in a low one. As to Port, it is a useful piece of knowledge to be aware, that it may speedily be rendered aged by heat. And in this case it deposits its colour, and assumes the marks of old wine to the eye as well as to the palate. One year will thus do that for Port which might have required five or six; but the period of its entire duration is consequently shortened, as might be expected. The effect of heat is indeed such in this case as is suspected by few. In America it is a well known practice to boil Madeira, or to heat it to the boiling temperature, and the effect is that of rendering it good and old wine, when previously harsh and new. The same practice is applicable to Port. If newly bottled wine be exposed to the sun, it begins shortly to deposit, and improves in flavour; and even the rawest wine of this kind may, by heating it in hot water, be caused, in the course of a day, to assume the quality which it would have had after many years of keeping. It is so far from being injurious, as might be imagined, that it is a valuable secret; and, as we believe, one that is but little known to those whose interest it is to give the complexion of old wine to new, and who generally effect this purpose in a fraudulent manner, by putting it into foul and crusted bottles.

It is important, in another view, to consider the effects which follow from a portion of undecomposed sugar remaining in wine. It is supposed to be a means and a test of the security of wine; and the French chemists assert, that as long as any portion

Wine-  
Making

Wine-Making.

remains undecomposed, such wine cannot run into the acetous fermentation. This appears true only in a limited sense. In Hock, it would seem as if every atom of sugar had vanished, and yet the durability of that wine appears to be endless. If that is not absolutely the case in Claret and Madeira, still these are very durable wines; the most so, after Hock, at least of the dry class. None of these, when of a good quality, ever run into the acetous fermentation. Perhaps this may depend on some peculiar balance of principles which chemistry has not yet found the means of discovering. For, in other cases, it is certain that the chemists in question are under an error; and that the acetous fermentation will come on, though sugar should still be present. This happens in many of the French wines of the lighter kinds. If, in the sweet wines from the grape, that effect does not take place, it is very certain that it happens in the wines made in this country in imitation of them from various substances. In these cases, even sweet wines are found to be occasionally *pricked*, as the technical term is, or vinegar and sugar are coexistent in the fluid at the same time. Nor are even all the foreign sweet wines of the grape exempt from this disease; as must be well known to those who have an extensive knowledge of wines, or of the wine market.

There is reason to believe that the cause of this must be sought as a circumstance which these chemists seem to have overlooked. If the balance of principles in a sweet wine has been perfect, and the process of fermentation has also been complete, and if, in addition to this, these wines have been so carefully racked and fined, that no lee or leaven remains in them, they may be safe, because there is nothing left in them to re-excite a fermentation, or to bring on the acetous stage. But if that is not the case, if any impurity, any leaven in any form remain, the sweetness offers no security against the change into vinegar, or at least against that partial change which constitutes a *pricked* wine. The acetous fermentation may commence and proceed as far as the circumstances allow; and thus vinegar and sweet wine may exist together in the fluid. The nature of the acetous fermentation is indeed very ill understood; as little as that of the vinous; and we are at present incompetent to reason much about it. It is a common opinion that it must be preceded by the vinous; yet this does not appear to be true. Certain mixtures of sugar, leaven, and water, will immediately tend to vinegar, without our being able to detect a previous vinous stage; and this seems always the case when the solution is very weak, or the water in large quantity, provided, of course, there be access of air. It is indeed unquestionable, that in the common process of making vinegar, the acetous fermentation is going on in a saccharine fluid; so that the mixed taste of vinegar and sugar is perceptible until that process is completed. Vinegar can also be produced by passing alcoholized carbonic acid through water, another obscure operation; and in the human stomach it is produced in a very few minutes, when we can scarcely imagine that any previous vinous stage can have taken place.

When all the favourable circumstances above stat-

ed are present, the fermentation begins and passes through its regular stages till there is produced wine, perfect and dry, if the sugar has been thoroughly and accurately proportioned to the other ingredients; sweet, if it has been in excess; and acid, as in Hock, when this substance has been in undue proportion to the other ingredients. The unfavourable circumstances must be sought in the temperature, or in the quality of the fluid. The juice of the grape rarely labours under any defect but the want of sugar, arising from a bad variety of this fruit, from a bad season, or from imperfect ripening. In the latter case, however, there may be added to defect of sugar or excess of water, an excess of acid and an excess of extractive matter.

In the wine countries the defect of sugar is remedied by different expedients. In some, sugar or honey is added to the juice, or must; in others, a portion of the juice is evaporated and added to the rest; and, sometimes, all the juice is boiled before it is submitted to fermentation. These seem to have been the *vina cocta* of the ancients, which, from other circumstances, we know to have been thick and sweet wines, requiring dilution. They could not have been boiled to any consistence after they had become wine, without losing all their properties; and as to wines that were to be cut by a knife, it is plain that we must have misapprehended the meaning of the term *vinum* in this case, as no wine could exist under such a form. To gain the same ends, it is a practice in many countries to dry the grapes partially, by suffering them to remain on the vine; but this is chiefly resorted to for sweet wines, as in the case of Cyprus, Tokay, Lipari, and others. The other expedient for increasing the properties of sugar in the juice is by plaster of Paris, or gypsum, not an uncommon ingredient; and this effect, as well as that of absorbing and destroying superfluous acid, is also partially attained by the use of lime.

The management of the fermentation, supposing the fluid to be perfect, is regulated by the intended nature of the wine. If sweet wine is desired, not only must the proportion of the water be diminished by one or other of the means above mentioned, if necessary, but the proportion of extractive matter or leaven must be reduced, to prevent it from running to the ultimate stage, and producing a dry and strong wine. In this case, the yeast is separated as fast as it rises by mechanical means; as by fermenting in full casks in such a manner that it may be continuously ejected at the bung-hole as fast as it is formed. Should the reverse be desired, or a dry wine be the manufacturer's object, the yeast is suffered to remain on the surface in the vat, that it may be continually returned into the liquor by the internal agitation, or else it is stirred, or rolled in a cask, or in the vat, so as to protract the fermentation. Lastly, if the wine is to be brisk, to retain carbonic acid, as in the wines of Champagne, not only must the proportions of water and leaven be increased, but the fermentation must be conducted in vessels partially closed, and these also must be fully closed before the fermentation is completed. The management of the temperature is easily deduced from the principles already laid down. A deficiency of heat is

Wine-Making.

Management of fermentation.

Wine-Making.

easily remedied by artificial means, by a fire, or by exposure to the sun; and this is sometimes done by heating a portion of the fluid, and then mixing it with the mass. An equal temperature in the vat is also procured by agitation, and when it is necessary carefully to maintain a mean heat, this is frequently done in the wine countries, by surrounding it with straw or other bad conductors, or by other obvious artifices.

On apparently minute attentions of this nature, far more depends than would, on a superficial view, be imagined; and the great superiority of the wines of France above those of Spain, Italy, and Greece, depend often much more on delicacies of this nature than on any difference in the quality of the grape. In wine-making, indeed, more seems to depend on art often than on nature; and it is both to the praise and advantage of the French, that, by these minute attentions, they have contrived to excel all Europe in this art. Italy, Spain, and Greece, with better climates, and every natural advantage, are thus the manufacturers of a thousand detestable wines, which, in the hands of Frenchmen, might rival the produce of that country. The recent improvements made in the Sicilian wines in new hands, are a proof how much depends on these attentions; and those who have drunk the nauseous, putrid, acid, and disgusting common wines of Italy and Spain, where nothing is wanting but management and care, will know how to appreciate the value of these.

In conducting the fermentation, some other considerations are necessary, on which some remarks are also required. The first of these is the flavour. That evanescent and delicate property, the *bouquet*, as it is called, depends on attentions no less minute. The flavour is very apt to be dissipated by a violent or a long fermentation, or by an open one; and hence, for the finer wines, great care is required through every stage of that process. It is the same for the brisker wines; as, if this be neglected, this volatile substance, on which their peculiar property depends, may be irrecoverably dissipated. A consideration of the general divisions of the quality of wines will render these remarks more intelligible.

They may be divided into four classes: the sweet and strong; the dry and strong; the delicate and light, which are generally weak compared to the former; and the effervescent or brisk. Malmsey, Tokay, Frontignan, are examples of the first, and the second are peculiarly familiar to England. Hermitage holds an intermediate rank, as does Claret, between these and the third class; of which the lighter Burgundy wines, the white wines of Greece, and those of the Rhine and the Moselle, may be considered pure examples; and, of the last, Champagne is almost the only one that deserves to be named.

If, therefore, the intention is to make either a strong sweet wine or a strong dry one, the fermentation is commenced in an open vat. But, in the former case, it is not suffered to remain there long, as it is in the latter. For the driest wines, or for those which are manufactured for distillation, the fermentation is allowed to expend itself in the vat, and the wine is not tunned till it is made; the completion of the process merely, or the final solar fer-

mentation, being reserved for the cask. In the sweet wines, on the contrary, it is soon removed from the vat to the casks, that it may be more in the operator's power to suspend the process, and thus to prevent the annihilation, or total conversion, of the saccharine matter. In the third class again, in the highly flavoured wines, of which Burgundy may be selected as an example, the fluid is only suffered to remain a few hours in the vat; from six perhaps to twenty, that period varying according to the state of the temperature, the particular quality of the juice as to goodness or strength, and the other views of the manufacturer. This is done to prevent the dissipation of the flavour, which would be injured if not destroyed by an open fermentation. The same practice is followed for the wines of Champagne, though there is here little flavour to preserve; the purpose being, in this case, to secure the power of checking the fermentation by pressure, so as to retain the wine in a low stage of this process, and thus to secure a supply of mixed, or combined carbonic acid, at the period of use or drinking.

There is nothing which more strongly distinguishes the bad, or inferior wines of Spain and Italy from those of France, even from those which, from their cheapness, must be considered as belonging to the same class, than the various disgusting flavours which they commonly present. Wines may have bad qualities from other causes,—from the nature of the soil or the grape; but there is far less difference in this fruit in different countries than there is in the care bestowed on the manufacture. To use a short and intelligible term, it is *filth* which is the cause of the bad quality of these wines; filth and neglect in every stage of the process, from the gathering to the pressing, the fermentation and the tunning. In the fermentation, no precaution too great can be used to have all the vessels clean and entirely free from every odour. There is no substance more delicate than wine, nor any one which is so easily contaminated and destroyed by bad flavours, even in the minutest quantity.

The same rules apply to the casks as the vats. New casks communicate the well known flavour of oak, often found in wines, and that, fortunately, is so agreeable a one, that it is often given designedly by means of oak shavings. But in the finer wines, where it would be injurious, it is extracted from the wood by washing, and by hot water and by salt. The more destructive evil of musty vats or casks, so often a cause of the nauseous flavour of the common wines above mentioned, is remedied by scraping, by washing with boiling water, and, most effectually, by firing or charring the insides; while staves which are injured deeply are replaced by new ones. Hot lime and water are also used for the same purposes.

Another precaution is that of removing all the insoluble matter, of whatever nature, during every stage of the process; and from this neglect it is also that the great mass of bad wines is produced in those countries where this art is neglected. Thus the seeds are always to be removed as fast as they rise to the surface, as they both render the wine harsh and communicate a bad flavour. The same is done with the husks when they have performed their duty in giving out their colour. It is most peculiarly ne-

Wine-Making.

Further Precautions in Fermentation.

Wine-Making.

cessary to be watchful over these, lest they should become moulded or musty; whence often arises that taste which resembles that of what is called *corke* wine; a disease also arising from a bad cask, and often attributed wrongfully to careless bottling. In the finer wines, a single musty seed or husk will ruin a whole tun. In transferring the wine from the vat to the cask, or from one cask to another, whether by drawing off or pumping, care must be taken not to disturb the sediment; and more especially still, to separate any of the scum which may be on the surface, as this is always in danger of becoming musty, more particularly where it is most injurious, that is in the lighter and finer wines.

When the quantity of the fermented fluid is considerable, the remaining wine, which adheres to the solid matter, is separated by the press, and made into wine of an inferior quality, either for use or distillation. That refuse is also subjected to distillation with water, in some cases; sometimes, by means of water, it is converted into vinegar, or used for the manufacture of white-lead or of verdegriis; or, lastly, formed into cakes with the other refuse of the first pressing of the grapes, and used for feeding cattle.

If, after the wine is made and tunned, it were suffered to go on fermenting, it would, in many cases, be destroyed. This, it has already been seen, does not easily happen in the sweet wines, where a large portion of the saccharine matter remains unchanged, though even these are not absolutely exempt. Nor does it very easily happen in the stronger dry wines. Yet it does happen to all, and is almost inevitable in the light still wines, and in the brisk ones, whatever the strength or sweetness of the latter may be. Champagne would quickly become vapid, Burgundy would become stale and sour, and Claret would become vinegar. For though the natural progress is supposed to be from the vinous to the acetous stage of fermentation, there are phenomena in practice which show us that we are yet imperfectly acquainted with the exact nature and varieties of fermentation. Champagne, for example, becomes mucilaginous and flat; while, though Burgundy becomes acid, it is scarcely possible to make it pass to the exact state of vinegar.

Yet the tendency to the acetous stage must be considered as general,—for want of a better expression; and, on this view, the management after the great fermentation is regulated. If it is suspected that even intended sweet wine has been over wrought, boiled must or sugar is added to it; and thus, in the tedious fermentation of the cask, it is secured or restored. But it must be remarked, that if the acetous stage should have commenced, that addition would only serve to accelerate and determine it. The remainder of the general management consists in regulating the fermentation of the cask by the general principles before laid down; that is, if the wine is incompleated, it is not suffered to rise to the bung-hole, so that the new leaven, which is disengaged, may fall back again and protract the fermentation; while this is also aided by heat, by stirring up the lees, and by agitation. If the reverse be the case, and that it is necessary to check the secondary fermentation, then a cool temperature and rest are adopted; while, as fast as the wine wastes, it is kept

close to the bung by fresh additions, that so the disengaged leaven may escape. Some of the other requisites to the completion of wine will fall better into another section of this little essay; but the process of sulphuring belongs to the second stage of management, as well as to the final operations of the manufacture.

However vulgar and mechanical the process of <sup>Fining, Sulphuring, and Clarifying</sup> fining, sulphuring may appear, it is a refined chemical operation, the practice of which was long known before the theory, however discovered; and the theory of which, in a scientific and rigid view, is not very well understood even now. It has been already shown, that the process of fermentation has a perpetual tendency to continue as long as all the requisites are present, and, more particularly, as long as there is present that peculiar and obscure substance, the extractive matter, or leaven, on which it mainly depends. If, also, this substance has been entirely separated in the two forms of yeast and lee, the process terminates naturally; the produce being dry or sweet, according to other circumstances now understood. But if any portion of leaven remains in the liquor, then the acetous, or some similar stage, may come on, and the wine will be destroyed.

The processes of racking and mechanical separation just described, are all intended to separate this matter: and whenever the wine remains turbid, it is always in danger, because the fermentation may at any time be renewed. But often these operations are insufficient to disengage all the leaven or lee; as much of it not only continues mixed, so as to produce the turbid state, but the extractive matter itself, which has not been brought to this insoluble form, remains combined with the fluid.

The merely turbid state is remedied by the process called fining, which precipitates all the insoluble or disengaged lee and leaven that will neither subside nor rise; thus removing one part of the hazard, besides communicating that brightness and beauty which is demanded in all wines. That brightness, therefore, is more than a beauty, since, without it, there is no security,—at least in the finer and lighter wines. Various substances are used for this purpose, and the action of many of them is very obscure. They are either chemical or mechanical. The mechanical substances are sand and gypsum, both of which have the property of precipitating the insoluble matter; while the latter also absorbs water. Beechwood chips are sometimes used for the same purpose; but the mode in which these act is not known. But the matters chiefly in use are chemical ones, gluten and albumen. Of the latter, eggs and milk are both used; but the former are preferred. Of gluten, isinglass alone is used; for, from some causes hitherto undiscovered, the gluten of terrestrial animals, or common glue, does not produce this effect to the same extent that it is obtained by the glue of fishes. It is also usual to adopt albumen for the white wines, and gluten for the red; as the former is found to precipitate much of the colour from these last. The proportion used is very small, an ounce of isinglass being sufficient for a hundred gallons. To these chemical matters we might have added starch, gum, rice, and blood,

Wine-Making.

Management after Fermentation.

Wine-Making.

but they are very little used. The action of the albumen appears more mechanical than chemical; becoming coagulated, and then entangling the dust, if it may so be called, which is suspended in the fluid, in the same manner as it would purify muddy water. In the case of the gluten, however, a new chemical combination is formed with the tannin of the wine; and the produce is that well known substance resembling bird-lime, which is the basis of leather. Hence, also, fining diminishes the astringency of red wines.

Presuming that one of these substances has been introduced, the fluid is strongly agitated and suffered to repose till clear, when it is again racked into a fresh cask. It is found very important to select for this purpose dry cold weather, and, as is particularly remarked, north-east winds. From some mysterious cause, in close weather, and fogs, and southerly winds, the precipitated matters rise again, and defeat the objects of the operation. The other precautions are those of using a syphon instead of a cock, as affording greater security; or, what is now used in all the best French manufactories, blowing off. This is performed by a condensing engine, as in the drawing of porter, and thus access of air is prevented. This is very important where fine flavoured wines are concerned, as it is in brisk wines; because the carbonic acid which would thus be lost, carrying away also a portion of the alcohol or strength of the wine, is thus preserved.

But the leaven held in solution cannot be separated in this manner; and for that purpose recourse is had to the process of sulphuring. The most common and the simplest practice in this case, is to fill the proposed cask into which the wine is to be racked, with sulphurous gas, by burning matches in it till full. The wine, being then introduced, becomes turbid, and, after the necessary time, it is found as before. Should the fermentation still be renewed or dreaded, this operation is repeated as often as it may be necessary. If, as in the case of some of the Bourdeaux wines, the quantity of leaven in the wine is so great, that it cannot be overcome in this manner, the combustion of the sulphur within the cask is repeated at intervals during the process of filling it. But it is also a practice in that country to impregnate with sulphurous acid a quantity of wine, and this substance or mixed fluid, called *Muet*, is reserved for adding to those which may require it; by which means the efficacy of the operation is better ensured.

The theory of this practice seems, to a certain extent, simple. The sulphurous acid, or possibly its oxygen, unites to the extractive matter, or the soluble leaven, and renders it insoluble, as happens in the act of fermentation itself; and thus it becomes capable of being separated by the mechanical processes of racking and fining. It is for this reason also, that sulphuring is largely used for the sweet wines, to ensure their preservation in that state. It has been said that manganese, and other substances, containing much oxygen, will produce the same effect; but the cheapness and simplicity of the common process renders other expedients unnecessary.

Supposing wines of any class to have thus been obtained, there is yet much more to be done before they become the wines which we know in our market. The processes in use for this end, to make marketable wines, are badly distinguished by the term medication, as they are of various natures. There is a great deal of wine, indeed, which can scarcely be considered as strictly natural; though it is a common prejudice that all wines are so, except when fraudulently mended, or altered, or mixed. It is difficult, indeed, to draw the line between what may be considered fraud and what is legitimate; and certainly by those who expect that all wine is to be what it is commonly thought, the mere produce of the grape, and of one process on one grape, every subsequent process may be esteemed a fraud. We must here limit ourselves to some of the most important and remarkable operations, as the whole would run into a very long detail.

The simplest process is that of mixing different wines together, whether of the same quality or country, or of different ones. In either case, this practice may sometimes be considered fraudulent, and, in the latter, especially so. But, in a degree, it is inseparable from the nature of the manufacture, and the mode in which it is conducted. The larger makers, or the capitalist on the spot, buying in small lots from the petty manufacturers, is obliged to adopt this practice, partly to ensure a certain quality, and partly for the purpose of remedying those that are defective, by the addition of better ones. He must often also have recourse to the same expedient, and for the same reasons, when he is himself the manufacturer.

The mode of performing this operation, which requires great experience and judgment, is to select, first, that period of the year in which the wines show a disposition to renew their fermentation, which is in the spring. They are then said, in English, to bear the *fret*; and hence the operation is called fretting-in. It is only thus that a new and *fine* wine can be produced. The operation of mixing different wines, in all cases, disturbs both, so that they become foul. They also tend to ferment again, till a new balance of all their principles is produced; and thus it is expedient to accelerate and determine this fermentation, so as to form a proper compound, without which the new wine would be perishable. After this, also, it becomes necessary once more to have recourse to sulphuring, fining, and racking; and not till all this has been gone through is the wine completed. In the Bourdeaux practice of mixing Clarets, the Muet or sulphured wine is sometimes added at the same time, where the wines, being of very discordant qualities, a dangerous fermentation might be excited.

In the wine countries, it is usual to cultivate particular grapes or wines, rough, or coloured, or astringent, or high flavoured, for the mere purpose of mixing with others; so far is this art from being so simple as is commonly imagined. In many also it is a practice to import the wines of one country to mix with those of another, and thus to suit the taste of purchasers, or obtain other ends. This practice is

Wine-Making.

On the further Processes in Wine-Making.

Mixing Wines.

Wine-Making.

Wine-Making.

pursued even by the importers into Britain; and, as we need not say, opens a door to endless frauds, while it may also be innocent. Thus, in this country, as well as in Portugal, the wines of Spain, Alicante, Barcelona, and so forth, are mixed with Port wines; as are the cheaper Clarets of the south of France, and some other of the strong flavoured wines of that country. In a similar manner, the wines of Fayal and the Canaries are manufactured into Madeira, as are those of Sicily; and thus, too, Sherry is largely compounded out of many of the wines of Spain and Portugal, and of the islands of the African coast.

But the most extensive operations of this nature are carried on at Bourdeaux with the wines which we call Claret; not one-thousandth part of which are of a good quality, or unmixed in some way, and the one-half of some of which, perhaps, are not French but Spanish wine. The following statement, while it is curious in itself, will illustrate this. In the year 1814, the total quantity of the Clarets, or Bourdeaux of the first class, was as follows:—

	Tons.
Chateau Margaux	80
Latour	70
Chateau Lafite	80

In the second class it was thus:

	Tons.
Margaux de Madame Derauzan	60
M. Chevalier	25
M. Monterison	25
M. Montalambert	25
St Julian Leoville	80
Lanoze	70
Pauillac M. Depichon	60
Brame Mouton	80

We cannot afford room for the remainder of this statement, comprising the produce of the fourth and the fifth qualities; but it is plain, that very few of those persons who imagine that they are drinking the first growth of Bourdeaux wines, can even be drinking the second.

The first growth of Claret, it is thus seen, amounts only to 230 tons for an average; and that, even of the second, is only 425: a fraction, indeed, in the consumption of Europe. But, in the third class, of which we cannot afford to give the details, there are 1061 tons, and in the fourth, 825, making a general total of 2541 tons. Besides this, there are other inferior wines which do not enter into the enumeration; and it is by mixing the greater number of these in various proportions that the market is supplied; it being necessary to reserve many of the better wines to render the others saleable.

We must however remark, that, among the districts which produce the inferior wines, such as those of the Bas and the Petit Medoc, a few farms produce small quantities, of a quality equal nearly to the good St Julian or Lafite wines; and these add to the bulk of the better kinds, being generally reserved, and sold at high prices. In the district Medoc, the seat of the better wines already mentioned, there are

besides the third and fourth classes, six or eight kinds of wine known by the names of *Gros Bourgeois*, *Petit Bourgeois*, *Artisan*, and *Paysan*; and these are manufactured, with others, for the English and Irish markets chiefly, by means of Spanish wines,—by mixing with the strong wines of Benecasto and Alicante. The same is true of the Grave wines.

This is the great mixture, in fact, by which the market is filled to almost any extent with Claret wines, so called; and these mixed wines are almost the only ones we drink in this country. If that be a fraud, it must be remembered also that such is British taste in wine; and that Claret is in general esteemed here only in proportion to its strength. Of the stronger and finer wines there is not enough for even our consumption; and, as we must have them strong, they are thus made such by this process. That effect is also obtained, however, by some of the south of France wines also; by those of Côte, which are used for mixing with the weak Medoc and Grave wines, for the British market. This is the case with those of Queyries, such as Monferrant and Bassens; and those of Palu, such as Macaw, St Romain, Coddillac, St André, Lugon, and many more.

The French wines of which we have been speaking, will not endure to be rendered stronger by means of brandy. The property of this substance, thus mixed, is to decompose the wine in process of time; causing the extractive matter or mucilage to be deposited, as well as the colour, as is daily seen in Port wines, and thus diminishing their powers of duration. At the same time, it destroys their lightness and flavour; that peculiar indefinable delicacy well known to drinkers of good wine, but quite imperceptible to British drinkers of Port. In a certain sense, we may consider that it is only the bad wines which will bear this medicine; those which have no flavour of their own, and whose whole merit already is their strength. What sort of a compound is made of a weak wine with brandy ought to be known to those who drink what is called Lisbon wine. But a depraved taste has rendered it necessary to our nation; and thus it is largely used, even in those wines of Portugal and Spain, of which the chief fault is that of being too strong already. We may thank the Methuen *Treaty* for being condemned to drink what Mr Pinkerton calls wine fit for hogs only. This mixture is performed in the same manner, at the period of fretting; and the proportion is regulated, partly by the taste of the consumers, and partly by the badness of the wine. As it must have a certain strength, the worst wines require most; and hence, whenever we taste the brandy in wine, we may be sure it is bad. It is a taste sufficiently perceptible to those who know what real wine is.

Many wines have so little flavour naturally, that they can scarcely be considered to possess any. There are few, indeed, that possess this quality in any great degree; and, of these flavours, a large proportion is bad. Wines so highly perfumed by nature as Hermitage and Burgundy, are rare; indeed, these are almost the only examples; and, after them, we may consider the finest Clarets, and then the finest of the Rhine wines. The sweet wines which possess it are well known; and these also are but a small part of

Mixture of Brandy.

Flavouring of Wines.

Wine-Making.

the total number in this class; being almost limited to Paxaret and the Muscat wines, among which Rivesaltes stands first. Constantia has rather a taste than a flavour; and what the ordinary sweet Spanish wines possess is rather bad than good; though, like the taste of Sherry, and Porter, and Olives, they may become agreeable by habit.

Excepting these cases, and a few among the Italian wines, which we cannot afford room to detail, many of the flavours found in wines are communicated by art; and this forms part of the business of the manufacturer and merchant. Much of this is a secret, but some of the substances used for this purpose are known. The taste of Greece is now, as it was in ancient times, to perfume its wines with turpentine—the *vina picata* of the ancients; and this is effected by putting turpentine or rosin into the casks. In Britain, our Chivalrous and Baronial ancestors perfumed their wines with every strange ingredient that can be imagined; but that was the age of spicery and perfumes; and he who eat cinnamon with his pork, might drink ambergrease in his wine.

The flavour of Madeira is nothing; but that which we know is given by means of bitter almonds, and, we believe, of sweet almonds also; and the same practice is followed for the wines of Saint Lucar. That which is called the *borrachio* taste in wine is for the most part that of the tar with which the seams are secured. In Sherry, the flavour seems produced by the destruction of the acid, the consequence of the lime used, and possibly by some other action of that substance on the fruit. One of the most common ingredients used for flavouring wines is oak chips; and from this the wretched Lisbon wines acquire the little taste they have. Orris root is also a common ingredient: and the high flavoured wine of Johannesberg is imitated by a proportion of rose water. The orris root gives a very agreeable flavour, and is used in France; and there, also, it is the custom to use raspberries and other highly perfumed fruits. A very agreeable flavour is also said to be produced by wormwood. The flowers of the vine itself are also used for the same purpose, their smell much resembling that of our mignonette. This last is an ancient practice in Egypt.

The method of gaining this end requires some delicacy and attention. In particular, care is taken that it be not overdone. As the full fermentation would destroy the more volatile flavours, these substances are only introduced towards its decline. In Madeira the nut cake is put into the cask. Flowers are suspended in a net or cloth, either in the fluid or the vacant part of the cask, and thus a small quantity of raspberries communicate a very considerable flavour.

Colouring of Wine. The colouring of wine is also part of the business of the maker; because colour is, in a good measure, a matter of fashion and fancy. Some grapes contain naturally very little colour, while that of the Claret vine, and many of the grapes of Spain, are highly charged with the colouring principle. We already explained that the colour was contained exclusively in the husk. These latter wines are often, therefore, selected and reserved for this particular pur-

Wine-Making.

pose; and it is also a practice to use the dyeing woods, logwood and Brazil wood, for obtaining the same end. The elder berry, which is full of colour, is also resorted to; and in Portugal it used to be extensively cultivated for the purpose of dyeing Port wines. When white wines are thought too pale for the market, they are coloured browner by means of the well-known ingredient burnt sugar; and the chips of oak also produce the same effect. By some means also iron finds its way into some of the French wines, and thus, on exposure to air, they become black. This unpleasant effect is not unusual in the sweet wines from the south of France.

This property relates almost exclusively to the wines of Champagne, and it is one that may err in excess or defect. It is already apparent, that it is the produce of an unfinished fermentation, and, therefore, a due degree of it must depend mainly on the proper management of this process. It is secured by bottling at the proper season, March, and before the fermentation is exhausted; and, if in danger of excess, it is restrained or diminished by racking, or decanting, and sulphuring. But it happens not unfrequently that it fails altogether; either from accident in the management, or a bad season; from faults in the fruit, or fermentation carried too far, or a weak wine exhausting itself unexpectedly. In this case the remedy is to introduce sugar, not only into the casks but into the bottles. In the first case, the fermentation is renewed, and the wine may thus become legitimate and good. In the other, the effect is far different, and not good; and hence it is that all the very sweet Champagne wines are bad or indifferently. These are, in fact, a mixture of wine and sugar, rather than proper wine. And, in this case, the effect of the sugar is, not to produce a new fermentation, but to disengage the carbonic acid of the wine; as a salt or any other soluble substance would do, by a superior affinity. To gain this end, the solid sugar is corked up in the bottle; so that the disengaged gas is retained under the pressure of the cork, ready to fly out whenever that is removed. Thus Champagne, which has been destroyed by age, is rendered, at once, both sweet and effervescent; and this, however convenient a secret it may be to the possessor, is but a fraud, and a very common one too.

The acidity, or the pricked taste of wines, is a fault which, perhaps, ought never to be corrected, as, in this case, the wine is generally spoiled. This nevertheless is done, and sometimes to a considerable extent. Acidity arising from tartarous acid, or even from malic acid, if that really be the acid in wines which is not tartarous, may be a virtue and a quality; as it is very remarkably in Hock. But it is often thought otherwise, even when it is the natural property of the wine, arising from its own native acid, and after a correct fermentation. In this case, means are applied to remedy it, as a disease in the wine. In the manufacture of Sherry, it was already remarked, that lime was used to prevent it, and this is also applied in other cases, where tartar is in excess, as the tartrate of lime is insoluble, and can be fined down and separated by racking. It has been the fashion to use lead, metallic lead, for this pur-

Wine-Making.

pose; and, in France, it was formerly used largely in the wines consumed in Paris. It was then discovered, and the act made penal; and, if not abandoned entirely, it is less used at present every where. That this is a poisonous substance is too well known. But that has been overrated in this particular case. The tartrate of lead, like that of lime, is insoluble; so that, after the lead had done its duty, it was discharged by racking and fining. Had this not been the case, all Paris, at the time we speak of, must have been poisoned. Yet it is a substance that ought not to be used; because, in an acid wine, ascending from fermentation, it might produce either white lead, or subcarbonate of lead, or else sugar of lead, acetite; both of them poisons, if in different degrees.

For the acidity of wine from the commencement of the acetous fermentation, there is no proper remedy. It may be checked, if taken in time, as it would be prevented, by careful sulphuring. Here lead is highly pernicious; and it need scarcely be said, that to add sugar of lead, as has been done from ignorance and fraud united, is to add a poison without even obtaining a remedy. Chalk and lime may be used with impunity. Yet neither can these, and far less alkalies, be used to such an extent as to cure the disease; as they unite to the other acids, and also decompose and destroy the wine. To prevent it as far as possible, when commenced, a low temperature, and careful exclusion from the air, are necessary. But it must be remembered that air will find access, not merely through cork, but through sealing-wax, and, indeed, through all rosins also; and thus there can be no complete security; the best being that of placing the bottles on their sides, so that the fluid itself becomes its own cork. The Italian practice of using oil is thus far safer; but it is balanced by its various inconveniences.

Ropiness is a disease almost peculiar to the wines of Champagne, and its chemistry is very obscure. It is not a destruction of the wine, although it materially injures its flavour and other qualities. It occurs in this wine, from the quantity of extractive matter which it still contains, and which is that by which the fermentation is maintained. It is conceived to arise from the action of oxygen on this substance, converting it into a matter analogous to fibrine, instead of changing the whole into vinegar. Thus it resembles the mucilaginous deposit of vinegar called the *mother*. In the bottles, it may be often cured merely by heat; by exposure to the sun, or by immersion in hot water. When obstinate, it is remedied by uncasking, and by agitation; by exposing the fluid to the air. It is said also to be removed by a small quantity of any vegetable acid, as it also is by sugar; but when on a large scale, it requires the process of fining.

It is held essential by the French, who are our chief teachers in every thing that relates to wine, that a wine cellar should not only be dry, but preserved in a very uniform state of temperature, as near to the mean annual heat of the country as possible. We have already shown, however, when this rule may be usefully departed from, for the purpose of accelerating the ripening of wines. In the delicate

wines of that country, however, the rule still holds good; and very conspicuously too with regard to the wines of Burgundy and Champagne. It is equally true of the finer and lighter Italian wines. The wines of Spain and Portugal seem to defy every thing. It is also held by the French most essential, that a cellar should not be subject to the agitation of carriages; the reason of which is plain enough; and that it should be free of bad smells. As to moisture, however, we must remark, that, like heat, it seems to accelerate the deposition and consequent ripening of Port wines. On bottling, we need say nothing; only let it be remembered that corks cannot be too good, but that no precaution will absolutely prevent all communication through a cork, however secured and sealed.

The rules which we have thus given are all of a general nature; and though some of the particular distinctions in the modes of making the several classes of wine might be understood from them, there are yet a few niceties to be explained; while an example from each of the four classes into which we divided wines, will render the subject more intelligible.

The attentions required in Champagne wines are perhaps the most minute, and the most complicated, and they therefore stand most in need of being detailed. Champagne is a late country, and it frequently happens that the frosts have arrived before the grapes are ripe. Of course, it is an imperfect vintage. Yet, in a certain sense, this is an advantage; while it has also condemned that country, in a great measure, to limit itself to this particular class of wine. A very brisk wine is not easily secured from grapes absolutely ripe; and thus the half-ripened fruit of this district is brought into use. Yet the best of these wines, the finest class of Sillery, rarely seen in this country, is made from the ripened grapes. And hence it is, that the best of the Champagne wines are those which are least brisk or violent, and that great violence is a characteristic of the inferior kinds. When there is violence and sweetness both, we may easily conjecture what the wine is; and in those, as might be expected, there is no flavour.

The finest wine is thus produced here by a very light pressure of the grapes; in which case only the ripest give out their juice.

It is held necessary to gather them when the morning dew is off, to prevent water being added to the juice. The next pressure, and the least ripe grapes, are reserved for the inferior classes. When the juice is poured into the vat, it remains one night only, the seeds being carefully separated. In all cases also, the greatest care is taken to separate damaged grapes or rotten ones; and it is as much from this neglect as any thing, that the common Italian wines are so bad. If the Champagne is to be red, the fermentation is suffered to proceed on the husks a little longer, for the purpose of extracting the colour; and according to the length of this process, we have the *oeil de perdrix*, and the pink and red wines. But as we remarked before, this injures the flavour, as all good judges of Champagne know.

When the liquor is transferred to the cask, the discharge of yeast at the bung-hole is encouraged for

Bottling and Cellarage of Wines.

Wine-Making.

ten or twelve days; and when the fermentation has become moderate, the bung is put down, and a hole is made by its side. This hole is occasionally opened to give vent to the air, for a space of eight or ten days; when no more air is discharged, fresh wine is introduced, so as to keep the cask constantly full to the bung-hole. This operation is continued when necessary, till the end of December, when the wine generally becomes clear. It is then racked into a fresh cask, and fined. After this, it begins to ferment again, losing a portion of its sweetness, and improving in quality. If too sweet, it is not decanted and fined till the fermentation has been renewed by agitation. As the fineness of this wine is one of its essential qualities, and one difficult to obtain, on account of its perpetual fermentation, it is racked and fined a second time, and thus it remains till March. In March it is bottled; yet still it ferments, though corked, and again it begins to deposit. In the best wines, it thus remains from fifteen to eighteen months in the cellar, when it is bottled over again, and is then marketable. The inferior kinds are seldom bottled twice; but an expedient is used instead, to get rid of the sediment. For this purpose, the bottles are ranged in frames with their necks downwards; and when the sediment has been collected in the neck, the cork is dexterously drawn, and again replaced, after which the bottles are filled and completed for the market. There are varieties also in this general process, such as that of suffering the wine to remain in the cask for a year or more on its lees; but we need not enter into these collateral details.

Burgundy and Bourdeaux Wines.

There is little difference in the practice of Burgundy, except what refers to the retention of the carbonic acid. All else is the same; but great care is taken to clear these wines of their lees, as, from their extreme delicacy, they would soon lose their flavour, and also become sour. In the practice of Bourdeaux also, the first stages of the process are the same, excepting in as far as a longer fermentation in the husks is used to extract the colour from the red wines. But there is a difference as to the process of sulphuring, which is largely used in these, in the manner as already described. The red wines of Bourdeaux are racked about the end of March or the beginning of April, but the white in December; and in all these wines, great care is taken in all those circumstances which relate to cleanliness, however rude the people, and the operations may appear on a superficial view.

Italian Wines.

In the drier Italian wines, the must is allowed to ferment completely in the vat. In some vineyards, a quantity of selected and half-dried grapes is thrown into each tun when the wine is finished, so as to give it sweetness, and prevent the hazard of its running to the acetous stage; a rude and a bad process. In the manufacture of Florence wine, the must is withdrawn from the vat as soon as the head is raised, and the wine is transferred to a cask, where it is only suffered to remain thirty-six hours, when it is again decanted into a fresh cask at the end of a few hours, and so on, until it is clear and marketable. Thus it is completed in a short time, by little more than the process of racking.

Sweet Wines.

In different countries, the practices used for pro-

curing the sweet wines vary; but they will be found to depend on one or other of the principles already laid down. In Italy, as in the making of Florence wine, the fermentation is quelled by repeated racking and shifting. Thus the other processes are partly or entirely saved. But it is necessary that very sweet and rich grapes should be used if this process is to be followed. To ensure sweetness, on the principles formerly laid down, the grapes of Tokay are partially dried before they are used; and this is also done for the wines of Cyprus, and for some of those of France and Spain. The remaining processes, consisting in sulphuring, &c. need not be detailed again, as they are nearly the same in all countries.

Wine-Making.

In Oporto, for the dry wines, the practice is to carry on the complete fermentation of the must in the vats. The wine is then introduced into large tuns, capable of holding twenty-five pipes each, and at this stage, the brandy is added at the discretion of the maker. In Madeira, the second or insensible fermentation is effected in pipes, and, at the end of three months, the wine is racked, when a certain portion of brandy is added. In both these practices, it would seem as if the union of the brandy with the wine was less perfect than it might be rendered by a different management of this part of the process. Hence, probably, it arises, in a great measure, that the taste of brandy is so sensible in many of these wines. In the best, the quantity is said to be about a twentieth part; but, in the worst class of Port wines, it seems sometimes to amount to a fifth or more. The process followed in making Sherry is rather more complicated. The grapes, in this case, are first slightly dried, and then sprinkled with quicklime. They are then wetted with brandy when introduced into the press, and a farther portion is again added to the must before fermentation. It is highly probable that, by this practice, the brandy is more perfectly combined in the wine, and the fluid rendered more uniform; and hence also, probably, it arises, that the taste of brandy is not to be perceived in genuine Sherry, though often found in those baser imitations which are manufactured from the tasteless wines of the Canary Islands, and of other parts of Spain. The remainder of the process for Sherry consists in racking repeatedly at intervals of a month or two; fresh brandy in small quantities being added at each stage of this process.

We may, in conclusion, remark, that in the attempts to make wines in our own country from native fruits, the same rules are of universal application, and that an attention to them would render these domestic processes more complete than they now are, and the results more valuable. In Britain, also, it is easy to make very good wine from immature grapes, by the addition of sugar in the necessary proportions; and these can be procured in almost any season, so that this might even become an object of a petty domestic commerce. Nor is the manufacture limited to the fruit alone, since the leaves and tendrils, by infusion, admit of the same treatment, and with the same results. Very tolerable wine, perfectly resembling the wines of France, can thus be made, and at an expence of little more than the very moderate cost of the sugar. (P. P. P.)

Worcester-shire.  
Boundaries and Extent.

WORCESTERSHIRE, an inland English county in the Oxford circuit, and nearly in the centre of the kingdom. It is bounded on the north by Staffordshire and Shropshire; on the south by Gloucestershire; and on the east by Warwickshire. Its figure is very irregular; and it is remarkable for having several detached portions scattered about the neighbouring counties, which make it difficult to be accurate in its dimensions. It may be stated as about thirty miles in length, and twenty-four in breadth, and to be 736 square miles, or 502,040 acres in extent.

Population.

According to the census taken in 1821, it appeared that the number of houses in the county were 35,950, inhabited by 39,006 families; of whom 14,926 were chiefly employed in agriculture, 18,566 in trade, manufactures, or handicraft, and 5514 were comprised in neither of those classes. The whole number of persons was 184,424; of whom 90,259 were males, and 94,165 females. The rate of increase between 1811 and 1821 was 15 per cent.

Face of the Country and Agriculture.

There is a soft beauty on the face of this county when viewed from any elevation, such as the Malvern or Abberley Hills, which is highly gratifying. From such spots the state of its cultivation appears to great advantage, as there are no parts of any considerable extent so barren or neglected as to be destitute of an agreeable and profitable verdure. With the exception of those hills, the former of which rise to the height of 1440 feet, the whole county consists of gentle undulations, wholly inclosed, well wooded, and intersected by the great rivers Severn and Avon, and their several tributary streams. The abundance of orchards of pear-trees and the scattered hop plantations give a peculiar richness to the autumnal scenery. Even the poorer parts of the county, between the towns of Droitwich and Bromsgrove, have of late been cultivated; and, though they do not rival in beauty the vale of Evesham, they are far from the aspect of sterility which they exhibited twenty years ago. The farms are generally of small extent, from forty to three hundred acres, and the cultivation is generally well conducted. The arable land, which, in the rotation of crops, produces artificial grasses, is estimated to be 360,000 acres; the permanent grass land 100,000 acres, and the woods, wastes, rivers, roads, sites of towns, and gardens, 40,000. The crops of wheat, barley, and especially of beans, are more productive than the average of England. Hops are extensively cultivated, and the pear-trees are so abundant and so productive as to afford perry for the common drink of the labourers in agriculture. There is no breed of cattle peculiar to Worcestershire, as it is found more profitable to buy oxen and sheep in a lean condition from poorer districts, and to fatten them in Worcestershire, than to breed them on its rich soil.

Rivers and Canals.

The great rivers Severn and Avon are both navigable, the former to an extent of near two hundred miles from its mouth, and the latter to Stratford from its junction with the former. The Severn abounds with salmon, shad, and lampreys, though none of those delicious fish are ever known to ascend the Avon. The other rivers are, the Stour, the Salwarpe, the Ledden, and the Rea. This county has

partaken largely of the benefit communicated by internal navigation. The canals are, the Trent and Severn, the Droitwich, the Worcester and Birmingham, the Dudley and the Locominster. The town of Stourport has risen into importance since the extension of canals, and exhibits a large maritime town in the centre of the kingdom, connecting its various productions in a focus, and distributing them where needed.

Worcester-shire.

The manufactures of the county are various and extensive. Worcester produces great quantities of gloves and some of the most beautiful porcelain. At Stourbridge are many glass-houses. Dudley is employed in the iron-trade, especially in making nails. At Bromsgrove some table-linen is made, and small articles of iron, such as needles, nails, and tenter-hooks. Kidderminster has attained much opulence by its manufactures of carpets and of goods composed of silk and worsted, and of silk and mohair. At Evesham there is much oil and oil-cake made from linseed. The productions of the county are easily conveyed to London, Liverpool, Bristol, or Hull, by inland navigation; and, from this state of things, its commerce is very extensive.

The salt made at Droitwich supplies nearly one-half of England with that indispensable article. The duty collected there before the abatement of the tax amounted to more than L.1000 per day. The water, from which the salt is made by evaporation, is more highly saturated than any other that has been discovered. Researches in the bowels of the earth have shown that a river of salt water, about twenty-two inches in depth, runs about 250 feet below the surface. Immediately above this subterranean stream is a bed of gypsum 130 feet thick. When this stratum is penetrated by the borer, the spring rises to the surface, and yields a never-failing supply of water, so fully saturated, that no more salt can be dissolved in it. The springs at Droitwich hold in solution about one-fourth of their weight in salt; no other in England holds more than a ninth. The subterranean river runs over a bed of rock salt, whose thickness has not yet been ascertained. Besides the springs at Droitwich, other mineral springs are found at Malvern, which are resorted to for their healing properties, as well as for the pure air of the district. The combinations of the wells are carbonate of soda, carbonate of lime, carbonate of magnesia, carbonate of iron, sulphate of soda, and muriate of soda.

Salt Springs.

The titles derived from this county are, Marquis of Worcester; Earl of Beauchamp; Viscount Dudley and Ward; and Barons Foley, Lyttleton, and Northwick. Two members are returned to the House of Commons by the county; two each from Worcester, Droitwich, and Evesham, and one from Bewdley.

Titles and Representation.

The most considerable places and their population are, Worcester, 17,023; Dudley, 18,211; Kidderminster, 15,296; Bromsgrove, 7519; Stourbridge, 5090; Bewdley, 3725; Evesham, 3487.

Towns.

Among numerous seats of noblemen and gentlemen in this county the most distinguished are, Mardresfield, Lord Beauchamp; Hagley, Lord Lyttleton; Croome Court, Earl of Coventry; Northwick,

(w. w.)

Progress of this State.

WURTEMBERG, a kingdom in the interior of Germany, formed within the few last years out of the ancient duchy of the same name, with the addition of several smaller territories progressively combined with it, in the reigns of the two last Sovereigns, by an accommodating policy, and a sedulous regard to their own interest during the progress and conclusion of the French Revolution. By an armistice made with France in 1796, all the territories on the left bank of the Rhine were ceded to that power; but by the opportune peace of Luneville in 1801, and a separate treaty which followed as a consequence of it, Wurtemberg was raised to the dignity of a grand duchy, and obtained several districts which had been either portions of small independent states or ecclesiastical dominions. Among these were the cities of Heilbron, Gmünd, Hall, Rothweil, and some others, with the districts around them. The whole of these acquisitions extended over 633 square miles, and contained 115,000 inhabitants. The former territory on the left of the Rhine being only 165 square miles, with 50,000 inhabitants, Wurtemberg was considerably augmented. In December 1805, in consequence of the part taken in the war between France and Austria, the kingly dignity was assumed, and the possession of several other portions guaranteed by the former power. These acquisitions comprehended several districts on the Danube, whose inhabitants were estimated to be 158,000. In 1806, when the Confederation of the Rhine was formed, Wurtemberg joined it, and stipulated to contribute to its support 12,000 men; in consequence of which, other considerable additions to its territory were made. Several exchanges of dominion took place with Baden and Bavaria; but rather for the sake of rendering the limits more distinct than to increase possessions. The part taken by Wurtemberg in the wars declared by France against Prussia in 1806, and against Austria in 1809, led to a further augmentation; and by choosing the precise moment for deserting the cause of Buonaparte in 1813, the King was enabled, at the subsequent Congress of Vienna, to obtain the sanction of all the great European powers to the title he had assumed, and to the territory that had been acquired. The kingdom of Wurtemberg was thus fixed in the condition described in the following pages.

Boundaries and Extent.

The whole is nearly inclosed between Baden and Bavaria, the former bounding it on the western and northern sides, and the latter on the eastern and southern; except that on one part of its southern frontier, the Lake of Constance separates it from Switzerland. It is of an irregular form, extending from 47° 35' to 49° 35' north latitude. On a very small portion of its northern boundary, it comes in

contact with the grand duchy of Hesse Darmstadt. Its whole extent is 7573 square miles, or 4,846,720 English statute acres. Wurtemberg.

The ancient divisions of the duchy of Wurtemberg were various, according to their position and feudal claims; and the additional territories, that had been recently acquired, were in very irregular and unequal allotments. Of late, a new division has taken place into circles, which are again subdivided in *Oberamts* or *Bailliewicks*; besides these circles, the capital, the city of Stuttgart, forms by itself a separate division, though its inhabitants are included in the population returns of the Neckar circle.

The circles, their extent and population, are,

	Extent in Statute Acres.	Population.
Circle of the Neckar, .....	904,320	384,599
Circle of the Jaxt, .....	1,318,400	318,999
Circle of the Black Forest, ...	1,204,480	360,951
Circle of the Danube, .....	1,468,160	360,849
	4,895,360	1,425,794

This population is found in 130 cities (having or formerly having had walls), 128 market towns, 1115 parishes, 558 hamlets, 2591 farms, and 269 castles or seats of the nobility. The increase of population, calculated by the excess of births over deaths, has been about 10,000 on an average of several years.

The inhabitants are partly of Swabian, and partly of Franconian origin, and retain the peculiar pronunciation of the races from which they are descended. With these are also some settlements of the Waldenses. The Swabians make use of many words very different from the other German people, and adopt many variations in the idioms not known elsewhere. These may be observed to alter at every ten or twelve miles in travelling through the country.

The prevailing religion in Old Wurtemberg was the Lutheran, for which it suffered most severely during the Thirty Years' War. No toleration was granted to any other sect except to the Waldenses, and they were confined within prescribed limits, and even in those spots were under some strict regulations, and excluded from the rights of citizenship. Since 1806, the three religious parties have enjoyed the free exercise of their modes of worship, and a participation in all civic rights, with eligibility to all public offices. The Lutherans in the whole kingdom are 950,000, the Catholics about 430,000. There are many sectaries, such as Separatists, Baptists, Hernhutters, and others, who are neither favoured nor persecuted by the government. Through the whole of Protestant Wurtemberg, there are a great number of persons distinguished by the appellation of Pietists, who hold their private meetings for devotion, but do not in other respects separate from their churches. The Lutheran church is under the direction of six superintendents, whose dioceses are divided into fifty deaconries, and supplied with 818

Wurtemberg. pastors. The Catholics are governed by a Vicar General, who is assisted by a council consisting of clerical and lay members, the priests under them are about 640. The Lutheran clergy are in general better supported, and taken from a somewhat higher class of people, than in most of the other parts of Protestant Germany. The Jews who have established themselves chiefly in the new provinces of Wurtemberg amount to about 8000 persons.

Wurtemberg. about three miles in length and breadth, and those of Laufen and Pfaffen, which are smaller, lie within its boundaries.

The land of Wurtemberg has been recently thus Agriculture, and its Productions. classed: meadows 640,000, arable 1,620,000, woods and forests 1,520,000, and vineyards 61,000 acres; the remainder is either waste or occupied by the lakes, rivers, cities, and towns. In no part of Germany is so much attention directed to agriculture as in this kingdom, and in no part of it are the practices so generally good. The cultivation of green crops is much diffused; turnips, but more especially mangel wurzel, are grown to clear the land from weeds, and to a great extent have superseded the former mode of fallowing. Potatoes are very extensively cultivated, and not only form the chief food of the working classes, but are used for the purpose of making brandy, as well as feeding cattle. The rape and poppy plants are grown for making oil; and that which is expressed from the latter is found to be equal, if not superior, for the use of the table, to the oil of olives. Hemp and flax are raised in abundance, the former chiefly in the middle provinces, and the latter most extensively in the district of the Black Forest. The harvests of corn are tolerably productive of wheat, rye, oats, and, in some of the warmer districts, of maize. The supply of grain is estimated for the whole kingdom at about 28,000,000 bushels, from which, as potatoes are extensively used for food, some is every year sent to supply the wants of the neighbouring states. The woods afford more fuel and building materials than is demanded for domestic consumption, and the surplus, by means of the rivers, is conveyed to the countries lower down the several streams. The vineyards produce abundance of wine, and, though generally not of a good quality, and much of it very bad, its culture is found very beneficial. The best wines usually comprehended in the general class of Neckar wine are those made on the hills near the old castle of Wurtemberg, at Uhlbach, Fehlbach, Upper and Lower Turkheim, Lichtenberg, Rosswag, Maulbroun, and Tauberthal. The most productive vineyards are those on the western borders of the eastern Alps, where a single acre has been known to yield more than 2000 gallons; but it more resembles vinegar than wine. It is generally remarked that the Neckar wines have much deteriorated of late years; which is attributed to negligence in the choice of the most proper plants, and to attention being principally paid to such as yield much, rather than to such as yield the best wine. The wine made in the year 1811, as was the case on the banks of the Rhine, and in most parts of Germany, was of an unusually good quality; and such of it as now remains sells for 300 florins the emir, whilst the wines of later years are not worth more than 130 florins. The whole value of the wines made in the kingdom on an average is L.400,000 Sterling.

Education. Few parts of Germany have exhibited more or better specimens of knowledge and talent than have been produced from the institutions for education in Wurtemberg. The state has, for its population, more means for acquiring learning. The classical endowed schools are fifty-five, from which the theological pupils are transferred to the University of Tubingen, where they are maintained from the funds of the institution. In these establishments the pupils are not confined to mere professional pursuits, but have their attention directed to general knowledge. The University of Tubingen has long been considered one of the best in Germany. There are, besides, the Gymnasium at Stuttgart, and seminaries for the Protestant clergy at Maulbroun, Schoenthal, Ulm, Heilbron, and Ochriengen, and for Catholics at Rothenburg, Rothweil, and Ellwang. Schools for instructing the poorer classes of the people are amply provided in every part of the kingdom, so that the knowledge of reading, writing, and arithmetic, is almost universal. No village is without its school, and scarcely a market town without a classical instructor.

The kingdom may be considered as hilly, if not mountainous. On the eastern part is the group of the Swabian Alps, and on the western the Black Forest, a continuation of the Swiss Alps. The highest points of these two groups of elevations are from 2500 to 2800 feet. The eastern are not so lofty as the western ranges of hills, but they are more bleak, raw, and unhealthy. There are no plains, but some extensive and beautiful valleys, highly fruitful, of which that of the Neckar, with its branches, and that of the Danube from Tutlingen to Ulm, are the most celebrated. The various smaller valleys, running up between the hills, and terminating on the banks of the several rivers, present rich and beautiful prospects. The woods are extensive, and contain almost every kind of forest tree; but the absence of hedge-rows is a great drawback to the beauty of the country in most parts of the kingdom. The scenery is much indebted to the rivers and the several tributary streams, which run through all the valleys. The Neckar rises in the southern extremity of Wurtemberg, and, with many windings, leaves the kingdom on its northern frontier, in its course to join the Rhine. It collects the waters of the Kocker, the Jaxt, the Rems, the Ens, the Erms, and the Zaber. The Danube rises in this kingdom, from the mountains of the Black Forest, and leaves it at Ulm, on the frontiers of Bavaria. It is increased by the several streams of the Iller and the Brentz. The Tauber, in the north, is one of those streams which contribute to the waters of the Main. The Schussen and the Argen are two small rivers that empty themselves into the Lake of Constance. That lake borders a small part of the kingdom. The Feder Lake, Cattle.

Mountains, Rivers, and Lakes. The cattle in Wurtemberg have been carefully attended to, and the cows especially are of a very good description; which is attributed to the care in improving the breed, and to their being generally stall-fed, or soiled with green food. The butter is excellent, and in many districts good cheese is made; but the last less extensively than, with due pains, it might

Wurtem-  
burg.

be. The sheep have been much improved by constant crossings between the old races of the country and those of the Rousillon and Merino breeds, and now the greater part of the flocks are of the fine-woolled kind. The breed of horses was at one time much improved by the introduction of Holstein and English stallions; of late years they have been retrograding, but the government has now been induced to take steps, by introducing studs of the best horses, for improving them again. The number of cattle, in the year 1820, was thus enumerated: horses 80,870, cows 599,490, sheep 488,940, swine 114,200, goats 16,620, asses 1008.

Fisheries.

The fisheries are very productive both in the lakes and the rivers. The Lake of Constance, especially, affords abundance of salmon-trout, perch, carp, and barbel; the other lakes and the rivers yield trout, eels, barbel, pike, and several other kinds of fish; and in the Feder Lake, the shad is found of a very large size.

Minerals.

The only mines that are extensively worked are those of iron, at Neuhausen, Fluorn, Neuenberg, Aalen, and Wasseralfingen. The ore from these mines is prepared both by smelting and the hammer, and supply the manufacturers of Fredicksthal, Christophsthal, Ludwigsthal Harras, and Heidenheim, with minerals for their cutlery and ironmongery. There are saline springs at Hall, Sultz, Offenau, and Weisbach, from whence is annually made about 8000 tons of culinary salt; and a new spring, lately opened at Kochendorf, promises to afford a more copious supply, so as to dispense with the quantity of that commodity now purchased from the kingdom of Bavaria.

Manufac-  
tures.

The chief manufactory of Wurtemberg is that of linen. The inhabitants of the eastern Alps and of the Black Forest are employed in this branch of industry. In those districts, almost every female is occupied, in the winter, in spinning; and every peasant is a weaver. Both fine and coarse linen is produced, and also diaper and sail-cloth. In Münsengen, there is a manufactory for damask table linen, which produces most excellent goods. In some parts of the kingdom, the females find employment in making a coarse kind of bone lace. The cloth manufactures are inconsiderable, and seem to be far from flourishing; and much of the wool clipped within the kingdom is either exported in the raw state, or, after being spun, to the neighbouring countries. Cotton spinning and weaving have been introduced at several places, but those establishments are in a languishing state. Leather, glass, paper, snuff, beer, hardware, cutlery, with oil, pitch, tar, and potash, are all made in different parts of the kingdom. The breweries, and especially the distilleries, are numerous. In the large village of Mossingen are no less than 280 stills for making brandy and whisky. This is the country for making wooden clocks, and those works produced in Wurtemberg, or from natives of it, who have transferred their labour to other countries, are to be seen in almost every part of Europe.

Commerce.

The chief commerce of Wurtemberg consists in the exchange of its commodities with the adjoining states. It sells to them 18,000 oxen, 12,000 cows, 75,000 sheep and lambs, and 550,000 lbs. of wool more than it buys. The usual export of corn be-

yond the import is 80,000 quarters. The other sales consist of linens, leather, snuff, pitch, tar, potash, oil, and wood, and wooden toys of various descriptions. The imports are silk, cotton wool, East and West India productions, flax, hemp, hides, and salt. The balance of payments is usually in favour of Wurtemberg.

Wurtem-  
burg.

The government of Wurtemberg is at present an hereditary limited monarchy. The King is the sole sovereign, and acts without control, by his ministers, in every executive department. He appoints to all offices, makes war and peace, commands the forces, distributes rewards, confers dignities and honours, executes justice, and dispenses pardons. Under the ancient Dukes, within the original territories of Wurtemberg, there existed a feudal constitution. The States, consisting of fourteen prelates and seventy-one deputies from the cities, exercised some legislative authority; but on the assumption of the kingly dignity, and the addition of the acquired provinces in 1806, the monarch assumed unlimited power; until the termination of the war, and the end of the Congress of Vienna, when a new constitution was promulgated. Two legislative chambers were instituted. The upper was composed of the mediatised princes, the high nobility, and the prelates of the Protestant and Catholic churches; the lower consisted of the deputies from the cities of Stuttgart, Tubingen, Ludwigsburg, Ellwang, Ulm, Heilbron, and Reutlingen, from the learned institutions, and from the several bailiwicks. The privileges of the nobles were thought by themselves to be invaded, and they did not concur in this constitution. Difficulties arose in reducing to practice the project, and how far it may be realized, or how it may ever work, is at present a doubtful matter. In the opinion of some, too much regard has been had to ancient rights and customs, whilst others think that such rights and customs have not been sufficiently respected. The nobility are dissatisfied with the constitution, though it secures to them some exclusive privileges, and exempts them from some descriptions of taxation, and from military conscriptions. The citizens and the peasants have equal rights, and the feudal slavery of the latter, called *Leibeigenschaft*, is universally abolished. All have equal pretensions to public employments, and all the Christian sects enjoy the same rights. The feudal tenures are destroyed, and the estates formerly subject to them are converted into freehold properties.

The administration is executed by six ministers, whose departments are thus denominated,—Justice, Foreign Affairs, Domestic Affairs, War, Finance, and Police. Each of these ministers are at the head of the several Boards which regulate their branch of the executive government. The law is founded upon the ancient feudal principles which prevailed in Wurtemberg at the earliest period, but in some instances tempered by the addition or intermixture of the Roman civil law. The administration of justice in smaller matters, not exceeding five pounds, is executed by provincial judges. There are four superior courts for the four circles; and a supreme tribunal of appeal and revision is established at Stuttgart.

The national income, derived partly from the do-

Wurtemberg  
||  
Yorkshire.

mains of the king, and from direct and indirect taxation, amounts to about 11,000,000 gulden annually. The taxes of late years have been lessened, and the whole administration of the finances much simplified and improved. The amount of the national debt, in 1817, was 30,000,000 gulden, or about L. 3,000,000 Sterling, at which period a sinking fund was established, calculated to liquidate the whole in forty-five years by the application of the surplus revenue. The whole expenditure, as appears by the accounts of 1817, was somewhat under 10,000,000 gulden. Of this, 1,000,000 was appropriated by the king for his civil list, and 650,000 for the other members of the royal family. The State paper, a species of certificate somewhat resembling our Exchequer bills, is nearly equal to metallic money.

Wurtemberg  
||  
Yorkshire.

A new system of weights and measures was introduced in 1807, which is generally adopted now throughout the whole kingdom. It is founded on the old denominations, but adjusted to decimal divisions. The stund or hour is 1300 roods, or 13,000 feet. Two stunden make a mile, equal to the 15th part of a degree of latitude. The rood is 10 feet 100 inches, or 1000 lines. The foot of Wurtemberg is equal to 127 Parisian lines. Square measure is reckoned in Jaucherten (day's work, or man's mowing), which is 1½ morgen, or 384 square roods, each rood being 100 square feet. For measuring corn the scheffel is used. The scheffel is 8 simri, the simri 4 fierlings, the fierling 4 achtel, the achtel 4 ecklein; the simri contains 942 cubic inches. Liquid measure is the eimer, making 16 ini, 160 mass, or 640 schoppen. The mass is 78 cubic inches. The weights are of two kinds, one according to the practice of Nuremberg, the other that of Cologne. The pound of Nuremberg is equal to 32 loths of Cologne.

Weights  
and  
Measures.

Forces. The army is recruited by an annual ballot, to which almost all are subject on attaining their twenty-first year; but from which those are exempt who pay a certain sum into the treasury, or who, on being drawn, provide a substitute. The term of service is six years. The army consists of 12,284 infantry, 3614 cavalry, and 2452 artillery, including officers, the staff, artificers, and the invalids. Besides the regular army, there is a corps of *gens d'armes* under the direction of the police.

Chief Cities. The most considerable cities and their population are the following: Stuttgart, 30,000, including military; Ulm, 11,027; Reutlingen, 8831; Heilbronn,

(w. w.)

Y O R

YORKSHIRE, an English county of more than double the extent of any other of the divisions of the united kingdom that are so denominated. It is not more distinguished by its extent than by the numerous and extensive sources of national wealth which, with the various branches of commerce and manufactures conducted by its inhabitants, contribute to the general prosperity of the empire.

North, and West. The southern part of the county is comprehended within the limits of the East Riding. Each of these Ridings is again divided into *wapentakes* (a name, in the northern equivalent to that of *hundred* in the southern counties), and into a city and several towns, with their contiguous liberties or dependencies, as will be noticed in the account of the separate Ridings.

Extent and Boundaries. Yorkshire is in its greatest length from north to south about 86, and its extreme breadth from east to west about 95 miles. Its surface is calculated to be 5960 square miles, or 3,814,400 statute acres. According to the returns under the late Property-tax, the average rent of the land, including the tithes, was 16s. 10d. *per acre*. This county is bounded on the east by the German Ocean; on the north by the counties of Durham and Westmoreland; on the west by the latter county and Lancashire; and on the south by Cheshire, Derbyshire, Nottinghamshire, and Lincolnshire. The river Tees on the north, and the Humber on the south, are boundaries marked by the hand of nature, and so, in some degree, are the ranges of hills on the western sides; but these last are indefinite, and, like most other divisions of countries, those of Yorkshire are mostly imaginary lines, whose position is chiefly ascertained by local tradition.

In elections for the county the freeholders of the Ridings vote indiscriminately. Hitherto they have returned two members only, but from this time, in consequence of the disfranchisement of the borough of Grampound in Cornwall, and the transfer of the choice of the two members that were returned by it to Yorkshire, the county will return four members to the House of Commons. These, with two each from the city of York, and the boroughs of Aldborough, Beverley, Boroughbridge, Hedon, Hull, Knaresborough, Malton, Northallerton, Pontefract, Richmond, Ripon, Scarborough, and Thirsk, make thirty-two members from Yorkshire. The titles of Peers derived from this county are—Dukes, York, Richmond, and Leeds; Earls, Doncaster (Duke of Buccleuch in Scotland), Scarborough, Pomfret, Beverley, Craven, Mulgrave, and Harewood; and Barons, Hawke, Bolton, Ribblesdale, and Prudhoe.

The whole population of Yorkshire, according to the census of 1821, consisted of 1,173,187 persons, of whom 580,456 were males, and 592,731 females.

Members of  
the Legislature.

Population.

Yorkshire.

The number of *families* were 240,696; of whom 63,830 were chiefly employed in agriculture, 137,011 in trade, manufactures, or handicraft, and 39,818 were not comprised in either of the preceding classes. The West Riding exceeds in population both the others together. Between the years 1811 and 1821, the increase in the population in the East Riding was 14 *per cent.*, in the North Riding 20 *per cent.*, and in the West Riding 23 *per cent.*

Rivers and Canals.

The wealth and fertility of Yorkshire is much promoted by the rivers that in various directions pass through it; and by the several navigable canals, which either unite the different branches of those rivers, or draw from them a supply of water for their immediate use. The Tees forms a boundary to Yorkshire on the side of Durham; but a very small portion of its waters is collected from the former county. In the West Riding, the rivers Ribble and Wenning run to the Irish Sea; they are inconsiderable streams till they enter Lancashire. All the others that have their sources in Yorkshire empty themselves into the German Ocean, in a united river, then denominated the Ouse, through the great estuary, the Humber. The Ouse is composed of the two small rivers, the Swale and the Ure, which unite below Boroughbridge, and soon after receiving the waters of the Nidd, passes by the city of York, to which place it is navigable. It soon after is increased by the reception of the Wharfe on its right bank, and of the Derwent on its left. It then receives the river Aine, whose waters near Snaith have been increased by those of the Calder, and its numerous tributary rivulets; and soon after, on the same bank, the river Don, when its breadth is nearly equal to that of the Thames. The most important canal is the Leeds and Liverpool, which connects together, by internal navigation, the two important ports of Hull and Liverpool; and affords to the manufacturers facilities of exporting their productions from either of those places, as may be most suitable for the various markets to which they are destined. There are several shorter canals which connect the towns with the navigable rivers, or convey from the coal mines their important produce.

North Riding.

The North Riding of Yorkshire is divided into ten wapentakes, two liberties, and the towns of Richmond, Scarborough, and Whitby. The population, in 1821, amounted to 183,381; of whom 90,153 were males, and 93,228 females: the whole number of *families* were 38,731: of whom 16,737 were chiefly employed in agriculture, 11,570 in trade or manufactures, and 10,424 were included in neither of those classes. The largest places, and their population, are the following: Whitby, 12,331; Scarborough, 8533; Northallerton, 4431; Malton, 4005; Pickering, 3555; Richmond, 3546, and Thirsk, 2533. The extent of the Riding has been estimated by Mr Tuke to be 2048 square miles, or 1,311,187 acres, of which 442,565 are uncultivated; the remainder comprises the inclosed lands, open fields, woods, and roads. It is believed, that of the part returned as uncultivated, more than one half might be converted into arable or pasture land.

Face of the Country.

The land on the sea shore is generally lofty, and the cliffs precipitous, varying in height from one

hundred and fifty to nine hundred feet. Within Yorkshire. this narrow sea boundary is a tract called the Eastern Moorlands, about thirty miles from east to west, and fifteen from north to south. It is apparently a barren country, penetrated with some beautiful and fertile vallies, which are, indeed, narrow, but the hills that rise on both sides of them are cultivated nearly to the top. Rosebury-Topping, a mountain, whose summit is 1480 feet above the level of the sea, overlooks the beautiful vale of Cleveland, and the other parts of the western division of this riding, especially the rich and picturesque districts in the vicinity of Boroughbridge and Richmond. The western moorlands are superior in fertility to the eastern. Some of the dales in this district are celebrated for their beauty and fertility, particularly Wensley Dale, Swale Dale, and some of the smaller sheltered spots.

The cultivation varies so much, that it is difficult Agriculture. to give even an outline of the different practices. The greater portion of the land is in pasture. In Cleveland and Rye Dale the best wheats are grown; the average produce is somewhat more than twenty-three bushels to an acre. Barley is not much grown, nor rye, except on poor and sandy soils. Oats are extensively cultivated, and great crops are produced in Rye Dale, and some other of the vales; they are chiefly consumed in the manufacturing districts, where they form the food of the greater part of the labourers. In many parts of this riding, a mixture of wheat and rye is sown; this corn is commonly known by the name of meslin, and is made into flour, from which the bread of almost the whole district is composed. The breeding and fattening cattle, and the operations of the dairy, are of more importance to this riding than the growth of corn. The cows are generally of the short-horned kind, and they are of small size, but clean made, and fine in the bone. The average weight of the oxen, when fat, is about forty stone. The sheep are still mostly of the old large coarse-boned race, but improvements are proceeding by the gradual mixture of the Dishley and Northumberland breeds. The fine wool clipped in this district is mostly consumed in the domestic manufactures of hosiery, in the knitting of which the females are very generally occupied.

The whole of Yorkshire has been long celebrated for its attention to the breeds of horses, but the chief seat for rearing them is in the North Riding. The horses of Cleveland, being clean made, strong, and active, are well calculated for draft; those of the vale of York, by the introduction of the racing blood, are fitter for the saddle. The vales of the eastern moorlands rear many horses of a smaller but useful breed.

The mineral productions of this division of Yorkshire. Minerals. shire are not of great account. To the west of Richmond some lead mines are advantageously worked. Iron and copper have been formerly raised; the former metal is still produced near Whitby and Scarborough, but the mines of the latter are abandoned. Coal is found in various parts of the riding, but the quantity is small and the quality bad; and hence the chief supply of fuel is obtained from Durham. The most valuable mineral production is alum,

**Yorkshire.** which is collected and prepared in large quantities at different works on the northern shore of the riding.

**Commerce.** The manufacturing industry of the district is productive of some very good linens, of rather a coarse quality, of some knit hosiery, and of gloves, made in and around York. The building of ships is an extensive branch of industry, and is carried on upon a large scale at Whitby, and in a smaller degree at other places. On the same part of the coast, the herring fishery gives employment to some thousands of the inhabitants. The town of Scarborough is much frequented in the summer months for the sake of sea-bathing, as well as for some mineral springs which have been discovered in the neighbourhood. Redcar, a small town in the north-east corner of the county, has lately become a place for sea-bathing, and has considerably increased in consequence of it.

**Antiquities.** The most striking remains of antiquity in the riding are Scarborough Castle, and those of the abbeys of Rievaulx, Byland, and Whitby.

**Gentlemen's Seats.** Among a vast number of seats of noblemen and gentlemen, some of the most conspicuous and celebrated are—Bishopthorpe, Archbishop of York; Castle Howard, Lord Carlisle; Duncombe Park, C. S. Duncombe, Esq.; Hornby Castle, Duke of Leeds; Kirkleatham Hall, Sir Charles Turner, Bart.; Marske Hall, Honourable L. Dundas; Mulgrave Castle, Earl Mulgrave; Newby Park, Lord Grantham; Brompton, Sir George Cayley, Bart.; Rokeby, J. B. S. Morritt, Esq.; Gersham, Earl of Darlington; and Aske, Lord Dundas.

**East Riding.** The East Riding of Yorkshire is divided into six wapentakes, city of York, Liberty of York, and a district called the Ainsty of York, the borough of Beverley, and the town and county of Kingston-upon-Hull. The population in 1821 amounted to 190,449 persons, of whom 92,761 were males, and 97,688 females. The whole number of *families* was 40,499; of whom 15,480 were chiefly employed in agriculture, 16,637 in trade, manufactures, or handicraft, and 8382 not comprised in either of the preceding classes. The largest places, and their population, was as follows: York city, 20,787; Kingston-upon-Hull, the borough, 28,591, the country part, 2834, and the adjacent parish of Sulcoates, 10,449; making together 41,874. Beverley has, in the town and liberties, 7503 inhabitants, and Howden 4443; none of the other places contain so many as 3000 persons.

**Face of the Country.** This division of Yorkshire is not marked with any strong or peculiarly striking features, though, in some few parts, the scenery is good, and, including the sea views, the prospects near the coast rather pleasing. The whole extent of this riding is estimated to be about 920,000 acres, being the smallest of the three. The riding may be divided into three parts, as far as regards its productive powers. The first is a tract of level land, extending from the river Humber to nearly the northern boundary of the district. This is in part a rich soil, and, including Holderness, contains some of the best feeding land in this island. The next division is the Wolds, running from north to south, parallel to the former. They are a range of chalky hills, elevated above the

level country about 600 feet. The soil is rather a light and chalky loam, in some places mixed with gravel, in others with clay. The extent is from 300,000 to 400,000 acres. Thirty years ago, a very small portion of these wolds was cultivated; but of late years much of it has been inclosed and converted into corn land. The want of good roads is still felt in this part of the country, though the materials for making such roads are abundant and near at hand. The third natural division of the East Riding extends from the western foot of the wolds to the boundaries of the North and West Ridings. This tract, commonly called the Levels, is every where flat and unpicturesque. The soil is various, but, in general, of a clayey nature; from Gilberdyke to Howden it is very heavy, and though the country is well covered with villages and hamlets, it is extremely dirty, disagreeable, and difficult to travel over.

No part of England shows more proofs of recent agricultural improvements than this riding of Yorkshire; the wolds have been, by paring and burning, changed from sheep pasture into corn-bearing land. In the low lands, also, great improvements have been made; extensive tracts, formerly flooded a great part of the year, and scarcely producing any thing but rushes, have been drained, and are covered with such crops of grain, that the value of the land has been increased in a most extraordinary degree. The wolds, in their former state, were very well adapted for breeding horses; but in their present improved state, are more profitable as affording pasture for sheep, and as growing corn. The warrens for rabbits were formerly very numerous and extensive, but are now, for the most part, more productive by being covered with herbage of a better quality. The farms, especially on the wolds, and in the southern parts of Holderness, are generally large, renting from L.200 to L.2000 *per annum*. The climate of the East Riding varies considerably. Near the coast, the air is cold, and frequently charged with dense fogs. On the wolds, the cold is more severe, and the snow lies longer; but to the westward of the hills, the air is warm, moist, and tends to produce agues. There are no mines in this riding, nor any manufactures, except it be the spinning of flax, which is performed by the ancient method, and is carried on by all the females in the farming houses at their leisure time. The foreign and internal commerce of the riding is wholly carried on through the port of Hull, a place which has thriven during the last forty years as much as any portion of the kingdom. During that period, its population has been more than doubled, and its mercantile shipping and other property been increased far beyond that ratio.

Extensive docks have been constructed for the reception of vessels, and for affording facilities in the landing and storing their cargoes. Around these docks a new town has arisen, on what was formerly a swamp, which surpasses the ancient part in cheerfulness and beauty. The foreign trade of Hull consists in the importation from Russia, Sweden, and Denmark, of naval stores, and the other productions of those countries, and in the exportation to them of the manufactured goods produced in the counties of York, Lancaster, Derby, Cheshire, and Nottingham,

Yorkshire.

Yorkshire. with which the town is connected by means of canal and river navigation. The same description of trade is carried on betwixt Hull and the ports of Holland and Germany, as exists betwixt it and the towns on the Baltic Sea. Although these are the most ancient and the most natural sources of the commerce of Hull, yet it is by no means confined to them. Considerable trade is carried on with the United States of America, with the West Indies, with the ports of the Mediterranean, with Spain and Portugal, and recently with South America. The building and equipping of ships is a source of great employment, and some ships as large as of 74 guns have been built here during the war. Many vessels belonging to Hull ship-owners are to be hired for freight, and may be found in almost every part of the globe. The whale-fishery has, from the first years of the discovery of Greenland, been pursued by the inhabitants of Hull; but with pre-eminence ever since the year 1766, when an individual merchant of that town gave an impulse to that branch of industry by which its prosperity has been much promoted. The internal trade through Hull is of great extent; the calculation of the amount of the goods passed through it to and from the interior, by means of the rivers and canals, makes it upwards of L.15,000,000 Sterling annually.

The fishing for herrings is carried on, though to a small extent, in some of the coast towns of this riding.

Interesting  
Objects.

The most interesting objects in this division of Yorkshire are, the natural caves at Flamborough Head; York Minster; Howden Church; Kirkham Priory; Bridlington Priory, and Trinity Church in Hull.

The most distinguished seats of noblemen and gentlemen are, Wressle Castle, Lord Egremont; Birdsall, Lord Middleton; Boynton, Sir William Strickland; Cave Castle, H. B. Barnard, Esq.; Burton Constable, Francis Constable, Esq.; Ferriby, Sir H. Etherington; Hotham, R. C. Burton, Esq.; Ragwell, D. Sykes, Esq.; Sledmere, Sir M. M. Sykes, Bart.; Woodhouse, Robert Denison, Esq.; Melburn, Sir Henry Vavasour, Bart., and Scampson, Sir William St Quintin, Bart.

West  
Riding.

The West Riding of Yorkshire is by far the most important, whether as regards its extent, population, activity, or wealth. It is divided into nine wapentakes, and into a small district denominated the Ainsty of York. The population in 1821 amounted to 799,357 persons; of whom 397,542 were males, and 401,815 females. The whole number of families was 161,466; of whom 31,613 were chiefly employed in agriculture, 108,841 in trade, manufactures, or handicraft, and 21,012 were not comprised in either of the preceding classes. The great increase of inhabitants in the West Riding of Yorkshire has chiefly arisen from the various manufactures which have been established there in consequence of the cheapness of fuel, and of the numerous rivers, whose streams are calculated to turn powerful machinery. It has hence followed, that the greater numbers of the people are in townships and parishes rather than in what can properly be called towns. Many of these parishes are continued

streets of buildings, but more of them are scattered Yorksh. clumps of houses, each known by some designating name. The population of the towns and parishes of more than 5000 souls are as follows:—Halifax town, 12,628; the whole parish which, in 1811, contained 73,415 persons, had increased, in 1821, to 92,850; Leeds town and liberty, 83,796; Sheffield town, 42,157; but the parish, 52,105; Bradford town, 13,064; but the parish, 62,954, though, in 1811, only 36,358; Huddersfield parish, 24,220; Almondbury, 23,979; Wakefield, 22,307; Kirk-Heaton, 21,870; Birstall, 21,217; Dewesbury, 16,261; Calverley, 14,134; Kirk-Burton, 13,695; Ripon, 13,096; Ecclesfield, 12,496; Rotherham, 9633; Otley, 9358; Keighley, 9223; Doncaster, 9117; Pontefract, 8824; Guisley, 8409; Barnsley, 8284; Bingley, 7375; Rothwell, 6253; Thornhill, 5458; Skipton, 5479; Knaresborough, 5283, and Mirfield, 5041.

The West Riding is about 95 miles in length Face of the from east to west, and about 48 in its greatest Country. breadth from north to south. The square extent is estimated at 2500 miles, or 1,568,000 statute acres. The face of the country furnishes scenes strikingly contrasted. The eastern portion stretched along the banks of the Ouse is generally a flat, moist, and marshy district, in some parts fruitful, but in all uninteresting to the tourist. The middle part, as far as Sheffield, Bradford, and Otley, is an undulating country, finely varied, and rising gradually till it reaches the most western portion, which is very rugged and mountainous. Beyond Sheffield black moors are the only objects, till Blackstone Ledge is reached, on the confines of Lancashire. The western part of Craven presents heaps of rocks and mountains in the most picturesque forms and situations. Among these Pennygant, Wharnside, and Ingleborough, the most conspicuous, may be considered some of the loftiest mountains in England. According to the *Trigonometrical Survey* of Colonel Mudge, the height of Wharnside is 2263 feet, of Pennygant, 2270, and of Ingleborough, 2361. Amidst the hilly and mountainous tracts of this riding are many romantic and some sequestered valleys, presenting the most beautiful scenery. The most extensive of these are Netherdale, watered by the Nid; Wharfedale, and the vale of Aire; but many of the smaller vales vie with them in picturesque beauty; and, being generally inclosed, well wooded, and thickly studded with villages and houses, present, from the surrounding eminences, most enchanting prospects; combining often in the same view the most sublime and the most lively of rural scenery. The roads from Knaresborough or Ripon to Pateley Bridge; from Tadcaster to Otley and Skipton; from Leeds, by Bradford and Keighley, to Skipton; from Bradford to Halifax, and from Halifax, by Dewesbury, to Wakefield, unfold some of the finest scenery that can be seen in this island. The climate of this riding is very much varied; in the eastern part near the Ouse it is warm and moist; in the middle district the air is sharp, clear, and generally considered healthy; in the western parts the climate is cold, tempestuous, and rainy. The mountains of Craven and the moors near Blackstone Ledge are the most foggy, rainy, and stormy dis-

Yorkshire. tricts in England, though the climate is considered to be salubrious to those of sound constitutions, and the inhabitants have a robust and healthy appearance.

Yorkshire. although there are many in other parts of the riding. Iron is found in the greatest quantities near Bradford, and often in the same mine with coal. The best strata of coals are those found under the seams of iron, at a depth of from 220 to 240 feet below the surface. The chief mines of lead are at Grassington, a manor belonging to the Duke of Devonshire, about ten miles to the westward of Pateley Bridge.

Agriculture and its Productions. A very great portion of the land of this riding is possessed by small proprietors, although some few noblemen have extensive tracts of land. Most of the occupancies are rather small; none are large; the greater part are less than fifty acres. A great part is kept exclusively in grass, and used for the dairy, or for fattening cattle. On the arable lands a greater quantity of wheat is raised than of any other grain. It is mostly of the red kind, and is sown after fallow or turnips, but sometimes on a clover ley. Rye is not cultivated to any great extent. Barley is raised in much less quantities than wheat. Oats are cultivated to a great extent, but little attention is paid to procuring the best seed, though oatmeal forms the chief part of the food of the inhabitants, especially in the more western parts of the riding. Pease are not much raised, nor beans, except on the moorish soils near the Ouse. The turnip husbandry is not so extensively practised as good farming requires, and where it is pursued, it is generally executed in a slovenly and imperfect manner. Great crops of potatoes are raised in the part of the riding below the junction of the river Aire with the Ouse. In the same part of the country much flax is grown, the preparation of the land for which employs the labour of many hands, as does the dressing and preparing the article for market. Rape for making oil, and woad for the dyers, are both cultivated in this riding, but not to any great extent. The waste lands in the West Riding were estimated about twenty-five years ago at 400,000 acres, of which 250,000 were considered capable of profitable improvement, and the rest fit for no other purpose but that of planting. Since that period much marsh land has been drained, many commons inclosed, and some bleak hills planted with Scotch firs and larches. Vast improvement has been made on some large tracts of land by the operation locally called *warping*. It is performed by permitting the river, at the highest of the tide, to overflow the land. The rich mud with which the turbid rivers abound is deposited on the surface, and each return of tide increases the earth thus deposited, so that a depth of alluvial soil of fourteen inches has been raised by this means on a field which previously was scarcely of any value. The lands thus improved are so enriched, that they will yield abundant crops for several successive years without any manure. The horned cattle, sheep, and horses of the West Riding have no distinguishing characteristics, but vary in kind as in the other two ridings. There is not here the same care exercised in improving the breed of horses as in the other two divisions of Yorkshire.

Manufactures. The great branches of industry which have so rapidly peopled, and so vastly enriched the West Riding of Yorkshire, are the several manufactures that have been established in every part of it. Scarcely a hamlet or even a house is to be found wherein some part of one or other of the occupations of manufacture, or of those subservient to it, are not seen in different stages of progress. The iron and other hardware goods are produced at Sheffield, Rotherham, and all the villages in the vicinity of those towns. A little to the northward the large towns of Leeds, Halifax, Bradford, Huddersfield, Wakefield, and the overflowing villages of Almondbury, Kirk-Heaton, Birstall, Dewesbury, with many other places, are devoted to the production of woollen, worsted, cotton, and some linen goods. To name every description of these goods which are perfected in this district, would be to enumerate the whole catalogue of British manufacture. The manufactures have enriched, to an almost incredible extent, the soil in the vicinity of the towns in which they have been expanding, and increased the population in a corresponding ratio. Whilst in the period from 1811 to 1821 the population in the East Riding of Yorkshire, which is an agricultural country, has increased 14 *per cent.*; in the West Riding, as has been before noticed, in the same period it has increased 23 *per cent.*

Antiquities. The most remarkable remains of antiquity in this riding are Selby Abbey, Knaresborough Castle, Fountain's Abbey, Skipton Castle, Bolton Priory, Kirkstall Abbey, Conisbrough Castle, and Roche Abbey.

Gentlemen's Seats. In proportion to the great extent of the West Riding of Yorkshire, it contains more seats of noblemen and gentlemen of distinguished beauty than any other part of Great Britain. Our limits do not allow of our even noticing one tenth part of them, but the most remarkable are the following: Wentworth House, Lord Fitzwilliam; Harewood, Lord Harewood; Farnley Hall, Walter Fawkes, Esq.; Ripley Castle, Sir William Ingilby; Thundercliffe Grange, Lord Effingham; Methley Park, Lord Mexborough; Gisborne Park, Lord Ribblesdale; Brodsworth, Lord Rendlesham; Sandbeck, Earl Scarborough; Studley Royal, Miss Lawrence; Ribstone Hall, Sir Henry Goodricke, Bart.; Copgrove, Henry Duncombe, Esq.; Bramham Park, James Lane Fox, Esq.; Ledstone Lodge, M. Angelo Taylor, Esq.; Wentworth Castle, Henry Vernon, Esq.; Cusworth Hall, William Wrightson, Esq.; and Campsall, Bacon Frank, Esq.

Minerals. In this division of Yorkshire the mines produce great quantities of coal, ironstone, and lead, and vast quarries of limestone. The coal and limestone, indeed, appear to be almost inexhaustible. The limestone district commences on the tract between Doncaster and Tadcaster, and extends to the western limits of the county. The coal mines are most numerous between Leeds and Wakefield, and in the neighbourhood of Bradford, Barnsley, and Sheffield,

## Z A I

Zaire.

ZAIRE, a very considerable river of Southern Africa, sometimes called *Congo*, from the district of that name in the possession of the Portuguese, through which it flows and discharges a large volume of water into the Southern Atlantic, in latitude  $5^{\circ} 50'$  south, longitude  $12^{\circ} 40'$  east.

It may be noticed, however, that the word *Zaire*, like those of *Nile* or *Ganges*, is a general appellation for any great river, and that the proper name of the one in question is *Moienzé Enzaddi*, the *Great River*, or the river which absorbs all other rivers.

There are some peculiarities in the lower part of the Zaire which had long attracted the attention of English traders; but owing to the combined effects of Portuguese jealousy, ignorance, and total indifference to all research which had for its object the extension of human knowledge, the baneful influence of which is felt in all their foreign establishments, nothing whatever was known of its source, or even of the general direction of its course through the continent, beyond some 80 or 90 miles from its mouth.

The accounts that had been given by early writers of the violence and impetuosity of its current, which was said to carry its waters perfectly fresh for twenty leagues into the sea, and the unfathomable depth of its channel, drew from Purchas, the quaint compiler of the *Pilgrimage*, the following amusing description, in his usual and best style: "The Zaire is of such force, that no ship can get in against the current but near to the shore; yea, it prevails against the ocean's saltness threescore, and as some say, fourscore miles within the sea, before his proud waves yield their full homage, and receive that salt temper in token of subjection. Such is the haughty spirit of that stream, overrunning the low countries as it passeth, and swollen with conceit of daily conquests and daily supplies, which in armies of showers are, by the clouds, sent to his succour, runnes now in a furious rage, thinking even to swallow the ocean, which before he never saw, with his mouth wide gaping eight and twentee miles, as Lopez affirmeth, in the opening; but meeting with a more giant-like enemy, which lies lurking under the cliffs to receive his assault, is presentlie swallowed in that wider wombe, yet so, as always being conquered, he never gives over, but in an eternall quarrell, with deepe and indented frownes in his angry face, foaming with disdain, and filling the aire with noise (with freshe help), supplies those forces which the salt sea hath consumed."

The first correct account of its real magnitude and velocity was given by Mr Maxwell, who, in the capacity of an African trader, resided in the country, and surveyed the lower part of it. The tendency of its channel to a northerly direction, the times of its flooding, and the great body of water which it discharged, induced him to think that it might be a prolongation of the Niger,—an idea which the late Mungo Park caught up and warmly adopted in the progress of his last unfortunate attempt to solve the problem of the course and termination of this mys-

terious river. Park had learned from a native of Kashna, that the Joliba, near that city, took a direction towards the right hand; and if so, it was not unnatural to conclude, that, if one great river ran to the southward without any known termination, and another great river came from the northward, whose source was equally unknown, there was at least a probability that they might be one and the same river. And as there was not the shadow of any information which tended to refute this supposition, and as the hypothesis involved no physical impossibility, while many plausible arguments were offered in favour of it, the Board of Admiralty, with that readiness which it has always shown, since the conclusion of the war, to afford opportunities for correcting and extending our geographical knowledge, sent out a small vessel, together with a transport, under the command of Captain Tuckey, with the view of tracing the course of the Zaire as far as it might be practicable. On the arrival of the vessels, destined for the examination, opposite to the mouth of the Zaire, they experienced no little difficulty in getting within it against the stream of a rapid current; and they found that the accounts given of the turbid water, the floating islands covered with trees and bushes, which had been torn from its banks and washed down into the sea, had not been greatly exaggerated. The rapidity of the current between the two headlands which form its mouth, being generally at the rate of five or six miles an hour, renders it impossible to obtain soundings. In the chart of Mr Maxwell, the mid channel is marked at 100 fathoms; but Mr Fitzmaurice, the master of the *Congo*, employed on the expedition, could get no bottom with 160 fathoms, at the distance of 25 miles above the mouth: where the river is contracted to something less than three miles, the depth was still found to be about 100 fathoms. At 50 miles, the stream is broken and interrupted by rocks and islets, and divided into a number of branches; but at 90 miles, it was again found to be one channel of a mile to a mile and a half in width, and of various depths, from 50 to 30 fathoms; and this depth and width it maintains as high up as Point *Sondie*, 140 miles from its mouth. Here it suddenly contracts its stream to the width only of 400 or 500 yards, and continues so to a place called Inga, about 40 miles above *Sondie*; being bristled all the way with rocks, so as to be unnavigable except by boats, and that not without difficulty and considerable danger.

The banks by which the river is thus contracted are composed of slate, and every where precipitous. In numerous places, ledges of slate cross the river from bank to bank, forming rapids or cataracts, known to the natives by the name of Yellala. That which first occurs is the highest and the most formidable of these barriers; being a sloping bed of mica slate, over which the river falls from a height of about 30 feet perpendicular, in a slope of 300 yards. In the low state of the river when Captain Tuckey visited it, this Yellala scarcely deserved the name of cataract; but it was said by the natives to make a

Zaire.

Zaire.

tremendous noise when swelled by the rains. Compared with Niagara (says Captain Tuckey), it was a mere brook bubbling over its stony bed. One thing, however, surprised the party; it was, that the quantity of water which fell over the ledge was but a small portion of the volume below; and the only explanation which offered itself to them was, that a subterranean communication existed between the upper and lower part of the cataract beneath the sloping bed of slate.

At Inga, where the narrows terminate, the river once more became navigable, and stretched out into a magnificent sheet of water, expanding to the width of two, three, and even more than four miles, flowing with a gentle current of two to three miles an hour. Thus it continued to the distance of about 100 miles beyond Inga, or 280 miles from Cape Padrou. Here, however, the whole party were compelled to stop, partly from sickness, but chiefly because the natives refused to accompany them farther. At this place it is said the river had "a most majestic appearance; that the scenery was beautiful, and not inferior to any on the banks of the Thames; that the natives of this part all agreed in stating, that they knew of no impediment to an uninterrupted navigation of the river upwards; that at no great distance it divided into two branches; and that there was only one obstruction in the north-eastern branch, occasioned by a single ledge of rocks, forming a kind of rapid, over which, however, canoes were able to pass."

All this, under more prosperous circumstances, would have held out the strongest inducement to proceed; but it was found impossible, and, therefore, the question of the identity of the Niger and the Zaire was left pretty much in the same state of uncertainty as it was before the expedition. Little doubt, however, seemed to remain on Captain Tuckey's mind, that the north-eastern branch had its source in Northern Africa; for he observes, that, "Combining his observations with the information which he had been able to collect from the natives, vague and trifling as it was, he could not help thinking that the Zaire would be found to issue from some large lake, or chain of lakes, considerably to the northward of the line." He was the more inclined to this opinion, from the low state of the river, even so late as August; and he adds, "Should it begin to swell in the early part of September, an event I am taught to expect, I shall conclude that my hypothesis is correct." It did begin to swell at the period anticipated, and he notes down in his journal, in two words, "Hypothesis confirmed." The idea of its flowing out of a lake seems to have arisen from its "extraordinary quiet rise," which was only from three to six inches in twenty-four hours; whereas, had the swelling of the river been occasioned by rains falling to the southward of the line, and by the pouring into its channel of mountain torrents, the rise must have been sudden and the stream impetuous; but coming on, as it did, in a quiet and gradual manner, it was concluded that it could proceed only from the gradual overflowing of a lake.

Thus, the course of the Niger still remained

1

Zaire.

as a matter of speculation, and the swamps of Wangara (a name no longer known in Africa), the Bahr el Abiad, the Zaire, and the Rio Formosa and other sluggish waters which are discharged into the Bight of Benin and Biafra, continued each to have their advocates. The two latter hypotheses must, however, now be for ever abandoned. The accounts which have recently been received from the African travellers, Oudney, Clapperton, and Denham, set the question completely at rest, as far as the Zaire and the Rio Formosa are concerned. We may now safely say, that these waters are completely divided from those of the Niger by a barrier of lofty primitive mountains, from the southern side of which they undoubtedly receive their supply of waters, as the Niger and the lake of Bornou receive theirs from the northern side.

Having disposed of the Atlantic rivers, it remains only to be shown what progress has been made in determining the course and termination of the Niger beyond Timbuctoo; indeed, we may say, beyond Houssa, for to that extent it has unquestionably been traced in its easterly course, by every modern authority, written and verbal. By Houssa must be understood, a considerable tract of country to the northward of the Niger, interjacent between Timbuctoo and Bornou; of which Kashna or Kasina is the capital. Considerable light has been thrown on this part of Northern Africa by a native of the above mentioned city, who has recently left Cape Coast Castle with Belzoni on his journey home. This man had served many years in the British navy, under the name of William Pasco, but his real name is Abou Beker. By his own account, he travelled with a party of merchants from Kashna, or, as he calls it, Birnie-Kashna, to the Bight of Benin. To the southward of this city, and at the distance of four long days' journey, or about 100 miles from it, they crossed the *Quarra-luan-dadi*, or river of fresh water, which he describes to be as wide as the Gambia at St Mary's, running to the eastward. Five days further, still travelling south, they crossed a deeper and broader stream, also running east, called the *Gulbi*, which passes through the countries named *Guari* and *Nooffi*; and he has been told, and believes, that these two rivers unite at *Zugum* near *Kaba*, and proceed towards the rising sun to Birnie-Bornou. Several days after this, they reached a high range of mountains, one part of which had the top white like marble, and in its appearance resembled *Fogo*, one of the Cape de Verd Islands. Having crossed the mountains, and a small river called *Echoo* running at their feet, they saw the sea; and continuing their route towards the setting sun, having the sea in sight at intervals on the left hand, in ten days he reached Annamaboo on the coast, and entered on board his Majesty's ship the *Lille Belt*.

Abou Beker is represented as an intelligent man, and the account he gives of his journey is considered by the writer of a late article in the *Quarterly Review*, on the progress made by our African travellers, as worthy of credit. No other river than the two branches he mentions intervened in his route to the southward; and this corresponds

Zaire.

with the account given by Major Denham of his route in the same direction, but on a more easterly meridian, who met with nothing like a stream in travelling directly south between the river Yaou, in latitude  $13^{\circ} 30'$ , and a part of the chain of mountains crossed by Abou Beker, in latitude about  $10^{\circ} N$ .

This Yaou is, in fact, the only stream of water that occurred to our travellers between Mourzouk and the mountains above mentioned, and cannot possibly therefore be any other than the Niger or Joliba; unless we are to suppose this river to have sunk or been evaporated before it reaches thus far to the eastward. Indeed, it appears, from the latest letters received from Dr Oudney, dated in July last (1823), that they had followed up the Yaou 200 miles to the westward, and found it sometimes a stream between deep banks, and at other times swelling out into small lakes. As Noofi, or the lake of Soudan, into which the Niger is known to fall, could not be more than 100 miles from the spot to which the party proceeded westerly, there can scarcely be a doubt that the Yaou and the Niger are identical. Beker states, he has often heard his grandfather say, that Birnie-Bornou was about fifteen days' journey from Birnie-Kashna towards the rising sun, which accords pretty well with the accounts given by Hornemann and others. This traveller (Hornemann) names the river in that part of its course where it enters Bornou the *Zad*; and says (what is now confirmed) that it falls into a large lake, which Burkhardt states to be in Bornou, and that it is a fresh water lake.

It will be seen that under the Article AFRICA it is stated, as a speculation grounded upon the reports of various travellers, that a great lake or inland sea would one day be found in some part of Northern Africa, as a common receptacle of the several rivers, of the course of which so many contradictory statements have been given. It was not pretended to assign the precise situation of this lake, but it was conceived it might be somewhere "in an extensive tract of desert, immediately to the east of the modern position of Houssa;" meaning thereby to the eastward of Kashna. That lake is no longer a matter of speculation but of fact. Dr Oudney and his companions fell in with it at a place called *Lari*, the frontier town of Bornou, in latitude  $14^{\circ} 40'$  north, longitude  $13\frac{1}{2}$ , being very nearly in the same meridian with Mourzouk. Its name is the *Tsaad*, being the same as that given to the river which falls into it about sixty miles farther south, by

Hornemann and Burkhardt; but which, as already mentioned, is called by the present travellers the *Yaou*. The western shore of the lake was traversed not less than 220 miles, in a direction almost due south; and at the southern extremity a large river of the name of *Shari*, a full mile in width, was found to flow into the lake in latitude about  $11^{\circ} 30'$ . It came from the south, and undoubtedly had its rise in the great chain of mountains visited by Major Denham, and crossed by Abou Beker. How far the lake *Tsaad* may extend to the eastward is yet uncertain; but it is to be hoped, that the next accounts from the travellers will settle this interesting point, and determine the question whether, on that side, a river flows out of it in an easterly direction towards the Nile of Egypt, or that it is the great sink of Africa, receiving its waters from all directions. It is said that no mention is made whether the waters of the *Tsaad* be fresh or salt; the very omission of which we think is decisive of its being fresh; and if so, there is certainly a strong probability of its having an eastern outlet; a circumstance which would afford an equal probability of the identity of the Niger and the Nile, their union being effected through the channel of the Bahr el Abiad: for, in such a climate, and such a soil as those of central Africa, every lake without an outlet must be more or less salt, like the lake Asphaltites, and the numerous salt lakes of Persia. As the country all around, for many hundred (perhaps thousand) miles, is a dead flat, stated to be from 1200 to 1500 feet above the level of the sea, we want only to ascertain the level of the plain of Sennaar, where the Bahr el Abiad joins the Nile, to determine at least the possibility of the waters of the *Tsaad* emptying themselves into the Mediterranean.

We shall here only add, that the *Tsaad* must be of very considerable extent to the eastward, as a set of ferocious people, of the name of *Buddooma*, inhabiting some of its islands, come on rafts from that quarter, and carry off women, children, and cattle, from the western shores of the lake, beyond the possibility of their ever being recovered; at least, hitherto, the people of Bornou, who have boats sewed together from forty to fifty feet in length, have never ventured far enough to discover their haunts. Beautiful little islands, covered with the Papyrus, are seen floating about the lake in various directions, according to the quarter from which the breeze blows. (κ.)

$$\left. \frac{3}{4(hl \frac{1}{y})^2} - \frac{3.5}{8(hl \frac{1}{y})^3} \dots \right)$$

See Méc. Cél. X. p. 253.

No. 572. read  $\int e^{x^m} dx = e^{x^m} x - e^{x^m} \frac{m}{m+1} x^{m+1} + \dots$

Add—Some other similar fluents of logarithmic quantities may be found in the *Journal* of the Royal Institution for October 1823.

**INTERPOLATION.** Few disquisitions in modern mathematics have greater practical utility than those concerning the extension and interpolation of the terms of numerical progressions. But the modes of solution generally proposed, however ingenious and refined, are often too complex for ordinary purposes. We therefore avail ourselves of this opportunity to point out a procedure of extreme simplicity and most ready application. It will embrace any system of numbers, but seems peculiarly fitted for the computation of logarithms.

Napier first published, in 1614, his canon *Mirificus Logarithmorum*, comprised in a very thin and small quarto volume, exhibiting, as far as seven places, the logarithms only of the sines and tangents to every minute of the quadrant; those of the ordinary numbers being left to be deduced from the nearest sines or tangents. In the summer following, Briggs, then Professor of Geometry in Gresham College at Lon-

don, who was enchanted by that noble discovery, paid a visit to its illustrious author at Merchiston, in the vicinity of Edinburgh. During an agreeable stay of a month, it was concerted between them, to change the natural system of logarithms into another of a more artificial form, but adapted to our denary scale of notation, the labour of the calculation, however, being devolved upon Briggs, as younger and enjoying robust health. Next season, Briggs performed a second journey to Edinburgh, and showed to Napier a table which he had computed of the new logarithms for the first chiliad or thousand of the series of natural numbers. But the great inventor was now fast declining in years, and expired on the 3d of April 1618. Briggs employing most skilfully all the abbreviations which ingenuity could devise, prosecuted his most arduous task with such vigour and active perseverance, as to compute, in the space of seven years, to fourteen places of figures, not only the logarithms of

Interpolation.

the sines and tangents of every degree and centesimal minute of the quadrant, but also the logarithms of thirty chiliads of numbers. These tables were printed, in 1624, in a *folio* volume, entitled *Arithmetica Logarithmica*. In his anxiety, however, to bring out this stupendous work, Briggs contented himself with calculating the logarithms from unit to 20,000, and from 90,000 to 100,000, leaving the computation of the seventy intervening chiliads to be afterwards supplied. The very ingenious author annexed a full explanation of his mode of framing the tables, grounded chiefly on the consideration of differences, and he thus traced the first steps of that important theory. But he likewise gave instructions for the reader filling up of the intermediate logarithms, abridging the toil of calculation no doubt, yet detailing a procedure sufficiently irksome and complicated. "To encourage some skilful persons to perform this task, he offered to furnish them with paper he had by him, ready prepared, and divided into columns proper for that purpose, as likewise to inform them at what part to begin, that they might not interfere one with another; and promised, when the whole was finished, to endeavour to procure a new edition of the work so completed." This slender boon seems not to have tempted the mathematicians in England. In Holland, however, Adrian Vlacq, chancing to meet two years afterwards with a copy of the work, and prompted only by his patriotic zeal, had the resolution to revise and compute the whole canon, reducing it to ten places of figures, which he printed in *folio* at Gouda, as early as 1628. The same able calculator, only five years afterwards, published, likewise in *folio*, at Gouda, a very extensive system of logarithmic sines and tangents, to every ten seconds of the quadrant, having restored the sexagesimal subdivision, which Briggs had partly changed into a centesimal one. These two volumes may be deemed a precious *thesaurus* of logarithms, from which succeeding compilers have drawn very liberally. They form the basis of the *Tables* published by Vega at Leipzig in 1794, which are esteemed the best and completest now extant.

But though the *Tables* of Vlacq, carried only to ten places of figures, are sufficiently accurate for every ordinary purpose, and even for the most delicate calculations in astronomy, yet many persons have often regretted that the original system of Briggs was never completed. The celebrated Legendre has employed that table, imperfect as it is, in some of his most refined numerical investigations. It is well known that Mr Baron Maseres devoted a considerable portion of his time, and of his fortune, to the republication of the works of the early writers on logarithms. In the course of this extensive undertaking, he entertained some thoughts of giving a new edition of the *Arithmetica Logarithmica*, and expressed an earnest wish that the vacant chiliads were filled up. To promote the liberal designs of the Baron, the Author of this Article was induced to bestow some reflection on the subject, and a very simple mode occurred to him, which would have reduced the labour of computing those logarithms to little more than the trouble of mere transcription. But

the project of completing the canon was deferred for a time, and afterwards gradually forgotten. The method of interpolation then proposed seems, however, to deserve notice on account of its great simplicity, and its ready application, not only to the immediate object, but to other questions of a similar nature. We shall, therefore, now state the principle, and illustrate its application by a few examples.

The square root of the quantity  $a^2+1$  is evidently expressed by the continued fraction  $a + \frac{1}{2a+1}$   
 $\frac{1}{2a+1}$  &c.

If two terms only of the fractional part be taken, the expression will become  $\sqrt{a^2+1} = \frac{4a^3+3a}{4a^2+1}$ , and consequently

$$\sqrt{\left(\frac{a^2+1}{a^2}\right)} \text{ or } \sqrt{\left(\frac{2a^2+2}{2a^2}\right)} = \frac{4a^2+3}{4a^2+1},$$

a very near approximation. Put  $b=2a^2$ , and by substitution  $\sqrt{\left(\frac{b+2}{b}\right)} = \frac{2b+3}{2b+1}$ ; wherefore

$$\frac{1}{2} \log. \frac{b+2}{b} = \log. \frac{2b+3}{2b+1}. \text{ Hence half the alternate}$$

differences of the logarithms of the series  $b, b+1, b+2, \&c.$  added to the logarithm of  $2b+1$ , must give the logarithm of  $2b+3$ . By this simple process then, any table of logarithms is carried to double its actual extent through all the odd numbers, those of the even ones being found by the mere addition of the logarithm of 2.

To find the limits of approximation, let three terms

of the fractional series be taken, and  $\sqrt{\left(\frac{a^2+1}{a^2}\right)} =$

$$\frac{8a^4+8a^2+1}{8a^4+4a^2}, \text{ or } \sqrt{\left(\frac{b+2}{b}\right)} = \frac{2b^2+4b+1}{2b^2+2b} =$$

$$\frac{2b+3}{2b+1} \left( \frac{4b^3+10b^2+6b+1}{4b^3+10b^2+6b} \right) =$$

$$\frac{2b+3}{2b+1} \left( 1 + \frac{1}{(2b+3)(2b+1)b} \right). \text{ Whence}$$

$$\frac{1}{2} \log. \left( \frac{b+2}{b} \right) = 1. \frac{2b+3}{2b+1} + 1. \left( 1 + \frac{1}{(2b+3)(2b+1)b} \right);$$

and, therefore, since this last quantity exceeds unit only by a very minute difference,  $\frac{1}{2} \log. \frac{b+2}{2} =$

$$\log. \frac{2b+3}{2b+1} + \frac{M}{(2b+3)(2b+1)b}, \text{ where } M \text{ denotes the}$$

modulus of the system. If the number  $2b+3$  or  $2b+1$  be expressed by  $N$ , this small correction will amount

$$\text{but to } \frac{M}{\frac{1}{2}N^3} \text{ or } \frac{2M}{N^3}. \text{ Consequently } \log. \frac{2b+3}{2b+1} =$$

$$\frac{1}{2} \log. \frac{b+2}{b} - \frac{2M}{N^3}. \text{ It may hence be computed, that}$$

the correction on the first approximation will only reach unit in the last figure for the numbers un-

**Interpolation.** der 206 in tables of seven places, for those under 2055 in the tables of ten places, and for the numbers under 44286 in tables extending to fourteen places.

Whence are derived,

**Interpolation.**

The corrections needed in Briggs's *Tables* will therefore correspond to these limits,

35150	— 2	23151	— 7
30706	— 3	22143	— 8
27899	— 4	21290	— 9
25898	— 5	20557	— 10
24372	— 6	19913	— 11

Suppose it were required to find the logarithms of the odd numbers above 300, to seven places of decimals. Assuming the logarithms of the series of half those numbers, let their alternate differences be taken, and these again bisected.

Numbers.	Logarithms.
4001	3.8021885514 2170387
4003	3.6023855901 2169303
4005	3.6026025204 2168220
4007	3.6028193424 2167139
4009	3.6030360563

Numbers.	Logarithms.	Alternate Differences.	Their Halves.
150	2.1760913		
151	2.1789769		
152	2.1818436	57523	28761
153	2.1846914	57145	28572
154	2.1875207	56771	28386
155	2.1903317	56403	28201

Hence the logarithms of the doubles are formed by the mere addition of these halves.

Again, to compute the logarithms in Briggs's Canon.

Numbers.	Logarithms.
301	2.4785665 28761
303	2.4814426 28572
305	2.4842998 28386
307	2.4871384 28201
309	2.4899585

In this manner, the operation may be continued; but, to prevent any accumulation of errors, the logarithms of the composite numbers should serve as standards, being formed by the addition of the logarithms of their several factors. The logarithms of the intermediate even numbers, 302, 304, 306, 308, and 310, are easily determined by adding .3010300 to the logarithms of 151, 152, 153, 154, and 155.

To extend the process a little farther, let Vlacq's logarithms be computed for the numbers above 4000.

Num- bers.	Logarithms.	Alternate Differences.	Their Halves.
9995	3.99978279845413		
9996	3.99982624745441		
9997	3.99986969210827	8689365404	4344682707
9998	3.99991313241658	8688496217	4344248108
9999	3.99995656838020	8687627193	4343813596
10000	4.00000000000000	8686758342	4343379171
19991	4.30083451916161 4344682696		
19993	4.30087796598857 4344248097		
19995	4.30092140846954 4343813585		
19997	4.30096484660539 4343379161		
19999	4.30100828039700		

The additive parts here consist of those differences diminished by 11 and the last one by 10, since the numbers now approach to the limit 20557.

The first mode of interpolating, thus derived from the nature of logarithms, and so commodious for their computation, might likewise be deduced from general considerations. Let  $A, B, C, D, E, \&c.$  represent any series of numbers. If they advance regularly and slowly, their first differences,  $B-A, C-B, D-C, E-D, \&c.$  may be viewed as constituting an arithmetical progression. Wherefore the sum of the extremes will be equal to that of the mean terms, or  $(E-D) + (B-A) = (D-C) + (C-B)$ , that is,  $E-A =$

$$2D - 2B, \text{ and therefore } D - B = \frac{E - A}{2}, \text{ whence } D =$$

$$B + \frac{E - A}{2}. \text{ Applying this to the logarithms of eight}$$

places of figures, let  $A, B, C, D, E, \&c.$  represent

Numbers.	Logarithms.	Alternate Differences.	Their Halves.

## POPULATION.

England. The Returns of the Census of 1821, as given in the *Abstract* printed by order of the House of Commons, England. not having been published till this work was nearly finished, it appeared to be proper to insert here such parts of the information contained in that *Abstract*, as are necessary to bring into one point of view, all the material facts connected with the progress and present state of the Population of the British Empire.

*Counties of England and Wales, their Extent, Population, &c. (See Population Abstract, p. 32, and Returns at the end of each County.)*

WALES.....	7,425	559,000	13	632,600	16	731,800	350,487	366,951

Note.—These numbers include the estimated proportions of the Army and Navy belonging to each county, at the respective periods of taking the Census; but the *Actual Total* in England, in 1821, was 11,261,437; in Wales it was 717,438; and in Scotland it was 2,093,456; as then enumerated, and as is shown in these Summaries, by the numbers of Males and Females.

THE METROPOLIS.

The rapid increase of the population in the suburbs, since the beginning of the last century, shows how rapidly the metropolis increases in extent, although its population has not increased so fast as that of the nation at large. In 1700, the metropolis contained almost an eighth part of the inhabitants of England and Wales; in 1750 and in 1801, about a tenth part; but in 1811 and at present, only about a twelfth part.

Objections might be made to the propriety of the limits of the metropolis as herein assumed, and it may therefore be right to add, that the population of all the parishes, of which the churches are situate within eight miles rectilinear around St Paul's Cathedral (including the before mentioned addition of one twenty-fifth part), would, in 1801, have amounted to 1,031,500;—in 1811, to 1,220,200;—and in 1821, to no less than 1,481,500; without including the parish of Woolwich, which contains 17,008 additional.

N. B. The population ascribed to the city of Paris is comprised within a district of full such an extent.

The arrivals of coasting vessels in the port of London may be estimated to have been about 5500, in the year 1700;—6400, in the year 1750;—10,400, in 1801;—13,500, in 1811; and at about 17,000 *per annum*, since the year 1817. This produces a constant, though fluctuating accession to the population, to a larger amount than elsewhere, and consequently, a twenty-fifth, instead of a fiftieth part, is to be added to form a comparison with the Parish Register Returns in the General Abstract. With this addition, the metropolis, in the year 1801, contained about 900,000;—in 1811, about 1,050,000;—and in 1821, about 1,274,800 inhabitants. The totals would then be, in

	1700.	1750.	1801.	1811.	1821.
	674,350	676,250	900,000	1,050,000	1,274,800
The actual totals, as enumerated, were			864,845	1,009,546	1,225,694

The Censuses were taken as directed by the respective Acts on the 10th of March, in the year 1801; on the 27th of May, in the year 1811; and on the 28th of May, in the year 1821.

## REFRACTION, DOUBLE, AND POLARISATION OF LIGHT.\*

*Polarisation of Light.* UNTIL a very few years since, the greater number of natural philosophers, and almost all mathematical opticians, were agreed in considering the rays of light as composed of extremely minute molecules, darted, in every possible direction, by a luminous body, with very great velocities. The form of these molecules remained undetermined; but as it was inferred from some observations, made long ago, that certain rays had not the same properties in every part of their circumference, it was natural to compare them to little magnets, and to suppose them possessed of poles. Hence the appellation of a *polarised ray* was applied to every ray of light, so modified, as to exhibit the polar properties of its molecules. We shall begin this article by describing the different methods that have been discovered for obtaining polarised rays.

SECT. I.—Of DOUBLE REFRACTION, considered as a Mode of POLARISING Light.

Supposing a pencil of *natural light*, that is to say of light coming directly from a luminous body, without having undergone any change by refraction or by reflection, to fall upon a crystal of carbonate of lime, perpendicularly to one of its surfaces, either natural or artificial: this pencil will in general undergo a bifurcation as it enters the crystal; one half of the incident light continuing its course in a right line, according to the ordinary laws of refraction, and the other exhibiting a very remarkable phenomenon, and assuming an oblique direction, notwithstanding its original perpendicularity. The former half is called the *ordinary pencil* or ray, the latter the *extraordinary pencil* or ray. The plane passing through these two pencils must obviously be perpendicular to the surface of the crystal; this plane is of great importance in the phenomena of polarisation, and it is denominated the *principal section* of the crystal.

According to this definition, it appears that every ray of light, at each point of incidence on a given crystal, will have a principal section corresponding to it; and we have only to observe that all these sections will be parallel to each other. In a rhomboid of Iceland spar, the principal section cuts the natural faces of the crystal in a line parallel to the diagonal joining the obtuse angles of the parallelogram, and dividing it into two equal parts.

Now, the *ordinary* and *extraordinary* rays both acquire within the crystal *new properties*, not inherent in the direct light.

In order to show this, it will be sufficient to remark what happens to these rays when they fall on a second crystal which has the properties of double refraction: and, first, with respect to the ordinary ray,

which has preserved its rectilinear direction without deviation. *Polarisation of Light.*

If the principal section of the second crystal is parallel to the principal section of the first, the ray will undergo no double refraction in the second, but will continue its course without any subdivision. But if the principal sections of the two crystals are perpendicular to each other, the ray which was *ordinarily* refracted in the *first* crystal, will become an *extraordinary* ray in the *second*; and will be refracted obliquely when its incidence is perpendicular. But when the principal sections are neither perpendicular nor parallel to each other, this same ordinary ray will be subdivided in the second crystal, but its portions will be of different intensities, except when the sections form an angle of  $45^\circ$  with each other.

The extraordinary pencil exhibits phenomena of a similar nature. It remains an extraordinary pencil in every crystal of which the principal section is parallel to that of the crystal which has transmitted it, and becomes an ordinary pencil when the principal sections are at right angles to each other; it is subdivided into two pencils of equal intensity, if the two sections make an angle of  $45^\circ$  with each other, and in every other position, into two pencils of unequal intensities.

It is very easy to verify these propositions by experiment. We place on a horizontal table a piece of black paper, and draw two very fine lines at right angles to each other, with a white spot of a certain magnitude at their intersection; and we lay on the paper a rhomboid of calcareous spar, and with our eye immediately above the spot we see two images of it, situated in a line parallel to the shorter diagonal of the upper face of the rhomboid. One of these images is seen in the true place of the spot, as is easily ascertained by two lines which cross in it, and of which the portions not covered by the crystal point at it; these rays have therefore undergone no deviation, and have been ordinarily refracted. The other rays have been bent, since they do not pass through the true place of the spot, and therefore afford the extraordinary image.

We now place a second crystal on the first, in such a manner that the shorter diagonals of the faces in contact may be parallel: we still find only two images of the white spot, but they are more remote from each other. The one retains its natural situation, whence it follows, that the rays which afford it are no more deflected from their course in the second crystal than they are in the first, and that they have always remained ordinary rays. With regard to the second image, since it is more remote from the true place of the object than when seen through the first crystal only, it is obvious that the rays, which have al-

\* This article has been obligingly furnished by M. ARAGO, and has been translated, with some additions, by a distinguished friend, already well known to our readers. The state of the author's health will, it is hoped, be received as an apology for the very great and unexpected delay which has taken place in the completion of his undertaking.—ED.

ready been extraordinarily refracted in the lower rhomboid, have undergone the same kind of refraction in passing through the upper.

If we only turn the upper rhomboid round the vertical line, so as to remove its principal section from its parallel position, each of the two images will be subdivided into two others. The new images will at first be very weak; their intensity will augment by degrees at the expense of the original images, in proportion as the angle formed by the two sections becomes greater; and at last, when it is a right angle, the two primitive images will have disappeared, and the new images alone will remain. One of them will be at a distance from the true place of the spot, in the direction of the shorter diagonal of the upper rhomboid, about equal to the result of the double refraction of the second crystal if it were separate from the first. This image is therefore formed by rays which have been refracted ordinarily in the first crystal, and extraordinarily in the second. And it will be equally manifest that the other image is derived, on the contrary, from rays refracted at first extraordinarily and then ordinarily, in the respective crystals.

As it is difficult to procure very thick rhomboids of carbonate of lime that are quite transparent, the same experiments may be performed by means of two prisms, cut out of doubly refracting crystals, and rendered achromatic by combining them with prisms of common glass, placed with their bases in opposite directions. Through two such achromatic prisms, placed on each other, the image of a candle appears quadruple or double, according to the relative positions of the principal sections: we thus see very distinctly that the images which disappear are not confounded with the other two, but that they become fainter gradually, while the others increase in intensity by the same degrees.

It appears then, first, that the direct light is *always divided* into two pencils in its passage through the natural faces of a crystal of carbonate of lime: and on the contrary that the light of which either of the two pencils is composed, when submitted to the action of such a crystal, in *some particular positions* of the principal section, *is not divided*, and gives but a single pencil.

Secondly, the two images furnished by the direct light have always an *equal degree* of brightness; but the light of the ordinary or extraordinary pencils, when it undergoes a further double refraction, gives almost always images of unequal intensities.

Hence it follows that in the act of double refraction, this last light has received some new properties, by which it may always be distinguished from natural light.

But are these properties necessarily of such a nature as to be inexplicable without supposing the elementary molecules of the rays to possess certain poles? This is a question which we are now to examine.

We will suppose that a rhomboid of carbonate of lime is placed horizontally: that the incident light falls perpendicularly on its upper surface, and that the principal section, which will be vertical, is in the plane of the meridian, or that it runs north and south:

observing, however, that these directions are only chosen to facilitate our comprehension of the facts.

The ordinary pencil afforded by this crystal, when it is submitted to the action of a new rhomboid similarly placed, that is to say, having also its principal section in the plane of the meridian, passes through it, as we have seen, without lateral refraction, and continues its course in a right line, remaining as an ordinary ray.

But when the principal section of the second crystal, being still vertical, is directed from east to west, the ordinary ray, transmitted by the first crystal, will be refracted laterally in it, although it falls perpendicularly on the surface, and will become an extraordinary ray.

In the first case, the principal section of the second rhomboid intersected the ray, or the luminous molecules supposed to compose it, from north to south: in the second, these molecules were intersected from east to west. It may be remarked, that this is the only circumstance in which the cases differ from each other, the ray falling in both cases on the same point of the crystal, and in the same angular direction. It must therefore be concluded, that in the ray of light, or in the elements of which it is formed, the north and south sides must have different properties from those of the east and west.

When we analyse the extraordinary pencil with the second crystal, if the principal section intersects this pencil from north to south, it undergoes the extraordinary refraction, but it follows the ordinary course when this same plane intersects it from east to west; which is exactly the contrary of what occurs with the ordinary pencil. The north and south sides of this pencil have therefore the properties of the east and west sides of the extraordinary pencil, and the reverse: nor is there any other difference between the pencils: the sides possessed of similar properties are only differently directed: so that if we could cause an extraordinary ray transmitted by any crystal to make a quarter of a revolution on itself, it would be impossible to distinguish it from the ordinary ray that has been separated from it.

When natural philosophers say of a loadstone or a magnet that it has poles, they merely understand, by this expression, that certain points about the circumference of the magnet possess properties which do not belong, either at all, or in the same degree, to the other parts of the circumference. It was then equally correct to say of the ordinary and extraordinary rays derived from the subdivision of natural light, in the crystals of carbonate of lime, that they had *poles*, or were *polarised*. It is only necessary to remark, in order to avoid extending the analogy between the rays of light and the magnet, beyond its proper bounds, that for every element of the ray, the sides or poles diametrically opposite to each other, that is, in the position here supposed for illustration, the north and south poles of the ordinary ray, appear both to possess exactly the same properties; and it is at the angular distance of  $90^\circ$  from these points, that is, on a perpendicular to the line that joins them, that we find in the same ray poles possessed of different properties: and if we compare with each other the two pencils transmitted by a given crystal, the poles pos-

Polarisation  
of Light.

essed of the same properties will be situated in directions perpendicular to each other.

Let us once more consider the two rays transmitted by a crystal of which the principal section is supposed to be in the plane of the meridian. There is no reason whatever for assigning the denomination of poles to the north and south sides of the ordinary ray rather than to the east and west; but as it is necessary to make some distinction, it has been generally agreed to apply the name of poles to the north and south sides. Hence it has been usual to say, that the *ordinary ray* is polarised in the *plane of the principal section*: which is as much as to say that the different elements of the ray have the faces, which we have called poles, situated in that plane. The *extraordinary ray* is polarised perpendicularly to the *principal section*: its poles are situated perpendicularly to that plane, since it becomes perfectly similar to the ordinary ray, when it is made to describe a fourth of a revolution round itself.

When we have arrived thus far, it becomes natural to ask whether we are to suppose that the separation of the light within the crystal has *given* poles to the molecules, or that the poles, already *preexisting*, have merely been turned towards the same points of space. This question is a very difficult one: but we shall find hereafter, if not a demonstration of the second hypothesis, at least some plausible reason for adopting it. It will here be sufficient to remark, that the modification, undergone by the rays, is entirely independent of the nature of the crystal, provided that it only produce a double image; and that the phenomena presented by two rhomboids of calcareous spar, placed on each other, would be reproduced, with their minutest details, if we combined, for example, one of these rhomboids with a crystal of carbonate of lead: or if the first crystal were of sulphur and the second of quartz, or of sulphate of barita.

But it is not only in the phenomena of double refraction that the particular properties of polarised rays are exhibited: the *reflection* of these rays, at the surfaces of *transparent bodies*, affords also a method of *distinguishing* them from *common light*.

When a pencil of natural light falls on a transparent mirror with any inclination whatever, it is divided into two parts; the one passes through the substance of the mirror, the other is reflected. This latter portion is always found in the plane, passing through the primitive pencil, and the line perpendicular to the surface; which is called the *plane of reflection*, and which must be carefully distinguished from the *reflecting surface*.

If we now place the principal section of a doubly refracting crystal in a vertical position, and throw a pencil of common light perpendicularly on its surface, receiving the two emerging pencils on the horizontal surface of some water: and let us suppose the ordinary pencil to make with the surface of the liquid an angle of  $37^{\circ} 15'$ ; [the crystal being held in a position inclined to the horizon]: this pencil will undergo a partial reflection like the direct light, while the extraordinary pencil, when its angle of incidence is also  $37^{\circ} 15'$ , will enter the liquid completely, without the reflection of any of its molecules: a character which constitutes a marked distinction between this pencil and the natural light.

All other circumstances of the experiment remaining the same, let us now cause the crystal to make one fourth of a revolution round the incident pencil, so as to bring the principal section into a position perpendicular to its first situation: we shall then find that the ordinary pencil alone will be entirely transmitted by the liquid; the other will undergo a partial reflection, exactly equal to that which we had first observed in the ordinary ray: the experiment affording a new proof, that the two rays only differ in the direction, which is assumed by their corresponding sides.

We find also that in all positions of the principal section, intermediate between these two, the two pencils will both undergo a partial reflection so much the stronger, for the ordinary pencil, as the principal section is the nearer to a coincidence with the plane of reflection, and for the extraordinary pencil, as these planes are more nearly perpendicular to each other.

We shall finish this section with an account of the mathematical law which appears to determine the comparative intensities of the ordinary and extraordinary pencils into which polarised light is separated, when it is analysed with a doubly refracting crystal. Let  $F_o$  be the intensity of the ordinary pencil transmitted by any crystal, and  $F_{oo}$  and  $F_{oe}$  the intensities of the ordinary and extraordinary pencil derived from it in passing through the second crystal: let  $i$  be the angle formed by the two principal sections: then we shall have  $F_{oo} = F_o \cos^2 i$ ;  $F_{oe} = F_o \sin^2 i$ .

In particular cases we shall have from these formulas, if  $i=0$ ,  $F_{oo} = F_o$ ,  $F_{oe} = 0$ ; if  $i=90^{\circ}$ ,  $F_{oo} = 0$ ,  $F_{oe} = F_o$ ; and if  $i=45^{\circ}$ ,  $F_{oo} = \frac{1}{2} F_o$ ;  $F_{oe} = \frac{1}{2} F_o$ .

These three consequences of the formula, as we have seen, are conformable to observation. It will not however be proved to be mathematically exact, until we have also verified it for some values of  $i$ , intermediate between these limits.

The formulas belonging to the extraordinary ray are equally simple:  $F_e$  being the intensity of this ray, and  $F_{eo}$  and  $F_{ee}$  those of the two ordinary and extraordinary pencils into which it is divided by the crystal,  $i$  preserving its former signification, we shall have  $F_{eo} = F_e \sin^2 i$ , and  $F_{ee} = F_e \cos^2 i$ . If  $i=0$ ,  $F_{eo} = 0$ , and  $F_{ee} = F_e$ ; and in fact there is no ordinary ray in this case, the whole light following the extraordinary path: if  $i=90^{\circ}$ ,  $F_{eo} = F_e$ , and  $F_{ee} = 0$ : which is

again confirmed by observation, since the extraordinary ray, coming from a certain crystal, follows only the ordinary course in passing through another, of which the principal section is perpendicular to that of the first. The same agreement between the calculation and the experiment will be found when  $i=45^{\circ}$ ; which, however, does not supersede the necessity of verifying these formulas, as well as the former, by direct experiments at intermediate angles.

## SECT. II.—Of REFLECTION, considered as a mode of Polarising Light.

Reflection, at the surface of a transparent body,

Polarisation  
of Light.

*Polarisation of Light.* affords, as we have seen, a *criterion* for the distinction of polarised from ordinary rays; we must also add, that such a reflection is also capable of polarising ordinary light.

Throwing, for example, a pencil of natural rays on a mirror of common glass in a horizontal position, in such a manner that the inclination of the ray to the surface may be about  $35^\circ$ : we shall find that a part of the pencil will pass through the glass; the other part will be reflected; and the reflected portion will be polarised in the same manner as the ordinary pencil transmitted by a crystal, of which the principal section coincides with the plane of reflection.

In fact, if we analyse the light, thus partially reflected, by the assistance of a crystal, of which the principal section coincides with the plane of reflection, it is not subdivided, and affords only a single ordinary image. Nor is it again subdivided in passing through the crystal, when the principal section is perpendicular to the plane of reflection; but in this case it only affords an extraordinary image. In every other position we have both an extraordinary and an ordinary image, the intensity of the latter being expressed by the formula,  $F \cos^2 i$ : in which  $F$  is the total intensity of the pencil subjected to the experiment, and  $i$  the angle formed by the principal section of the crystal with the plane of reflection. This formula obviously coincides with that which we have given for the ordinary pencil in the case of two crystals combined. The plane of reflection here performs the office of the principal section of the first crystal; it is therefore in this plane that the ray has become polarised by the reflection.

Before we assert, however, that there is an identity in the species of polarisation effected by partial reflection with given inclinations, at the surface of a transparent body, and that which results from double refraction, we must submit the ray polarised by a first reflection to the test of new reflections.

These second reflections will obviously throw the light downwards if the mirror is above the ray, or upwards if below; from right to left, if the mirror receives the ray on its [left hand] surface, and the reverse if on the [right] surface.

Now, if the second mirror is above or below the ray, so that the new plane of reflection coincides with the old, there is a partial reflection at all incidences. But when, on the contrary, this mirror is presented to the ray on the left or the right side, and in such a manner that the new plane of reflection may be perpendicular to the old one, all reflection ceases at the inclination of about  $35^\circ$ , already mentioned. In the intermediate positions of the mirror, and with the constant inclination of  $35^\circ$ , the intensity of the reflection varies in proportion to the square of the cosine of the angle formed by the two planes of reflection with each other.

The least attention will show how much analogy this experiment has with those which have been made with a rhomboidal crystal. In those experiments, in order to see if the ordinary ray had the same properties with respect to each point of its circumference, we caused the crystal to revolve round the ray as an axis, so as to bring in succession its principal section, and consequently the poles con-

*Polarisation of Light.* tained in it, into a vertical direction, from right to left, and so forth; in these different positions we threw the ray on a transparent substance. Here, we left the first plane of reflection immovable, and the second turned round the ray, which was thrown on its different sides. This trial is evidently similar to the former, and the result is identical.

We may therefore now affirm, that the ray which is reflected at the upper surface of the glass, with an inclination of about  $35^\circ$ , possesses in all respects the same properties as a ray transmitted by a crystal, of which the principal section coincides with the plane of reflection.

We have supposed the substance employed in this experiment to be transparent; but we must add, that some opaque bodies, such as black marble, ebony, and some varnishes, possess in an equal degree the property of polarising rays which are reflected at their surface. These substances, when made to revolve round a polarised ray, exhibit the same effect, with regard to the reflected light, as the transparent substances which have been considered.

### SECT. III.—Of Rays PARTIALLY Polarised.

Rays partially polarised are those which possess properties that may be called intermediate between the properties of ordinary light and of light completely polarised. They are distinguished from polarised light by affording always two pencils, in their passage through a crystal possessed of the property of double refraction: they differ from natural light in not affording always two pencils of the same intensity, in all positions of the principal section of the same crystal.

It may be asked, if a ray partially polarised may not be considered as consisting of a portion,  $A$ , of polarised and a portion,  $B$ , of natural light. This latter portion would *always* be equally divided into an ordinary and an extraordinary pencil, in its passage through a crystal possessing the properties of double refraction; the other would pass *sometimes* entirely as an ordinary or an extraordinary pencil. In a certain position of the principal section, therefore, the comparative intensities of the two pencils would be  $\frac{1}{2}B+A$ , and  $\frac{1}{2}B$ ; and after one fourth of a revolution, they would become  $\frac{1}{2}B$ , and  $\frac{1}{2}B+A$  respectively. In all other positions,  $A$  would be divided between the two images: the portion belonging to the ordinary image being expressed by  $A \cos^2 i$ ,  $i$  being the angle contained by the plane of polarisation of  $A$  and the principal section of the crystal: and when  $i=45^\circ$ , the two images would be of equal intensity.

All these consequences of the hypothesis, that we have assumed, are conformable to experiment: and we may therefore suppose that a ray partially polarised is composed of two separate portions, the one,  $B$ , in its natural state, the other,  $A$ , totally polarised. [Dr Brewster's experiments on partial polarisation will be mentioned hereafter.]

In every pencil reflected perpendicularly by a transparent substance, the portion  $A$  vanishes: it acquires greater and greater values in proportion as the angle of incidence increases; but at the angular situation of complete polarisation  $B$  vanishes, and

Polarisation of Light.

*A* comprehends the whole pencil. Still farther from the perpendicular, we find again in the pencil natural light, *B*, and polarised light, *A*. Lastly, when the incident and reflected light sweeps, as it were, the surface of the mirror, *A* is again very inconsiderable with respect to *B*.

Metallic mirrors do not completely polarise the rays that they reflect at any angle of incidence. As in the case of transparent substances, *A* is evanescent for perpendicular rays; but it becomes sensible in every other case, and the light becomes partially polarised. The angle of polarisation of a metal is that which makes the quotient  $\frac{A}{B}$  a maximum.

There exist also some transparent bodies, such as the diamond and sulfur, which never produce complete polarisation of the light that is reflected at their surfaces; but the quotient  $\frac{A}{B}$  acquires, at least, much greater values for their substances than for the metals.

The mathematical law, which connects the value of *A* with that of the angle of incidence, and of the refractive form of the mirror, has not yet been discovered. It is only known, that at regular angular distances above and below the angle of complete polarisation, the proportion of *A* to *A*+*B* is nearly the same, although the absolute value of *A* and *B* may have changed very considerably.

Thus, in the case of the glass of St Gobin, for example, in which the complete polarisation takes place when the inclination of the ray to the surface is about 35°, we find that the reflected pencils contain the same proportion of polarised light at the following angles:

65° 42'	63° 54'	60° 18'
and 7 12	7 55	11 40
<hr/>	<hr/>	<hr/>
mean 36 27	35 55	35 59

For water, the relation of *A* to *A*+*B* is nearly the same at the angles 3° 29' and 73° 48': the mean of these, 38° 36', exceeds by 1¼° only the true inclination of complete polarisation, though it is deduced from angles which differ from it more than 30°.

In the same manner, therefore, as astronomers determine the instant of the passage of a luminary over the meridian, by corresponding altitudes, observed before and after that passage, we may obtain, with tolerable precision, the angle of complete polarisation, by taking the half sum of the inclinations corresponding to equivalent partial polarisations, especially if we take care not to deviate too far from the angle required: and this method has its advantages, when we make the experiment on bodies which do not polarise the rays of light completely at any incidence.

SECT. IV.—Of the Laws which connect the REFRACTIVE DENSITIES of Bodies with the Angles of Polarisation.

It is sufficient to look over the tables which have been published, of the angles of complete polarisation for rays reflected by substances of various kinds,

in order to observe that these angles, reckoned from the perpendicular, approach so much the more to right angles, as the refractive densities of the substances are greater; but it was not so easy to detect the remarkable connexion which exists between these two elements, and which we shall now proceed to examine.

When a ray of light, *IO*, passes from a vacuum into a certain medium, *SS'*, it is refracted at the point of incidence *O*, approaches to the perpendicular *PQ*, and follows, for example, the direction *OR*; the angles *POI* and *QOR* being for

each medium connected by the proportion  $\sin POI : \sin QOR = m : 1$ , in which the quantity *m* is constant for all values of the angles. This quantity, which is always greater than unity, has been called the *index of refraction*, appropriate to the medium. It is necessary to distinguish it carefully from the refractive power, a numerical expression depending on *m*, and on the density, and chiefly relating to the particular properties attributed to refractive substances in the theory of emission.

This being understood, if the angle of incidence be supposed such, that the reflected ray *OF* may be completely polarised, it is found, that *the tangent of the angle of incidence will be equal to the index of refraction*.

In the following table, the angles of polarisation, determined by experiment, are compared with those which result from the general law; and the errors are not greater than may be attributed to the unavoidable error of observation.

Substances.	Observed Angle.	Computed Angle.	Difference.
Air, - - -	45° to 47°	45°	[1°]
Water, - - -	52° 45'	53 11'	-26'
Fluor spar, - - -	54 50	55 9	-19
Obsidian, - - -	56 3	56 6	-3
Sulfate of lime, - - -	56 28	56 45	-17
Rock crystal, - - -	57 22	56 58	+24
Topaz, - - -	58 40	58 34	+6
Iceland crystal, - - -	58 23	58 51	-28
Ruby spinel, - - -	60 16	60 25	-9
Zircon, - - -	63 8	63 0	+8
Glass of antimony, - - -	64 45	64 30	+15
Sulfur, - - -	64 10	63 45	+25
Diamond, - - -	68 2	68 1	+1
Chromate of lead, - - -	67 42	68 3	-21

This law is capable of being expressed in two other remarkable forms.

Since in all cases  $\sin POI : \sin QOR = m : 1$ , we have universally  $\sin POI = m \sin QOR$ : but for the angle of complete polarisation  $\tan POI = m$ , and

since  $\tan = \frac{\sin}{\cos}$ ,  $\frac{\sin POI}{\cos POI} = m$ , and  $\sin POI = m \cos$

Polarisation  
of Light.

$POI = m \sin QOR$ , and  $\sin QOR = \cos POI$ , consequently,  $QOR + POI = 90^\circ$ ; hence, when the polarisation is complete, the inclination of the incident ray to the surface is equal to the angle of refraction; and the reflected and refracted rays are perpendicular to each other.

It is of consequence to examine some objections which have been made to the accuracy of the law in question. If it were mathematically accurate, the rays of different colours, it has been observed, would not be polarised exactly at the same time; since they enter the refractive medium in different directions. Hence it would follow, that in the usual mode of investigating this angle of complete polarisation by analysing the reflected light with the assistance of a doubly refractive crystal, we ought not, in any case, to lose sight of one of the images: that when we arrived, for instance, at the angle which causes all the red light of the mixed pencil to be polarised, and to pass into the ordinary pencil, the observer ought to see an extraordinary image formed of the white wanting the red, that is, green; and the same for the other colours. Notwithstanding this, it has been added, in the greater number of cases, the crystal being properly arranged, one of the images is weakened by little and little, as we approach to the appropriate inclination, and at last disappears entirely without presenting any visible traces of colour.

It may be answered, in the first place, that there actually are substances in which this appearance of colour is manifest: and which, therefore, do not polarise the rays of different kinds at the same angle, but accord with the law of the tangent. Among others may be adduced the instance of specular iron ore, in which the phenomenon is very striking; and the oil of cassia, of which the great dispersive power renders it also perfectly distinct. It may be added, too, that there is every reason to hope, that more accurate observations made with homogeneous light from different parts of the spectrum, and more precise measurements of the quantities of light that escape polarisation, at inclinations approaching to that of complete polarisation, will hereafter remove the slight appearance of disagreement between experiments and a law too nearly approaching to the whole mass of the phenomena, to be considered as otherwise than rigorously accurate.

The table already inserted contains the names of several mediums, such as the diamond, and sulfur, which do not completely polarise light: the law of the tangent seems therefore applicable to such mediums as these, provided that we understand, by the angle of polarisation, that in which the reflected pencil contains the greatest proportion of polarised light. In this case, the observation of this angle for metals would be the more important, as their refractive density has not been hitherto determined.

The angles of greatest polarisation, measured from the perpendicular, appear to be, for mercury  $76\frac{1}{2}^\circ$ ; for steel, above  $71^\circ$ : hence the index of refraction for mercury and for steel ought to be 4.16 and 2.85. [The oxid colouring the surface of heated steel has been found to give about 2.1 for its index, which agrees sufficiently well with this experiment.]

We have hitherto only spoken of the polarisation which takes place at the first surface of transparent surfaces, entered by the light; the second surfaces possess analogous properties with respect to light passing out of them.

The angle, measured from the perpendicular, at which light is polarised when it is on its passage from a vacuum into a refractive medium, is greater than that in which the same phenomenon is observed when the light coming from the medium tends to pass into the vacuum; it is also shown by experiment that the sine of the former angle is to the sine of the latter as the index of refraction is to unity. We might express the same fact by saying that at the second surface, as well as at the first, the ray completely polarised by reflection is perpendicular to the refracted ray. It follows, also, that if a medium is contained between two parallel surfaces, and if we throw a pencil of rays on the first surface, in the angle which affords complete polarisation, the transmitted portion of the pencil will also fall on the second surface in the angle which again produces complete polarisation.

Thus, if MN, RS, be the parallel surfaces, OR the incident ray;  $n$  the index of refraction; and OV the refracted ray; the angle of refraction VOP' will always be equal to the angle OVZ, formed

by the refracted ray with VZ the perpendicular to the second surface. Now, according to the assigned law, when POR is the angle of complete polarisation for the first surface,  $\sin POR : \sin$  angle of polarisation at the second surface  $= n : 1$ , whence  $\sin POR = n \sin$  angle of polarisation at the second surface. But from the law of the sines, as in the other cases, we have  $\sin POR : \sin VOP' = n : 1$ , therefore  $\sin POR = n \sin VOP' = n \sin ZVO$ ; an equation which, combined with the former, gives the angle of complete polarisation at the second surface  $= ZVO$ .

Hence it follows that if the incident ray, being previously polarised, is such as to escape all partial reflection at its entrance into a substance terminated by parallel surfaces, it will also escape reflection upon its passage out of the substance.

If ROP has the appropriate value, OF becomes completely polarised, and VK likewise; the subsequent refraction in K makes no alteration in this ray: so that when we wish to procure polarised light by reflection from a transparent plate, there is no occasion to blacken the second surface of the plate, supposing it parallel to the first, the polarisation will be equally complete, and the reflected pencil will be brighter. It will only be proper to take care, by placing at a distance from the plate a black substance, as a piece of velvet, for example, to intercept the rays

Polarisation  
of Light.

*Polarisation of Light.* which might be transmitted by the plate from other objects beyond it.

The law from which these consequences have been deduced is only a particular case of a more general law, which may be thus enunciated.

*The sine of the angle at which a pencil must be reflected at the first surface of a refractive medium, in order that it may contain a certain PROPORTION of polarised light, is to the sine of the angle at which a reflection at the second face only would cause an EQUIVALENT POLARISATION in the same pencil, as the sine of incidence to the sine of refraction.*

It has been found by experiment, that the sine of the angle, at which a certain proportion of a natural pencil is reflected at the first surface of a transparent substance, is to the sine of the angle at which an equal proportion of the same pencil would be reflected at the second surface, if it arrived there immediately, as the sine of incidence to the sine of refraction. This law of photometry, combined with the former, leads to a very simple enunciation.

*The first and second surface of a transparent substance polarise light in an equal degree, at the same angles which enable them to reflect light in an equal degree.*

We have now seen in what manner light is polarised either in passing from a vacuum into a given substance, or in returning out of the substance into the vacuum. We must next examine the laws relating to the polarisation which occurs at the surface separating two mediums possessed of unequal refractive powers.

Let  $m$  and  $m'$  be the indices of refraction for the two mediums: suppose  $m$  to be greater than  $m'$ : it is proved by experiment that the tangent of the angle of complete polarisation at the common surface is

equal to  $\frac{m}{m'}$ , [which in fact is the index of refraction for that surface.]

Hence it follows that the reflected and refracted rays are perpendicular to each other, as in other cases of complete polarisation.

#### SECT. V.—Of REFRACTION considered as a Mode of Polarising Light.

It was believed, for some time, that the rays of light were only polarised by transparent substances in the act of reflection, and that the refracted pencil always retained the properties of ordinary light. But this opinion was erroneous. It is true that the simple transmission of light through one or even two surfaces of any known substance is not sufficient for completely polarising a pencil of light; but at certain obliquities it occasions at least a partial polarisation; for in examining the rays transmitted obliquely by a plate of glass with parallel surfaces, by means of a crystal possessed of the property of double refraction, it is found that the two images differ sensibly in intensity.

Let  $A'$  be the part of the transmitted pencil which is polarised,  $B'$  the portion of the same pencil not so modified; and  $A$  and  $B$  the analogous portions of the pencil reflected at the same incidence.

*Polarisation of Light.* We have already said that  $A$  is polarised as an ordinary ray would be, transmitted by a crystal having its principal section coinciding with the plane of reflection; the poles of  $A'$ , on the contrary, are placed like those of the extraordinary ray of the same crystal. If we analyse with a rhomboid the light reflected by a plate of glass, we find, for example, when in a certain position of the principal section, the image on the right hand is the more brilliant: and the relative position of the plate, the crystal, and the eye, remaining unaltered, it will be the opposite image, on the left hand, that will become the most conspicuous when we examine the transmitted light. All these results may be thus enumerated.

*The plane which contains the poles of the transmitted light is perpendicular to that which contains the poles of the reflected light.*

These different pencils are therefore polarised in directions at right angles to each other.

If we submit the reflected light  $A+B$  to the action of a crystal of carbonate of lime, of which the principal section coincides with the plane of reflection, the intensities of the ordinary and extraordinary pencil will become  $A+\frac{1}{2}B$  and  $\frac{1}{2}B$ .

In the same position of the plate and of the crystal, the intensities of the same images, furnished by the transmitted pencil, will be  $\frac{1}{2}B'$  and  $A'+\frac{1}{2}B'$ .

$A$  will therefore be the quantity by which the ordinary image, furnished by the reflected pencil, surpasses the extraordinary image, while  $A'$  will express, for the transmitted pencil, the quantity by which the extraordinary image will surpass the ordinary. With respect to this phenomenon, a remarkable result of experiment may here be noticed: that is, that in every possible inclination  $A=A'$ , or, in other terms, that the intensities of the two images afforded by the crystal differ in the same degree, whether we consider the reflected or the transmitted pencil.

Let us suppose that a plate of glass  $ED$  is placed in the position that the figure represents, before a medium  $AB$  of a uniform tint,

for instance a sheet of fine white paper. The eye placed at  $O$  will receive simultaneously the ray  $IO$ , reflected at  $I$ , and the ray  $BIO$  transmitted at the same point. Place at  $mn$  an opaque diaphragm, blackened, and perforated by a small hole at  $S$ . Lastly, let the eye be furnished with a doubly refracting crystal,  $C$ , which affords two images of the aperture.

If now, by means of a little black screen, placed between  $B$  and  $I$ , we stop the ray  $BI$ , which would have been transmitted, the crystal, properly placed, will give an ordinary image  $=A+\frac{1}{2}B$ , and an extraordinary image  $=\frac{1}{2}B$ . But if the screen were placed between  $A$  and  $I$ , and the ray  $AI$  were intercepted, we should still have two images of the hole, and their intensities would be  $\frac{1}{2}B'$  and  $A'+\frac{1}{2}B'$  respectively. Consequently, without any screen, if the whole of the reflected light  $AIO$  and the transmitted  $BIO$  are al-

Polarisation of Light. lowered to arrive at the eye, we shall have for the ordinary image,  $A + \frac{1}{2}B + \frac{1}{2}B'$ , and for the extraordinary,  $\frac{1}{2}B + A' + \frac{1}{2}B'$ .

Now it appears, from actually making the experiment, that the two images are perfectly equal, whatever may be the angle formed by the ray AI with the plate of glass, which can only be because A is always equal to A'. Consequently,

*The quantity of polarised light contained in the pencil transmitted by a transparent plate, is exactly equal to the quantity of light polarised at right angles, which is found in the pencil reflected by the same plate.*

Hence it follows, that at the angle of complete polarisation by reflection, the two images of the transmitted pencil given by a crystal properly placed, differ in intensity by a quantity equal to the whole of the reflected pencil. So that if ever a body should be discovered, that could reflect half of the light incident at this angle, the pencil transmitted, at the same inclination, would also be completely polarised.

In order to simplify this reasoning, we have supposed throughout that there was only one efficient surface in the plate ED; it would be entering into too much detail if we proceeded to demonstrate in what manner this supposition might be justified: and it will be sufficient to remark, that the experiment in question succeeds equally well when ED is a simple plate of glass with parallel surfaces, which implies that the second surface polarises also equal quantities of light by reflection and by refraction. But, lastly, in order to remove every doubt respecting the accuracy of these results, it may be added, that when some natural light, and some light that had passed through a rhomboid of carbonate of lime was thrown on a plate of glass reflecting at one of its surfaces, or at both, it was found that the reflected light contained the same quantity of polarised rays in both cases. Now the reflecting plate exercises no particular action on the two equal pencils of light transmitted by the rhomboid, and polarised in directions perpendicular to each other; it only divides them unequally: and if the reflected pencil contains an excess of rays polarised in one direction, there will be found in the transmitted pencil an excess precisely equal of rays polarised in the direction perpendicular to it. In this case, the law here laid down must necessarily be true: and in order to extend it to natural light, it is sufficient to have assured ourselves, as we have done, that it is affected in the act of reflection and in that of refraction precisely in the same manner as the combination of two equal pencils, polarised at right angles to each other.

One of the best modes of verifying the accuracy of physical laws is, to inquire what their results are in extreme cases. The law now in question, supposing it universally true, leads us, for example, to this conclusion, that where there is no transmission of light, there can be no polarisation: and in fact, if we cause a pencil of light to fall on the interior surface of a prism, at an inclination which produces complete reflection, we shall find no trace of polarisation in the reflected pencil, although at incidences but little different, a considerable part of the light, and even the whole may have been polarised.

VOL. VI. PART II.

Polarisation of Light. Let us represent by  $A$  the part of the pencil  $I$  which is polarised by reflection, at the angle of  $35^\circ$  from the two surfaces of a plate of glass; the pencil transmitted will be  $I - A$ ; now in this quantity of light there will be, according to the law laid down,  $A$  rays of which the plane of polarisation is perpendicular to that of the reflected rays, so that the quantity of natural light remaining will be  $I - 2A$ , which we may call  $= I'$ . Then the pencil  $I' + A$  falling on a second plate, parallel to the first, and consequently at the same angle as before,  $A$  will entirely escape the partial reflection, and abating what may be lost by absorption, will be found entire in the pencil transmitted by the second plate;  $I'$  will be divided in the same manner as  $I$  was at first; a portion  $A'$  of  $I'$  is polarised by reflection, the remaining portion  $I' - A'$  is transmitted, and will contain  $A'$  of polarised rays, so that the natural light, after passing through the second plate, will be reduced to  $I' - 2A'$ , and the quantity polarised by refraction will be  $A + A'$ . Making  $I' - 2A' = I''$ , the light  $I'' + A + A''$  will furnish, in its passage through a third plate, parallel to the two former, a new quantity  $A''$  of light polarised by refraction, which will be added to  $A + A'$ , and so forth.

The pencils  $I, I', I''$ , and so forth, consisting of natural light, are polarised in equal proportions, by

the respective plates: the quotients  $\frac{A}{I}, \frac{A'}{I'}, \frac{A''}{I''}$ , will

constantly have the same value. If, for instance, one sixth part of the pencil  $I$  is polarised by reflection at the surfaces of the first plate,  $\frac{1}{6}$  of  $I'$  will be polarised at the surfaces of the second;  $\frac{1}{6}$  of  $I''$  by the third, and so forth; and the pencils transmitted by these same plates will contain respectively of natural light, or of light possessing the same properties,  $\frac{4}{6}$  of  $I, \frac{4}{6}$  of  $I', \frac{4}{6}$  of  $I''$ , and so forth. Hence, whatever may be the number of plates employed, the pencil ultimately transmitted will contain, mathematically speaking, a certain quantity of natural light; but this quantity will be rapidly diminished, and will finally become completely insensible. [Dr Brewster, on the contrary, maintains, that it wholly disappears after transmission through a finite, and even a moderate number of plates.]

It may be said, in this sense, that a pile of parallel plates polarises the light which passes through them, in a direction perpendicular to the plane in which the rays would be polarised, by reflection at the same surfaces.

We have here supposed the incident light to meet the plate of glass at the inclination capable of polarising it completely by reflection; but the same result is obtained whatever the inclination may be: it is only necessary that it should be composed of a number of elements, so much the greater as the direction of the rays is nearer to the perpendicular.

With a given inclination, the number of plates, necessary to produce by transmission a polarisation nearly complete, depends also on their reflective power: we have already observed, for example, that a single plate, capable of reflecting half the incident light at the angle of polarisation, would, of itself, be sufficient to constitute a pile.

Polarisation  
of Light.

There are certain natural bodies, the agate, for example, which modify the transmitted light precisely as a pile of plates would do. If we cut a plate of agate sufficiently thick, in a direction perpendicular to that of its laminae, the light which passes through it acquires a polarity in the direction of the plates. A similar property is observed in the tourmaline, and it is here the more remarkable, as this mineral, when pure, exhibits no lamellar structure whatever. If the two opposite faces of a prism of tourmaline are polished so as to form it into a plate with parallel surfaces, about  $\frac{1}{3}$  of an inch in thickness, the light transmitted by it, whatever its angle of incidence may be, will be polarised in a direction perpendicular to the axis of the column.

It will be proper to mention here the phenomena exhibited by piles of plates when they are exposed to rays that have been previously polarised: supposing always that the pile is formed of parallel plates of glass; and besides, that the angle of inclination to the first surface is about  $35^\circ$ , reckoning from the surface itself.

If the primitive plane of polarisation of the incident ray coincides with the plane drawn through this ray and the perpendicular to the first plate at the point of incidence, a part of this ray more considerable than if we employed natural light, will be reflected; at the point of incidence on the second plate, the luminous pencil transmitted by the first will undergo reflection in the same proportion as the former pencil: the same effect will take place in the third plate and so forth. The transmitted ray, however intense it may have been in the first instance, will thus be gradually weakened in a geometrical progression, and at last will become insensible; so that if we look at the pile on the opposite end it will appear to be an opaque body, perfectly impervious to light.

Every thing else remaining in the same state, if we turn the pile round the ray as an axis through an angle of  $90^\circ$ ; the new plane of reflection will be perpendicular to the former, and the plate will have reached the situation which has been already mentioned, in which the reflective property wholly disappears, and the whole of the light will pass through it. But the second plate, the third, and all the following plates, which are parallel to the first, will be found in the same circumstances possessing the same properties, and will not reflect any of the incident light; so that setting aside the effect of absorption, the apparatus actually transmits light without weakening it.

The pile of plates possesses therefore, with respect to polarised light, the singular property of being either completely opaque or perfectly transparent according to the side which it presents to the light, notwithstanding that the inclination of the light to the first surface remains constantly  $35^\circ$ . In the intermediate positions the quantity of transmitted light increases gradually as we proceed from that in which nothing is transmitted, to the other extreme in which the light is only weakened by absorption.

Tourmalines and agates appear to be true piles of plates, so that they must produce similar effects: and in fact, a plate cut, for example, in a direction

parallel to the axis of a column of tourmaline transmits rays which are polarised in a plane perpendicular to the axis, and totally stops, on the other hand, rays of which the primitive plane of polarisation is parallel to that axis.

Polarisation  
of Light.

When we place such a plate between the eye and a reflecting surface of water or glass situated in the open air, and look at it with an inclination producing complete polarisation, it appears either fully enlightened or quite dark, or in intermediate states according to the situation of the plate in its own plane. A circumstance, which adds to the singularity of this experiment, is that it succeeds completely even when the incidence on the plate is perpendicular; while for a pile properly so called, unless it be composed of an immense number of plates, it is necessary that the distance of the ray from the perpendicular should be very considerable.

Whatever may be the cause of these phenomena, it results evidently from what has been mentioned, that two planes of tourmaline placed so that their axes form a right angle, must compose a system perfectly opaque with respect to light of all kinds. If, for example, the incident light is in its natural state, it is obvious that the portion transmitted will be polarised in the direction of the axis of the plate, and that the second plate, situated in a perpendicular direction will consequently stop the whole of the light so polarised.

#### SECT. VI.—Of the DEPolarisation of Light.

After having examined in what manner ordinary light is converted into polarised light, we must now proceed to study the modifications which this latter undergoes in its turn when it is subjected to reflection or refraction at surfaces of different natures, and differently situated with respect to its poles.

When a polarised pencil falls on the surface of a well polished mirror, in such a manner that its plane of polarisation coincides with the plane of reflection, or is perpendicular to it, the light regularly reflected at this surface is completely polarised, like the incident pencil, in a direction parallel or perpendicular to the plane of reflection; and this happens whatever the nature of the mirror may be.

But whenever the primitive plane of polarisation of the incident pencil is any otherwise situated, it will be found that the reflected pencil is modified, and the modification will depend on the nature of the mirror.

When we employ for these experiments a mirror either transparent or opaque, which is capable of completely polarising natural light; the rays previously polarised which fall on this surface will again be completely polarised after their reflection; but not in the plane of their primitive polarisation. This deviation of the plane of polarisation of a luminous pencil, produced by its reflection at the first surface of a transparent mirror, depends both on the angle of incidence and on the direction of the plane of reflection with regard to the poles of the ray.

For given inclination, the deviation is so much more considerable as the plane of reflection makes with the plane of primitive polarisation an angle more nearly approaching to  $45^\circ$ .

Polarisation  
of Light.

Polarisation  
of Light.

Let us first suppose, in order to assist the imagination, that the reflecting surface is horizontal; that the eye of the observer, and the rhomboid which is to furnish the polarised pencil remain constantly situated the one to the north, the other to the south of the point of reflection, so that the plane of reflection may always coincide with the meridian: and that lastly the principal section of the crystal, which contains in its plane the poles of the ordinary pencil, makes an angle of 45° with the meridian.

When this ordinary pencil falls perpendicularly on the mirror, it will be reflected without any deviation of its plane of polarisation: so that this plane, having at first formed, by the suppositions, an angle of 45° with the meridian, the inclination to the meridian will remain the same after the reflection.

If we cause the direction of the incident light to vary more and more from the perpendicular, we shall first remark that the plane of polarisation of the reflected light approaches by degrees to the plane of reflection; and that it coincides exactly with it when we have arrived at the angle of complete polarisation; that afterwards the reflected ray is polarised in a plane which is more remote from the plane of reflection in proportion as it forms a smaller angle with the surface of the mirror; and that at last when the ray is nearly parallel to the surface, its plane of polarisation coincides with that of the incident light, as it did when the incidence was perpendicular.

Let us call the angle of incidence, reckoned from the perpendicular,  $i$ , the corresponding angle of refraction for the substance concerned,  $i'$ : the tangent of the angle, formed by the plane of polarisation of the reflected light with the plane of reflection, will be expressed by  $\frac{\cos(i+i')}{\cos(i-i')}$ .

This formula may be illustrated by applying it to particular cases. If  $i=0$ ,  $i'$  being also  $=0$ ,  $\frac{\cos(i+i')}{\cos(i-i')} = 1$ : but the angle of which the tangent is unity is an angle of 45°. Consequently, if the formula is correct, the plane of polarisation for the reflected ray, when the incidence is perpendicular, must coincide with the primitive plane of polarisation of the light employed; and this is conformable to observation.

The angle of which the tangent is  $\frac{\cos(i+i')}{\cos(i-i')}$  becomes also 45° when  $i=90^\circ$ : that is to say, when the rays are parallel to the surface concerned, since then  $\cos(i+i') = -\cos i'$ , and  $\cos(i-i') = +\cos i'$ . The light preserves, therefore, in this case also, its primitive plane of polarisation, as the experiment had shown.

If  $i+i'=90^\circ$  the angle  $i$ , as it has already been observed, (Sect. III.) is that of complete polarisation, and  $\frac{\cos(i+i')}{\cos(i-i')} = 0$ : so that the plane of polarisation of the reflected ray coincides with the plane of reflection; which has already been shown by experiment.

The following table will show that, for interme-

diated angles of incidence, the agreement between this mode of calculation and the observation is as satisfactory as it was possible to expect.

On Glass.

Angles of Incidence.	Observed Deviation of the Plane of Polarisation.	Computed Deviation.	Difference.
24°	38° 55'	37° 54'	+1° 1'
39	24 35	24 38	-0 3
49	11 45	10 52	+0 53
56½	0 0	0 0	0 0
60	5 15	5 29	-0 14
70	19 52	20 24	-0 32
80	32 45	33 25	-0 40
85	38 55	39 19	-0 24
87	40 55	41 36	-0 41
88	41 15	42 44	-1 29
89	44 35	43 52	+0 43

On Water.

Angle of Incidence.	Observed Deviation.	Computed Deviation.	Difference.
53°	0° 0'	0° 0'	0° 0'
60	10 20	10 51	-0 31
70	25 20	24 48	-0 32
80	36 20	35 49	+0 31
85	40 50	40 32	+0 18

The formula, thus compared with experiment, supposes, that the primitive plane of polarisation of the light employed makes an angle of 45° with the plane of reflection: but a slight addition is sufficient to accommodate it to all other cases. If we make  $a$  the angle of which the particular value is here assumed 45°,  $i$  and  $i'$  retaining their values, the tangent of the angle expressing the deviation of the plane of polarisation of the incident pencil, after reflection, will in general be represented by  $\frac{\cos(i+i')}{\cos(i+i') \cos a}$ .

It is easy to observe, that in the most material cases, this formula correctly corresponds with the experiments: but we are still in want of an experimental demonstration of its truth for any very diversified combinations of the values of  $a$  and  $i$ .

The deviations of the planes of polarisation follow the same gradations when the reflection takes place at the second surface of transparent mirrors, from the position of perpendicular incidence to that of the beginning of total reflection. But beyond that inclination, the phenomenon acquires a character totally different: we have then no longer a simple change of the direction of the primitive poles of the ray; for unless the plane which contains the poles either coincide with the plane of reflection or be perpendicular to it, the ray will undergo a true depolarisation, so that however we place the rhomboid through which we cause it to pass, we shall always

Polarisation  
of Light.

observe, that two images are formed. The same happens also when the mirror is metallic: The particular and very remarkable modifications which the light undergoes in these two cases will shortly be mentioned.

SECT. VII.—*Of the Phenomena of INTERFERENCE, so far as they are modified by a previous Polarisation of Light.*

It has long been known, [having, however, first occurred to the translator of this article in the room and at the table on which he is now writing,] that if, after having cut in a thin plate of metal, two very fine slits very near to each other, we cause them to be enlightened by a pencil proceeding from the same radiating point, we may observe behind the plate a formation of iridescent fringes, derived from the action exerted by the rays scattered from the left hand slit on the rays scattered from the right hand slit, in the points where these two parcels of rays are intermixed.

This experiment, when studied in all its details, has led to the simple law, which may be thus enunciated: Two rays of homogeneous light, *proceeding from the same source*, and arriving from a given point of space by two different routes, a little unequal in length, co-operate with each other, or are destroyed, and form, on a screen which receives them, either a bright or a dark spot, according to the magnitude of the difference of their routes.

The two rays always co-operate completely, when they are united after passing through a route of equal length. If the smallest difference of routes, which will cause them again to co-operate, be called  $d$ , they will co-operate wherever the distance is any member of the series  $2d, 3d, 4d, \dots$ ; and the intermediate values  $0 + \frac{1}{2}d, d + \frac{1}{2}d, 2d + \frac{1}{2}d, \dots$ , will show the cases in which the two rays, when combined, produce darkness. The magnitude of the quantity  $d$  varies with the species of light concerned, and with the nature of the medium which transmits it.

If two rays destroy each other after having passed through routes differing, for example, by the quantity  $d'$ , they will also destroy each other after having passed through, either perpendicularly, or with the same obliquity, two plates of the same nature, and of the same thickness.

A difference of thickness or of refractive density, in the two plates interposed, may produce the effect of an inequality in the routes described: the difference will give rise, in certain cases, to a displacement only of the fringes: but in others they will entirely disappear.

These laws relate to the rays of light in their natural state; if we employ polarised light, we obtain results, which, independently of the numerous applications of which they are susceptible, deserve for their singularity to arrest our attention.

Let us first suppose that instead of enlightening the two slits of the plate of metal with natural rays, we employ polarised light, the fringes will be formed equally in both cases.

If we then try the effect of the light polarised in one direction and transmitted by one of the slits on

the light polarised in a perpendicular direction, and transmitted by the other; an arrangement which may be obtained by placing two piles properly directed in the passage of the different rays: we shall find that when the directions are correctly perpendicular, there is no trace of fringes behind the perforated plate.

Polarisation  
of Light.

It has been remarked that any material difference in the mediums through which the two rays pass, is sufficient to annihilate the effects of interference which would otherwise be observable. The experiment now mentioned would therefore be wholly inconclusive, if we had not previously assured ourselves that the piles, which are supposed to be of the same nature, are also exactly of the same thickness. The best mode of ascertaining this is evidently to render the two planes of polarisation parallel: if in this case we perceive fringes, and if after having turned one of the piles one fourth of a revolution round its axis without changing their mutual inclination, we find that they disappear, we may fairly conclude that this disappearance must be attributed to the direction of the polarisation of the rays of light concerned.

This experiment would be a very difficult one to make with success if the piles had any considerable thickness: but they may be made very thin by means of plates of mica, or of bits of glass blown in a lamp: and then by dividing them in the middle, we may obtain a pair of piles of thicknesses perfectly equal. Besides, nothing prevents our varying gradually the inclination of one of the piles, so as to compensate in this manner for the effect of a slight difference of thickness, if it exists.

But there is another mode of observation which is more convenient. We take a crystal of tourmaline cut in a direction parallel to its axis, so as to form a plate with parallel surfaces; we divide it into two parts, and apply the two portions, one to the slit on the right hand of the plate, and the other to that on the left. We then find that fringes are produced when the two axes of the fragments are parallel; and that no traces of them are left when they are perpendicular to each other; and that in changing the positions of the portions of tourmaline from one of these relations to the other, the intensity of the fringes gradually disappear.

Supposing now the piles to remain fixed to the slits in perpendicular directions, so that no fringe may be visible; and placing a third pile before the eye of the observer, in a plane that forms an angle of  $45^\circ$  with the planes of incidence of the two former: this last plane must reduce to a similar polarisation the rays coming from the two slits, which before they met were polarised at right angles; so that there seems to be no reason why the rays should not again interfere: and yet whatever pains we take in the experiment, we shall discover no trace of fringes. [Might there not, however, be fringes if the rays met behind the third pile rather than before it? T.R.]

It is unnecessary to remark, that a tourmaline of any kind may be substituted for the third pile, as the two former may be exchanged for the two halves of a piece of tourmaline with parallel surfaces: the result will be precisely the same.

Polarisation  
of Light.Polarisation  
of Light.

Let us lastly suppose, in order to exhaust all possible combinations, that the plate of metal is illuminated with polarised light, and that two piles or two tourmalines are so placed, as to transform the rays passing through the two slits from rays polarised in the same direction, into rays polarised in directions at right angles to each other: and that before the interference of the rays we bring them back to a similar polarisation, either by the assistance of a third pile, or by that of a tourmaline, as in the former experiment: the observer will then find, and, no doubt, with great surprise, that the rays are again susceptible of interference; or that in mixing together they produce a very visible group of iridescent fringes.

The series of experiments here related leads us to the following conclusions.

1. Two pencils converted from natural light into light polarised in the same direction, retain, after this modification, the property of interfering with each other.

2. Two pencils, which are made to pass directly from the state of natural light to that of light polarised in two perpendicular directions, are no longer capable of interference, either while they remain in this state, or after they have been restored to a similar polarisation.

3. Two pencils polarised in contrary directions, do not interfere, whatever may have been the modifications that they have undergone before they arrive at this state from that of natural light: but when restored to a similar state of polarisation, they become capable of interfering, provided that in their passage from the natural state to that of polarised light the **FIRST** planes of polarisation of the two pencils were parallel.

Thus it appears that in these phenomena the mode of action of the rays does not depend on *what they are* only when they meet, but also on *what they have previously been*.

SECT. VIII.—*Of the kind of Polarisation which is exhibited in the appearance of Colours, and which has therefore been called COLOURED POLARISATION.*

We may first examine the *nature* of the new modification of light that is concerned in these appearances; and secondly, the *means* of producing it.

Supposing a ray of direct light to be polarised in any of the ways that have been described, and then to pass through a plate of rock crystal, cut perpendicularly to the edges of the hexaedral prism, about a quarter of an inch in thickness, and having both its surfaces perpendicular to the ray: when it emerges from the surface, it will no longer possess the properties of common polarised light; and yet it will not have reassumed the characters of direct light: for if we submit it to the action of a rhomboid of carbonate of lime, instead of affording one image only in a particular position with respect to the principal section of the crystal, it will be *constantly* subdivided into two pencils: so that it cannot be identical with common polarised light.

Neither is it simply natural light: for a white pencil of natural light is always divided by a doubly refracting crystal, into two white pencils of equal in-

tensity: the white pencil which has passed through the plate of quartz, on the contrary, gives always two images, but they are distinguished by the most vivid colours. If the ordinary image is red, the extraordinary is green, and the reverse; and the case is the same with regard to the other prismatic colours; that of the ordinary pencil is complementary to the tint of the extraordinary pencil, and they both vary according to the position of the principal section of the rhomboid which causes the separation.

The prismatic telescope of Mr Rochon affords an apparatus perfectly adapted to the performance of these experiments, and which requires to be mentioned first, because it exhibits the tints with great brilliancy; secondly, because it gives us the means of assuring ourselves, that the images viewed lose nothing of their distinctness by the interposition of the plate, and that its effect is not owing to any irregular dissipation of the light concerned; and thirdly, on account of the facility with which it allows us to show that the tints are complementary to each other.

This instrument is nothing more than an ordinary telescope, furnished, between the object glass and the eye glass, with a prism of rock crystal or of carbonate of lime, rendered achromatic. This prism being moveable at pleasure along the axis of the telescope, the observer is enabled to separate more or less, at his pleasure, the two images of the object which he is viewing.

Having then before the object glass of this telescope the plate of quartz in question, and adapting besides to the eye glass a greenish dark glass of a particular kind, which is much employed by astronomers because of its property of absorbing a good deal of light, without sensibly colouring the transmitted pencil: if we observe the sun directly with this instrument, we shall see two images of the sun, both white, and of equal brightness; whence it follows that the plate produces no particular effect on natural light: but if on the contrary we look at the sun's image as reflected by a plate of glass not silvered, we shall perceive two more suns, each of them coloured; and while the telescope performs half a revolution on its axis, they will both run through nearly the whole series of the prismatic colours. Thus, the image, that was red, will become successively orange, yellow, greenish yellow, bluish green, and violet: and at this period the telescope will have made half a turn; its movement being continued, the violet image will become first red, then orange, and so forth. The second image will always give us the complementary colour: for if, instead of completely separating the images, we allow them to overlap each other, the part common to both the discs will remain constantly white: while the remaining lunular portions will exhibit the most vivid colours.

The reflection of a transparent plate may also be employed for more directly exhibiting the distinctive properties of the light transmitted by the plate of quartz.

If we cause a plate of glass to turn round a pencil of natural light forming with its surface an angle of about  $35\frac{1}{2}^\circ$ ; the reflected pencil will be directed in succession to all the points of the horizon, but it will constantly preserve *the same intensity*.

Polarisation  
of Light.

But if the incident pencil is polarised, we shall find, on the contrary, two positions diametrically opposite to each other, in which the mirror will not reflect a single ray.

Making, now, a similar experiment with the light that has been transmitted by a plate of rock crystal, we shall see that it becomes coloured by reflection, though it falls white on the plate, and that the nature of the colour depends on the side of the ray that is presented to the reflecting surface. These reflected colours succeed each other during the revolution of the plate, in the same order as in the prismatic spectrum: they are also observed in the transmitted light, being always complementary to those of the light reflected at the same time.

If the properties of polarised rays depend, as is supposed by the partisans of the system of emission, on the particular arrangements assumed by the molecules of which they are formed, it will be easy to describe the intimate composition of the ordinary polarised ray; and that of the same ray after it has passed through the plate of rock crystal: in the former, the axes of all the molecules of the different colours, must be parallel; in the latter, the molecules of different tints must have their poles turned towards different parts of space.

It now becomes necessary to examine according to what law the direction of these poles is varied, both as they depend on the particular tint of each molecule, and on the greater or less thickness of the crystal that they have passed through.

If we employ homogeneous polarised light, we shall readily find, that, supposing a given plate of quartz to turn the poles of a certain ray of light through an arc of 20° from their primitive direction, a plate of the same crystal twice as thick will cause a double deviation, and will turn the pole through an arc of 40°; a plate of thrice the thickness will cause a triple deviation, amounting to 60°, and so forth without limit.

With regard to the simple rays of different colours, in passing through a given plate, they undergo deviations so much the more considerable as they are more refrangible, and this in the inverse proportion of the numbers which Newton calls the lengths of the fits; or, what comes to the same result, in the inverse proportion of the quantities which have been designated in this article by the letter *d*. (Sect. VII.)

When, therefore, we know the deviation for a given plate, we may find the effect of a thicker or thinner plate of the same substance by a simple proportion.

*Table of the Deviations of the Planes of Polarisation of the different "Homogeneous" Rays in passing through a Plate of Rock Crystal perpendicular to the Axis of the Prism, of which the thickness is a millimetre, or .03937 E. I.; [according to the Newtonian division of the spectrum.]*

Polarisation  
of Light.

There is no reason to suppose that the angular deviations will undergo any alteration in their values when all the molecules pass through the crystal at the same time. Consequently, in the white pencil transmitted by a plate of a millimetre, the axes of the elementary red rays will form an angle of 8° with the axes of the first orange rays; of about 5° with those of the first yellow rays, and of 26.5° with the axes of the extreme violet rays: and if we analyse this white pencil by means of a rhomboid, the differently coloured rays will not be divided in the same proportions between the two images: hence there will necessarily be appearances of colour. It is obvious, for example, that when the rhomboid is so placed that its principal section shall coincide with the poles of the red ray, this ray will remain altogether in the ordinary pencil, and the red tint will be wholly wanting in the extraordinary image.

We may obtain an exact idea of the modification which a plate of quartz produces in a white pencil of polarised light, by conceiving a combination of red rays polarised by reflection at the surface of a certain transparent substance, of orange rays polarised by a second surface placed in a different angular situation, of yellow rays polarised by a third surface, and so forth. The necessity of the intimate mixture of all these kinds of molecules in each line of white light, and some other obstacles, would render it impossible to realise this fiction without a very complicated apparatus: while a simple plate of quartz is sufficient, on the other hand, to give to the different constituent parts of the white pencil these individual polarisations situated in different azimuths.

The phenomena which have been described are produced by plates of quartz with parallel surfaces cut perpendicularly to the axis of the hexaedral prism. Now in a direction perpendicular to these surfaces quartz exhibits no double refraction: so that the causes, which in this case produce the deviation of the planes of polarisation of the luminous molecules, are different from the causes which occasion the separation of the two pencils in other sections of the crystal. And it is remarkable that the properties of these plates have been found in bodies not possessed of regular crystallization, as flint glass, and even in perfect fluids, such as the essential oils of turpentine and of lemons, or the solution of camphor in alcohol, the simple syrup of sugar, and so forth. The only difference is in the absolute value of the thicknesses which afford the same tints: the other laws remaining the same. Thus the thickness of oil of turpentine must be 69 times as great as that of a plate of rock crystal to produce the same effect: and the action of the oil of lemons is to that of the oil of turpentine as 17 to 10 [or to that of crystal as 1 to 41].

We have seen that a plate of quartz a millimetre in thickness causes the poles of the red molecules to describe an arc of 17.5°. We may suppose this motion to have taken place from right to left: then every other plate, of whatever thickness, cut out of

Polarisation  
of Light.

*the same crystal*, will cause the poles to deviate still farther in the same direction, that is to turn still from right to left: while other plates, on the contrary, cut out of a different crystal, may turn them from left to right. This phenomenon, at first sight, must appear very singular; but if we reflect that the rays pass through the plates in a direction which affords no double refraction, we shall be aware that a deviation of the poles, directed constantly the same way in every specimen of the crystal would be not at all less astonishing.

It has not hitherto been possible to point out any exterior signs which shall indicate the direction of the deviation that will be produced by a given crystal, except in one very remarkable case. In some varieties of quartz, the solid angles, situated at the base of the pyramid by which the prism is terminated, are replaced by as many facets placed obliquely with respect to the edges. Now the direction of the deviation, which these *plagiedral* crystals give to the poles of the luminous molecules, is constantly that of the obliquity of these little facets.

When a polarised ray passes successively through two plates producing contrary rotations, the ultimate deviation of the poles is the difference of the effects which each plate would have produced separately. The ray exhibits exactly the same tints as if it had passed through a single plate, of a thickness equal to the difference of the thicknesses of the two plates.

If the plates thus combined are equal in thickness, the pencil transmitted, having been turned first in one direction, and then turned back in the contrary direction, seems not to have its polarisation ultimately changed.

The essential oil of turpentine causes the axes of the molecules of the polarised ray to turn from the right to the left of the observer receiving the ray: the essential oil of lemons from left to right. These fluids do not lose their peculiar properties, when they are mixed; so that if their proportions in the mixture are inversely as their rotatory forces, the ray which has passed through them retains its primitive polarisation.

SECT. IX.—*On the Phenomena of DEPOLARISATION, and of COLOURS produced by CRYSTALLIZED PLATES not cut perpendicularly to the Axis of Double Refraction.*

We are next to inquire how a white pencil, polarised in a single direction, is modified in passing through a crystalline plate possessed of double refraction.

For this purpose we may place the principal section of a rhomboid of calcareous spar in the plane of polarisation of a white pencil, which of course will be subjected to the ordinary refraction only: we may then place the plate in question before the rhomboid, so that the rays may pass through it perpendicularly. If now the principal section of this plate is parallel to that of the rhomboid, we shall still see but one white image; and the same will happen if the principal sections are perpendicular to each other: but in every other situation of the plate, the

rhomboid will furnish two pencils, and they will be distinguished by *complementary tints*.

The motion of the plate in its own plane does not alter the *nature* of the tints: their brightness only varies, and becomes greatest when the angle formed by the two sections is equal to  $45^{\circ}$ .

These tints vary with the thickness of the plate, and degenerate into perfect whiteness when the thickness becomes considerable. In the sulphate of lime, the appearances are no longer observable when the thickness is about half a millimetre, or one fiftieth of an inch.

Supposing *O* to be the tint of the ordinary pencil, and *E* that of the extraordinary: the experiment shows that the tint *E* is nearly that of one of the coloured rings seen in the light reflected from two object glasses touching each other, as in the celebrated experiments of Newton; and that the tint *O* is that of the corresponding transmitted ring. This rule, however, is not perfectly general; for in many crystals the tints *E* by no means resemble those of the rings.

When the regular sequence of the Newtonian rings is observable, the successive thicknesses of the same crystal, which afford the respective colours *E*, are proportional to those which Newton has assigned for substances not crystallized: it is only found that, for any given density, the absolute values of these thicknesses greatly surpass the thicknesses shown in the Newtonian tables.

We find also a remarkable relation between the tint *E*, the thickness of the plate, and the elements of its double refraction, which it is important to point out. The image *E* only appears when the principal section of the plate is neither parallel nor perpendicular to the primitive plane of polarisation of the ray which passes through it. If we suppose this plate to possess only the ordinary properties of double refraction, the ray will in general be divided by it into two pencils, one of which will be refracted ordinarily, the other extraordinarily: so that two pencils from the same origin meet, after having passed through different routes, and *interfere*. There is a certain inequality of the lengths of these paths at which the red rays destroy each other; at another interval, the yellow rays, the green, the blue, and so forth. If we determine, from these principles, the tint resulting from the interference of the different rays, taking into account the thickness, and the intensity of the double refraction of the plate, we shall always find a very satisfactory agreement between the calculation and the experiment. [See the Article CHROMATICS, in this *Supplement*.]

The singular deviation which these thin plates seem to produce in the poles of the molecules of different colours which constitute white light, was extremely difficult to be discovered: and nothing shows this difficulty better than the general assent of natural philosophers to the laws which have been the foundation of the *theory of moveable polarisation*. It is not therefore sufficient to explain here the true principles on which these phenomena are founded: the confutation of an erroneous theory becomes absolutely necessary in this stage of the investigation;

Polarisation  
of Light.

Polarisation  
of Light.

especially when it is plausible in appearance, and when it is brought forwards with confidence in the latest works, notwithstanding the decisive objections which had been opposed to it.

The fundamental theorem of this *moveable polarisation* has been thus enunciated. "When a ray of natural light, polarised in a certain fixed direction, passes perpendicularly through a crystallized plate, which is parallel to the axis of double refraction, the molecules of light penetrate at first to a certain distance without losing their primitive polarisation: after this they begin to perform periodical oscillations round their own centres, so that their axis of polarisation is carried alternately on each side of the principal section of the crystal, or of the line perpendicular to it, like a pendulum passing from one side to the other of the vertical line which is its quiescent position. Each of these oscillations is performed in a given thickness  $2e$ , twice as great as that in which the molecule had made its excursion in one direction. Thus, from the thickness zero to a certain fundamental thickness  $e'$  the homogeneous molecules of which the ray passing through the crystal is composed, are affected, after their emergence, as if they had not quitted their primitive polarisation; from  $e$  to  $2e$ , they are affected as if they had assumed a new polarisation, differing from the former by the azimuth  $2i$ ;  $i$  being the angle which the principal section of the plate forms with the original plane of their polarisation: and they appear in short alternatively polarised in their former azimuth, and in an azimuth at the distance  $2i$  from it."

To this law it may be objected, first, that whenever the light emerging from a crystal with one axis, whether thin or thick, is composed of two distinct pencils, we find that they are polarised in directions at right angles to each other, whether the incident light may have been natural or polarised: and no exception to this rule has yet been discovered. Now it is difficult if not impossible to conceive, in the system of moveable polarisation, how the transition can be made from that state into the state of polarisation in two directions at right angles, which, for the sake of distinction, has been called the fixed polarisation.

But there is a still more direct objection to this theory. If we place a plate of sulphate of lime in such a manner that its principal section may make an angle of  $45^\circ$  with the primitive plane of polarisation of homogeneous light that is to pass through it; the angle  $2i$  being then equal to  $90^\circ$ , the transmitted pencil, according to the doctrine of moveable polarisation, would be ENTIRELY polarised either in the primitive plane, or in the plane perpendicular to it, and when analysed by means of a rhomboid, it would exhibit, in two positions of the principal section of this crystal, only a single image. But this is so far from being true, that if the plate is of a proper thickness, the pencil will be constantly divided into two images of equal intensities, whatever the direction of the principal section of the rhomboid may be.

When two pencils, derived from the same origin, and possessing the same velocity, are made to intersect each other at a very small angle, after having travelled by different paths, of which the lengths are slightly different, they may destroy each other com-

pletely, as we have already seen: and this destruction would as readily take place if they came by the same path with different velocities. Let  $d$  be the difference of the paths which determines, in the first case, the periodical series of the points of space in which two rays of a certain homogeneous light produce complete darkness by their interference: the same letter  $d$  will express, in the second case, the quantity by which one of the rays will require to be more advanced than the other by the excess of its velocity, in order that the light may again be destroyed. When, in a crystallized plate, the difference of the tracks described by the ordinary and extraordinary rays of a given kind of light, or when the effect of the difference of velocity is  $0, nd$ , or  $(n + \frac{1}{2})d$ ,  $n$  being a whole number, a pencil previously polarised, and transmitted by the plate, WILL APPEAR ENTIRELY polarised in the primitive plane, or in the azimuth  $2i$ , as the principles of the doctrine of moveable polarisation require.

When the plate has such a thickness, that the difference of the paths described by the ordinary and extraordinary pencils is included in the general formula  $(n + \frac{1}{2})d$ , the transmitted light will appear to have become common light, if the principal section of the plate makes an angle of  $45^\circ$  with the primitive plane of polarisation of the incident light: which, as we have already seen, by no means agrees with the doctrine of moveable polarisation.

Lastly, when the thickness of the plate employed is not comprehended in any of the preceding expressions, the completely polarised rays, which pass through it, emerge with the characters of a partial polarisation. This result is no less inconsistent than the former with the laws of moveable polarisation; since, according to these laws, the polarised incident ray ought always to emerge completely polarised, with a simple change of the azimuth of its poles.

It is not, therefore, generally true, that a pencil of polarised homogeneous light, which passes through thin crystallized plates, either preserves its primitive polarisation, or assumes a new one at the angular distance of  $2i$ : and with this falls the whole fabric of the oscillatory motions attributed to the molecules of light. With respect to the objection already made to this theory, regarding the connexion to be established between the phenomena of thin plates and those of thick crystals, it seems to retain its full force, since it has not been established by experiment that the rays concerned in the phenomena of thin plates are polarised in two rectangular directions.

Supposing, however, for a moment, that this were the case, and that a luminous pencil, passing through a thin plate of sulphate of lime, is divided into two rays, the one ordinary and the other extraordinary, polarised at right angles: let us examine what would be the consequence. Mathematically speaking, these two rays follow in general different routes within the crystal; but it is not possible to separate them physically, because the imperfection of our organs forces us to contemplate objects of a certain extent. The advocates of a moveable polarisation will examine this light in a mass. They will find in certain cases that it appears to have preserved its primitive polari-

Polarisation  
of Light.

Polarisation  
of Light.Polarisation  
of Light.

sation; and in others that it seems to be polarised in an azimuth differing by  $2i$ ; and they will hence conclude that thin plates act very differently from a thick crystal.

This conclusion, however, may be disputed. When we make use of a thick crystal, the ordinary and extraordinary images are separated; we study the properties of each apart. In the case of the thin plates the observer has to do with light which is mixed and complicated. Now who can affirm, without having made the experiment, that two rays really polarised at right angles, will not seem, in cases of interference, to have lost their primitive polarisations, and will not exhibit an intermediate polarisation the result of the others, which might be considered as *composing* it?

The reader will now have conjectured, that, in order to elucidate these mysterious phenomena, it will require to be proved, first, that two pencils are actually formed in the thin plates of crystallized substances, as well as in thicker crystals, polarised at right angles to each other; and secondly, that these pencils, when they are mixed, may exhibit the *appearance* of a polarisation intermediate between the two separate directions. Such then is the object of the very delicate experiments which are now to be related.

A pencil of homogeneous solar light being concentrated into a very small point, by the aid of a lens of a short focus, fixed in the shutter of a dark room, the pencil of diverging rays is to be received on two plates of glass slightly inclined to each other, and making an angle with the ray of about  $35^\circ$ : the pencils reflected by the two plates will then be completely polarised, and where they intersect each other, they will form light and dark stripes; and whatever the position of the plates may be, the stripes will be polarised in the same direction as the two pencils which afford them.

If we now take a very transparent plate of sulphate of lime, and divide it in the middle, so as to have two plates of exactly the same thickness: if we fix one of the halves of this plate before the mirror, in such a situation that it may transmit that pencil only which is reflected by the first mirror, and so that the principal section may make an angle of  $45^\circ$  with the primitive plane of polarisation: and then the other half of the plate in the way of the polarised light reflected by the other mirror, but with its principal section at right angles to that of the other plate, and making an angle of  $45^\circ$  with the primitive plane in a contrary direction: *then, if these plates act in the same manner as thick plates*, however small the measure of their double refraction may be, they must divide the reflected rays which pass through them into two pencils of the same intensity, and polarised at right angles to each other: but in the positions here assigned to them, it will evidently happen that the plane of polarisation of the ordinary pencil coming, for example, from the right hand plate, will be parallel to the plane of polarisation of the extraordinary pencil of the left hand plate: and the same will be true of the two remaining pencils of the respective plates.

This being admitted, it is easy to see what will

happen at the points in which the two pencils intersect each other. The ordinary rays of the right hand plate will at once interfere with the extraordinary rays of the left hand plate, since they are polarised in the same direction, and will form a group of light and dark stripes: and a second group will be afforded by the extraordinary rays of the right hand plate and the ordinary of its companion. The two groups will be the further separated from each other as the plates are thicker, and as their double refraction is more strongly marked. In the intermediate space we shall find the rays of the same description furnished by the two plates; but as they have now received contrary polarities, they intersect each other without exhibiting any of the phenomena of interference, and the eye has the sensation of a uniform light only.

A fact which is no less evident than the existence of the two systems of stripes, is, that when we employ the sulphate of lime, each of the systems is completely polarised, in a plane perpendicular to the principal section of the plate which is nearest to it.

Now there is no one of the consequences of the supposition with which we set out, that is, the supposition that every plate divides polarised light passing through it *into two pencils polarised at right angles*, that is not fully confirmed by this experiment. The truth of the hypothesis is therefore demonstrated, for every other mode of separation or of polarisation of the rays, that for example which is deduced from the principles of moveable polarisation, would lead to phenomena totally different from those which have been described.

A little attention to the passages (SECT. VII.) containing an account of the circumstances under which polarised rays are capable of occasioning appreciable effects of interference, will be sufficient to convince the reader, that the two systems of stripes which have been the subjects of these experiments can only have been the result of the interference of the ordinary rays of one plate with the extraordinary rays of the other. But if any doubts were entertained on this subject, they might be removed in the following manner.

We might substitute for the two thin plates, which have been employed, two thick crystals, for example two rhomboids of carbonate of lime, in which the double refraction would be manifest. As we might then follow separately the course of each pencil, and intercept them in turn by screens, it might thus be proved by the most direct evidence, that for the formation of the two groups of stripes, it is necessary and sufficient that the ordinary pencil of one of the crystals should meet the extraordinary pencil of the other, and the reverse. The direction of the polarisation of these fringes, determined by the aid of a rhomboid, would also be exactly the same as in the case of the employment of thin plates. The only remarkable difference between the two experiments would be in the degree of separation of the two groups of fringes. This distance, depending on the difference of the paths described by the ordinary and extraordinary rays, would be "greater" [or rather smaller] with the crystals than with the plates. It might even happen, if the crystals were very thick,

Polarisation  
of Light.

that in order to "bring the stripes within the field of view," [or to render them visible], it would be necessary to compensate for a part of the difference of the lengths of the paths, or of the velocities, by the assistance of a plane glass, fixed in the way of one of the pencils; but in every case the results of the experiment would be equally clear and decisive.

It may also be added, in the last place, as a full answer to every objection that might be raised against this explanation of the formation of the two groups of stripes, in the thin plates, that the interval which separates the two systems is always so dependent on the double refraction of the plates, that its exact numerical value may always be deduced from the elements of the double refraction, as obtained by experiments on other portions of the same substance. [See CHROMATICS.]

We must now consider how it will be possible to reconcile the experiment which has been related, and which proves the subdivision of the light into two pencils, polarised at right angles to each other, with the other fact, which seems to be opposed to it, that when the plate is of a proper thickness, the whole group of polarised rays, that pass through it, shall appear to be polarised either in the primitive plane, or in another making with it an angle of  $2i$ .

We make, in a dark room, a very small radiant point of homogeneous light, by means of a lens, as already mentioned. We receive the diverging pencil, on a plate of glass, having its posterior surface covered with a black varnish: supposing the plate to be in a vertical position, and the diverging pencil to be nearly horizontal, and to make an angle with the surface not much differing from that of complete polarisation: when this arrangement is completed, we place in the way of the reflected light a rhomboid of calcareous spar, its principal section making with the horizon, or with the plane of reflection, an angle of  $45^\circ$ . In this position of the rhomboid, the light passing through it is divided into two pencils, the one ordinary and the other extraordinary, polarised at right angles, and of equal intensity. After having passed through the first rhomboid, the two pencils fall on another rhomboid of the same thickness, but having its principal section perpendicular to that of the former. The ordinary pencil will then be subjected to the extraordinary refraction in it, and the reverse: and the two pencils will emerge from the second rhomboid, one polarised in the plane of its principal section, and the other perpendicularly to it.

Let us now follow the course of each of the pencils: in the first place it is evident that on account of their divergence, they will intersect each other in a space so much the wider as they become more remote from the rhomboid: their points of emergence being distinct, and sensibly separated, the observer may intercept in turn with a screen either the ordinary or the extraordinary pencil, and enlighten at pleasure any other object either with the one or the other separately, or with both at once.

This delicate and complicated experiment being so far advanced, let us place a glass slightly roughened, in a part of the field of view common to the two pencils: marking, by a very fine opening in an

opaque plate covering the glass, the precise spot on which we fix our attention; and employing, as usual, a doubly refracting crystal to analyse the different kinds of light, which, after passing through the slit in the diaphragm, depict an image within the eye.

It will now easily be observed that the ordinary ray, when it arrives alone at the aperture, wherever it may be placed, undergoes no modification, and remains polarised as it was before: and the same is true of the extraordinary ray: but if both these rays intersect each other in the slit, and enter the eye together, the phenomenon is by no means so simple, and its nature changes according to the place occupied by the slit: so that moving this slit gradually by means of a screw, we soon find the point where the light, composed of the two pencils that pass through it, seems to be wholly polarised in the same manner as the pencil was at its first reflection from the plate of glass: further on, the plane of polarisation seems to be perpendicular to the primitive plane: and in a position intermediate between these, the rays transmitted afford no material traces of polarisation at all.

This experiment therefore offers us the singular phenomenon of two pencils, polarised at right angles, which, after having intersected each other in the ground glass, unite within the eye, and form together, as the test of the rhomboid shows, a pencil polarised sometimes in one direction, and sometimes in an opposite one, or sometimes without any sensible trace of polarisation, according to the magnitude of the difference of the paths described by the two pencils.

It is only to assist the imagination that the piece of ground glass has been supposed to be employed: for its presence is not necessary to the success of the experiment. A lens alone may be used for observing the stripes formed in the air by the interference of the luminous pencils. If, however, we merely placed ourselves with this lens before the two rhomboids, the eye would only receive a uniform and continued light: but as soon as a doubling crystal is perfectly *interposed* between the lens and the rhomboids, or between the lens and the eye, we shall observe two systems of dark and bright stripes, the bright stripes of one of the images corresponding always with the dark stripes of the other. The middle stripes, for example, will be bright in the ordinary image, if the principal section of the interposed crystal is parallel to the primitive polarisation of the rays on the blackened glass; and in the same case the middle stripe will be dark in the extraordinary image. The point of space, occupied by the middle of the image, seems therefore to transmit to the eye, through the crystal, only such light as is polarised in the primitive plane, because it affords only an ordinary image of the light: and this circumstance shows also that the effects of interference in the extraordinary image require, for their computation, the addition of  $\frac{1}{2}d$  to the difference of the paths described.

When the principal section of the crystal interposed between the eye and the rhomboid is perpendicular to the original plane of polarisation, the two kinds of pencils interchange their effects: and in this case the central stripe of the extraordinary image is bright, and that of the extraordinary image is completely

Polarisation  
of Light.

Polarisation  
of Light.Polarisation  
of Light.

dark, as if the difference of the paths of the rays forming it were  $\frac{1}{2}d$ .

It has been hitherto supposed that the original pencil contained only homogeneous light; so that it produced only bright and dark stripes. But if we employ white light, the stripes will be coloured; because  $d$  has different values for the rays of different tints; and these tints are precisely the same as are developed by polarised light in their passage through crystallized plates of all possible thicknesses.

A few words will now be sufficient to show the mode of action of these plates in the phenomena of the colours first described.

A polarised ray, passing through a crystallized plate, which possesses the power of double refraction, is divided by it, mathematically speaking, into two pencils polarised at right angles: but two pencils of this description do not interfere: the plate will therefore not exhibit colours to the naked eye, whatever its thickness may be, even when it is only exposed to polarised light: and this result is confirmed by experiment.

Each of the ordinary and extraordinary pencils, transmitted by the plate, will again be divided into two, when it passes through an achromatic prism of crystal, or a rhomboid of calcareous spar. Of these four emergent pencils, the two, which follow the ordinary path, will be no more separated than they were at their emergence from the plate: and the same is true of the two extraordinary pencils, so that the eye will ultimately perceive but two distinct images.

Of the two pencils which thus concur in the formation of the ordinary image, the one was ordinary in its passage through the plate, and has remained ordinary in the rhomboid placed near the eye, while the action of this rhomboid has been required for bringing the other pencil from the extraordinary to the ordinary refraction. The different kinds of rays have different velocities in crystals capable of double refraction; and an inequality of velocity gives rise to the phenomena of interference, as well as an inequality of distance described. If, in the plate employed, the difference between the velocities of the ordinary and extraordinary ray corresponds, either on account of its thickness or of the diversity of the two refractions, to a certain quantity,  $d$ , or its multiple, the kind of rays of which the interval  $nd$  determines the destruction,  $n$  being a whole number, will be wanting in the ordinary image transmitted by the rhomboid. And this effect, it must again be repeated, depends on the interference of the two pencils of which this image is really formed, and which, in the plate, possessed different velocities.

If the experiment with the two rhomboids had not taught us that in order to calculate the mutual actions of the luminous rays, which in passing through different crystals possessed of doubly refractive powers, have several times changed their planes of polarisation, the ordinary laws of interference require some modification, we should have found ourselves arrested by a considerable difficulty.

The difference of the velocities being the same for the two pencils, of which the extraordinary image afforded by the rhomboid consists, and for the two

which concur in the formation of the ordinary image, it would seem that the rays of the same colour ought to be destroyed at once in both the images, and that they ought to exhibit the same tint: but if we recollect that after having calculated for one of the images the effect of interference corresponding to the difference  $d$  in the path, we are obliged, when we proceed to the other image, in order to obtain results conformable to experiment, to add  $\frac{1}{2}d$  to the difference of the paths or to the effect of the difference of the velocities, this difficulty will disappear. Supposing " $d$ " [ $nd$ ] in the ordinary image to occasion the destruction of the red rays, " $d + \frac{1}{2}d$ " [ $nd + \frac{1}{2}d$ ] will correspond on the contrary to their most complete agreement in the extraordinary image, and these two images will exhibit tints rigorously complementary to each other, as the experiment shows.

The colours developed by polarised light, in passing through crystallized plates, being only, to speak correctly, portions of stripes produced by interference, we must expect to find in them, by varying the thicknesses of the plates, the same apparent deviations of the planes of polarisation, as we found in the experiment on the narrow stripes produced by means of the rays transmitted by two plates of sulphate of lime, of which the principal sections were perpendicular to each other: and it has already been remarked that this analogy is supported by observation.

It can scarcely be doubted that this explanation will readily be adopted as fully satisfactory, by all those who will give themselves the trouble to examine it with sufficient attention: and the subject may now be concluded with the formulas which express the intensities of the ordinary and extraordinary images, for the case of a polarised ray which has passed through one or two crystallized plates, with a perpendicular incidence, whatever may be the situation of their principal sections.

For a single plate, making unity the intensity of the primitive homogeneous pencil;  $i$  the angle made by the principal section of the plate with the primitive plane of polarisation;  $s$  the angle made by this same plane with the principal section of the rhomboid or of the achromatic prism, by means of which we analyse the emergent light:  $o-e$  the difference of the paths of the ordinary and extraordinary rays at their emergence:  $d$  the interval already explained, and  $\pi$  the circumference of the circle of which the diameter is unity: we shall then have,

$$\text{For the ordinary image, } \cos^2 s - \sin 2i \sin 2(i-s) \sin^2 \pi \frac{o-e}{d}.$$

$$\text{For the extraordinary image, } \sin^2 s + \sin 2i \sin 2(i-s) \sin^2 \pi \frac{o-e}{d}.$$

When the polarised pencil has passed through two plates, there must be an additional element in the formula, that is, the angle formed by the principal section of this second plate with the primitive plane of polarisation: let this angle be  $t$ , all the others retaining the same symbols, and let  $o'-e'$  be the difference of the paths belonging to the second plate: the intensity of the ordinary image afforded by a pen-

Polarisation  
of Light.

cil of homogeneous light will then be represented by

$$\cos^2 s + \sin 2t \sin 2i \cos 2(t+i-s) \sin^2 \pi \frac{o-e}{d} -$$

$$\sin 2t \cos 2i \sin 2(t+i-s) \sin^2 \pi \frac{o'-e'}{d} - \cos^2 t \sin 2i$$

$$\sin 2(t+i-s) \sin^2 \pi \frac{o-e+o'-e'}{d} + \sin^2 t \sin 2i$$

$$\sin 2(t+i-s) \sin^2 \pi \frac{o-e-(o'-e')}{d} : \text{ and the inten-}$$

sity of the extraordinary image is found by subtracting this expression from unity.

If we calculate separately, according to these formulas, the intensities of the rays of the different colours which compose white light, we obtain the *tint* of the ordinary or of the extraordinary pencil, whether the light, previously polarised, has passed through one or two crystallized plates: and if, in this calculation, we employ for  $o-e$  and for  $o'-e'$  the values corresponding to the *individual* double refractions to which the different species of rays are subject, we shall find the *most perfect agreement* between the formulas and the experiments, even in those crystals which afford tints that appear to bear *no resemblance* to those of the coloured rings of Newton.

The phenomena of these thin plates therefore, which seemed to some persons to afford an unexceptionable demonstration of the system of emission; which seemed to require the assistance of the most singular oscillations of the molecules of light; which seemed to enable them to discover, in those particles, an axis of rotation, a pair of poles, and an equator; and even a kind of precession of the equinoctial points: these phenomena are in fact only, as we have just seen, the immediate and unavoidable consequences of the simple but inexhaustible laws of interference.

#### SECT. X.—On CIRCULAR Polarisation.

The kind of polarisation which is now to be considered differs essentially from those which have been hitherto examined.

Suppose that, having polarised a pencil of light, we cause it to undergo twice over, at the angle of  $54^\circ$ , a total reflection within a parallelepiped of glass, as seen in the figure: the new planes of reflection being also supposed to be inclined at an angle of  $45^\circ$  to the plane of primitive polarisation: the emergent pencil will then have acquired some particular properties, which are very remarkable.

When this emergent pencil is analysed with a rhomboidal crystal, it is *constantly* decomposed into two rays of the same intensity, whatever

may be the direction of the principal section. From this circumstance it might be supposed that it had resumed the character of ordinary light: but if it be transmitted through a crystallized plate before it is subjected to the action of the rhomboid, we shall soon perceive a distinction: for in this case, common white light would afford two white images, of the same intensity; while the light of the parallelepiped is divided into two pencils, both strongly coloured.

This new kind of rays has also some other peculiarities. It has already been remarked (Sect. V.) that one or more total reflections make no difference in the properties of ordinary light; but they modify, on the contrary, in a remarkable manner, the pencil which has passed through the parallelepiped: for this pencil resumes all the qualities of polarised light when it has been subjected to two total reflections similar to the first, whatever may be the azimuth of the latter planes of reflection with regard to the former.

The pencil of light in question is decomposed, then, into two coloured images, when it is only analysed by a rhomboid after having been transmitted through a crystallized plate: but it must be remarked that the colour of each of these images, on the chromatic circle of Newton, is about one fourth of the circumference distant from the place which the colour of the same image would have occupied, if we had employed only common polarised light.

It may also be added, as another distinguishing character, that this last kind of light gives rise to no phenomena of colour after being transmitted through plates of rock crystal perpendicular to the axis, or through columns of oil of turpentine or of other essential oils.

A polarised ray, modified by two total reflections, has therefore some very particular characters, which distinguish it equally from a direct ray, and from an ordinary polarised ray: and as these characters have no relation to the different sides of the ray, the modification, thus obtained, has received the name of *circular polarisation*. If any person should think the denomination too little supported by the facts described, he may be informed that it has been partly derived from some theoretical considerations, which appear to justify it.

The mode of obtaining the circular from the ordinary polarisation by means of two total reflections having been described, there remains to be mentioned a very remarkable method of procuring the circular polarisation more immediately from common light.

We cut out of a column of rock crystal a very obtuse prism with its two faces forming an angle of about  $150^\circ$ , and equally inclined to the axis of the column, and we make it achromatic as well as we can with two prisms of glass cemented to its opposite faces: or since this method must always be imperfect, we employ, instead of the glass, two other prisms of rock crystal, taken from pieces which possess the opposite qualities which have been described in speaking of plagiedral crystals; and this arrangement has also the advantage of a separation of the images to a double distance. We obtain by means of this little combination the effects of double refraction; but the

Polarisation  
of Light.

Polarisation  
of Light.

two pencils to which it gives birth, when they have been transmitted in a direction parallel to the axis of the column, have not acquired the same modification which Iceland spar, for example, would produce in them, but they are *circularly* polarised. Thus, if we analyse them with a rhomboid, they are always divided into two pencils of equal intensity, and when they have undergone two total reflections within a parallelepiped of glass at an angle of incidence of  $54^\circ$ , they are found completely polarised in two planes inclined  $45^\circ$  to the plane of reflection, the plane of polarisation of the one being to the right, and that of the other to the left.

There exists, therefore, a particular kind of double refraction which communicates to the rays of light a circular polarisation, as the double refraction of the Iceland crystal produces in them the ordinary polarisation.

It follows, besides, from all the phenomena of this class, and from the general laws of interference, that a pencil circularly polarised may be considered as composed of two ordinary pencils polarised at right angles, one of them, however, being supposed to be retarded in its path, in comparison with the other, by a quarter of the interval which has been already denoted by  $d$ .

The properties of rays circularly polarised afford us a very curious mode of reproducing exactly all the phenomena of colours, that we have observed in the plates of rock crystal, cut perpendicularly to the axis, and in certain liquids.

For this purpose we must place a thin crystallized plate between two parallelepipeds of ordinary glass crossed at right angles, and similar to that which has been already represented by a figure. A pencil, passing perpendicularly through the first parallelepiped, undergoes within it two total reflections at the angle of  $54^\circ$ ; after its emersion, it is transmitted by the crystallized plate, and further on it enters the second parallelepiped, and is again twice reflected within it; but in a plane perpendicular to that of the former reflections: at last it emerges into the air, perpendicularly to the last surface of the parallelepiped. Now we may always obtain, in the emergent ray, the appearances of a polarised ray which has passed through a plate of rock crystal cut perpendicularly to the axis, or a certain depth of the essential oil of turpentine: and it will be sufficient for this purpose, that the pencil incident upon the first parallelepiped should be previously polarised, and that the axis of the interposed crystalline plate should make an angle of  $45^\circ$  with the two planes of the total reflections.

[SECT. XI.—Enumeration of the PRINCIPAL MINERALS which are possessed of particular Properties with respect to Polarisation. Added by the Translator.

i. All such regular crystals as belong to the rhomboidal or pyramidal systems of crystallization, described by Mohs, are found to have one axis of double refraction, coincident with the crystallographic axis of these solids.—(Brewster's *Edinburgh Encyclopædia*, Article OPTICS, p. 572.) The axis of a refraction governed by the law of the *oblate* spheroid is called by Dr Brewster a *negative axis*; by M.

Biot a *repulsive axis*; and the axis of the oblong spheroid a *positive* or an *attractive axis*; the crystals are distinguished by the signs — and + respectively.

Polarisation  
of Light.

iii. The crystals which have been enumerated appear to be symmetrical with respect to a single axis, so as to have similar properties in every plane passing through that axis: but Dr Brewster discovered in 1816 that in a great multitude of crystals the refractive powers are different in different planes passing through the principal axis; the phenomena and the laws of refraction being such as may be explained from the combined effects of two axes perpendicular to each other, and unequal in the ellipticity of the spheroids to which they belong.

"All regular crystals which belong to the primitive system of Mohs, or whose primitive forms are the *right prism*, with its base a rectangle, a rhomb, or an oblique parallelogram; the *oblique prism*, with its base a rectangle, a rhomb, or an oblique parallelogram; or the *rectangular and rhomboidal octaedron*, have two axes of double refraction, coincident with some permanent line in the primitive form."

1. Thus, all the combinations of the sulfuric, tartaric, and acetic acids, with single earthy, metallic, and alkaline bases, have two axes of double refraction.

2. The two *apparent* axes of crystals with two axes [or the lines in which the double refraction seems to be neutralised] have no symmetrical relation either with the faces or prominent lines of the primitive or secondary forms of minerals.

3. The two *rectangular* axes, the principal one of which is in the same plane with the two apparent axes, and *equidistant* from them, have a constant symmetrical relation to the faces and axes of the primitive forms in which they crystallize.

4. The line exhibited at any point of the sphere, by the joint properties of two axes, is represented by the diagonal of a parallelogram, of which the sides correspond to the tints belonging to the separate axes, and make with each other an angle twice as great as the angle formed by the planes passing through the given point and the two axes: and the increment or decrement of the square of the velocity of the light may be computed in the same manner as this line representing the tint.

iv. The necessity of any very minute investigation of the properties of particular substances, with regard to double refraction, is in great measure superseded by the very important facts first observed by Dr Brewster in 1814 and 1815, relating to the effects of heat and of compression in producing double refraction and polarisation. He found that compression was capable of producing colour when a soft animal jelly was only touched by the finger: and that when a "negative" crystal, like that of the carbonate of lime, is compressed in the direction of the axis, the tints that it affords "descend," and that they "rise" when it is dilated: whence it seems to follow, that simple dilatation of a homogeneous substance in a given line will constitute that line the axis of an oblate spheroid: but the results require to be distinguished by a greater variety of experiments. M. Fresnel has succeeded in exhibiting not only colours by a strong pressure, but a very manifest reduplication of the image of a line, seen through a piece of glass strongly compressed by screws: and he performed this ex-

periment very successfully at a meeting of the Parisian Academy of Sciences in 1822.]

Polarisation  
of Light.

SECT. XII.—HISTORICAL DETAILS respecting the Discovery of the Different Properties of Light concerned in POLARISATION.

It will now be necessary to enumerate the natural philosophers to whom we are indebted for the discoveries, of which the importance has been explained in this article: and it will be convenient to do this in the order of the sections.

i. HUYGENS appears to be the first person that observed, in the two pencils derived from a single one, by means of double refraction, the existence of particular properties after their passage through the crystal, which they did not possess when they entered it. "It seems," he says, "that we are obliged to conclude, that the undulations of light, by passing through the first crystal of Iceland spar, acquire a certain form, or a certain disposition, by which, when they fall on the substance of a second crystal, in a certain position, they are enabled to affect both the kinds of matter which serve for the two species of refraction, and when they fall on it in another position, they only act on one of these substances."

Thus, according to this great philosopher, in the act of double refraction, the undulation, or the ray, changes its *form*, and loses its symmetry, so as to give room for the distinction of its different *sides*, or, changing the expression only, its different *poles*.

Huygens is therefore the first that observed a phenomenon of polarisation, and this discovery was made in 1678, though it was only published in 1690. From the time of Huygens to the year 1809, no observer, with the exception of the immortal author of the *Opticks*, had studied the subject of double refraction in this point of view: and it must even be acknowledged that, with respect to the facts in question, nothing was added by Newton to what the Dutch mathematician had discovered. He only insisted much more strongly on the necessity of admitting poles in each of the rays, derived from the subdivision, which light undergoes, in passing through an Iceland crystal. To MALUS belongs the honour of having brought back the attention of natural philosophers to the properties of light which form the subject of this article. It was he that first pointed out the singular phenomena exhibited by the ordinary and extraordinary rays when they meet with transparent reflecting surfaces, at certain inclinations: and it is to him that we are indebted for the mathematical law, which appears to connect intensities of the different pencils, into which the light is divided, when it passes through two rhomboids of the spar in succession. (*Mémoires d'Arcueil*, II. 8vo. Par. 1809.)

ii. The anecdote, which has been often told, of the fortunate circumstance that led MALUS to the discovery of the polarisation of light by reflection from transparent substances, is perfectly correct. This philosopher, so early arrested in his pursuit of science by a premature death, and so universally lamented by his friends, has often related to the author of this article, that as he happened to be decomposing, by means of a rhomboid of carbonate of lime, towards

Polarisation  
of Light.

the end of the year 1808, the light of the setting sun, reflected from the glass of the windows of the Luxembourg, he first observed the difference of the intensity of the two images in different positions of the rhomboid: but it is not true, as has sometimes been stated, that one of the images actually disappeared in this observation; for the polarisation of the light, at the moment of the experiment, was only partial. A similar difference of intensity must have been before the eyes of mineralogists whenever they had been trying to examine the double refraction of crystals, and had projected the needle, which they used for an object of view, on a clear and serene sky, which affords a curtain of polarised light. But the fact had not excited their attention. Malus observed it, was struck with all its importance, completely analysed it in all its forms, with the most singular sagacity, and thus became the creator of a new branch of optics. It is to this celebrated observer that we are indebted for all the experiments related in the second section. (*Mémoires d'Arcueil*, II.)

iii. The measurements related in the third section, which appear to show that at equal angular distances above and below the angle of complete polarisation, the reflected rays contain nearly equal quantities of polarised light, were obtained by Mr ARAGO.

iv. It was Dr BREWSTER that discovered the remarkable law, which connects the angle of complete polarisation with the refractive density of the substance. It was communicated to the Royal Society on the 16th March 1815. (*Philosophical Transactions*, 1815.)

The relation of the angle of complete polarisation at the second surface of a transparent medium to the angle belonging to the first surface, had before been shown by Malus. (*Mém. d'Arc.* II.) The same relation may be extended to the angles, at the same surfaces, which afford polarisation of equal proportions of the light falling on them. So that the rule given by Malus is only a particular case of a general theorem, which Mr Arago has deduced from a long series of experiments that have not been published.

v. It was discovered also by Malus that the pencil transmitted by a transparent plate is partially polarised in a plane at right angles to the plane of polarisation of the reflected pencil. This fact was communicated to the Institute on the 11th March 1811, and published the next day in the *Moniteur*. See also the *Memoirs of the Mathematical Class* for 1810. The photometrical experiments of Mr Arago have established a relation between these two kinds of polarisation which had been unobserved by Malus: it is contained in this simple enunciation. "The quantity of polarised light contained in the pencil, which any transparent plate transmits, is exactly equal to the quantity polarised in the contrary direction, which is found in the light reflected by the same plate." These experiments were made in 1812, but they were first published in 1814 by M. Biot, to whom M. Arago had communicated them. (See *Recherches Expérimentales et Mathématiques sur les Mouvements des Molécules de Lumière*. 1814.)

It follows from this law, as Mr Arago had also ob-

served, that at the angle of total reflection, and at all greater obliquities, the light wholly escapes polarisation.

The phenomena exhibited by piles of plates were analysed by Malus, immediately after his discovery of polarisation by refraction.

The observation that some natural bodies, agates for example, act on light precisely like these piles of plates, is due to Dr Brewster. (*Treatise on New Philosophical Instruments*. 8. Edin. 1813.)

vi. The laws and experiments related in the sixth section belong to Mr FRESNEL. Malus had before attempted to discover in what manner the planes of polarisation changed their directions: but there are several inaccuracies in the results which he has published. (*Mém. Inst.* 1810.) The formulæ of Mr Fresnel are some of the most valuable additions that have been made of late to the science of optics. A general account of the deviations undergone, in reflection, by the plane of polarisation of a ray, previously polarised, is found in two Memoirs presented to the Academy by Mr Fresnel, on the 24th November 1817 and the beginning of January 1818: but the mathematical laws of the phenomena were not discovered and published till 1821. (See *Annales de Chimie et de Physique*. XVII.)

vii. Mr Arago and Mr Fresnel are hitherto the only philosophers who have examined the effect of polarisation in modifying the phenomena of interference. The Memoir, in which they first recorded the results which are inserted in the seventh section, appeared in the *Annales de Chimie* for 1819, Vol. X.

viii. It was Mr Arago that first observed the changes in the properties of polarised rays when they pass through crystalline plates; he showed that they acquire the property of being divided by calcareous spar into two coloured pencils, and of being reflected by transparent substances with tints which vary according to the angular position of their surfaces. His Memoir was read to the Institute on the 11th of August 1811, and printed in the volume of the *Memoirs* of that year.

Dr Brewster published some similar experiments in his *Treatise on Philosophical Instruments*, which appeared in 1813. He says that they were made before he had seen Mr Arago's paper, and even "before any of his countrymen had any knowledge of what had been done in France." (*Edinburgh Encyclopædia*, Art. OPTICS, p. 587.) We must take Dr Brewster's word for the first part of this assertion; but since an extract of Mr Arago's Memoir was inserted in the *Moniteur*, on the 30th August 1811, there would be some difficulty in proving the truth of the second part.

The phenomena exhibited by plates, cut perpendicularly to the axis, were also described by Mr Arago in the same Memoir.

We are indebted to Mr BROU for the rule, according to which the deviation of the poles is effected, whether on account of the particular kind of "each luminar molecule," or on account of the more or less considerable thicknesses of the plates by which these "molecules" have been transmitted. His Memoir was read to the Institute in September 1818, and printed shortly after.

Polarisation  
of Light.

Polarisation  
of Light.

Mr Herschel is the author of the curious observation relating to the facets of plagiedral crystals. (*Transactions of the Philosophical Society of Cambridge*, I.)

The extension of the properties of plates perpendicular to the axis, by which they are assigned to the strata of certain liquids, was made by Mr Biot in 1815. (*Bulletin des Sciences*, Dec. 1815.)

ix. The laws of the depolarisation produced by crystallized plates, parallel to the axis, are reduced to the three following.

1. The motion of the plate in its plane does not alter the tints of the images furnished by a rhomboid. This result is implicitly comprehended in the first *Memoir* of Mr Arago; since in the description of all the motions which cause a change of the tints, the motion of the plate in its own plane is not included.

2. The tints of the two images are those of the coloured rings of Newton, seen by reflection or by transmission. This law had been laid down by Mr Biot; but Mr Herschel has shown in the *Cambridge Transactions* that it is not universally true: so that its theoretical importance is lost.

3. In a crystal of variable thickness, the same phenomena of polarisation are reproduced at thicknesses which form a series like that of the coloured rings of Newton. When we examine with a rhomboid a crystal cut in a proper manner, so that two of its faces form an angle, and which is projected on a back ground affording polarised light, each image appears bordered by regular streaks, parallel to the angular edge of the prism, and separated by equal spaces. Mr Arago, when he described this phenomena in August 1811, advanced it as a sufficient proof of this third law. The Academy of Sciences, and Mr Laplace in particular, did not admit the conclusion as demonstrated, and a direct admeasurement of the thicknesses was required. Count Rumford, who was present, offered the use of an instrument which he had employed for some other purposes, and which seemed to promise a sufficient degree of precision: the common comparer was also mentioned as proper for the purpose. Mr Arago, upon these suggestions, undertook to make these further experiments. But Mr Biot anticipated him: and he has therefore a claim to the *first direct demonstration* of the law of the thicknesses.

4. The brilliant tints of each of these images may be calculated from the laws of interference, according to the difference of the paths and of the velocities of the ordinary and extraordinary rays. This important remark is due to Dr THOMAS YOUNG, who is believed to have published it in the *Quarterly Review*, XI. 1814, p. 42, 49.

It affords the true key of all these phenomena. It must however be added that Dr Young had not explained either in what circumstances the interference of the rays can take place, nor why we see no colours unless the crystallized plates are exposed to light previously polarised. The new properties, which required to be combined with the ordinary laws of interference, in order to obtain a *complete* explanation of the facts, were discovered by Mr Arago and

Mr Fresnel, as they have been described in the seventh section. The dates of the *Memoirs*, in which Mr Fresnel published this explanation, are 1816 and 1818.

The ingenious and delicate experiments, which have been employed as tests of the inaccuracy of the theory of moveable polarisation, are also due to Mr Fresnel, one of the most inventive theorists as well as one of the most skilful experimenters that have devoted themselves to science in this or in any age: the formulæ found at the end of the section are also Mr Fresnel's.

x. The phenomena of circular polarisation were discovered by Mr Fresnel, who described and analysed them in a *Memoir* read to the Academy of Sciences in November 1817, and in January 1818. His later researches on this subject are inserted in the *Bulletin* of the Philomathic Society, December 1822 and February 1823.

There are a few other particulars, relating to the developement of tints by repeated reflections at the surfaces of metallic mirrors; to the rings seen in crystallized plates cut perpendicularly to the axis when examined with a rhomboid held very near them; and to the phenomena of the absorption of polarised light by certain crystals. The first have hitherto been reduced to no *direct* analogy with other affections of polarised light: the second seem to be derived from a modification of the laws already explained in the ninth section; the discovery of the scattered phenomena belonging to the third head has been disputed by Mr Biot and Dr Brewster, but they appear to have been first observed by Mr Arago in 1814. (See Biot's *Recherches sur les Mouvements des Molécules de Lumière*. 4to. Paris, 1814. P. lxxxvi.)

[SECT. XIII.—THEORETICAL *Investigations intended to ILLUSTRATE the Phenomena of Polarisation.* Added by the Translator.

We are led, from the facts which have been enumerated in the 11th Section, to the remarkable coincidence between the discoveries of Dr Brewster respecting crystals with two axes, and a theory which had been published a few years *earlier* in order to illustrate the propagation of an undulation in a medium compressed or dilated in a given direction only, and to prove that such an undulation must necessarily assume a spheroidal form upon the mechanical principles of the Huygenian theory. As every contribution to the investigation of so difficult a subject may chance to be of some value, it will be worth while to copy this demonstration here, from the *Quarterly Review* for November 1809, Vol. II. p. 345.

"The proposition to be demonstrated was this: *An impulse is propagated through every perpendicular section of a lamellar elastic substance in the form of an elliptic undulation.*

"When a particle of the elastic medium is displaced in an oblique direction, the resistance, produced by the compression, is the joint result of the forces arising from the elasticity in the direction of the laminae, and in a transverse direction: and if the

**Polarisation of Light.** elasticities in these two directions were equal, the joint result would remain proportional to the displacement of the particle, being expressed, as well in magnitude as in direction, by the diagonal of the parallelogram, of which the sides measure the relative displacements, reduced to their proper directions, and express the forces which are proportional to them. But when the elasticity is less in one direction than in the other, the corresponding side of the parallelogram expressing the forces must be diminished, in the ratio which we may call that of 1 to  $m$ ; and the diagonal of the parallelogram will no longer coincide in direction with the line of actual displacement, so that the particle displaced will also produce a lateral pressure on the neighbouring particle of the medium, and will itself be urged by a lateral force. This force will however have no effect in promoting the direct propagation of the undulation, being probably employed in gradually changing the direction of the actual motions of the successive particles; and the only efficient force of elasticity will be that, which acts in the direction in which the undulation is advancing, and which is expressed by the portion of the line of displacement, cut off by a perpendicular falling on it from the end of the diagonal of the parallelogram of forces; and the comparative elasticity will be measured by this portion, divided by the whole line of displacement. Calling the tangent of the angle formed by the line of displacement with the line of greatest elasticity  $t$ , the radius being 1, the force in this line being also 1, the transverse force will be expressed by  $mt$ , the line of displacement

by  $\sqrt{1+tt}$ , its diminution by  $\frac{(1-m)tt}{\sqrt{1+tt}}$ , the diminished portion, which measures the force, by

$\sqrt{1+tt} - \frac{(1-m)tt}{\sqrt{1+tt}}$ , and the elasticity, in the given

direction, by  $\frac{1+mtt}{1+tt}$ . Hence it follows, that the velocity of an impulse, moving in that direction, will

be expressed by  $\sqrt{\frac{1+mtt}{1+tt}}$ .

"It is next to be proved, that the velocity of an elliptical undulation, increasing so as to remain always similar, by means of an impulse propagated always in a direction perpendicular to the circumference, is such as would take place in a medium thus constituted. It is obvious that the increment of each of the diameters of the increasing figure must be proportional to the whole diameter; and this increment, reduced to a direction perpendicular to the curve, will be proportional to the perpendicular falling on the conjugate diameter, which will measure the velocity. We are therefore to find an expression for this perpendicular, when it forms an angle with the greater axis, of which the tangent is  $t$ . Let the greater semiaxis be 1, and the smaller  $n$ : then the tangent of the angle formed with the greater axis by

the conjugate diameter, being  $\frac{1}{t}$ ; the tangent of the

angle subtended by the corresponding ordinate of

the circumscribing circle is found  $\frac{1}{nt}$ ; and the semi-diameter itself, equal to unity, reduced in the ratio

of the secants of these angles; that is, to  $n\sqrt{\frac{1+tt}{1+mntt}}$ ;

but, by the known property of the ellipsis, the perpendicular required is equal to the product of the semiaxis, divided by this semidiameter, that is, to

$\sqrt{\frac{1+mntt}{1+tt}}$ : we have therefore only to make  $mn=m$ ,

and the velocity in the given medium will always be such as is required for the propagation of an undulation, preserving the form of similar and concentric spheroids, of which the given ellipsis represents any principal section.

"If the whole of the undulation were of equal force, this reasoning would be sufficient for determining its motion: but when one part of it is stronger than another, this superiority of pressure and motion will obviously be propagated in the direction of the actual resistance produced by the displacement of the particles, since it is this resistance which carries on the pressure, and consequently propagates the motion. It is very remarkable that the direction of the resistance will be found, on the supposition which has been advanced respecting the constitution of the medium, to coincide every where with the diameters of the ellipsis, when the displacement is perpendicular to the surface. For it is proved by authors on conic sections, that the subnormal of the ellipsis is to the absciss, as the square of the lesser axis is to the square of the greater, that is, in this case, as  $mn$  to 1, or as  $m$  to 1; but if we divide the ordinate in the same ratio of  $m$  to 1, and join the point of division with the extremity of the subnormal, this line, which will evidently be parallel to the diameter, will express, as we have already seen, the direction of the force, when the normal represents that of the displacement. An immediate displacement in the direction of any diameter, making an angle with the axis of which the tangent is  $t$ , would

give a velocity of  $\sqrt{\frac{1+mtt}{1+tt}}$ , while the increment of

the diameter would require a velocity of  $\sqrt{\frac{m+mtt}{m+tt}}$ ,

which does not vary in the same proportion. It must, however, be remembered, that the rectilinear direction of the beam is not supposed to depend on this circumstance alone: Huygens considers each point of the surface of the crystal, on which a beam of light impinges, as the centre of a new undulation, which spreads in some measure, in every direction, but produces no perceptible effect except where it is supported by, and cooperates with, the neighbouring undulations; that is, in the surface which is a common tangent of the collateral undulations; but if this principle were applied to extraordinary refraction without the assistance of the obliquity of force, which may be deduced from the supposition of a stratified medium, it would lead us to expect that the elementary impulses, being propagated in a curvilinear trajectory, might be intercept-

Polarisation  
of Light.

ed by an object not situated in the rectilinear path of the beam; a conclusion which is not warranted by experiment."

However satisfactorily this mode of viewing the extraordinary refraction may be applied to the subsequent discoveries relating to the effects of heat and compression, there is another train of ideas, which arises more immediately from the phenomena of polarisation, and which might lead us to a more distinct notion of the separation of the pencil into two or more portions, though it does not seem to comprehend so entirely the phenomena depending on spheroidal undulations.

We may begin this mode of considering the subject in the words which have already been employed in the Article CHROMATICS, p. 161. "If we assume as a mathematical postulate, in the undulatory theory, without attempting to demonstrate its physical foundation, that a transverse motion may be propagated in a direct line, we may derive from this assumption a tolerable illustration of the subdivision of polarised light by reflection in an oblique plane. Supposing polarisation to depend on a transverse motion in the given plane; when a ray completely polarised is subjected to simple reflection in a different plane, at a surface which is destitute of any polarising action, and which may be said to afford a neutral reflection, the polar motion may be conceived to be reflected, as any other motion would be reflected at a perfectly smooth surface, the new plane of the motion being always the image of the former plane; and the effect of refraction will be nearly of a similar nature. But when the surface exhibits a new polarising influence, and the beams of light are divided by it into two portions, the intensity of each may be calculated, by supposing the polar motion to be resolved instead of being reflected, the simple velocities of the two portions being as the cosines of the angle, formed by the new planes of motion with the old, and the energies, which are the true measure of the intensity, as the squares of the sines. We are thus insensibly led to confound the intensity of the supposed polar motion with that of the light itself; since it was observed by Malus, that the relative intensity of the two portions, into which light is divided under such circumstances, is indicated by the proportion of the squares of the cosine and sine of the inclination of the planes of polarisation. The imaginary transverse motion must also necessarily be alternate; partly from the nature of a continuous medium, and partly from the observed fact, that there is no distinction between the polarisations produced by causes precisely opposed to each other, in the same plane." Another analogous hint is found in the *Philosophical Transactions* for 1818, p. 273. "Supposing the experiments to be perfectly represented by [Dr Brewster's] general law, it will follow that the tint exhibited depends not on the difference of refractive densities in the direction of the ray transmitted, but on the greatest difference of refractive densities in directions perpendicular to that of the ray. These two conditions lead to the same result, where the effect of one axis only is considered, but they vary materially where two axes are supposed to be combined . . . There can be little doubt

that the direction of the polarisation, in such cases, must be determined by that of the greatest and least of the refractive densities in question:" a "supposition," which Dr Brewster finds "quite correct."

Polarisation  
of Light.

We may add again to these hints the consideration, that when simple pressure or extension in the direction of any given axis produces a spheroidal undulation in a medium before homogeneous, this state is always accompanied by the condition, that a ray describing the axis, while the densities in all transverse directions remain equal, undergoes no subdivision, but that a ray moving in the plane of the equator, to which the perpendiculars are the axis and another equatorial diameter, undergoes the greatest possible separation into parts that are respectively polarised in the planes passing through these directions.

From these phenomena we are led to be strongly impressed with the analogy of the properties of sound, as investigated cursorily by Mr Wheatstone, and in a more elaborate manner by the multiplied experiments of Mr Savart, which have shown that, in many cases, the elementary motions of the substances transmitting sound are transverse to the direction in which the sound is propagated, and that they remain in general parallel to the original impulse.

The next transition carries us from the *mathematical postulate* here mentioned to the *physical condition* assumed by Mr Fresnel, that the relative situation of the particles of the ethereal medium with respect to each other, is such as to produce an elastic force tending to bring back a line of particles, which has been displaced, towards its original situation by the resistance of the particles *surrounding the line*, and at the same time to impel these particles in its own direction, and in that direction only, or principally, while the aggregate effect is propagated in concentric surfaces.

This hypothesis of Mr Fresnel is at least very ingenious, and may lead us to some satisfactory computations: but it is attended by one circumstance which is perfectly *appalling* in its consequences. The substances on which Mr Savart made his experiments were *solids* only; and it is only to solids that such a *lateral* resistance has ever been attributed: so that if we adopted the distinctions laid down by the reviver of the undulatory system himself, in his *Lectures*, it might be inferred that the luminiferous ether, pervading all space, and penetrating almost all substances, is not only highly elastic, but absolutely solid!!! The passage in question is this: (Vol. I. p. 627.)

"The immediate cause of solidity, as distinguished from liquidity, is the lateral adhesion of the particles to each other, to which the degree of hardness or solidity is always proportional. This adhesion prevents any change of the relative situation of the particles, so that they cannot be withdrawn from their places, without experiencing a considerable resistance from the force of cohesion, while those of liquids may remain equally in contact with the neighbouring particles, notwithstanding their change of form. When a perfect solid is extended or compressed, the particles, being retained in their situa-

Polarisation  
of Light.

tions by the force of lateral adhesion, can only approach directly to each other, or be withdrawn further from each other; and the resistance is nearly the same, as if the same substance, in a fluid state, were inclosed in an unalterable vessel, and forcibly compressed or dilated. Thus the resistance of ice to extension or compression is found by experiment to differ very little from that of water contained in a vessel; and the same effect may be produced even when the solidity is not the most perfect that the substance admits; for *the immediate resistance of iron or steel to flexure is the same, whether it may be harder or softer*. It often happens, however, that the magnitude of the lateral adhesion is so much limited, as to allow a capability of extension or compression, and it may yet retain a power of restoring the bodies to their original form by its reaction. This force may even be the principal or the only source of the body's elasticity: thus when a piece of elastic gum is extended, the mean distance of the particles is not materially increased. . . and the change of form is rather to be attributed to a displacement of the particles than to their separation to a greater distance from each other, and the resistance must be derived from the lateral adhesion only: some other substances also, approaching more nearly to the nature of liquids, may be extended to many times their original length, with a resistance continually increasing; and in such cases there can scarcely be any material changes of the specific gravity of these substances. Professor Robison has mentioned the juice of bryony as affording a remarkable instance of such viscosity.

"It is probable that the immediate cause of the lateral adhesion of solids is a symmetrical arrangement of their constituent parts: it is certain that almost all bodies are disposed, in becoming solid, to assume the form of crystals, which evidently indicates the existence of such an arrangement; and all the hardest bodies in nature are of a crystalline form. It appears, therefore, consistent both with reason and with experience to suppose, that a crystallization more or less perfect is the universal cause of solidity. We may imagine, that when the particles of matter are disposed without any order, they can afford no strong resistance to a motion in any direction; but when they are regularly placed in certain situations with respect to each other, any change of form must displace them in such a manner, as to increase the distance of a whole rank at once; and hence they may be enabled to cooperate in resisting such a change. Any inequality of tension in a particular

part of a solid is also probably so far the cause of hardness, as it tends to increase the strength of union of any part of a series of particles which must be displaced by a change of form."

It must however be admitted, that this passage by no means contains a demonstration of the total incapability of fluids to transmit any impressions by lateral adhesion, and the hypothesis remains completely open for discussion, notwithstanding the apparent difficulties attending it: which have appeared to bring us very near to the case stated in the same Lectures as a possible one, that there may be independent worlds, some existing in different parts of space, others *pervading each other unseen and unknown in the same space*. We may perhaps accommodate the hypothesis of Mr Fresnel to the phenomena of the ordinary and extraordinary refraction, by considering the undulations as propagated through the given medium in two different ways; some by the divergence of the elementary motions in the direction of the ray, and others by their remaining parallel to the direction of the impulse or of the polarisation: the former must be supposed to furnish the spheroidal, the latter the spherical refraction. It would indeed follow that the velocity of the spherical undulation ought to vary by innumerable degrees, within certain limits, according to the direction of the supposed elementary motion: while in fact the actual velocity of the spherical undulations seems to be uniformly equal to the velocity in the direction of the axis; but this objection may be obviated by supposing the surface so constituted, that for some unknown reason the parallel elementary motion can only be propagated in the regular manner when it takes place in the direction of the axis, or when it is made to assume that direction: a condition not very simple or natural, but by no means inconceivable: unless we saw any reason to consider the adhesion as a constant force, independent of the direction, and equal to the least or greatest elasticity, or unless it were possible to derive the phenomena of two supposed axes of polarisation, which Mr Fresnel has explained on the hypothesis of two spheroids, from the supposition of two spherical undulations propagating oblique elementary motions in the direction of the actual polarisation as already determined for these crystals.

If these conjectures should be found to afford a single step, in an investigation so transcendently delicate, it will be best to pause on them for a time, and to wait for further aid from a new supply of experiments and observations.] (x.x.x.)

THE END.
