rewarding effects caused by acute use of cocaine. Two clinical trials provided initial evidence of the robustness of the antibody response, as well as initial safety and early efficacy among cocaine users. A subsequent trial demonstrated that more robust immune responses to the vaccine blunted the subjective effects of smoked cocaine, with a statistical trend for decreased cocaine usage. Tachycardia was associated with antibody levels, perhaps as a function of increased levels of cocaine peripherally. A randomized placebo-controlled trial of 115 methadone-maintained cocaine-dependent participants was recently conducted and reported that while no main effects were observed in terms of probability of cocaine-free urine across a 24-week study period, antibody response was highly variable and was not expected to exert a therapeutic response for all individuals in the treatment condition. The data were reanalyzed with individuals stratified by immune responsiveness (38% of treatment group achieved adequate immune responses). Those with robust responses outperformed the low immune response and placebo group in terms of likelihood of total abstinence for the last 8 weeks of the trial. Although these findings are promising, there is value in development of a formulation that extends the period of adequate antibody levels to confer blockade of subjective effects and to expand the proportion of individuals who achieve these levels. Additionally, the approach would likely require substantial motivation and behavioral support to adhere to the repeated booster injections and to avoid trying to overwhelm the capacities of the antibodies by using high doses of cocaine. A multicenter trial with a targeted enrollment of 300 is currently underway.

EXPLAINING VARIABILITY OF TREATMENT OUTCOMES

Moderating Variables and Pharmacogenetics

Across most of the literature on cocaine pharmacotherapies, it is a common clinical observation that some patients respond favorably to a pharmacotherapy, while others with the same disease show no response. It appears that across many studies of “cocaine dependence” medications, substantial heterogeneity exists within this particular class of patients. Demographic variables, psychiatric comorbidity, co-abused substances, social support levels, neurobiological characteristics, and genetic factors, among others, have been demonstrated as moderators of treatment responsiveness. While frustrating, the identification of key factors that define subgroups of patients is a key issue, as moderating variables have interfered with identification

of broadly effective cocaine medications. Across trials, the most consistent factor that corresponds with treatment outcome is level of baseline cocaine use at baseline – generally, those patients with lower levels of baseline use of cocaine respond better to treatment (measured by urine benzoylecgonine and by retention) than those with higher levels of use at baseline. As well, severity of pretreatment dependence and of withdrawal symptoms has been a generally consistent predictor of treatment failure. Concurrent heroin abuse presents an additional challenge to treatment compliance and alcohol use is generally associated with poorer outcomes, although there are inconsistencies in the literature. Given the complex pharmacological and common interactions of stimulants with cigarette smoking, it is perhaps not surprising that nicotine dependence and cocaine may have synergistic effects and compromise treatment outcomes.

In addition to the variables highlighted above, genetic characteristics function as moderators of therapeutic responsiveness. The substantial between-individual variability in medication response, paired with generally small inpatient variability, suggests the role of heritable factors in medication response. Such observations have generated considerable interest among addiction researchers in pharmacogenetics – the study of genetic factors that account for the variability in treatment responsiveness. Through a variety of biological mechanisms – drug metabolism, absorption, distribution, and excretion – genetic factors interact with pharmacotherapies to impact treatment outcomes. Pharmacotherapies tailored for specific genetic profiles may promote positive therapeutic responses, mitigate problems associated with toxicity, and improve compliance. Single nucleotide polymorphisms (SNPs) – that represent stable and identifiable biomarkers – account for the vast majority of genetic diversity. Etiological studies linking particular genetic factors with specific psychiatric disorders have identified candidate genes but these genes confer weak and nonspecific risk that interacts in complex ways with other pathogenic factors. However, preliminary suggestions from studies of psychotropic medications suggest that certain pharmacogenetic effect sizes may be larger than those for etiological candidate genes. Candidate gene polymorphisms might be related to dopaminergic function, metabolism of a medication or drug of abuse, or etiologically significant genetic markers. Promising discoveries have been made regarding the role of pharmacogenetic responses to putative medications for opiate and alcohol dependence. Less work exists for cocaine and the psychostimulants as genetic modulators of dopaminergic function may contribute to inconsistent responses to medications across drug classes. While in an early stage of development, these polymorphisms have been identified that

may affect dopamine beta-hydroxylase (C-1021T), dopamine transporter function (SLC6A3), and genes regulating the dopamine receptor (D2) availability, which may encourage more targeted medication development approaches.

CONCLUSIONS AND FUTURE DIRECTIONS

Before highlighting the positive developments, it is worth acknowledging that the number of trials with negative results is striking. Several possibilities may account for this fact. First, medication adherence is lower than would be expected in trials for nonaddictive disorders. Extensive efforts are undertaken to mitigate this problem, including pill counts and fluorescing urine specimen to detect riboflavin, which is commonly included with the medications. These methods are imperfect and the development of technologies to support adherence may be useful. Second, attrition is quite high – often substantially more than 50%. Generally, assumptions are made that a participant who has dropped out of the study is using cocaine and positive urine screens are imputed. While attrition likely signals treatment failure, the absence of confirmatory data makes estimates of therapeutic effects more conservative. Statistical methods to minimize the bias created by missing data are available but popular models used to analyze trial data, such as generalized estimating equations, require assumptions about attrition that are often untenable. Third, powerful moderating variables – often unmeasured – dilute medication effects for subgroups. The promise of pharmacogenetics is great although sample size limitations often preclude detailed investigations within a single trial. The need for researchers to make the collection of genetic material routine for all study participants is great. Finally, the complexity of neuroadaptations consequent to chronic drug administration is humbling: The brain's attempt to maintain homeostasis amidst an unprecedented capacity to alter neurochemistry using cocaine broadly disturbs the balance between and within brain regulatory systems. As well, the vulnerability to drug dependence is positively associated with liabilities for other psychopathological conditions which further complicate outcomes. Given these factors, it is unsurprising that development of pharmacotherapies for addiction has been difficult.

Despite these challenges, there are some promising developments in the pharmacotherapy of cocaine dependence. There have been some signals for vigabatrin, ondansetron, disulfiram, and modafinil, although the evidence is mixed. While meta-analytic approaches analyzing an entire class of medications have been

negative, this may not always be the optimal way of interpreting the findings from diverse trials. The immunotherapy approach is novel and preliminary data have been encouraging. New directions include cannabinoid receptor antagonists and medications that modulate HPA functioning. The importance of distinguishing between abstinence initiation and relapse prevention has been emphasized and medications may be useful for one outcome while ineffective for the other. The prognostic significance of baseline cocaine use is clear. It may thus be useful to establish baseline abstinence through a brief inpatient period as treatment is initiated. While as a field, trial procedures are far better defined than when significant effort to identifying a medication for cocaine dependence 25 years ago, there are substantial efforts needed to reduce heterogeneity and to increase precision in assessing potential medication efficacy.

Glossary

Agonist a chemical that binds to and triggers a response from a receptor, often mimicking the action of a naturally occurring substance.

Antagonist a chemical that blocks the action of an agonist.

Benzoyllecgonine the primary metabolite of cocaine in urine.

Meta-analysis a statistical technique that combines the outcomes from several trials to evaluate the effect size for a particular type of treatment compared to a placebo condition.

Partial agonist a chemical that binds at a receptor, but produces a response submaximal to a full agonist.

STIMULANT USE, ABUSE, AND DEPENDENCE

Stimulant medications, for example amphetamine analogs, have been extensively used to treat specific medical and psychiatric problems including narcolepsy and attention deficit and activity disorders. They were used in the past with some benefit to treat overweight conditions. Amphetamine analogs have also been used in the past to treat depression and are now sometimes used as adjuncts, or additional medications when standard antidepressant effects must be bolstered. These medications can also be used to enhance performance that has deteriorated due to boredom or fatigue. This has been true of the amphetamine analogs, and a novel stimulant, modafinil, has been approved by the US Food and Drug Administration (FDA) to modulate sleep-wake disturbances and performance impairment in shift

workers who must change from night, to day, or afternoon schedules frequently. These drugs can have psychological effects that are perceived as 'positive'. A large illicit trade in cocaine, as well as methamphetamine supports excessive use of these agents for these non-therapeutic effects. In turn, as the problem for the individual becomes more and more severe, treatment is essential. This section considers the treatment strategy of administering controlled regimens of a drug very much like the drug that has caused problems. This strategy has been called 'substitution', 'replacement', 'agonist treatment', or 'agonist-like' treatment. As discussed, it is effective in the treatment of heroin, as well as nicotine dependence. Extensive research and clinical experience suggest that stimulant medications may be effective for treatment of stimulant dependence. Certainly the controlled clinical trials and some community treatment programs to date have demonstrated

'proof of concept'. However, while research and discussion of the strategy continue, it is not an approach currently supported by the FDA. More research and further demonstrations of safety and effectiveness will be necessary to move the approach to the forefront of treatment of severe stimulant dependence, but there is growing support for the strategy.

HISTORICAL PERSPECTIVE

Low to moderate dose stimulants, with the capacity to sustain wakefulness, enhance mood and performance, have been used safely throughout human history. Yet, when ingested at high doses they can cause behavioral and psychological aberrations and biological damage. Caffeine, and its surrogates across cultures, are and have been the mostly widely used and generally socially acceptable drugs. Yet these relatively benign agents can be packaged in formulations that lead to untoward consequences. For example, some 'energy drinks' have high caffeine levels ("Cocaine" – 288 mg, "Spike Shooter" – 300 mg) in small volumes; repeated ingestion in short periods, particularly in the face of drug interactions, can have serious consequences. The US Food and Drug Administration in November of 2010 specifically issued warnings to companies producing beverages combining high caffeine doses with up to 10% alcohol. Oral coca leaf use as practiced in the South American Andes for centuries was relatively benign, while extracted and refined cocaine (salt or base) repeatedly injected or smoked can have enduring social, psychiatric, and medical consequences (including death).

There have been successive epidemics of hazardous stimulant use in United States and world history, the first 130 years ago in the 1880s. David Musto, psychiatrist and historian, has noted that societal and public health response to a dramatic increase in cocaine use that began in the 1970s, and more recently the surge of methamphetamine use, reflect clear failure to learn from past episodes. Stimulants effects (some therapeutic and beneficial with others being exceptionally hazardous) combined with characteristics of the productivity and pharmaceutically oriented culture, require that thoughtful consideration be given to efficacious use, prevention of misuse, and treatment of stimulant use disorders when they emerge. Here the focus is on development of one component of effective treatment when disease prevention efforts fail and dangerous use and societal consequences result.

PREVALENCE

A long standing project (Monitoring The Future) to track drug use among high school students

conducted by Lloyd Johnson and colleagues indicates that cocaine use among high school seniors peaked in the 1978–1988 period in the range of 7–10%. Since then use has fluctuated in the 3–7% range. Use has generally been more common among young people with fewer educational and other resources, in large metropolitan areas, among Hispanics and Whites compared to African Americans, and more common among males than females. Many surveys, including this one segregated 'crack' from cocaine (hydrochloride), for which use was in the 1–4% range with the same peak periods. Methamphetamine use (which has been tracked by MTF since 1991) has generally persisted in the 1–5% range in this population.

A complementary survey conducted by SAMHSA titled "National Survey on Drug Use & Health" generates data on use in individuals 12 years and older from a national sample. The ever-used sample in 1998 (versus past year or past month) indicated an average of 10% of those surveyed had some experience with cocaine (hydrochloride) compared to 2% for "crack". In 2009, the SAMHSA survey reported 1.6 million current cocaine users and about half that number of methamphetamine users. Again, while the prevalence of use of cocaine and other non-prescription stimulants varies, the general patterns of use persist. While declines in use have occurred since the most recent peaks there is some evidence that use is again increasing.

Obviously, potentially harmful stimulant use occurs broadly in the world. The European Monitoring Centre for Drugs and Drug Addiction has reported that lifetime cocaine use across the European Union countries ranges from less than 1% to over 8% (mean approximately 4%) and lifetime use of amphetamine analogs ranges from less than 1% to approximately 11% (mean approximately 3%). Amphetamine analog use in several Asian countries is reportedly substantially higher than those in Australia, the EU or US according to the United Nations Office on Drug Abuse and Crime (UNODC). However, as noted by the 2010 report of the International Harm Reduction Association, the data sources are highly variable in quality and many caveats apply to their interpretation; for example, the UNODC report indicated a range from 16 to 51 million users worldwide. Still, it is clear that the problems are substantial and broad in scope.

These oscillating patterns of amphetamine analog and cocaine use, with periods of accelerated use and peaks every so many decades, indicate that use of these or alternative robust stimulants will emerge in the future. It is thus essential that there be a clearly prescribed suite of interventions that can be applied as needed when recurrences of these disorders emerge.

DETERMINANTS OF COCAINE AND OTHER STIMULANT USE DISORDERS

Substance use disorders, here cocaine and other stimulant abuse, as with some other medical conditions, reflect a complex interplay of biological, behavioral, and social factors. Thus, a wide range of factors ranging from the social environment to molecular genetics contributes to the observed effects of stimulant drugs. Cardiovascular disease or obesity, sometimes intertwined, are consequences of genetics, other biology, behavioral factors (e.g. eating or inactivity), along with social and environmental circumstances. Similarly, stimulant use is established in a social-environmental context (e.g. peers). Stimulants have pronounced and significant effects on neurochemistry (inherent to the rewarding or reinforcing effects) of the brain that might promote or diminish use. Moderate use at intermediate doses produces effects that are perceived as positive, while protracted use or binges of high dose use have distinctly adverse psychological/psychiatric consequences. As dose increases and binges or chronic use emerge, risk of adverse medical consequences including cardiovascular collapse, heart attacks, and stroke greatly increase. Further, higher doses and chronic use can produce a shift from a sense of well being to severe psychiatric and behavioral disturbances. Biological and psychiatric effects may be influenced by genetic factors predisposing some individuals to positive responses to stimulants. The relative contribution of any of these determinants to use, progression to persistent use, or for that matter avoiding use varies across individuals. Yet the behavioral end point, for example, among those engaging in use to the point of detrimental consequences, appear the same. Conversely, those not using, are non-users whether due to genes, unpleasant psychic responses, or discomforting cardiovascular response.

One set of determinants is related to the drug and the manner in which it is used. While 'cocaine is cocaine', the route of administration and preparation form and, of course, dose, can greatly influence response. In the 1970s as cocaine availability and use in the population escalated, Ronald Siegel of UCLA followed a large group of users who self-administered by the intranasal route. Among those who shifted to smoking cocaine, consequences and severity of resultant disorders increased while somewhat stable use existed among those who continued to use intranasally. It is suggested that higher doses and higher peak blood, and brain, levels can be achieved via inhalation (here smoking) than nasal administration and ultimately more severe dependence and disease burden for the individual. Conversely, use of coca tea preparations as practiced in the Andes areas of South America reportedly is analogous to coffee drinking.

With multiple factors influencing use, the optimal intervention required in the face of compulsively persistent hazardous use becomes complex. Development of effective treatments has proven difficult and much research has found patients to be refractory to even intensive psychosocial interventions.

TREATMENT OPTIONS FOR STIMULANT ABUSE AND DEPENDENCE

In the two decades from 1990 to the present, substantial research efforts have been undertaken to identify effective treatments for stimulant dependence. Much of this research has been funded by the US National Institutes of Health through its National Institute on Drug Abuse. The two main foci were behaviorally based interventions and medications, with the addition over the last decade of efforts to develop a vaccine. The premise of the vaccine strategy is that cocaine antibodies would develop, binding with the molecule, thus preventing drug action. Behavioral therapy development efforts were of several types; some focusing on motivational features, but the bulk focusing on cognitive therapy or clear contingency management based behavioral interventions. Scientific studies of these interventions point directly to the substantial efficacy and effectiveness of contingency management approach, under a variety of names, with effectiveness of 'cognitive behavioral' also evident. Concurrent with funding therapy studies, NIDA devoted substantial funding to supporting investigators conducting studies with medications for cocaine dependence, and later methamphetamine dependence. It is assumed that the optimal treatment for stimulant dependence might come from joint action of behavior therapy combined with medication. Thus, virtually all medication clinical trials had some form of behavioral intervention. Still, given the diversity of the stimulant using population, it is likely that there will be individual differences in need and responsiveness to behavioral therapy, medication, or combinations.

Conceptually, the approaches to developing a pharmacologically based intervention for cocaine dependence, or other drug dependence, are an antagonist-like treatment, an agonist-like treatment, and symptomatic treatment. An antagonist treatment would be the analog of naltrexone for heroin/opioid use, that is a medication that 'blocks' the effects when an opioid is taken, whether by mouth, intravenously, or by smoking. Examples of medications with some 'antagonist' like properties for cocaine include the antipsychotic drugs haloperidol, risperidone, and olanzapine. While some preclinical research has suggested such medications might block self-administration or attenuate effects of

stimulants, results of clinical research have been unfavorable. Further, these antagonists have substantial untoward side effects. An agonist treatment would be equivalent to methadone for opioid dependence; that is, limited 'replacement' or 'substitution' of the abused drugs effects with another agent. Examples of agonist-like medications for cocaine and other stimulants include cocaine itself, amphetamine analogs, methylphenidate, novel agents like modafinil, as well as l-dopa. As with any medication, these two have varying levels of side effects, some potentially serious. Generally, as efficacy increases for the specific purpose of stimulant dependence treatment, magnitude of potential side effects increases. Thus, the critical issue is establishing a well-controlled treatment regimen. Symptomatic treatment would be equivalent to using medications that alleviate one or another of the symptoms during the period after cessation of use. An array of other medications has been examined including gabapentin, carbamazepine, selegiline, fluoxetine, and other SSRIs. Logical theoretical rationale has underpinned investigation of each but little support has emerged from clinical evaluations.

GOALS OF AGONIST TREATMENT

At the neurochemical level, agonist-like treatment, that is 'replacing' some though not all of the effects of the problem drug, can take several forms. For example, one major effect of stimulants is on the dopamine system. Dopamine levels can be affected by blocking its reuptake into neurons or enhancing its release from neurons by modulating various elements of the dopaminergic system. Scientists in preclinical animal laboratories, human laboratory settings and clinical environments have argued for and conducted research to determine optimal medications to modulate or regulate dopamine. Others have focused on the role of the serotonin and other systems. Of course, the systems of the brain work in concert. Perturbations in one system or one brain area necessarily alter relative effects of other systems. Cocaine and other stimulants have broad actions on multiple systems and thus broader consideration of the neurochemistry and plausible treatments is considered important. Richard Rothman and Michael Baumann, two scientists at the National Institute on Drug Abuse intramural research program, as well as others, have argued that the most efficacious medications will broadly effect or replace, some of the actions on dopamine and serotonin.

Ultimately there are at least three clear goals in the agonist-like strategy for treatment of stimulant dependence. One is related to stabilizing cognitive function in the individual who might have experience permanent

or temporary damage or dysfunction as a consequence of stimulant abuse. Stimulant drugs do have substantial efficacy in enhancing 'performance' that has been impaired, for example by sleep deprivation, or in this case drug abuse. Long-term excessive use of stimulants can also affect other functions; thus biological stabilization can be another goal. The primary goal is to eliminate or at least drastically reduce drug abuse itself, that is diminish the individuals desire/craving and most important, the behaviors directed at seeking and taking the stimulant drug.

FACTORS PRESUMED NECESSARY FOR EFFECTIVE TREATMENT AND DIMINISHED RISK

Just as any medical treatment has risks, agonist treatment of stimulant dependence could have associated problems. Some voice the concern that the treatment medication itself will be misused by patients or "diverted" and be misused by others. These concerns exist in opioid substitution treatment, were one of great concern regarding nicotine replacement, but might also be problematic for other treatments involving psychoactive drugs. This problem can be substantially obviated by an effective well-designed treatment regimen. When prescribed by clinicians in the United Kingdom and Australia, this has been accomplished by requiring daily pharmacy/dispensing visits, much like the methadone treatment system in the United States. While problems emerge in opioid replacement treatment, substantial controls on distribution, use of daily monitored dosing early in treatment, and so on are in place to reduce risk. On the other hand, unduly arduous requirements will likely diminish participation in treatment.

Stimulant drugs also have risks associated with their direct effects, for example, increases in blood pressure and heart rate and other cardiovascular consequences. These risks can be diminished by implementing a controlled regimen but also by careful pre-treatment evaluation. Clinical studies in which stimulant drugs have been administered in stable therapeutic regimens have found only modest changes in blood pressure and heart rate that are not clinically significant. Similarly, concerns that the psychic effects of stable dosing might lead to reinitiation of excessive illicit drug use have not been substantiated.

What steps can be taken to diminish risk while providing therapeutic benefit? The answers come from converging findings of preclinical research with animals, research with drug users and normal volunteers in human laboratory settings, well-controlled clinical trials, experience with other agonist therapies such

as methadone, LAAM, or buprenorphine and observing patterns of excessive drug use. First, as mentioned, a stable daily regimen with well-controlled dosing is essential. (Consistent medication taking as prescribed is essential to any effective therapeutic effort.) Second, the regimen must be as simple as possible. (The more doses required per day, the less likely there will be consistent adherence to the regimen.) The characteristics of action, or effect of the medication when taken are important. Recall that the most hazardous problematic drug use occurs when there are high peak effects that occur nearly immediately after dosing, for example when drugs are smoked or administered intravenously. Common patterns of excessive and hazardous stimulant use involve frequent drug taking, high doses with high peak effects, and a route of administration with rapid onset, followed by offset and renewed dosing. A stimulant 'binge' may involve repeated dosing over days. Conversely, the data and observations indicate that the ideal therapeutic regimen involves a drug preparation form that has slow, gradual onset, prolonged stable action, and slow offset using the minimum dose necessary to diminish illicit drug use while stabilizing function.

CLINICAL EVALUATIONS OF AGONIST-LIKE MEDICATIONS FOR STIMULANT DEPENDENCE

A number of early reports, many from England, in the 1980s and 1990s described clinicians prescribing d-amphetamine for the treatment of amphetamine dependence, particularly in patients who were using the drug intravenously. These reports characteristically described patients engaging in severely problematic drug use. Not uncommonly, the individuals had additional medical or psychiatric problems (e.g. HIV, psychosis) not directly related to the drug abuse but greatly complicating treatment. The clinicians prescribed moderate to high doses of d-amphetamine (e.g. 60–120 mg) that were ingested daily. Unfortunately, the available preparations were often 'immediate' release rather than 'sustained' or 'extended' release. While use of the extended release forms would be preferred based on current data, the clinicians found substantial amelioration of the drug dependence problems in many patients.

From here forward, the premise of this presentation is first, that a number of 'agonist-like' medications are available and could be approved and applied to treatment. These agents differ substantially in robustness as stimulants and typically in the scope of action, some being very specific, others modulating multiple aspects of brain neurochemistry and behavior. Second, it is clear

that there are differing levels of disorder severity among individuals who appear for treatment. There are some users who engage in controlled intermittent use. Some individuals are intermittent, infrequent users who nonetheless at intervals engage in persistent compulsive use to use. Others engage in chronic use, using substantial quantities of stimulant drugs many times a month. In some cases, these more severe users have multiple related or unrelated medical or psychiatric problems. Combining the two observations; first that there is a suite of agonist-like agents with different action spectra and robustness as stimulants and, second that there is a spectrum of severity of use in individuals seeking treatment, one arrives at the logical conclusion that the optimal approach may reside in matching the medication characteristics with severity of the presentation. This parallels practice in other areas of psychiatry specifically, and medicine generally. Based on this we make a hierarchical presentation combining the two features, agonist robustness and disorder severity. The bulk of the clinical research described here has been conducted by researchers at the University of Texas, University of Minnesota, and the University of Pennsylvania in the United States, at the University of Adelaide, as well as community clinics in Melbourne and Sydney, in Australia. Providing additional background and support for the agonist approach, the preclinical and human laboratory research was conducted primarily by scientists at the University of Kentucky, Columbia University, Harvard University, and the Medical College of Virginia. Virtually all of the work conducted in the United States was funded by the National Institute on Drug Abuse, one institute of the National Institutes on Health.

l-Dopa/Carbidopa

An approved medication combination, l-dopa/carbidopa, is approved for use in Parkinson's disease and as a precursor is presumed to directly increase brain dopamine levels. It is highly specific in its action (altering only dopamine levels directly but presumably indirectly modulating other systems) and has essentially no abuse liability. That is, the stimulant users who might receive the medication in treatment could not achieve substantive 'positive' psychic effects/highs. Based on its action, its primary function would be to produce relatively stable dopamine levels and modulate behaviors directly related to this effect. While the medication does have side effects they are nominal at the doses that have been examined for cocaine dependence. Only a few clinical studies have been conducted and they have involved administering l-dopa/carbidopa to cocaine using subjects. Mooney and his colleagues found that

while the medication was well tolerated and safe in a population that had moderate disorder severity, there was no reduction in cocaine use over the 12-week study. However, other colleagues headed by Schmitz conducted and reported the results of a complex study combining l-dopa/carbidopa with several behavioral therapies. One therapy, contingency management, combined with behavior therapy did produce significant improvement, that is, reductions in cocaine use. Still, it is clear that l-dopa/carbidopa treatment of stimulant dependence would likely only be effective in the least severe patients, and then only when combined with a relatively powerful behavior therapy approach.

Modafinil

The mechanism of action, or means by which modafinil produces an effect, is not well understood but appears to differ from that of other 'stimulant' like agents such as methylphenidate or amphetamine analogs. Still, it appears to interact in some way with the dopaminergic system as well as others. Behaviorally, it can enhance mood and produce wakefulness. It is approved for use in treatment of narcolepsy and for wake-sleep cycle disturbances produced, for example, by shift work. In standard models to determine abuse liability, that is the extent to which the medication might have positive and sought-after psychic or behavioral effects, it has some effect and thus might be misused. It is plausible that the "misuse" will be for purposes of perceived benefits to "productivity" rather than achieving euphoria or highs. The side effects are relatively modest. In studies initiated by Dackis, Kampman, O'Brien, and colleagues there appeared to be a positive effect of modafinil in reducing cocaine use. Later clinical research suggested that the efficacy of modafinil in reducing cocaine or amphetamine use was modest, though more evident in certain less severe patient groups. It does appear that modafinil produces some essential effects such as mood enhancement, increased activity, and wakefulness that may contribute to utility it might have in treatment of stimulant dependence. Still, the composite data suggest that it may be most effective as the agonist-like, or substitution treatment for individuals with less severe dependence and generally less complicated medical and psychiatric presentations.

Methylphenidate

As an FDA approved medication, methylphenidate is widely used for the treatment of attention deficit and hyperactivity disorders and narcolepsy. There are a number of preparation forms including oral immediate and extended release as well as transdermal

(patch) versions. Methylphenidate has distinct stimulant-like actions and acts on various central nervous system arousal mechanisms. It is similar to amphetamine analogs and cocaine in its actions and increases availability of dopamine, inhibiting reuptake, and to a much lesser extent norepinephrine. Methylphenidate has clear positive psychic effects and abuse liability in all preclinical and clinical models used to evaluate this characteristic of drugs. It can produce serious psychiatric disturbance as well as other serious side effects, notably cardiovascular when used at high doses, particularly when used in continuous binges. In the 1980s, scientists at Yale University suggested potential benefit for treatment of cocaine dependence, but in particular in individuals who were 'self-medicating' to self-treat, for example, attention related problems; the results were negative. Subsequently other researchers administering low to moderate doses reported negative results in relatively severe cocaine-using patients, though preclinical research suggested that might reduce stimulant intake. Recently, a group in Denmark headed by Tiihonen reported that high doses of methylphenidate reduced amphetamine abuse but that the effect emerged slowly (e.g. over an 18-week period, and that this persisted over the year long observation period). It seems likely that methylphenidate could serve as an agonist-like or replacement agent, though the conditions for successful treatment may be somewhat limited.

d-Amphetamine

As an FDA approved medication, the primary indications of d-amphetamine, are narcolepsy as well as attention deficit and activity related disorders. d-Amphetamine neurochemical effects include direct release of dopamine and norepinephrine and decreased reuptake. As with other medications in this class, whether used in therapeutics or misuse, effects on the dopaminergic systems are pronounced. It should also be noted that, d-amphetamine can also affect serotonin systems. Thus, it has multiple effects and is distinctly a robust stimulant. It also has relatively high abuse liability by most measures. As mentioned, some UK clinicians administered immediate release d-amphetamine with the hope that they could stabilize and treat patients using illicit amphetamines. Grabowski and his colleagues developed and completed a series of studies examining amphetamine analogs for the treatment of cocaine dependence. Notably, they emphasized use of a preparation form of d-amphetamine that had slower onset and longer duration of action than the immediate release preparations. The successive studies provided critical support for the agonist strategy for treatment of

stimulant dependence. This work also indicated that a well-controlled regimen was safe and well tolerated by the subject/patients in the studies. In particular, the effects on cardiovascular function were nominal and not clinically significant. It is assumed that this was due in part to the subjects' existing tolerance to stimulant type medications. However, the stabilized and apparently normalized cardiovascular function may also have been related to the elimination or substantial reductions in stimulant use by many patients. This research also included redundant strategies to measure compliance using mechanical means (e.g. specialized dispensing bottles, pill blister packs) and a biochemical marker (riboflavin). The composite data indicated high rates of compliance with the medication regimen by the subjects and there was no evidence of diversion. Other investigators including Longo, White, and colleagues, and earlier Shearer and Wodak, in Australia have provided further support for proof of concept in treatment of individuals misusing amphetamines. Most recently, in a study initiated by Herin, a new d-amphetamine preparation, lisdexamfetamine, with presumed benefit in longer duration, limited peak effects and some reduction in abuse potential is being examined for treatment of cocaine users. Concurrent and subsequent research by other scientists (e.g. Negus, Rush, Hart) provided corroboration from preclinical animal studies and human laboratory research for some of the assumptions underlying the agonist strategy.

Methamphetamine

This medication is used for the treatment of narcolepsy, attention deficit, and activity related disorders. It has effects on dopamine, serotonin, and norepinephrine systems in the brain, acting to release these neurotransmitters and block reuptake. As with other amphetamine analogs, cardiovascular effects are of concern but are dose dependent and modest within the therapeutic dosing range. As with other robust stimulants, methamphetamine can have profound psychological and behavioral effects when consumed chronically at high doses. As noted regarding prevalence of illicit use, methamphetamine can be abused and has high abuse liability in preclinical animal and human laboratory models designed to test this characteristic. As with other stimulants, it can enhance mood and performance and transiently diminish fatigue within the normal dosing range. A sustained/extended release form of methamphetamine was evaluated for the treatment of cocaine dependence in a controlled clinical trial reported by Mooney and Grabowski and colleagues. This work strongly supported

the agonist conceptualization for treatment of stimulant dependence. Generally, the function of the subjects was stabilized or normalized. Highly significant reductions, nearly suppression, of cocaine use were observed in the group receiving methamphetamine versus placebo. Further, there were no significant changes in food intake or cardiovascular parameters. And again, compliance with the medication regimen was excellent and diversion was absent in this treatment seeking population. This single, but well-controlled clinical trial using a robust stimulant with broad neurochemical action provides extremely strong support for pursuing development of the agonist strategy for the treatment of stimulant dependence. Most notable is that this study supports the hypothesis proposed by Rothman and Baumann and discussed by the authors of the research described in the foregoing sections. That is, a robust stimulant with multiple actions paralleling the drugs of abuse, but with slower onset and longer duration of action administered under a well-controlled regimen can be implemented to safely treat stimulant dependence with minimal risk.

IMPEDIMENTS TO DEVELOPMENT AND APPROVAL OF AGONIST MEDICATION FOR STIMULANT DEPENDENCE

Stimulant use disorders are prevalent and documented epidemics have been cyclic over the last 120 years. Yet stimulant drugs have been used effectively in therapeutics and social commerce for millennia. Clearly identifiable determinants separate the two cases. Therapeutic (e.g. methylphenidate, amphetamine analogs) and social (e.g. caffeine, khat) use typically involves the oral route of administration, dosing within a narrow range and a host of either regulatory or social controls guiding use. Hazardous or toxic use typically involves chronicity, high doses, and routes of administration with relatively instantaneous onset (e.g. intravenous, inhalation).

Recognizing these distinctions was requisite to establishing methadone for treatment of heroin dependence. While the regulations governing methadone treatment are onerous for the patient, many thousands have benefitted from maintenance on this robust opioid, which is also used for cancer or other diseases involving chronic pain. Further, problems such as criminal activity, medical consequences, and the like associated with effective treatment are diminished. Cigarette smoking and other tobacco use have been effectively treated with a variety of nicotine preparations. Contrasted with opioid and stimulant dependence, the concern over nicotine replacement was not illicit immediately disabling drug use or criminal activity, but instead it

revolved around the long-term consequences of morbidity and mortality associated with a publicly promoted and legally available product. Again, there was resistance to use of an agonist, nicotine, for treatment. Here too, as with methadone, the primal objections were twofold, "there will be deaths and diversion" (one fear was that children would become dependent on the gum). Particularly important in each case is that the initial treatment strategy involved a medication that raised legitimate concerns due to side effects, misuse and the like, but that now, in each case, safer medications were developed, are now available and are extremely effective; varenicline and bupropion for nicotine dependence and buprenorphine for opioid dependence. In the case of stimulants, development of new, effective, and safer medications (e.g. lisdexamfetamine) can be expected.

The foregoing points prompt consideration of the risks and benefits as well as the objections to development and approval of stimulants for treatment of stimulant dependence. Objections are primarily those related to the possibility that an individual treated with the medication might sell, or otherwise convey it to others. While such risks can exist, they have not been found to be present in treatment seeking patients in clinical studies and can be addressed by a well-controlled treatment regimen. Risks to the patient, who is seeking treatment because she or he has used illicit stimulants, will also be determined by the regimen and composite treatment provided; and it must be recalled that these will be individuals who have made the initial step by seeking help. Establishing the opportunity for access to treatment that may facilitate long-term abstinence from the hazards of the world of illicit drug use certainly seems adequately justified.

As proposed above, one aspect of the conceptualization that has been considered is a graded approach to treatment based on the available medications and severity of the disorder. There is a spectrum of medications from specific with low abuse liability and limited efficacy to robust agents with broad action, high efficacy, but also high abuse liability. Patients come to treatment with differing severity. In clinical trials and clinic practice alike, low severity patients are commonly found to be reasonably successful in treatment whether receiving active medication or placebo and simply receiving effective behavior therapy. Thus, a strategy of matching severity to medication, as is done in many areas of medicine is reasonable.

Ultimately, accepting the existing data as well as new data as they emerge supporting the agonist approach to treatment, the impediments to development are both more substantial and more concrete. There must be support among professional and governmental entities devoted to the science and treatment of substance use

disorders. There must be a commercial entity willing to take on the responsibility of conducting final pivotal research that will support an FDA approval of use. The commercial entity would likely require assurances of economic incentives for development since the population requiring treatment is small and profits will be limited. This reality does not negate the severity of the condition but recognizes the circumstances of medication development and use, at least in the United States. Beyond this, it can be expected that substantial resistance to the approach will come from both governmental agencies (e.g. the Drug Enforcement Administration) and private groups who are not necessarily supportive of the analogous treatments (e.g. methadone or buprenorphine for opioid dependence). The case is made more difficult by treatment framework proposed; using a graded approach of medication administration associated with severity. This dictates that the target population is limited and profit is lessened, though in general more severe is the standard for the disorder. Conceivably, special legislation could be developed that would permit bypassing some regulatory hurdles.

CONCLUSION

Accumulating scientific data indicate that use of stimulants is a safe, tolerable, and efficacious approach to treatment of stimulant dependence. In many domains of medicine, the data would be adequate to proceed along the standard drug approval mechanisms. Some clinicians are currently prescribing stimulants for stimulant dependence in a number of countries. Some jurisdictions (metropolitan areas) in several countries are developing pilot projects and establishing treatment availability based on the premise of harm reduction. These are important efforts to demonstrating effectiveness and practicality yet are impractical solutions to wide spread availability. In the domain of substance use disorders many social factors, stigmatization, and criminalization of those with the disorder, and far ranging concerns do impede progress toward making treatment available. Thus, political and social factors as well as scientific data will converge to determine the course of approval of efficacious medications for stimulant dependence.

INTRODUCTION

Amphetamine (AMP) and its *N*-methyl derivative methamphetamine (MA) are potent psychostimulants. Oral formulations of AMP and MA are used therapeutically for the treatment of attention deficit hyperactivity disorder (ADHD) and narcolepsy and occasionally to treat obesity. AMP and MA are also commonly abused, with AMP being the form most often abused in Europe and MA more commonly abused in North America, Asia, and Australia. Abuse of AMP/MA usually involves much higher doses than those used therapeutically and may be via oral, intranasal, smoked, or intravenous route. Acute administration at therapeutic doses results in moderate stimulation of the central nervous

and cardiovascular systems producing increased alertness, decreased sleep, improved cognition, and increased heart rate and blood pressure. High doses typical of chronic abuse result in an intense euphoria and may cause agitation, hallucinations, and frank psychosis.

AMP/MA dependence is characterized by tolerance, compulsive use, cravings, and inability to control use. Following chronic abuse, a characteristic withdrawal syndrome occurs on cessation with symptoms of fatigue, increased sleep (called a “crash”), depressed mood, anhedonia, and impaired cognition. Similar to cocaine, AMP/MA increases central nervous system monoamines (dopamine, norepinephrine, and to a lesser degree serotonin), although the mechanism of action

differs. While cocaine increases synaptic monoamines by blocking neuronal reuptake, AMP/MA triggers release of monoamines from neurons via reverse transport via the dopamine transporter. The half-life of AMP/MA is 12–16 h and as a result intense binge use episodes seen with cocaine are not as common with AMP/MA with as many as half of patients seeking treatment in clinical trials for AMP/MA using the drug daily. Personal and public health consequences of AMP/MA abuse include the social sequelae of addiction including family problems and criminal activity; psychiatric symptoms including depressed mood, psychosis, and suicidality; cardiovascular complications including increased risk of heart attack, stroke, and arrhythmias; and increased HIV transmission especially among men who have sex with men and use MA.

Currently, no medications have been proven effective for AMP/MA dependence. Behavioral therapies including cognitive behavioral therapy (CBT) and contingency management are variably effective with high rates of treatment failure especially in patients using AMP/MA daily at treatment entry. As a result, development of an effective medication to augment existing behavioral therapies is an important public health imperative. Medication development for AMP/MA usually begins with assessment of a potential pharmacotherapy in animal models with medications that reduce AMP/MA self-administration in animals being of particular interest. Initial clinical testing occurs in a phase I safety/interaction study usually in an inpatient human laboratory setting where the objective is to determine the safety of the medication in combination with AMP/MA and to insure that the medication does not augment the cardiovascular adverse effects of AMP/MA. Initial efficacy testing is usually in an outpatient phase II clinical trial that compares active medication to placebo, with a behavioral platform such as CBT, in a treatment-seeking population of AMP/MA users.

The following is a summary of medications that have completed initial testing in randomized, double-blind, placebo-controlled clinical trials (phase I and in some cases phase II). Owing to the importance of monoamines and the mesolimbic dopamine system in AMP/MA dependence, several medications targeting dopaminergic systems have been tested. But medications targeting other neurotransmitter systems have also been evaluated including GABA, acetylcholine, opioids, glutamate, serotonin, and angiotensin-converting enzyme. AMP/MA abuse is associated with cognitive deficits particularly in the domains of attention, memory, and executive functions and targeting of these cognitive deficits with pharmacotherapies to treat AMP/MA dependence is a promising area of research. To date, no medication has been approved for AMP/MA dependence, although bupropion has shown

preliminary efficacy in several small clinical trials. Detailed results of phase I/phase II clinical trials completed to date are discussed below followed by a summary of implications for future research aimed at the development of safe and effective medications for AMP/MA dependence.

BUPROPION

The medication with the greatest support for safety and efficacy in clinical trials for AMP/MA dependence is bupropion, a dopamine/norepineprine reuptake inhibitor and noncompetitive nicotinic acetylcholine receptor antagonist, which is an approved treatment for depression and cigarette smoking cessation. Bupropion's clinical effect in AMP/MA dependence (and cigarette smoking cessation) was originally thought to be due to dopamine transporter (DAT) blockade and subsequent increases in dopaminergic tone resulting in reduced cravings and withdrawal symptoms, particularly anhedonia. But studies documenting only weak DAT blockade (approximately 25%) by clinical doses of bupropion in humans suggest that additional mechanisms are likely involved. Bupropion also blocks the norepinephrine transporter (NET) and reduced firing of noradrenergic neurons following AMP/MA administration due to NET blockade, and auto-inhibition via presynaptic norepinephrine receptors has also been hypothesized as a mechanism for bupropion in AMP/MA dependence.

In addition to blockade of catecholamine transporters, bupropion has effects on neuronal cellular dopamine processing that may contribute to its effect in AMP/MA dependence. AMP/MA disrupts functioning of neuronal vesicular monoamine transporter-2 (VMAT-2) resulting in impaired ability to sequester cytosolic dopamine in synaptic vesicles, generation of toxic reactive oxygenation species, and increased release of dopamine into the synapse via DAT reverse transport. Bupropion increases VMAT-2 function and triggers trafficking of vesicles into the cytoplasm of presynaptic neurons *in vitro* via an unknown mechanism involving DAT and presynaptic D2 dopamine receptors. As a result, bupropion may counteract AMP/MA-induced cellular disruptions in dopaminergic functioning by restoring the normal cellular processes responsible for neuronal dopamine disposition and processing.

Recent research has also identified a potential role for cholinergic modulation of the mesolimbic dopamine system via the habenulo-interpeduncular pathway in the actions of a variety of drugs of abuse including AMP/MA. In preclinical studies, MA causes the release of acetylcholine in the interpeduncular nucleus and blockade of $\alpha 3\beta 4$ nicotinic acetylcholine receptors in

the medial habenula, interpeduncular nucleus, and the basolateral amygdala reduced MA self-administration in rats. Bupropion is a noncompetitive antagonist at multiple nicotinic acetylcholine receptors including $\alpha 3\beta 4$, and antagonism of nicotinic receptors may underlie bupropion's effect in AMP/MA dependence, although human studies to support this mechanism of action are lacking.

Clinical studies support bupropion as a safe and efficacious medication for the treatment of AMP/MA dependence in specific patient subgroups. In a human lab study with nontreatment-seeking MA-dependent participants, bupropion reduced the subjective (quality of drug high and any drug effect) and cardiovascular (heart rate and blood pressure) effects of MA more than placebo. Bupropion also significantly reduced MA metabolism, as expected due to bupropion's known inhibition of the 2D6 cytochrome P450 isoenzyme which metabolizes MA into AMP, yet the altered MA pharmacokinetics with bupropion did not result in enhanced cardiovascular or adverse effects. Whether altered MA metabolism is involved in the altered MA subjective effects with bupropion is not known but warrants further investigation.

Several clinical trials have evaluated the safety and efficacy of bupropion versus placebo, provided in conjunction with outpatient behavioral therapy, in treatment-seeking MA-dependent participants. Two independent trials ($N = 151$ and $N = 73$) found no significant effect for bupropion on MA use in the total sample, but both found a statistically significant effect for bupropion in reducing MA use in the subgroup of participants with lower frequency of baseline MA use (self-reported MA use on 18 or fewer of the past 30 days in one study and 0–2 of 6 baseline urine screens positive for MA in the other). Re-analysis of data from the larger study found a statistically significant effect for bupropion on rates of MA abstinence in the final 2 weeks of treatment for all but daily MA users (24% of bupropion participants MA abstinent during the final 2 weeks versus 6% of placebo participants, $p = 0.01$, effect size 0.4 for bupropion). An additional small trial of bupropion versus placebo in high-risk MA using men who have sex with men found bupropion to be acceptable and well tolerated, but the trial was not powered to detect potential treatment effects on MA use. Additional studies in this important clinical population are warranted. Bupropion has been safe and well tolerated in human MA studies to date, and in particular there have been no major cardiovascular toxicities detected. Rare but important side effects of bupropion are seizures and suicidality, and it is important to note that clinical trials have excluded patients at high risk for these conditions.

Additional clinical trials attempting to replicate the efficacy of bupropion for treating MA dependence in

MA users with less than daily use are currently underway (results expected in 2012) and if positive may lead to the eventual approval of bupropion for this indication. Yet despite these encouraging results, many important research questions and clinical problems remain unanswered. Although better than placebo, only approximately one quarter of participants with less than daily MA use achieve MA abstinence by the end of treatment with bupropion, and bupropion has no demonstrated efficacy in the most severely affected subgroup, daily MA users. The mechanism of action responsible for bupropion's effect in AMP/MA dependence has also not been established. As a result, research to optimize outcomes with bupropion and/or identify medications with superior efficacy is needed. For example, human lab studies show a blunting of MA subjective effects following 30 mg of intravenous MA (a low dose relative to those typical for daily MA users) and bupropion failed to benefit heavy/daily MA users in clinical trials, but whether bupropion may benefit heavy/daily MA users following a reduction in MA use frequency/dose, either via existing behavioral therapies or a future pharmacotherapy, is not known. Furthermore, clarification of bupropion's mechanism of action in AMP/MA dependence would provide a molecular target for future medications that may be effective in patients who do not respond to bupropion.

NALTREXONE

Naltrexone is a mu-opioid receptor antagonist that is approved for the treatment of opioid dependence and alcohol dependence. Preclinical and clinical studies support a role for the endogenous opioid system in AMP/MA dependence via interactions with mesolimbic dopaminergic neurons. Naltrexone reduces AMP/MA-induced behavioral and locomotor sensitization, conditioned place preference, and reinstatement of drug-seeking in rodent models and decreases AMP self-administration in rhesus monkeys. Intra-nucleus accumbens naloxone (another mu-opioid receptor antagonist) reduced AMP-induced impulsive behavior in rats while the development of MA-induced behavioral sensitization was attenuated in mu-opioid receptor knockout mice. Naltrexone significantly reduced AMP subjective effects in human lab studies with non-AMP-dependent as well as AMP-dependent volunteers. In a randomized clinical trial among AMP-dependent participants who had achieved initial AMP abstinence during a 2-week lead-in period ($N = 80$), AMP use and cravings were significantly lower and time to AMP relapse longer with naltrexone relative to placebo. A small clinical trial among nontreatment-seeking MA-dependent participants comparing the combination of naltrexone and *N*-acetyl cysteine to

placebo, without a behavioral therapy platform (as participants were not treatment seeking), found no difference in cravings or self-reported MA use with naltrexone/*N*-acetyl cysteine relative to placebo. If confirmed in subsequent studies, these results may suggest that naltrexone has efficacy in preventing relapse following initial AMP/MA abstinence, but may not be effective in inducing abstinence during active AMP/MA use. An additional consideration for future studies of naltrexone for AMP/MA dependence is pharmacogenetic studies showing that response to naltrexone for alcohol dependence is influenced by a polymorphism in the mu-opioid receptor gene (OPRM1 A118G). Results of preclinical and early clinical studies with naltrexone, as well as the availability of a long-acting depot formulation of naltrexone for once-monthly injection, make naltrexone either alone or possibly in combination with other medications an attractive candidate medication for preventing AMP/MA relapse.

DEXTROAMPHETAMINE

A substitution approach to treating AMP/MA dependence has been tested using *D*-amphetamine. Substitution approaches are effective in treating cigarette smoking cessation (nicotine replacement) and opioid dependence (methadone and buprenorphine), but are limited by concerns related to potential adverse effects as well as the need for strict precautions to limit misuse, abuse, and diversion. A randomized trial of high dose *D*-amphetamine (20 mg day⁻¹ then increased 10 mg daily over the initial 14 days until stabilized or at a maximum dose of 110 mg day⁻¹; average stabilization dose of 80 mg day⁻¹) for MA dependence (*N* = 49) found significantly longer treatment retention and lower withdrawal symptoms with *D*-amphetamine relative to placebo. There was no statistically significant difference in MA use for *D*-amphetamine versus placebo, but severity of MA dependence symptoms were less with *D*-amphetamine at the end of treatment. There were no serious cardiovascular or psychiatric adverse events. *D*-Amphetamine was provided via daily supervised dosing at pharmacies with no take-home doses and 86% of participants used MA via the intravenous route. Another randomized trial examined sustained release of *D*-amphetamine 60 mg daily (60 mg once on day 1 followed by 30 mg BID thereafter) versus placebo for MA dependence (*N* = 60). MA withdrawal symptoms and cravings, but not MA use, were significantly lower with *D*-amphetamine relative to placebo and there were no serious cardiovascular or psychiatric adverse events with *D*-amphetamine. Based on these results, high dose *D*-amphetamine may have a role as a harm reduction approach for AMP/MA dependence when other treatments have failed but concerns about abuse and diversion of high dose

amphetamine in AMP/MA-dependent patients are a serious barrier to wide spread adoption of substitution treatment for AMP/MA dependence.

MODAFINIL

Modafinil is a non-amphetamine stimulant that is approved for narcolepsy and excessive daytime sleepiness associated with obstructive sleep apnea. While a variety of potential mechanisms have been proposed for modafinil, human imaging studies suggest that modafinil increases dopamine via DAT blockade. Chronic AMP/MA abuse is associated with cognitive dysfunction, particularly in learning, memory, attention, and executive functions, which may result in poor treatment outcomes especially with existing cognitive behavioral therapies. Modafinil improves cognition and may be effective for AMP/MA dependence via amelioration of cognitive dysfunction. Modafinil reduced cue- and MA-induced reinstatement of MA self-administration in rats. In human lab studies with MA-dependent volunteers, modafinil improves learning and memory, with the largest effect among participants with baseline deficits in cognitive function. Two randomized clinical trials of modafinil versus placebo (modafinil 200 mg daily, *N* = 80; modafinil 400 mg daily, *N* = 71) for MA dependence found no significant effect for modafinil on MA use in a general sample of MA users. Whether modafinil may be effective for AMP/MA dependence in subgroups of MA users with greater baseline cognitive dysfunction, similar to results of human lab studies, has not been assessed in clinical trials.

METHYLPHENIDATE

Methylphenidate is a dopamine-reuptake inhibitor approved for the treatment of ADHD. Similar to bupropion, methylphenidate counteracts MA-induced disruptions of VMAT-2 functioning and prevents the subsequent accumulation of cytoplasmic dopamine and toxic reactive oxygenation species that are thought to contribute to MA-induced neurotoxicity. But pretreatment with methylphenidate did not reduce MA self-administration in rhesus monkeys, while pretreatment with MA or bupropion did reduce MA self-administration in the same set of experiments. One randomized clinical trial comparing controlled-release methylphenidate (*N* = 17) or aripiprazole (*N* = 19) to placebo (*N* = 17) in intravenous AMP/MA users found significantly lower rates of AMP/MA use with methylphenidate compared to placebo, but evaluation of the results is hampered by the fact that the trial was discontinued early after an interim analysis found increased

AMP/MA use in the aripiprazole group. Another small trial compared methylphenidate to placebo in AMP-dependent participants with ADHD and found no difference in ADHD symptoms or AMP use for methylphenidate versus placebo. A phase II clinical trial of sustained-release methylphenidate for MA dependence is underway in the United States and conclusions concerning the efficacy of methylphenidate for AMP/MA dependence await completion of adequately powered clinical trials.

ARIPIPIRAZOLE

Aripiprazole is an atypical antipsychotic that is a partial agonist at D2 dopamine and 5HT_{1A} serotonin receptors. A dopamine partial agonist may be useful in treating AMP/MA dependence by providing some agonist effect (similar to substitution approaches but potentially safer) while antagonizing AMP/MA effects. Aripiprazole reduces the discriminative-stimulus and subjective effects of AMP in healthy non-AMP-dependent volunteers. But among MA-dependent participants in a human lab study, aripiprazole increased MA-induced craving and subjective effects and the one clinical trial to date of aripiprazole for AMP dependence was terminated prematurely due to significantly higher AMP use with aripiprazole relative to placebo in an interim analysis. As a result, aripiprazole is not considered a viable candidate medication for AMP/MA dependence.

BACLOFEN

Baclofen is a selective GABA_B agonist that may be effective for AMP/MA dependence via increasing GABA-ergic modulation of the mesolimbic dopamine system. Baclofen reduces the expression of MA-induced conditioned place preference and MA self-administration in rats. But in a randomized trial for MA dependence, baclofen did not reduce MA use more than placebo in preplanned analyses, although there was an effect in *post hoc* analyses for baclofen in reducing MA use among participants with the highest medication adherence. Thrice daily dosing and drowsiness, the most common side effect, may limit adherence, and thereby efficacy, with baclofen in MA dependence. Still, these preliminary results suggest targeting GABA may be effective for AMP/MA dependence. Future formulations/analogues of baclofen or other GABA-ergic medications may yet prove effective. For example, a GABA_B positive allosteric modulator reduced AMP-conditioned place preference in rats and may be available for clinical testing in the future.

GAMMA-VINYL-GABA

Gamma-vinyl-GABA (GVG) is an antiepileptic that irreversibly inhibits GABA transaminase, the enzyme that metabolizes the inhibitory neurotransmitter GABA, thereby increasing CNS GABA and inhibitory tone. Increased GABA may be an effective strategy for treating AMP/MA dependence as GABA-ergic neurons modulate mesolimbic dopamine functioning and may thereby dampen the rewarding effects of AMP/MA. In rats, GVG inhibits MA-induced increases in dopamine in the nucleus accumbens and prevents reinstatement of MA-conditioned place preference following MA administration. GVG was well tolerated in a small open-label clinical trial ($N = 30$) for MA dependence in Mexico. In a phase I safety-interaction trial in the United States, GVG did not significantly alter MA subjective effects relative to placebo and there was a trend toward enhanced cardiovascular response to MA with GVG. Subsequent development of GVG for MA dependence in the United States was halted due to potential cardiovascular safety concerns, although the mechanism whereby GVG would enhance cardiovascular response to MA is unknown. The best-known adverse effect of GVG is ocular toxicity resulting in peripheral visual field defects, but this has not been observed with short-term use in trials for AMP/MA dependence.

TOPIRAMATE

Topiramate is an anticonvulsant that increases GABA transmission and inhibits glutamatergic transmission and has shown preliminary efficacy for alcohol dependence. In a human lab study in MA-dependent volunteers ($N = 10$), topiramate increased MA subjective effects ("stimulate" and "euphoria") following experimental MA infusions. There was a trend toward increased MA plasma levels with topiramate, suggesting that enhanced MA effects with topiramate may be the result of a pharmacokinetic interaction, and further clinical development is unlikely to be safe or effective.

GABAPENTIN

Gabapentin is an antiepileptic that binds to voltage-gated calcium channels (VGCC). In mice, MA treatment increases levels of the $\alpha 2/\delta$ -1 subunit of VGCCs in the nucleus accumbens and frontal cortex. Gabapentin reduces MA-induced increases in the $\alpha 2/\delta$ -1 subunit and blocks expression of MA-conditioned place preference in mice. Gabapentin did not reduce MA use more than placebo in the one randomized clinical trial for MA dependence in humans.

VARENICLINE

Varenicline is an $\alpha 4/\beta 2$ nicotinic acetylcholine receptor partial agonist that is approved for cigarette smoking cessation. Similar to bupropion, which has shown preliminary efficacy for MA dependence in early clinical trials, varenicline may be effective for AMP/MA dependence by modulating mesolimbic dopamine transmission via binding to $\alpha 4/\beta 2$ nicotinic receptors on neurons in the ventral tegmental area and/or antagonizing of nicotinic acetylcholine receptors. Clinically, varenicline improves cognition, especially attention and memory, during smoking cessation treatment and may be useful in ameliorating the cognitive dysfunction that has been observed in chronic AMP/MA abusers. In a human safety-interaction study among MA-dependent cigarette smokers ($N = 12$), cardiovascular response and psychiatric adverse events following MA infusions were similar for varenicline and placebo. In a small pilot randomized clinical trial among treatment-seeking outpatients with MA dependence ($N = 20$), varenicline improved retention and reduced MA use and cravings more than placebo. Rare but serious psychiatric adverse events, including suicide, have been reported with varenicline in cigarette smoking cessation treatment but have not been observed in the limited clinical studies of varenicline for MA dependence to date. A phase II trial of varenicline for MA dependence ($N = 90$) is currently scheduled to begin enrollment in mid-2011.

LOBELINE

Lobeline, an alkaloid of *Lobelia inflata* (Indian Tobacco), is a nicotinic receptor antagonist, inhibitor of VMAT-2 function and has low affinity for the dopamine and serotonin transporters. MA disrupts VMAT-2 functioning resulting in increased cytosolic dopamine and release of dopamine into the synapse. Lobeline inhibits MA-induced dopamine release in vitro and reduces MA self-administration in rats presumably due to its effects at VMAT-2 and the dopamine transporter, but it has not been tested for AMP/MA dependence in human clinical trials. Gastrointestinal side effects (nausea and vomiting due to nicotinic effects) may limit the clinical utility of lobeline although related molecules more selective for VMAT-2 are in early stages of development and may be tested for AMP/MA dependence in the future.

RIVASTIGMINE

Rivastigmine is an acetylcholinesterase inhibitor with cognitive enhancing effects that is used to treat

dementia. In addition to increasing dopamine release, MA also triggers release of acetylcholine in the ventral tegmental area and donepezil, another acetylcholinesterase inhibitor, reduced MA-seeking behavior in rats. In a human lab study among nontreatment-seeking MA-dependent volunteers ($N = 23$), rivastigmine significantly reduced the subjective "desire" for MA relative to placebo, but did not reduce MA-self administration in a laboratory choice paradigm relative to placebo. Additional studies of cholinergic medications for AMP/MA dependence are warranted.

SELECTIVE SEROTONIN REUPTAKE INHIBITORS

Selective serotonin reuptake inhibitors (SSRIs) are antidepressants that increase serotonin via blockade of reuptake via the serotonin transporter. AMP/MA causes release of serotonin, in addition to dopamine and norepinephrine, and depressive symptoms are typical and often severe during AMP/MA withdrawal and as a result SSRIs were some of the first medications tested for AMP/MA dependence. Randomized clinical trials found no benefit for fluoxetine or paroxetine in reducing MA use relative to placebo. In a randomized trial of sertraline for MA dependence, treatment dropout and adverse events (particularly gastrointestinal symptoms and sexual dysfunction) were significantly higher with sertraline than placebo. As a result, SSRIs are not indicated for the primary treatment of AMP/MA dependence, but may have a role in treating AMP/MA users with depression that does not remit following abstinence from AMP/MA use, although bupropion may be preferred to SSRIs given the efficacy of bupropion in early MA dependence clinical trials.

ONDANSETRON

Ondansetron is an antiemetic that modulates mesolimbic dopamine function via blocking serotonin ($5HT_3$) receptors. Ondansetron blunted AMP subjective effects in a lab study in healthy non-AMP-dependent volunteers. A large randomized, double-blind trial ($N = 150$) of ondansetron for MA dependence failed to find an effect for ondansetron (0.25, 1, and 4 mg twice daily) on MA use relative to placebo.

PERINDOPRIL

Perindopril is an angiotensin-converting enzyme (ACE) inhibitor and antihypertensive. Preclinical

studies showing an effect of brain ACE systems on mesolimbic dopamine provide the rationale for testing ACE inhibitors for treating AMP/MA dependence. There was no significant effect of perindopril on MA cardiovascular or subjective effects overall in a human lab study, although MA subjective effects were lower relative to placebo among participants receiving 2 and 4 mg of perindopril, but not those receiving 8 mg perindopril, leaving open the possibility that future studies with intermediate doses may show an effect for perindopril in MA dependence.

SUMMARY AND FUTURE IMPLICATIONS

While no medications have been proven effective for AMP/MA dependence, bupropion has shown preliminary efficacy among MA users with less than daily MA use at treatment baseline. Two confirmatory clinical trials with bupropion in less than daily MA users are currently underway, and results of these studies will determine if bupropion is likely to be approved as a treatment for AMP/MA dependence. Regardless of the outcome of these trials, many important research and clinical questions regarding AMP/MA dependence pharmacotherapy remain unanswered. First, no medications have shown efficacy in achieving AMP/MA abstinence in the most severely addicted patients, including daily AMP/MA users, although substitution approaches may increase treatment retention and reduce severity of AMP/MA dependence. Research to better quantify potential health and societal benefits of treatments that reduce AMP/MA use but do not achieve total abstinence is warranted. Also, whether bupropion (or another medication) is effective in sustaining abstinence in daily users following a brief inpatient stabilization to achieve initial abstinence warrants investigation. Furthermore, clinical trial designs that account for the clinical and potentially biological heterogeneity among AMP/MA-dependent patients and are capable of isolating medication effects in specific subgroups are needed. It seems likely that like other areas of medicine, personalized approaches to pharmacotherapy for AMP/MA dependence will be needed in order to achieve optimal treatment outcomes for all patient subgroups. With this in mind, testing of medications with a variety of different mechanisms in multiple subgroups of AMP/MA users, especially those with varying frequency of AMP/MA use at treatment baseline, will likely be necessary in order to identify several effective medications such that clinicians can tailor pharmacotherapy to each patient's individual needs.

List of Abbreviations

ACE	angiotensin-converting enzyme
ADHD	attention deficit hyperactivity disorder
AMP	amphetamine
CBT	cognitive behavioral therapy
DAT	dopamine transporter
GVG	Gamma-vinyl-GABA
MA	methamphetamine
NET	norepinephrine transporter
SSRI	selective serotonin reuptake inhibitor
VGCC	voltage-gated calcium channels
VMAT-2	vesicular monoamine transporter-2

SEDATIVE DEPENDENCE

The term “Sedative dependence” describes the psychic and physical dependence from medications that are classified as “sedatives” because of their relaxing, sleep-inducing properties. Although various drugs can be classified as “sedatives,” i.e. barbiturates and antipsychotics with sedative properties, benzodiazepines and the “non-benzodiazepine” sedative hypnotics, in particular zaleplon and zolpidem, are those sedatives that are most clinically relevant.

Benzodiazepines are most commonly prescribed because of their quick sedative and hypnotic effects, which make benzodiazepines effective as co-medication in the treatment of various psychiatric diseases such as agitated depression, anxiety, and sleep disturbances. Besides these common indications, benzodiazepines are often (mis-)used because of their relaxing and mood improving properties.

The addictive potential of benzodiazepines ranks from medium to high depending on the individual benzodiazepine medication. In particular, the onset and the duration of action have been identified as pharmacological variables that contribute to the risk of addiction (see Subgroups of Benzodiazepine-Dependent Patients).

Substance dependence as defined by the criteria of the DSM-IV is defined by at least three of the following symptoms occurring in a 12-month period leading to the necessity of treatment:

1. Tolerance: Tolerance means the partial or complete loss of the effects desired caused by adaptive processes, although the drug is taken continuously. Tolerance typically results in self-directed, nonprescribed increase of the dosage taken.
2. Withdrawal: Tapering of dosage or stopping of intake is associated with a typical withdrawal

syndrome, that is substance specific and a manifestation of the substance-specific neuroadaptive process within central neurotransmission (e.g. symptoms of increased glutamatergic neurotransmission in patients suffering from benzodiazepine dependence).

3. Ongoing drug use over longer time periods than intended or prescribed.
4. Spending most of the days with activities that are associated with drug use as obtainment, intake, and recovering from side effects.
5. Disregard of any further activities due to drug use.
6. Ongoing drug use although the existing knowledge about potential harmfulness of ongoing drug intake or manifestation of permanent side effects.

BENZODIAZEPINES

Benzodiazepines are sedative drugs that are prescribed because of their anxiolytic, relaxing, and hypnotic (sleep-inducing) properties. Moreover, a positive mood effect is known. Besides those desired effects, benzodiazepines show side effects such as decrease of muscular tone, anticonvulsive, and amnesic effects (in particular anterograde amnesic effects that can contribute to the dementia like symptoms often seen in long-term benzodiazepine users). Because of their anxiolytic, relaxing qualities, benzodiazepines are widely used not only to treat insomnia and anxiety but also because of their muscle relaxing properties. The main effects and clinical uses of benzodiazepines include the following:

- Effects on mood and agitation: co-treatment in the case of agitated psychosis, catatonia, severe depression
- Anxiolytic properties: treatment of anxiety disorders
- Hypnotic properties: treatment of insomnia
- Muscle relaxing properties: co-treatment of spine diseases, dystonia, and muscle spasms
- Treatment of movement disorders, like akathisia and tardive dyskinesia following long-term treatment with typical antipsychotics
- Anticonvulsant properties: treatment of epilepsy and withdrawal syndromes (as alcohol withdrawal)
- Amnesic properties, in particular anterograde amnesia

The intake of benzodiazepines over longer time periods (e.g. continuous intake over a period of 2–4 weeks) has been proven to be associated with the risk of dependence and the occurrence of a typical benzodiazepine withdrawal syndrome (see Subgroups of Benzodiazepine-Dependent Patients) when treatment is stopped without tapering of dosage. Several risk factors that contribute to the development of benzodiazepine dependence have

been investigated by clinical observational studies: For example, certain personality traits like dependent and emotional unstable personality traits have been shown to increase the risk of benzodiazepine dependence. Also, the pharmacology of the benzodiazepine used, its bioavailability, the speed of absorption, diffusion, and invasion, has been shown to contribute to the risk of dependence. In particular, benzodiazepines that quickly reach high plasma peaks are known to increase the risk of dependence. Consistently, those benzodiazepines have been shown to be commonly misused in polydrug users via intravenous application in order to further increase the onset of drug action (e.g. flunitrazepam). Factors that increase the risk of dependence include the following:

- Duration of treatment (in particular treatment periods longer than 2 weeks)
- Dosage taken
- Chronic psychiatric diseases such as depression, dysthymia, anxiety
- Anamnesis or ongoing drug dependence
- Emotional unstable and dependent personality traits
- Properties of the benzodiazepine taken (bioavailability, half-life, plasma peak, oral versus i.v. use (e.g. flunitrazepam))

Table 49.1 gives an overview about various benzodiazepine derivatives and the pharmacological half-lives.

TABLE 49.1 Overview of Different Benzodiazepine Derivates

Benzodiazepine derivate	Pharmacological half-life	Diazepam equivalent dosage
Diazepam	20–100	10 mg
Alprazolam	6–12 h	1 mg
Bromazepam	10–20 h	4.5 mg
Chlordiazepoxid	5–30 h	20 mg
Clobazam	12–60 h	20 mg
Clorazepat	36–200	15 mg
Flunitrazepam	18–26	1 mg
Flurazepam	40–250	30 mg
Lorazepam	10–20	1–2 mg
Lormetazepam	10–12	1 mg
Medazepam	36–200	20 mg
Nitrazepam	15–38	5 mg
Oxazepam	4–15	30 mg
Prazepam	36–200	20 mg
Temazepam	8–22	20 mg
Triazolam	2	0.25 mg

Note: These estimates are based on the results from Heberlein A et al: Fortschr Neurol Psychiatr. 2009 Jan; 77(1): 7–15. Epub 2008 Dec 19.

SUBGROUPS OF BENZODIAZEPINE-DEPENDENT PATIENTS

Benzodiazepine dependence is a common disease: About 2% of general population have been reported to suffer from benzodiazepine dependence. In general, two groups suffering from benzodiazepine dependence can be distinguished: On the one hand, there is a large group of persons, who get a medical prescription aiming the treatment of anxiety or muscle spasm. Typically those patients use benzodiazepines as prescribed without increasing their dosages. Those who have trouble controlling their use of benzodiazepines often do so to avoid potential negative effects of treatment cessation. They fear the recurrence of those symptoms for which the benzodiazepines have been prescribed. Those persons, suffering from the so-called "*low dosage benzodiazepine dependence*," are usually elderly women (aging 60 years and above) suffering from depression, anxiety, or insomnia. The second, equally prevalent, group of benzodiazepine-dependent patients are patients with multidrug dependence, who suffer from "*high dosage benzodiazepine dependence*." Contrasting to the "low dosage benzodiazepine-dependent patients" this group shows typical addictive behaviors such as increase of dosage without medical prescription, increase of tolerance of intended drug effects, intravenous application or application with further addictive substances (as heroin, cocaine, amphetamines, antidepressants) in order to increase the drug effects as well as illegal drug-selling.

BENZODIAZEPINE WITHDRAWAL SYNDROME

Since the first discovery of the benzodiazepine chloridiazepoxide more than 40 years ago, benzodiazepine tolerance and withdrawal have been documented. Tolerance first develops to the sedative effects, followed by tolerance to benzodiazepines' anticonvulsant actions and its anxiolytic effects. Even low dose treatment with benzodiazepines over a distinct time period can provoke tolerance as well as withdrawal, supporting the relevance of "low dosage dependence." Signs and symptoms of benzodiazepine withdrawal include the following:

- Agitation
- Insomnia, inability to sleep, and disturbed sleeping
- Loss of appetite and weight loss
- Nausea, vomiting, and diarrhea
- Seizure
- Tremor
- Muscle spasms

- Increase of blood pressure, pulse, and body temperature
- Headache
- Hallucinations, in particular perceptual hallucinations
- Psychiatric symptoms such as anxiety, depression, and irritation

Besides the common physiological withdrawal syndrome also psychological withdrawal symptoms are known, caused by those "psychological" effects of the sedative independent from its pharmacological actions. In contrast to the typical physiological withdrawal syndrome noted above, the psychological withdrawal syndrome is mainly characterized by psychiatric symptoms such as depression, anxiety, and agitation and rather mild bodily symptoms that can be explained as a consequence of psychic agitation or anxiety.

NEUROBIOLOGICAL ACTIONS OF BENZODIAZEPINES

In the central nervous system, benzodiazepines are ligands at the GABA_A receptor. They bind to the benzodiazepine binding site, which enhances the affinity of the gamma-aminobutyric acid (GABA) to its (GABA_A)-receptor. Through this process, benzodiazepines reinforce the inhibitory effects of GABAergic neurotransmission in general.

The GABA_A receptor is known to be a ligand-gated ion channel like glycine or nicotinic acetylcholine receptors. It consists out of five different subunits that are circled around a central ion channel, which is selectively permeable to chloride ions. Benzodiazepines' binding to the receptor results in increasing the GABA mediated amount of Cl⁻ currents and the frequency of the chloride channel opening in response to GABA, without altering the mean duration of the channel opening time. The composition of the five subunits, which form the central chloride channel, differs: until now 19 differential subunits are known, containing the subunits α_{1-6} , β_{1-3} , γ_{1-3} , δ , ϵ , θ , π , ρ_{1-3} . Further evidence supports the existence of further subunits that have not been investigated yet. Though, GABA_A receptors consisting out of two α , two β subunits and an additional subunit, mostly γ are known to be most clinical relevant. Consistently, the most abundant combination – constituting a percentage degree of 43% in rat brains – is α_1 , β_2 , and γ_2 .

The benzodiazepine binding site is located between the γ_2 and the nearby α -subunit of the GABA_A receptor, whereby the existence of the γ_2 -subunit is exigent for benzodiazepine binding. Also, a homologous GABA binding site exists at the GABA_A receptor, that is

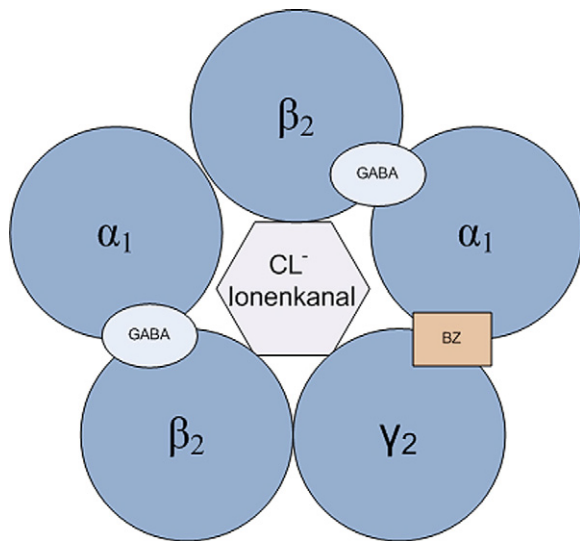

FIGURE 49.1 Composition of the GABA_A receptor and the GABA and benzodiazepine binding site (BZ, benzodiazepines). Adapted from Heberlein A et al: *Fortschr Neurol Psychiatr.* 2009 Jan; 77(1): 7–15. *Epub* 2008 Dec 19.

comprised out of the $\alpha_{1,2,3,5}$ and the β_2 subunit. Except the benzodiazepine and the GABA binding site, five other binding sites have been described that bind the sedative barbiturates, neurosteroids, picrotoxin, Cl⁻, and Zn²⁺ (see Fig. 49.1 for detail).

Because of the great diversity of the GABA_A receptor conformation and the distinct localization of the several GABA subunit compositions in the rat brain, it has been hypothesized that the composition of the subunits forming the GABA_A receptor could be responsible for the particular functions of the receptor and could even be involved in the constitution of tolerance and withdrawal during benzodiazepine therapy. Until now, this coherency is not completely proven, but evidence increases that the subunits of GABA_A receptors deliver different aspects of the effects of benzodiazepines:

1. The α_1 subunit has been associated with sedative, anterograde amnesic, and anticonvulsive effects of benzodiazepine therapy
2. The α_2 or α_3 subunit seems to deliver the anxiolytic effects of benzodiazepine treatment
3. The α_5 subunit seems to be involved in memory impairment due to benzodiazepine therapy.

Consistent with a subunit-specific delivery of the several effects of benzodiazepine therapy, in genetic modulated “knock-in” mice, that exhibit inoperable α_1 subunits because of a α_1 (H101R) point mutation, diazepam lacks sedative and amnesic effects. Moreover, in α_2 “knock out” mice that exhibit α_2 subunits, which are insensitive to diazepam because of an artificially engendered α_2 (H101R) point mutation, diazepam fails to show anxiolytic effects.

THE NEUROBIOLOGY OF BENZODIAZEPINE DEPENDENCE

Although intensive efforts have been made to investigate the underlying molecular mechanisms of tolerance and dependence associated with benzodiazepine therapy, the neurobiological basis of sedative dependence has not been fully elucidated yet.

Regarding the neurobiological processes underlying benzodiazepine dependence, alterations in the GABA_A receptor structure have been proven to exist, but these results remain inconsistent and are therefore not sufficient in elucidating the complex processes explaining the occurrence of benzodiazepine dependence. Also, alterations in the glutamatergic neurotransmission have been investigated due to benzodiazepine therapy. It is likely that regulatory mechanisms that oppose the pharmacological enhanced GABAergic neurotransmission result in the increases in glutamatergic neurotransmission observed. Furthermore, alterations in the activity of the hypothalamic pituitary axis (HPA) have been reported, which are directly or subsequently involved in the occurrence of the clinical benzodiazepine withdrawal syndrome. For example, the release of corticotropin releasing hormone (CRH), adrenocorticotropin, and cortisol is decreased during benzodiazepine therapy, whereas withdrawal from benzodiazepines results in an increase of these parameters. New psychopharmacological strategies utilize these newly investigated coherencies and try to modulate the activity of the HPA in order to treat patients suffering from sedative dependence.

Alterations in the GABA_A Receptor

In order to further scrutinize the involvement of special subunits in the development of benzodiazepine dependence, the expression of subunit-specific mRNA during therapy and withdrawal from benzodiazepines was investigated: Thus, greater alterations should be observable in those subunits that are mainly involved in benzodiazepine binding than in those that are not involved. Because of the assumption that α_4 and α_6 render the GABA_A receptor insensitive to benzodiazepine treatment, a possible higher expression of GABA_A receptors which contain the α_4 or α_6 and a lower expression of $\alpha_{1,2,3,4,5}$ was assumed to be a result of long-time benzodiazepine treatment. Though, the results obtained until today do not fully confirm the hypothesis of a subunit-specific adaption mechanism of the GABA_A receptor underlying the development of benzodiazepine dependence. Furthermore, the hypothesis that benzodiazepine treatment may result in downregulation of the total number of the GABA_A receptor has not yet been proven.

Alterations in the Glutamatergic Neurotransmission

Because of the hypothesis that prolonged therapy with benzodiazepines could provoke compensatory changes in those neuronal systems that normally oppose the GABAergic neurotransmission, the effects of benzodiazepine treatment on glutamatergic neurotransmission have been a main focus of research. According to this hypothesis, withdrawal symptoms could be explained as an enhanced excitatory glutamatergic neurotransmission that is no longer antagonized by the inhibitory GABAergic neurotransmission after cessation of benzodiazepine therapy. Indeed, a significant increase of *in vitro* glutamate release in the hippocampus of rats that were chronically treated with lorazepam was reported as well as neuroadaptive alterations in the receptors of the glutamate system due to benzodiazepine dependence. Thus, adaption of the glutamatergic neurotransmission seems to be involved, not only in the typical benzodiazepine withdrawal symptoms but also in long-term potentiation. Long-term potentiation is the basis of neuroplasticity – in the development of the so-called addictive memory, the consolidation of substance-related memories that increase the substance craving dependent on certain locations and situations (so-called cue reactivity).

Alterations in the Regulation of the HPA

Besides its modulation of GABAergic and glutamatergic neurotransmission, benzodiazepine treatment is known to affect further central regulatory circuits such as the HPA. In particular, alterations in the regulation of the HPA have been found to contribute to the development of benzodiazepine dependence as well as to the development of typical benzodiazepine withdrawal signs. For example, various studies showed time-dependent suppression of HPA-activity during treatment with benzodiazepines and an increase in HPA activity during benzodiazepine withdrawal, similar to withdrawal syndromes provoked by ethanol, opioids, and even cocaine. Regarding benzodiazepines, there is evidence that individual benzodiazepines can decrease the exercise-induced activation of the HPA, which fits well with the relaxing and anxiolytic properties of benzodiazepines in general. Moreover, preclinical study results suggest that benzodiazepines may even directly interfere with the regulation of the HPA by affecting the stress-induced transcription of the hypothalamic corticotropin releasing factor and thereby the downstream activity of the HPA and the cortisol release from the adrenal gland. See Fig. 49.2 for details.

MODEL OF THE DEVELOPMENT OF BENZODIAZEPINE DEPENDENCE

Clinical research indicates that both psychic and neurobiological causes contribute to the development of benzodiazepine dependence.

Similar to hypotheses regarding affective disorders, the development of benzodiazepine dependence has been explained by a multicausal model that consists of a combination of psychic factors, like stressful life events, and neurobiological factors, like genetic prevalence. Certain genetic risk profiles, like dependent, anxious personality traits, predispose the intake of sedative drugs. The drug profile of the benzodiazepine taken increases the risk of dependence by the presence of the desired effects and by the relief from unwanted symptoms. In this way, the relief gained by benzodiazepine treatment serves as positive reinforcement that supports the development of dependence. Figure 49.3 shows this hypothetical cascade of the factors contributing to benzodiazepine dependence.

TREATMENT OF BENZODIAZEPINE DEPENDENCE

Established Therapeutic Methods

Tapering of dosage after switching from a short-term benzodiazepine like lorazepam to a longer acting benzodiazepine like diazepam (see Table 49.1 for detail) is the most proven and most common strategy of benzodiazepine withdrawal. Dosage tapering without switching to medium-long half-life benzodiazepines has been associated with increased relapse during withdrawal because of the increase of intensity of withdrawal symptoms dependent on the half-life and the metabolism of the drug. Although some authors also recommend rapid dosage reduction strategies – for example halving the dosage in the beginning of the benzodiazepine withdrawal – clinical evidence suggests that slow tapering of the dosage is associated with lower relapse rates.

Various established drug strategies have been tested in terms of decreasing withdrawal symptoms and substituting for benzodiazepine's effects after successful withdrawal. However, therapeutic strategies such as the use of β -receptor antagonist Propranolol, the anxiolytic Buspirone, and the steroid hormone progesterone did not prove to be efficacious in randomized clinical studies. There are study results that suggest that the antihistamine hydroxyzin may prove efficacious in terms of reducing clinical anxiety and alleviation of benzodiazepine withdrawal symptoms. Though, study results that have replicated this

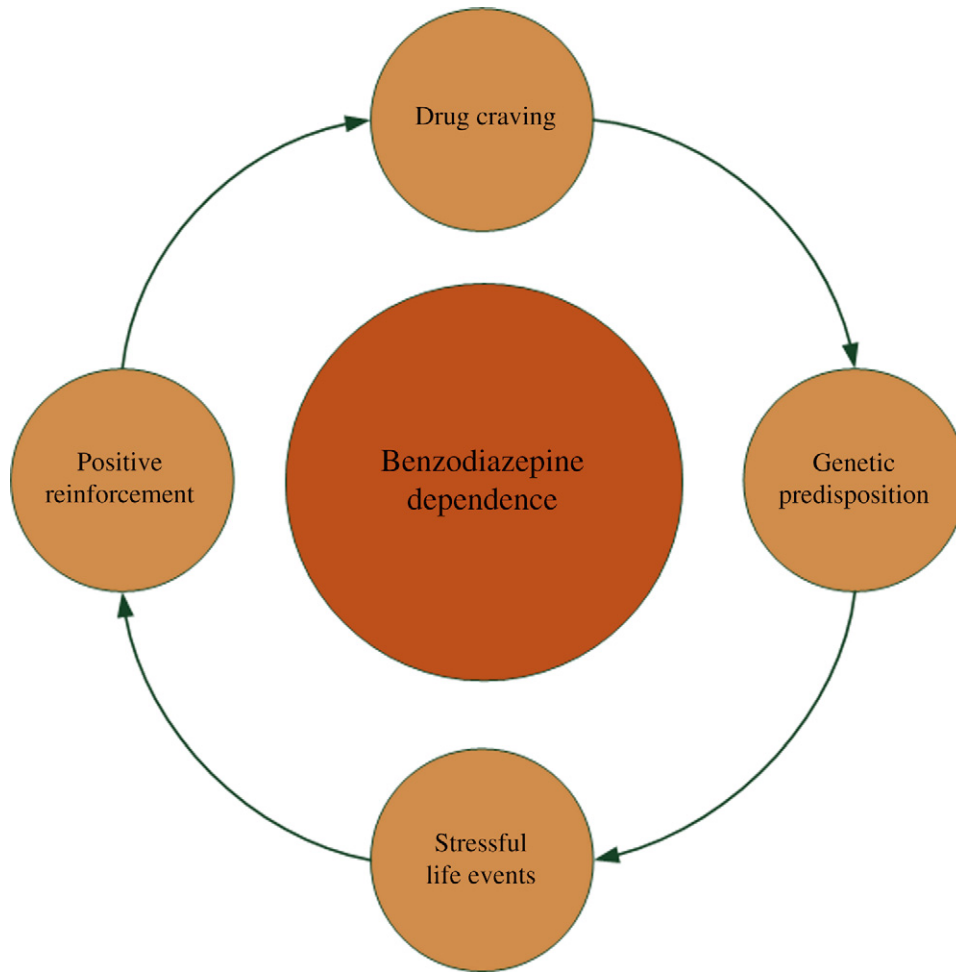

FIGURE 49.2 Cascade of the cortisol release from the adrenal gland. Although study results are not consistent, there is evidence that benzodiazepines decrease the transcription of corticotropin releasing factor and thereby decrease the activity of the HPA axis resulting in decreased release of cortisol from the adrenal glands.

finding are lacking. Tricyclic antidepressants may reduce withdrawal symptoms, most likely by their own sedative qualities, but a significant impact on relapse rate was not shown in clinical studies. Likewise, the anticonvulsant carbamazepine has been reported to alleviate the symptoms of benzodiazepine

withdrawal. Actual study reports show that the anxiolytic gabapentin is also effective in reducing the intensity of withdrawal and may reduce the relapse rates after successful benzodiazepine withdrawal. Below is an overview of substances that are known because to be effective in alleviation of benzodiazepine withdrawal symptoms.

FIGURE 49.3 Psychological and neurobiological reasons contributing together to the development of benzodiazepine dependence.

- Tricyclic antidepressants – intensity of withdrawal symptoms.
- Carbamazepine – intensity of withdrawal symptoms, anticonvulsion. Some study reports point toward a decrease of relapse rates by carbamazepine therapy throughout and following benzodiazepine withdrawal.
- Gabapentin – intensity of withdrawal symptoms and decrease of relapse.
- Hydroxycyn – intensity of withdrawal symptoms (contrary findings).

Substances That Are Currently Being Investigated

GABA_A Receptor

Recently developed substances, showing subunit selectivity at the GABA_A receptor, were used in order to further investigate the coherences between GABA_A subunit composition and related benzodiazepine effects: SL 65 14 98, for example, is a pyridole derivate that shows selectivity for non- α_1 containing GABA_A receptors and potentiates GABA effects fully at GABA_A α_2 receptors and with lower efficacy at GABA_A α_3 receptors. At α_1 and α_5 receptors, SL 65 14 98 shows only partial agonism as determined by measuring the modulation of GABA-mediated CL-flux in vitro. Studies in nonhuman primates revealed that SL 65 14 98 could engender anxiolytic effects similar to diazepam, whereas muscle weakness, sedation, and ataxia, regularly seen during diazepam treatment, appeared only at doses that were much higher than those that evoked the anxiolytic effects. In drug discrimination tests, SL 65 14 98 motivated the primates as well as triazolam to work for an intravenous injection, an effect, which could be blocked by the α_1 subunit antagonist beta-carboline-3-carboxylate-t-butyl ester (beta-CCT), probably because of a connectivity between reinforcing effects of benzodiazepines and their bindings properties to the α_1 subunit of the GABA_A receptor.

Similar to SL 65 14 98, L-838,417 shows no affinity difference in binding to GABA_A receptors containing $\alpha_{1,2,3,5}$ subunits. However, it shows only potentiation of GABAergic effects at GABA_A receptors that contain the $\alpha_{2,3,5}$ subunit. At α_1 containing GABA_A receptors, it acts as an antagonist. Like SL 65 14 98, L-838,417 shows anxiolytic and anticonvulsant properties without motor impairments or sedative effects. In suppressive tasks like the Vogel conflict test, L-838,417 engendered anti-conflict effects in mice without increasing unpunished drinking behavior in comparison to chlordiazepoxide or bretazani. Moreover, SL 65 14 98 did not invoke tolerance to its anticonvulsant effects nor shows physical dependence after repeated administration. After intermittent treatment, even a tendency to increase of effects was observed, which was denoted by a lower minimal dose required (3 instead of 10 mg kg⁻¹ bodyweight) in order to gain anxiolytic effects in suppressive tasks. In mice treated with L-838,417, or as well with SL 65 14 98, the inverse benzodiazepine agonist FG 7142 did not provoke clonic seizures, whereas in the same study, mice that were treated with either triazolam, clonazepam, diazepam, or alprazolam – substances that exhibit unselective affinity to GABA_A receptor subunits – showed seizures regularly after a single dose of FG 7142. Altogether a higher rate of clonic seizures under sudden withdrawal, provoked by treatment with FG-7142,

was encountered in mice that had been treated with nonselective benzodiazepines, in which the possibility of seizures was descending gradually: triazolam = clonazepam = diazepam > alprazolam = midazolam = lorazepam.

Also, benzodiazepines that exhibit a subunit-specific affinity to the GABA_A receptor like zolpidem – a substance which has a tenfold greater affinity to GABA_A receptors that contain an α_1 subunit – have been reported to show less tolerance and decreased sensitivity to seizures and likewise a reduced propensity to induce physical dependence in rodents, baboons, and humans. Likewise abecarnil, another GABA_A ligand, that binds with the highest affinity to the α_1 subunit and acts as a full agonist only at α_3 subunits, does not produce diazepam like tolerance and withdrawal symptoms. Although subunit selectivity is promising regarding the development of dependence, clinical evidence suggests that the non-benzodiazepine sedative hypnotics are associated with the risk of dependence, which is mostly explained by a dosage dependent loss of binding selectivity. Below is a list of substances with specificity for certain subunits of the GABA_A – receptors that have been associated with decreased risk for dependence:

- SL 65 14 98
- L-838,417
- the non-benzodiazepines zaleplone, zolpidem, and abecarnil

Glutamatergic Neurotransmission

Preclinical study results indicate that modulation of glutamatergic neurotransmission that is typically increased during benzodiazepine withdrawal may as well reduce benzodiazepine withdrawal signs. The NMDA receptor antagonists MK-801, dizocilpine, and ifenprodil were efficient in suppression of benzodiazepine withdrawal symptoms in animal models of diazepam dependence. Also, the AMPA-receptor antagonist GYKI 52466 reduced significantly diazepam withdrawal signs.

HPA

CRH1-receptor antagonists such as DMP-904 and R121919 showed efficiency in reducing anxiety and depression in preclinical studies. Therefore, CRH1 receptor antagonists may be as well useful in partly substituting the effects obtained by benzodiazepine therapy without any addictive potential (so far as known). Moreover, the CRH1-receptor antagonist R121919 was efficient in reducing benzodiazepine withdrawal symptoms in an animal model of benzodiazepine dependence. Therefore, CRH1 antagonists may be a valuable treatment option as well in respect of the effects currently obtained by benzodiazepines as in respect with the treatment of

benzodiazepine withdrawal, if further studies support the results obtained until now. Below is a list of substances that are currently investigated in order to treat benzodiazepine withdrawal symptoms:

- Modulation of glutamatergic neurotransmission:
NMDA antagonists: MK-801, dizocilpine, ifenprodil,
AMPA-receptor antagonists: GYKI 52466
- Modulation of the HPA: CRH1-antagonists: DMP-904,
R121919
- Gabapentin (promising results from clinical studies)

CONCLUSION

Benzodiazepine dependence is a prevalent chronically relapsing disorder. The gold standard of treatment of benzodiazepine dependence is a gradual dosage tapering that may be assisted by tricyclic antidepressants, carbamazepine, or gabapentin. Preclinical study results suggest that there may be further treatment options by modulation of the HPA or by development of substances showing specificity at the GABA_A receptor. Thus, further research is necessary in order to improve the treatment possibilities of benzodiazepine dependence.

DEFINITION OF CO-OCCURRING MAJOR DEPRESSION AND OF ALCOHOL DEPENDENCE

In this chapter, the term co-occurring major depression and alcohol dependence will be used to indicate the simultaneous presence of those two disorders, without necessarily implying any particular relationship between the two disorders. A discussion of the mechanisms underlying the associations between alcohol use disorders (AUDs) and depression is beyond the scope of this chapter. A discussion of other possible co-occurring conditions is also beyond the scope of this chapter, though patients with co-occurring major depression and alcohol dependence often demonstrate other substance use disorders and other psychiatric disorders as well.

The nosologic system that is currently used for diagnosis of psychiatric disorders is the *Diagnostic and Statistical Manual*, 4th Edition (DSM-IV) diagnostic system,

which was first published in 2000. A relatively minor revision of that diagnostic system was subsequently written, called the DSM-IV Text Revision, which focused on minor revisions of the DSM-IV text. According to the DSM-IV, there are two alcohol use disorders: alcohol abuse and alcohol dependence. In DSM-IV, the diagnostic criteria for those two alcohol-related disorders are the same as those for other substance use disorders. AUDs are characterized by maladaptive patterns of alcohol consumption manifested by symptoms leading to clinically significant impairment or distress. The diagnosis of alcohol abuse focuses on alcohol-related negative consequences of alcohol use, while alcohol dependence focuses on a pathological pattern of compulsive alcohol seeking and use that indicates addiction. Alcohol abuse is manifested by the presence of one or more specific alcohol-related symptoms from a list of four symptoms occurring within a 12-month period. Those four alcohol-related

symptoms of alcohol abuse include (1) recurrent alcohol use resulting in a failure to fulfill major role obligations at work, school, or home; (2) recurrent alcohol use in situations in which it is physically hazardous (such as driving while intoxicated); (3) recurrent alcohol-related legal problems; and (4) continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol (such as arguments with spouse about consequences of intoxication). DSM-IV alcohol dependence is manifested by the presence of three or more specific symptoms from a list of seven alcohol-related symptoms occurring at any time in the same 12-month period. Those alcohol dependence criteria include the following: (1) tolerance for alcohol, as defined by a need for markedly increased amounts of alcohol to achieve intoxication or markedly diminished effect with continued use of alcohol; (2) alcohol withdrawal; (3) the substance (alcohol) is often taken in larger amounts or over a longer period of time than was intended; (4) a persistent desire or unsuccessful efforts to cut down or control alcohol use; (5) a great deal of time is spent in activities necessary to obtain alcohol; (6) important social, occupational, or recreational activities are given up or reduced because of alcohol use; (7) alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol. Substantial changes in the diagnostic criteria for AUDs and for other diagnoses are being considered for the upcoming DSM-V diagnostic system, which is currently scheduled to be published in 2013.

According to DSM-IV, major depressive disorder is a clinical disorder characterized by one or more major depressive episodes without a history of manic, mixed, or hypomanic episodes. The essential feature of a major depressive episode is a period of at least 2 weeks during which there is either depressed mood or the loss of interest or pleasure in nearly all activities. Criteria for the diagnosis of a major depressive episode include the presence of five or more depressive symptoms from a list of nine possible symptoms that are present during the same 2-week period. At least one of the symptoms must be either (1) depressed mood or (2) loss of interest or pleasure. The other criteria include the following: (3) weight loss; (4) insomnia or hypersomnia; (5) psychomotor agitation or retardation; (6) fatigue; (7) feelings of worthlessness or guilt; (8) decreased concentration; (9) recurrent thoughts of death. In addition, the presence of this disorder must represent a change from previous functioning, and must not include symptoms that are clearly due to a general medical condition. Other depressive disorders can also be present among persons with major depressive disorder, such as the chronic depressive disorder of dysthymia.

EPIDEMIOLOGY OF CO-OCCURRING MAJOR DEPRESSION AND ALCOHOL DEPENDENCE

Major depressive disorder (MDD) and alcohol dependence (AD) are among the most prevalent psychiatric disorders in the United States, and both are associated with substantial society and personal costs. MDD is the most prevalent mood disorder in the United States. Alcohol dependence is the most common (non-tobacco) substance use disorder, and alcohol is the most commonly used psychoactive (mind-altering) substance in the United States. Those disorders co-occur more commonly than would be expected by chance alone. The co-occurrence of alcohol dependence and major depressive disorder (AD/MDD) is particularly common in treatment settings. Acute increases in depressive symptoms among persons with co-occurring MDD/AD are primarily related to drinking larger quantities per drinking occasion, are less related to overall drinking volume and relatively unrelated to drinking frequency.

In 2001–03, AUDs afflicted 17.6 million adult Americans, according to the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) study, including about 8 million adult Americans with alcohol dependence. The NESARC study was the largest and most ambitious comorbidity study ever conducted. The NESARC study was conducted in 2001–03, addressing a representative US sample involving the unprecedented sample size of 43 093 respondents, using a diagnostic instrument based on the DSM-IV. The 12-month prevalence of alcohol abuse and dependence were 4.7 and 3.8% in the NESARC sample; the total lifetime prevalence of any AUD was 30.3%. Alcohol dependence was more prevalent among men, whites, Native Americans, younger and unmarried adults, and those with lower incomes. In an analysis by Hasin et al. (2005) involving persons in the NESARC study with MDD in the prior 12 months, 14% had an AUD, whereas, among those with lifetime MDD, 40% had an AUD. Conversely, data from the NESARC study demonstrated that the lifetime rate of alcohol dependence among those with MDD is 21%. Thus, the co-occurrence of major depression and alcohol dependence is very common in the United States.

ONSET AND COURSE OF CO-OCCURRING MDD/AD

Most AUDs have their onset between the ages of 15 and 30, according to the NESARC study. The mean age of onset is 22 years of age, and the highest rate for onset of abuse and dependence occurs at age 19, decreasing thereafter. Comorbidity is the rule rather

than the exception among young people, though it continues to be very common in later life as well. The risk factor profile for co-occurring disorders is different from those for “pure” disorders. For example, co-occurring disorders tend to be more prevalent among younger person, while alcohol dependence and major depression alone are not more prevalent among middle age or older adults. Also, reports suggest that co-occurring major depression is more prevalent among women with alcohol dependence than among men with alcohol dependence. In addition, reports suggest that depressed males tend to have a more severe clinical profile with respect to their alcoholism than do depressed alcoholic females. Thus, demographic factors such as age and gender appear to affect the clinical presentation of co-occurring alcohol dependence/major depression, which could conceivably mean that treatment outcomes could vary across those demographic characteristics.

The presence of alcohol dependence has an adverse effect on the course of co-occurring major depression, and vice versa. For example, current depression predicts poorer treatment response and higher rates of alcohol relapse. Conversely, remission in alcohol dependence increases the chances of remission in depression. In some setting, such as chemical dependency treatment facilities, mood symptoms often resolve soon after abstinence is achieved, while in other settings, such as dual diagnosis units of psychiatric hospitals, depressive symptoms often persist after any alcohol withdrawal symptoms have abated. The level of alcohol intake among persons with AUDs typically decreases as individuals enter middle age and later life. Chronic mild to moderate depression (dysthymia) is common among persons with co-occurring disorders. Data from the NESARC study demonstrate that there is a substantial level of natural recovery from alcohol dependence, though participation in alcohol treatment is associated with improved outcomes. However, since alcohol dependence and major depression are typically chronic disorders, short-term alterations of alcohol intake or depressive symptoms are of limited importance in predicting long-term outcome, and long-term studies of course and treatment outcome are of crucial importance. Unfortunately, long-term treatment outcome studies are rarely performed among those with co-occurring major depression and alcohol dependence.

TREATMENT UTILIZATION OF CO-OCCURRING MDD/AD

Most persons with comorbid MDD/AD or with alcohol dependence alone do not seek treatment. The prevalence of treatment seeking in the past year noted in the NESARC study was only 6% among those with

an AUD alone, though that percentage increased to 22% among those with a comorbid disorder. Some estimates suggest that only 4% of full-time college students with an AUD received any alcohol service in the past year, and only 2% reported a perceived need for alcohol treatment, despite the widespread prevalence of AUDs among college students. In the NESARC study population, only one-quarter of the persons with alcohol dependence ever received treatment. The majority of individuals with an AUD never receive formal alcohol treatment, nor do they participate in self-help groups. Among persons with alcohol dependence, the presence of depression is associated with higher levels of treatment participation. Many communities lack integrated treatment systems that could provide for comprehensive diagnosis and appropriate integrated treatment of both the depressive disorder and the alcoholism. Persons with co-occurring disorders are frequently under diagnosed and are often undertreated when they present for evaluation. Several studies have concluded that some physicians have negative attitudes toward persons with alcohol dependence, and vary widely in their willingness to treat that disorder. In recent years, increasing stringent service utilization review criteria have often been imposed on treatment providers by third-party payers for alcoholism and mental health treatment services. Those more stringent review criteria have limited the availability of services and shortened the period of time those services can be provided to persons with co-occurring disorders. The selective serotonin reuptake inhibitor (SSRI) antidepressants are the most commonly prescribed antidepressant medications for treating depressed alcoholics, probably more because of their superior tolerability and safety following overdose rather than because of any advantage in efficacy versus other antidepressant medications.

ANTIDEPRESSANT PHARMACOTHERAPY FOR ADULTS WITH CO-OCCURRING MDD/AD

For decades, few data were gathered regarding the effectiveness of various possible treatments for co-occurring conditions because persons with co-occurring conditions were systematically excluded from treatment trials. Most of the controlled clinical trials of various antidepressant medications and other medications for the treatment of co-occurring major depression/AUD have been conducted in the last two decades, funded mostly by the National Institute on Alcohol Abuse and Alcoholism (NIAAA). Co-occurring major depression in combination with alcohol dependence is the most studied form of comorbidity during that time period, presumably because those disorders are particularly

prevalent. In the past, many clinicians were reluctant to treat depression in a patient with active alcohol dependence until a sustained period of sobriety had been demonstrated. However, over the past few decades, the treatment of co-occurring disorders has undergone a broad shift in approach, from treating alcohol abuse before providing mental health care to providing simultaneous treatment for each disorder, regardless of the status of the comorbid disorder.

The most common paradigm employed in the pharmacotherapy trials to date is the examination of the efficacy of a single antidepressant medication to influence both the depressive symptom and the alcohol use of the treatment population. A meta-analysis was conducted involving the treatment of co-occurring depression and alcohol or other drug dependence, which was published by Nunes and Levin in 2004. That meta-analysis involved 14 placebo-controlled clinical trials, with a total of 848 patients. Those studies included five involving tricyclic antidepressants, seven with selective serotonin reuptake inhibitors, and two from other classes of antidepressant medications. Slightly over half (8) of those 14 studies were reported as demonstrating significant or treating significant antidepressant effects, while the other 6 studies demonstrated no significant effect for decreasing depressive symptoms. The outcome findings were generally similar across the different classes of antidepressant medications. The pooled effect size of antidepressant treatment outcome was modest (i.e. 0.38). The rates of depression response were 52% for those taking antidepressant medication and 38% among those taking placebo. Placebo response, defined as the percentage reduction in the Hamilton Depression rating scale in the placebo group, was a powerful predictor of antidepressant effect, explaining 71% of the variance. Thus, most of the decrease in depressive symptoms was not attributable to the antidepressant medication, but instead resulted from other factors such as therapy or spontaneous improvement. The pooled effect size for antidepressant medication for alcohol and other substance reduction was low (i.e. 0.25). Thus, antidepressant medications had a larger effect on depressive symptoms than on alcohol consumption. The level of improvement in drinking and other substance use was related to the level of improvement in depressive symptoms. In studies demonstrating a strong effect on depressive symptoms, a significant decrease in alcohol use was often observed, but in studies with a small medication effect on depressive symptoms, very little improvement in level of drinking was noted. That meta-analysis concluded that antidepressant medication was effective in treating depressive symptoms among patient with alcohol dependence, but found a more modest therapeutic effect of antidepressant medications for treating

the pathological alcohol use of person with co-occurring disorders.

Another recent meta-analysis (Hesse, 2004) involving subjects with depression in combination with alcohol or other substance use disorders found that studies using cognitive-behavioral therapy (CBT) found no medication effect, whereas with no therapy intervention, medication was superior to placebo. That meta-analysis concluded that there is no evidence that antidepressant medication is more efficacious in reducing alcohol or drug use when used in combination with conjunctive psychosocial treat. The author of that paper further concluded that in the presence of an appropriate psychosocial intervention, medication may not be necessary for the majority of alcohol or other substance abusers with depressive disorders. Another meta-analysis (Johnson, 2008) concluded that SSRI medication may demonstrate efficacy only in certain subtypes of alcoholic.

Only one study to date (Cornelius et al., 1997) has evaluated the efficacy of an SSRI medication (or any other antidepressant medication) versus placebo among the most severely depressed subjects who commonly demonstrated suicidal ideations in addition to their other very prominent depressive and alcohol-related symptoms. That study recruited participants with co-occurring alcohol dependence and major depression from an inpatient dual diagnosis unit of a psychiatric hospital rather from a chemical dependency treatment facility or from an outpatient setting. The results of that study demonstrated superiority for the SSRI medication compared to placebo for treating both the depressive symptoms and the alcohol use of those persons.

To date, there is a limited experience with combinations of medications to treat major depression and alcohol dependence. Two placebo-controlled studies assessing naltrexone or disulfiram augmentation of sertraline concluded that the combination of medications was no more effective than the antidepressant medication alone for treating depressive symptoms or alcohol-related symptoms. Two other open-label studies suggested efficacy in depressive symptoms and alcohol-related symptoms with the combination of medications, though the open-label design of those studies and the lack of placebo-controlled groups limit the interpretation of their findings. In the last year, study results from the University of Pennsylvania were published comparing the combination of an SSRI medication (sertraline) and naltrexone versus either drug alone or placebo. The results of that study demonstrated superiority for the combination of antidepressant medication and naltrexone for achieving abstinence from alcohol. The authors of that study concluded that persons with both disorders would benefit from combination treatment with an

antidepressant medication and medication such as naltrexone for alcohol dependence. The results of that study have not yet been replicated nor refuted.

OTHER FORMS OF PHARMACOTHERAPY (DISULFIRAM, LITHIUM, NALTREXONE, ACAMPROSATE, ONDANSETRON, AND MOOD STABILIZERS) FOR TREATING CO-OCCURRING MDD/AD

Three medications have been approved by the Food and Drug Administration (FDA) for the treatment of alcohol dependence, including disulfiram, naltrexone, and acamprostate. Disulfiram (Antabuse) is an aversive agent that does not decrease craving for alcohol. Disulfiram has been used for decades to treat chronic alcohol dependence by producing an acute sensitivity to alcohol in which unpleasant effects occur when even a small amount of alcohol is consumed. Disulfiram is most effective when given to those who are highly compliant or who are receiving their medication under supervision. Trials involving lithium have not demonstrated superiority for that medication versus placebo for treating either the level of alcohol ingestion or the level of depressive symptoms of depressed alcoholics. In 1995, the US FDA approved the use of the medication naltrexone (ReVia) as an aid in preventing relapse among recovering alcoholics. At the time of its approval, naltrexone was the first medication approved by the FDA for alcoholism treatment in almost 50 years. However, naltrexone has a limited effect size, and it demonstrates significant side effects, so its level of use across the country has been relatively low. More recently, the medication acamprostate (Campral) has shown a small but statistically significant effect in European trials involving alcohol dependence, and it is relatively well tolerated. However, the results from the COMBINE Study, a large well-designed American Study, found no evidence of efficacy, which raises questions about its efficacy. Other newer medications have also shown promise for treatment of alcohol dependence, such as ondansetron and various mood stabilizers such as topiramate (which are often anticonvulsant medications), though those medications have not been fully tested, and have not received approval by the FDA for use in treating alcohol dependence. To date, no adequately powered double-blind placebo-controlled trials of disulfiram, naltrexone, or acamprostate, ondansetron, or mood stabilizers have been conducted among persons with co-occurring major depressive disorder and alcohol dependence, so the effectiveness of those medications in that population remains unclear.

PHARMACOTHERAPY FOR ADOLESCENTS AND YOUNG ADULTS WITH CO-OCCURRING MDD/AD

Adolescent-onset depression is associated with a higher level of co-occurring disorders than adult-onset depression. Nonetheless, progress in adolescent and young adult psychopharmacological research of psychiatric disorders and of substance use disorders has suffered notable delay, especially compared with the achievements in middle-age adult psychopharmacology. Adolescents with comorbid disorders have unique treatment needs both because of their stage of development and because of their comorbid disorders. Because data about medication safety and efficacy in middle-age adults can rarely be extrapolated to adolescents and children, there is no substitute for psychopharmacological research in that young population of persons with AUDs. The few studies involving antidepressant medications or other medications among comorbid adolescent populations which have been conducted to date have generally shown at most limited efficacy for those medications for treating depressive symptoms and have shown no clear efficacy for treating alcohol dependence or other substance use disorders. Consequently, to date no medication has clearly demonstrated efficacy for treating youthful populations with co-occurring major depression and alcohol dependence. Therefore, most youth with those co-occurring disorders are currently treated with counseling rather than with medications.

TWELVE-STEP PROGRAMS AND PSYCHOSOCIAL THERAPIES FOR CO-OCCURRING MDD/AD

A variety of psychosocial therapies have demonstrated some level of efficacy for treatment of non-co-occurring and co-occurring alcohol dependence. For example, 12-step self-help programs such as Alcoholics Anonymous (AA) and related self-help groups are a very commonly used form of therapy. AA focuses on 12 consecutive activities, or steps, that persons with alcohol dependence should achieve during the recovery process, in an attempt to attain lasting sobriety. AA appears to result in positive outcomes for many of its members, though its efficacy has rarely been assessed in randomized clinical trials. The beneficial effects of AA may in part result from the development of coping skills and from the replacement of the participant's social network of drinking friends with a group of AA members who can provide support for maintaining abstinence from alcohol. Twelve-step treatment programs are often used in combination with other forms

of treatment such as professional counseling or medication therapy. Few controlled studies to date have evaluated the effectiveness of AA or similar therapies among persons with alcohol dependence in combination with major depression or other psychiatric disorders, so the efficacy of AA among comorbid populations is unclear.

A variety of psychosocial therapies have been used in recent decades for treatment of alcohol dependence, such as CBT, motivational enhancement therapy, couples therapy, and a variety of brief interventions. To date, the largest study of psychosocial therapy for treatment of alcoholism was Project MATCH. Project MATCH was a large multisite clinical trial to assess whether persons with alcohol dependence could be matched to the most effective psychosocial treatment for their alcohol dependence, based on their clinical characteristics. That study focused on CBT, Motivational Enhancement Therapy, and Twelve-Step Facilitation. All three therapies appeared to demonstrate efficacy in that study, and produced similar outcomes. Essentially no consistent patient-treatment matches were found in that study (Cutler and Fishbain, 2005). The authors of that paper concluded that available data suggest that current psychosocial treatments for alcoholism are not particularly effective. Project MATCH did not evaluate whether co-occurring psychiatric disorders serve as a potential factor that might be used to more effectively match persons with alcohol dependence to optimal therapy. Thus, the optimal psychosocial therapy for co-occurring disorders remains unclear.

Recently, brief interventions have been designed for treatment of alcohol dependence and related disorders. Brief interventions have often focused on treatment of persons receiving counseling from primary care physicians. Brief interventions generally consist of information on negative consequences of alcohol consumption and advice on strategies to achieve moderation or abstinence. However, to date, no large-scale controlled studies have been conducted involving brief interventions for treatment of major depression and alcohol dependence. Therefore, it is unclear whether brief interventions are effective for treating that population.

CONCLUSIONS AND FUTURE DIRECTIONS FOR RESEARCH INVOLVING CO-OCCURRING MDD/AD

Co-occurring major depressive disorder in combination with alcohol dependence is a very prevalent condition. Despite the increased number of clinical trials among treatment populations with major depression and alcohol dependence in the last two decades, treatment needs for this population are still largely unmet, and the efficacy of currently available treatments for

this population continue to be suboptimal. Various medications and therapies have demonstrated partial efficacy for treatment of comorbid disorders, though the magnitude and scope of that improvement is often limited. To date, no medication or therapy or any combination of treatments has been found to be consistently effective in the treatment of this co-occurring population. No controlled trials have been conducted for many of the potential treatment modalities among populations with co-occurring disorders. Therefore, controversy persists regarding how to best treat patients with co-occurring major depression in combination with alcohol dependence. The number of studies that have been conducted involving various forms of treatment for co-occurring disorders remains small, and only a few such studies are currently ongoing.

Future studies are warranted to evaluate the efficacy of the full range of medications and therapies for treatment of persons with major depression in combination with alcohol dependence. Future studies are warranted to develop new medications and therapies for treating this co-occurring condition. For example, studies are warranted to assess the utility of cannabinoid CB1 receptor antagonism, modulators of glutamate or GABA transmission, opioid antagonists, or stress-related neuropeptides as possible treatments of "pure" or co-occurring alcohol dependence (Heilig et al., 2006). Future studies are needed to assess the efficacy of newer antidepressants with new mechanisms of action such as mirtazapine for treating depressed alcoholics. Future studies are warranted to evaluate predictors of treatment response, and to assess the efficacy of various combinations of medications and other treatments. Studies are warranted to clarify the optimal dose, duration, and sequence of treatment. Studies are needed to clarify the optimal behavioral therapy platforms to utilize in conjunction with treatment medications when conducting pharmacotherapy studies, since such behavioral therapies can result in ceiling effects which reduce the likelihood of being able to demonstrate medication effects. Studies are needed to assess which behavioral therapy platforms are best for use in combination with the various pharmacotherapies in clinical practice. Future studies are warranted to assess the efficacy of various treatments in special populations such as in adolescents, geriatric patients, jails, psychiatric hospitals, and inpatient and outpatient substance treatment facilities. Future studies are warranted to clarify how treatment of either the alcoholism or the depressive disorder affects the outcome of the other disorder. Long-term studies are needed to determine whether treatments which demonstrate efficacy in acute phase trials continue to demonstrate efficacy over longer periods of time, since alcohol dependence and major depression are often chronic illnesses. Studies are warranted to clarify the barriers to the translation of research findings into clinical

practice among persons with co-occurring disorders, and to clarify how to engage the practitioner community to incorporate medications and other therapies into the treatment process. Finally, treatment studies are warranted in conjunction with basic sciences studies to clarify the biological mechanisms underlying the co-occurrence of depressive disorders and AUDs, and to elucidate the pathways underlying their treatment response.

Glossary

Alcohol abuse one of two DSM-IV alcohol use disorders, which involves meeting one of four criteria related to certain negative consequences of alcohol use (i.e. impairment in role functioning due to alcohol use, hazardous alcohol use, alcohol-related legal problems, alcohol-related interpersonal problems).

Alcohol dependence one of two DSM-IV alcohol use disorders, which requires that three or more of seven criteria (i.e. tolerance,

withdrawal, using more or longer than intended, strong desire or failed attempts to limit use, much time spent using, reduce activities in order to use, substance-related psychological or physical problems) co-occur within a 1-year period.

Diagnostic and Statistical Manual (DSM) of Mental Disorders the DSM is published by the American Psychiatric Association, and provides operational definitions for common mental disorders. DSM is currently in its fourth edition (DSM-IV; 2000); a fifth edition will be published in 2013. DSM-IV recognizes two alcohol use disorders: abuse and dependence.

Major depressive disorder a clinical disorder characterized by one or more major depressive episodes without a history of manic, mixed, or hypomanic episodes. The essential feature of a major depressive episode is a period of at least 2 weeks during which there is either depressed mood or the loss of interest or pleasure in nearly all activities. Criteria for the diagnosis of a major depressive episode include the presence of five or more depressive symptoms from a list of nine possible symptoms that are present during the same 2-week period.

PREVALENCE OF SUBSTANCE USE DISORDERS IN PEOPLE WITH BIPOLAR DISORDER

Bipolar disorder (BPD) is a severe and persistent psychiatric illness characterized by periods of depression and mania/hypomania, and/or mixed states. In the Epidemiologic Catchment Area (ECA) study ($n = 20,291$), the US lifetime prevalence of bipolar I and II disorders was 1.3%. In the National Comorbidity Survey (NCS), the lifetime prevalence of mania (consistent with bipolar I disorder) was 1.6%. The lifetime rates of bipolar spectrum disorder, using a broader definition of mood symptoms, are between 3 and 6.5%. Thus, BPDs are more common than other psychiatric disorders, such as schizophrenia, or other brain diseases, including seizures.

Abuse and dependence of alcohol and other substances are also common. Kraepelin recognized the frequent occurrence of alcoholism in manic-depression

a century ago. The US lifetime prevalence of any substance use disorder (SUD) is between 9 and 27%. The prevalence rates of SUD in people with BPD are much higher than in the general population. In the United States, three large population-based studies have examined the prevalence rates of comorbid substance abuse and BPD. All three studies reported rates of SUD that were considerably higher in bipolar patients than in the general population. In the ECA study, 61% of patients with bipolar I disorder and 48% of patients with bipolar II disorder had lifetime substance abuse or dependence. The reported lifetime prevalence of any alcohol diagnosis in patients with a bipolar diagnosis (bipolar I and II) was 44%, and the lifetime prevalence of drug abuse and/or dependence was 34%. BPD had a higher lifetime prevalence of comorbid SUD than other psychiatric disorders, such as schizophrenia (47%), unipolar major depression (27%), and anxiety disorders (24%). In the NCS, the odds ratios in patients with a history of mania were

9.7 for alcohol dependence and 8.4 for drug dependence. The National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) reported the 12-month prevalence of SUD was 27.9% in persons with a history of mania, and 26.6% in those with a history of hypomania. By comparison, the rate of SUD was 9.4% in persons without a mood disorder. Thus, SUDs are clearly much more common in persons with BPD than in the general population.

IMPACT OF SUD ON BPD TREATMENT AND OF BPD ON SUD TREATMENT

The negative impact of SUD on BPD has been reported in numerous studies. Treatment nonadherence in bipolar patients with comorbid SUD compared to bipolar patients without SUD is well documented. Aggression and violence appear to be significantly greater in BPD patients with an SUD. These behaviors can be associated with interaction with the legal system. McDermott and colleagues reported that female inmates with BPD had over 38 times the risk and male inmates five times the risk of an SUD than patients with BPD in community treatment. Patients with BPD and comorbid SUD have significantly increased rates of suicidal ideation, attempted suicides, and recurrent suicidal behavior.

Comorbid alcohol and drug use disorders negatively affect the course and treatment outcomes of BPD. Weiss and colleagues observed that recovery from BPD is less likely in patients with past or current comorbid SUD than in patients without SUD, and recovery is less likely in patients with current than with past SUD. Furthermore, patients with current or past SUD report lower quality of life than those with BPD and no SUD. Increased rates of hospitalization and lower rates of recovery during hospitalization are also reported in BPD with SUD. Salloum and colleagues reported that persons with bipolar disorder and concurrent alcohol use disorders present with more severe, and a higher number of mood-related and manic symptoms, including mood lability, impulsivity, and violent behavior. Female bipolar patients with alcohol abuse/dependence report more depressive symptoms as compared to either male bipolar alcoholics or both male and female nonalcoholic bipolar patients. Ostacher and colleagues noted that SUD is associated with greater risk of switching from a depressed phase to a manic, hypomanic, or mixed phase, but not longer time to recover from depression, while Gao and colleagues reported that a factor that may complicate recovery is less than optimal treatment adherence.

TREATMENT CONSIDERATIONS IN PERSONS WITH COMORBID BPD AND SUDs

Pharmacotherapy of Co-Occurring BPD and SUD

Despite the frequency of SUDs in people with BPD, relatively few clinical trials have been conducted in this population. One reason that few trials have been conducted in patients with BPD and SUD may be that many large clinical trials (e.g. registration trials by pharmaceutical companies) specifically exclude participants with current, active substance use. Thus, the vast majority of research is conducted in BPD patients who are not using drugs or alcohol.

The first two randomized, controlled trials in this population did not specifically target patients with BPD, although some were included. Brady and colleagues examined carbamazepine in cocaine-dependent persons with ($n = 57$) and without ($n = 82$) affective disorders (including major depressive disorder or BPD) who were randomly assigned to 12 weeks of treatment. In patients with affective disorders, a trend was observed toward fewer cocaine-positive urine drug screens ($p = 0.08$) and a reduction in depressive symptom severity with carbamazepine as compared to placebo. In those without affective disorders, carbamazepine treatment did not have a greater impact on cocaine use than placebo. These results suggest that some medications may be relatively ineffective in "pure" cocaine-dependent populations, but potentially more effective in dual-diagnosis patients. Geller and colleagues gave 6-week, randomized, double-blind, parallel-group, placebo-controlled treatment with lithium into adolescents with bipolar I or II disorder, or recurrent major depressive disorder with predictors of future bipolar diagnosis (e.g. delusions, switching during antidepressant treatment, psychomotor retardation, and family history of BPD) and comorbid substance abuse (primarily alcohol or cannabis). The mean age of onset of BPD in the study was 9.4 years for bipolar I, 11.1 years for bipolar II, and 15.3 years for substance use. Those taking lithium had significantly fewer positive urine drug screens and greater improvement on a global measure than those receiving placebo.

The first randomized, placebo-controlled trial specifically targeting BPD and SUD evaluated the efficacy of valproate in 59 alcohol-dependent bipolar I patients in a 24-week, double-blind, placebo-controlled study by Salloum and colleagues. Participants were randomized to receive either valproate or placebo added to lithium and psychosocial treatment. Those assigned to valproate had significantly fewer heavy drinking days and a trend of fewer drinks per drinking day than those assigned to

placebo. Perhaps due to the add-on design, valproate was not associated with improvement in mood symptoms. However, changes in manic and depressive symptoms correlated with alcohol use outcomes. These findings suggest that valproate may have a positive effect on alcohol consumption in bipolar patients independent of improvements in mood.

Few controlled clinical trials have investigated the efficacy of atypical antipsychotics in dual-diagnosis patients. A randomized but open-label study evaluated discontinuing typical antipsychotics (neuroleptics) and, if needed, using the atypical antipsychotic quetiapine as a rescue medication, or continuing on the typical antipsychotics for 12 weeks in patients with cocaine or amphetamine abuse or dependence, and neuroleptic use was conducted by Brown and colleagues. Twenty-nine patients, 13 of whom were bipolar, were enrolled. The group discontinued from the neuroleptics had a significant reduction in drug craving as compared to those continuing the neuroleptics. The overall improvement in this group was largely due to a subgroup that was switched to quetiapine, in which significant improvement in craving as well as psychiatric symptoms was observed. Quetiapine was well tolerated, and patients randomized to quetiapine stayed in the study longer than the treatment-as-usual group. In a small pilot study, Brown and colleagues randomized 12 outpatients with BPD and cocaine dependence to 12 weeks of quetiapine or placebo as add-on therapy. Significant between-group differences were not observed on measures of cocaine use or craving. However, the quetiapine group had significantly fewer heavy drinking days than the placebo group and showed a trend toward longer treatment retention. Differences in depression scores also favored quetiapine with a large effect size. Nejtek and colleagues randomized 124 patients with BPD and cocaine or amphetamine dependence to 20 weeks of quetiapine or risperidone. Improvement in mood and reduction in drug craving was observed in both groups but no between-group differences were found. Two studies have investigated quetiapine for alcohol dependence and BPD. In a single site study, a total of 115 patients with BPD and alcohol dependence were randomized to quetiapine or placebo for 12 weeks by Brown and colleagues. In the sample as a whole no significant differences in alcohol-related outcomes were observed. However, those with heavier baseline alcohol use showed larger effect sizes on some measures. The group receiving quetiapine had a greater reduction in depressive symptom severity during the trial. This finding suggests that quetiapine may be effective for bipolar depression even in persons with active alcohol use. In a multisite study by Stedman and colleagues, 362 outpatients with bipolar I disorder and taking lithium or divalproex were randomized to

quetiapine (up to 800 mg day⁻¹) for 12 weeks. A trend toward greater improvement on the Clinical Global Impression with quetiapine versus placebo was observed. However, mood and alcohol-related outcomes did not differ significantly between groups.

Two trials of nutritional supplements have been reported. Citicoline is a naturally occurring medication sold as an over-the-counter nutritional supplement in the United States and a prescription drug in much of the rest of the world. It is involved in phospholipid metabolism and alters neurotransmitter (e.g. dopamine, serotonin, acetyl choline) levels in the brain. Citicoline is neuroprotective in animal models of hypoxia and large, controlled trials suggest that it improves cognition in patients with vascular dementia. A 12-week, randomized, placebo-controlled trial of citicoline in 44 patients with BPD or schizoaffective disorder and cocaine dependence by Brown and colleagues reported improvement in certain aspects of declarative memory, fewer cocaine-positive urines, and with no reported differences in mood with citicoline versus placebo. In this trial, citicoline was well tolerated with significantly fewer side effects than placebo. Pregnenolone is another naturally occurring nutritional supplement. It is a precursor to cortisol and gonadal steroids, and may decrease negative symptoms of schizophrenia. Pregnenolone was examined in a randomized, double-blind, placebo-controlled trial in 70 outpatients with major depressive disorder or bipolar depression and a history of substance use by Osuji and colleagues. No differences in substance use, craving, or cognition were observed. However, a significant reduction in manic and depressive symptoms was observed with pregnenolone as compared to placebo. Pregnenolone was well tolerated in this population.

The best-studied medication for alcohol dependence may be naltrexone, an antagonist at opiate receptors. Clinical trials support the efficacy of naltrexone in decreasing alcohol use and craving. Two controlled trials have examined naltrexone in patients with BPD. A reduction in alcohol consumption was reported by Petrakis and colleagues in a group of 254 dual-diagnosis patients with a variety of psychiatric disorders, including 49 with BPD, treated with naltrexone, disulfiram, or the combination. Recently, Brown and colleagues conducted a randomized, placebo-controlled trial of naltrexone in 50 outpatients with BPD. A reduction was reported in some alcohol use measures, alcohol craving, depressive symptoms, as well as some liver enzymes with naltrexone as compared to placebo. To date, no randomized clinical trials have been reported on the use of acamprosate, disulfiram, or topiramate in patients with BPD and alcohol dependence.

Psychotherapy can be used as monotherapy for substance use and depression and potentially

adjunctively with pharmacotherapy for BPD. Cognitive-behavioral therapy (CBT) approaches have been examined in controlled trials for BPD and SUDs by both Schmitz and colleagues and Weiss and colleagues. Integrated group therapy (IGT) is a treatment paradigm consisting of 20 weekly group sessions specifically developed for patients with BPD and SUDs. In a 6-month pilot study, patients receiving IGT remained abstinent longer than patients not receiving the treatment and were more likely to stay abstinent during the observation period. Individual CBT was examined in a 12-week randomized trial compared to medication monitoring in patients with BPD and an SUD. While patients receiving CBT during their medication treatment did not improve significantly more than those receiving medication monitoring on substance use measures, there were significant improvements in medication compliance and depressive symptoms in the CBT group. Thus, this intervention could be a useful adjunct to other treatments.

CONCLUSIONS

The treatment of patients with BPD and SUD has been the topic of relatively little investigation. This paucity of data has clinical implications because SUDs are more common in patients with BPD than any other Axis I illness, and are associated with greater rates of hospitalization, violence toward self and others, and treatment nonadherence. Based on the controlled studies that included at least some patients with BPD, the data suggest that lithium, valproate, citicoline, naltrexone, and possibly quetiapine and carbamazepine may be associated with a reduction in substance use. Carbamazepine, pregnenolone, and quetiapine may be associated with improvement in mood, and citicoline with improvement in memory, in this population. More research is needed in dual-diagnosis samples on both standard treatments for BPD and standard treatments for SUDs and combinations of these medications. An additional area in need of research is the combination of pharmacotherapy with psychotherapy. Given the limited available data, it is not possible to make specific treatment recommendations for the treatment of patients with BPD and SUD at this time. A general recommendation, not yet confirmed by controlled data, would be to effectively treat mood symptoms with medications for BPD and consider pharmacotherapy or psychotherapy targeting the substance of abuse.

Glossary

- Atypical antipsychotics** an imprecise term generally describing newer antipsychotics, which may be approved for both schizophrenia and mood disorder, and that frequently have fewer extrapyramidal side effects than older antipsychotics.
- Dual-diagnosis** the presence of a severe psychiatric illness, such as bipolar disorder or schizophrenia, along with a drug or alcohol use disorder.
- Epidemiology** a branch of medicine that studies diseases in populations.
- Mood lability** a state characterized by frequent or abrupt changes in mood.
- Receptor antagonist** a substance that prevents, rather than facilitates biological responses when binding to a receptor.

OUTLINE

Definition of Anxiety Disorders	489	<i>Self-Medication Theory</i>	491
Epidemiology	490	Prevention and Therapy	493
Reasons for Comorbidity of Anxiety Disorders and Substance Use	491	Future Prospects	494

DEFINITION OF ANXIETY DISORDERS

A number of different anxiety disorders are known and defined, such as generalized anxiety disorder, panic disorder with and without agoraphobia, social phobia, and specific phobias. Obsessive-compulsive disorder and posttraumatic stress disorder will not be addressed in this chapter. According to DSM-IV, generalized anxiety disorder (GAD) is characterized by an array of mental and somatic symptoms, including excessive worry – persisting for 6 months or longer – combined with autonomic, musculoskeletal, gastrointestinal, and respiratory symptoms. Current diagnostic criteria require prolonged feelings of anxiety and worry accompanied by at least three of the following six key symptoms: restlessness, fatigue, impaired concentration, irritability, muscle tension, and disruptions in patterns of sleep. Panic disorder (PD) is characterized by recurrent panic attacks with intense fear or discomfort, accompanied by at least 4 of 13 somatic and mental symptoms (14 in ICD-10). A panic attack usually reaches a peak within 10 min and lasts 30–45 min on average. Typically, the patient is afraid of suffering from a serious medical condition such as

myocardial infarction. About two-thirds of patients with PD also suffer from agoraphobia, which is characterized by fear of places or situations from which escape might be difficult or in which help may not be available in the event of having an unexpected panic attack. Typical risk situations include standing in a crowd or in line, being outside the home alone, or traveling in a bus, aircraft, train, or car. These situations are avoided or endured with marked distress.

Specific phobias are characterized by excessive or unreasonable fear of single objects or situations (e.g. heights, animals, flying, seeing blood, etc.). Social phobia (or social anxiety disorder, SAD) is characterized by marked, persistent, unreasonable fear of being observed or evaluated negatively by others in social performance or interaction situations and is associated with somatic and cognitive symptoms. The feared situations are avoided or endured with anxiety or distress. These situations include fear of speaking in public or to unfamiliar people or being exposed to possible scrutiny by others. Affected individuals may blush or show more severe symptoms.

The pathophysiology of GAD and other anxiety disorders is somewhat unclear. There is some evidence

for a modest genetic risk. Impaired serotonergic and GABAergic neurotransmission have been discussed as key factors in GAD; both neurotransmitters are also strongly modified by alcohol intake. Other relevant neurotransmitters involved are norepinephrine, cholecystokinin, and corticotrophin-releasing factors; impairments of the benzodiazepine receptor are also probably involved.

EPIDEMIOLOGY

Anxiety disorders are very frequent. In the US National Comorbidity Survey, the lifetime prevalence for any anxiety disorder was 28.8%, and for the 12-month prevalence 18.1%. GAD has a 12-month prevalence of 3.1% in the United States and a lifetime prevalence of 5.7–6.4% in the United States and Europe. Women have a two- to threefold increased risk for GAD. Lifetime and 12-month prevalence rates for agoraphobia without panic are 1.4 and 0.8%, respectively; for panic disorder, 4.7% and 2.7%; for specific phobia, 12% and 6.8%; and for the somewhat controversial diagnosis of SAD, 12.1% and 6.8%.

Table 52.1 gives an overview of the prevalence of dual diagnoses of various psychiatric disorders and substance use disorders (SUDs). Generally, epidemiologic studies indicate a two- to threefold increased risk for alcohol use disorders in patients with anxiety disorders. Grant et al. (2005) reported data on GAD from the National Epidemiologic Survey on Alcohol and Related Conditions, which studied a large ($N = 43\,093$) representative sample of the adult US population; prevalence rates for 12-month and lifetime GAD were 2.1 and 4.1%, respectively. Higher rates were found for males. GAD was highly comorbid with substance use in general and other anxiety, mood, and personality disorders. Specifically, the odds ratios for any alcohol use disorder were 2.0 for 12-month prevalence and 2.2 for lifetime prevalence. While the comorbidity with alcohol abuse was not increased (respective odds ratios 1.0 and 1.1), the odds ratios for alcohol dependence were significant (3.1 and 2.8). Similar results – i.e. an association with dependence but not abuse – were found for nicotine and drug dependence, which had the strongest relationship (odds ratios 9.9 and 5.2, respectively) In addition, as shown in previous studies, there was also a strong association of GAD with other mood and anxiety disorders. Further analysis of this database showed that men with GAD

ECA: Epidemiologic Catchment Area Study

NCS: National Comorbidity Study

Note: These estimates are based on the results from Moggi F, Dual diagnosis. Comorbidity of psychiatric disorders and addiction (in German). Bern: Huber publishers, 2nd edition 2007.

had significantly higher rates of comorbid alcohol and drug use disorders and reported greater use of alcohol and drugs to help relieve GAD symptoms.

An association of alcohol dependence, but not abuse, with anxiety disorders (and depression) was also shown in a recent Dutch Study. This study included 2329 people with lifetime DSM-IV anxiety disorders or depressive disorders or both and 652 controls. Prevalence rates for alcohol dependence in persons with combined anxiety/depression were 20.3% and in controls, 5.5%. Prevalence of alcohol abuse was similar in all groups (about 12%). Independent risk factors for alcohol dependence included male gender, vulnerability factors such as a family history of alcohol dependence or anxiety/depression, childhood trauma, smoking, drug dependence, and early onset of anxiety/depression.

More recent data come from a cross-sectional population-based study conducted in 2004–2005 in a nationally representative sample of 34 653 US adults. Mood, anxiety, and SUDs were addressed using the Alcohol Use Disorder and Associated Disabilities Interview Schedule-DSM-IV version. The authors defined five cluster alcoholic subtypes, some with heightened risk for GAD or social phobia, among numerous other factors (Clusters 3, 4, and especially 5). Follow-up data suggest that these empirical typologies predict differential clinical outcomes 3 years later.

For drug abuse, a large national epidemiologic survey in the United States indicated a 12-month and lifetime prevalence of 1.4 and 7.7%, respectively, which clearly exceeds the rates of drug dependence (0.6 and 2.6%, respectively). Drug use and dependence were associated with male sex, low socioeconomic status and other social variables, other SUDs, and antisocial personality. Drug dependence was associated with mood disorders and GAD. Twelve-month prevalence for drug use disorders was associated with any anxiety disorder with an odds ratio of 2.7. Among those, any panic disorder was associated with an odds ratio of 3.9 (with agoraphobia: 5.6, without: 3.1); social phobia, 2.6; specific phobia, 2.3; and GAD, 4.5. When adjusted for demographic characteristics and other psychiatric disorders, any anxiety disorder was associated with drug use disorders with an odds ratio of 2.1; drug abuse, 1.5; and drug dependence, 2.8. For drug dependence, GAD had an odds ratio of 2.5. In conclusion, these data correspond in part to studies in alcohol use disorders showing that drug dependence rather than abuse is associated with anxiety disorders, specifically GAD.

Comorbid mental and SUDs may occur concurrently and successively. The chronological relationship between the onset of the two disorders does not necessarily reflect the etiology or cause of the comorbidity. There are far fewer longitudinal studies on this issue. The temporal interrelationship between the onset of anxiety disorders and alcohol use disorders is complex. Long-term longitudinal

studies in studies of patients with anxiety disorders did not indicate an association of phobias with the onset of alcohol use disorders but rather a modest association between adult subclinical specific phobias and later-onset alcohol use disorders (odds ratio 3.2), which was stronger in women than men. Other studies also suggest that specific phobias occur prior to alcohol use disorders.

Flensburg-Madsen et al. (2010) studied the potential effects of alcohol intake (not alcohol use disorders) upon the risk of psychiatric disorders. This prospective cohort study included participants of the Copenhagen City Heart Study ($N = 18\ 146$), who were followed up for up to 26 years. Alcohol intake was measured by self-report, while psychiatric diagnoses were measured through registers. For women, drinking above sensible limits increased the risk for psychiatric disorders in general and especially for anxiety disorders (risk: 2.00). For men, a weekly low to moderate alcohol intake seemed to have a protective effect against developing a psychiatric disorder. Risk for anxiety disorders was lower in men drinking more than 14 drinks per week (0.79). The authors discussed the “apparent protective effect” of alcohol among men as a sign of mental and social well-being and normal functioning.

The database for drug use is more limited. Liang et al. (2011) performed a retrospective cohort study using data from the 2007 National Survey of Mental Health and Well-being (MHW) in 8841 adult Australians. Previously, Teeson et al. (2009) had reported data from this study indicating that 19% of males and 8% of females with an anxiety disorder had a co-existing SUD and 26% of males and 11% of females with an affective disorder had a coexisting SUD. Overall prevalence for drug dependence was 2.56%. Individuals with an affective disorder or anxiety disorder were at higher risk of harmful use and drug dependence (males: 9.3%; females: 3.9%). Again, the self-medication theory or common genetic factors were discussed to explain these findings.

REASONS FOR COMORBIDITY OF ANXIETY DISORDERS AND SUBSTANCE USE

Self-Medication Theory

Community-based epidemiologic studies show a 2.2-fold increased risk for anxiety disorders among individuals with alcohol dependence compared to the general population. There is a lifetime prevalence of 6–20% for anxiety disorders among alcoholics. Social and specific phobias have the highest risk. Differential diagnosis can be difficult because of overlapping symptoms.

As is the case in other psychiatric disorders comorbid with SUDs, some form of self-medication has been

discussed as a possible explanation. The relaxing, tension- and stress-reducing and sedating effects of alcohol in particular are well established and clear. Short-term consumption of alcohol or benzodiazepines diminishes anxiety in patients with panic disorder. This has been explained by means of cognitive processes and the expectancy of the drug's effect. In contrast, long-term use of alcohol and possibly other drugs may induce anxiety disorders. Anxiety is a frequent symptom in alcohol and drug withdrawal, but there is no clear experimental evidence for the induction of anxiety disorders by alcoholism. In SAD, clinical findings on the interrelationship with alcohol use are inconsistent.

Anxious patients may start to use alcohol or drugs to reduce anxiety and medicate their distress. Anxiety disorders frequently precede the onset of alcohol use disorders. Among individuals drawn from a nationally representative survey of US citizens ($N = 25\,342$), only 20% of anxious patients endorsed drinking to control anxiety symptoms. This small group of patients drank more alcohol, had a higher cross-sectional rate of alcohol dependence, and were at a higher risk for developing new alcohol dependence over 4 years compared to anxious non-self-medicators. It is not fully understood why some individuals with anxiety disorder use alcohol to relieve symptoms, while apparently many others do not. Cognitive factors such as the expected effect of alcohol may be relevant.

Another explanation is that alcohol or drug use disorders may cause anxiety. Anxiety and inner restlessness are frequent symptoms in alcohol or drug withdrawal and repeated withdrawals may trigger or kindle anxiety

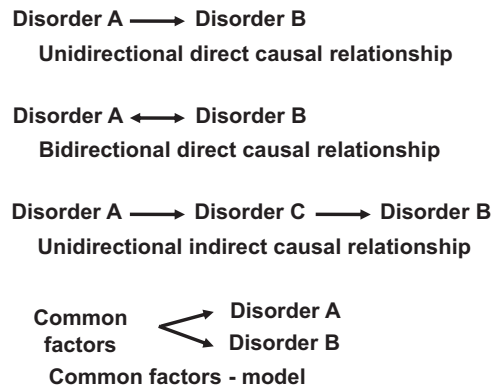

FIGURE 52.1 Model of the etiology of comorbidity of psychiatric disorders and substance use disorders. (from Moggi, 2007, with permission)

disorders. This theory has not been studied in great detail.

Finally, there may be common causes for anxiety and SUDs.

Animal studies indicate a genetic linkage between anxiety disorders and alcohol use disorders. A family history of alcoholism seems to be associated with alcohol and anxiety disorders in offspring. In addition, research in humans has tried to identify specific genes that are associated with both disorders. An integrated model to understand the relationship between SUDs and anxiety disorders has been proposed (see Figs. 52.1 and 52.2).

Sexual abuse and childhood trauma can also influence the risk of anxiety disorders and substance use. There is a plethora of studies on the association between sexual abuse and the risk for SUDs. A very recent study further evaluated the interrelationship by studying

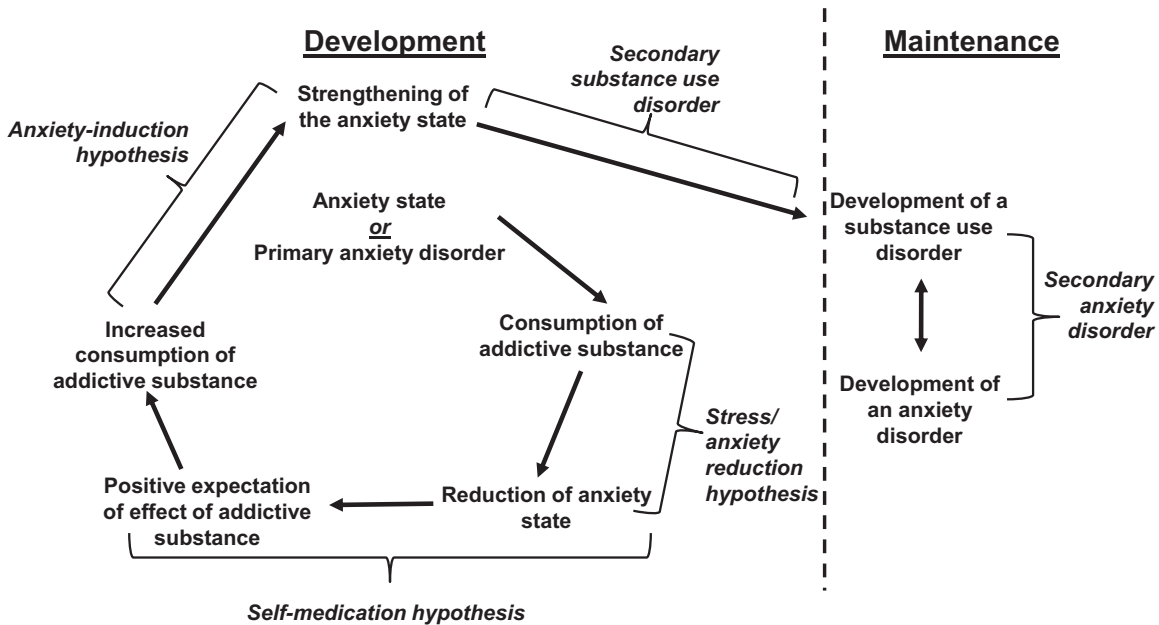

FIGURE 52.2 Vicious circle model of the comorbidity of anxiety and substance use disorders. Adapted from Moggi *f Dual diagnosis. Comorbidity of psychiatric disorders and addiction (in German)*. Bern: Huber publishers, 2. edition 2007.

psychiatric mediators in 192 alcohol-dependent, treatment-seeking women and healthy controls. The association of sexual abuse with alcohol dependence was limited to the most severe category of sexual abuse (vaginal or anal penetration). Of the five psychiatric disorders tested, anxiety, anorexia nervosa, and bulimia (but not posttraumatic stress disorder) were identified as potential mediators of the abuse-alcohol dependence association. In fact, the statistical association was strongest for anxiety disorders.

PREVENTION AND THERAPY

Anxiety and SUDs usually start in adolescence or early adulthood, although onset is not restricted to this age. Prevention strategies that include early diagnosis and intervention should be aimed at younger individuals. Although successful interventions for anxiety or SUDs are available, none has been studied in comorbid disorders. From a prevention point of view, identifying individuals at risk for later substance use is a key goal because it offers opportunities for early intervention.

Treatment seeking in dual-diagnosis patients is rather low, increases with the severity of personal problems related to substance use, and is highest in those with anxiety and depression. Individuals with a coexisting psychiatric disorder such as anxiety and SUDs usually have a poorer treatment response and outcome and more personal and social problems, suffer from more impairment, and generate larger costs. Anxiety disorders were found to predict negative outcome in some alcohol treatment studies but not in others. Only a few well-designed clinical studies exist for comorbid anxiety or depression and SUDs.

A number of pharmacologic agents are available for treatment of anxiety disorders without comorbid SUDs. Available compounds include selective serotonin inhibitors (SSRIs), selective serotonin norepinephrine reuptake inhibitors (SNRIs), tricyclic antidepressants (TCAs), calcium channel modulator pregabalin, reversible inhibitor of monoamine oxidase A moclobemide, irreversible monoamine oxidase inhibitors, benzodiazepine, the 5-HT_{1A}-agonist buspirone, antihistamines, atypical antipsychotics, anticonvulsants, beta-adrenergic blockers, and other homeopathic and herbal preparations.

In general, in the treatment of comorbid patients the same guidelines must be considered for treatment of nonsubstance-using patients. Pharmacologic interactions with alcohol or other drugs of abuse must be taken into account. All named drugs apart from benzodiazepines have no abuse potential. Benzodiazepines have a more rapid onset of action than other drugs.

Multiple studies have been performed on the pharmacologic treatment of anxiety disorders. In panic

disorder and agoraphobia, the clearest evidence is available for various SSRIs, the SNRI venlafaxin, the TCAs clomipramine and imipramine, and some benzodiazepines. For GAD, the most evidence has been obtained again for SSRIs, for the SNRIs venlafaxine and duloxetine, the TCA imipramine, pregabalin, the atypical antipsychotic quetiapine, and benzodiazepines. For SAD, several SSRIs are recommended, as well as venlafaxine and the MAOI phenelzine.

These recommendations deserve some clinical comments from the substance use perspective. The risk of interactions of TCAs with alcohol is significant (e.g. blackouts or cardiac dysfunction), therefore these drugs are not first choice, at least in nonabstinent patients.

For short-term use, treatment with benzodiazepines has been established, although these substances hold the risk for abuse and dependence, especially in patients with SUDs. However, longer treatment of up to 12 months is generally recommended. The TCA imipramine, buspirone, SSRIs, and SNRIs are established medications for longer use. Other antidepressants such as venlafaxine or more recently pregabalin have also been studied, with promising results.

Only a few pharmacotherapeutic trials have been conducted in patients with alcohol dependence and anxiety disorder. One study found that paroxetine reduces anxiety symptoms in patients with comorbidity, and another found that it reduces social anxiety in patients with alcohol use disorders. A meta-analysis of five published studies showed a positive effect of buspirone on treatment retention and anxiety, but the effect on alcohol consumption was less clear. Buspirone is no longer available in many markets.

Acamprosate is an anti-craving drug with proven efficacy in reducing relapse rates in alcohol-dependent patients. Some open-label studies suggest that the drug is effective as an augmentation for anxiety disorders, but no studies are available in comorbid patients.

Usually, both pharmacologic and psychotherapeutic approaches are combined for the treatment of anxiety disorders. A number of psychological interventions have been studied and have shown efficacy in anxiety disorders. The first step is usually some form of psychoeducation and information about the diagnosis, etiology, and treatment options.

Substance-induced anxiety symptoms frequently occur during detoxification from alcohol, benzodiazepines, or intoxication with cannabis or psychostimulants (cocaine, amphetamine) but usually improve or vanish within a few weeks. Anxiety disorders independent from substance use should be addressed in psychotherapy. Exposure therapy (usually in the form of gradual exposure *in vivo*, but also performed as “flooding”) and response prevention are very effective in specific phobia, SAD, and agoraphobia. In this treatment

setting, patients are usually confronted with a feared situation, for example using an underground train in agoraphobia or imagining and nearing a feared animal. Various cognitive strategies have been proposed for panic attacks and other symptoms that cannot be treated with exposure. The efficacy of cognitive-behavior therapy (CBT) was shown in a meta-analysis of 108 studies. CBT is based on cognitive models emphasizing the role of worrying, metacognitions, and avoidance behavior. A more recent review of meta-analytic findings also confirmed the efficacy of CBT in anxiety disorders, although few of these studies included a placebo condition. For anxiety disorders, studies comparing CBT with a wait-list control group found significantly larger effect sizes than those comparing CBT with an attention placebo. The evidence for psychodynamic therapies in anxiety disorders, although frequently used, is very limited. Treatment strategies are adapted to be used in different settings, ranging from one brief session to longer intervention over weeks and months. Both individual and group therapies are used in anxiety disorders.

Psychological interventions in comorbid anxiety and SUDs have not been studied in great detail. The fundamental question is whether it is best to address one disorder or the other or offer integrated treatment. Schade et al. (2005) reported results of a randomized controlled trial, 96 abstinent alcohol-dependent patients with comorbid social phobia or agoraphobia who were treated with an intensive 32-week psychosocial relapse-prevention program alone or in combination with CBT for anxiety and an optional SSRI. Additional anxiety therapy improved anxiety symptoms but not alcohol relapse rates. Avants et al. (1998) studied patients in an outpatient methadone program who were receiving either case management plus CBT (MA-) or case management plus an intensive manualized program (MAplus) and subdivided patients into social severe anxious (SAplus) and light anxious (SA-). SAplus patients were more abstinent from heroin, showed a stronger decrease in anxiety symptoms, and had less risk behavior when participating in the MA-group while there were no differences between MA-patients. The authors concluded that social anxiety patients in a methadone program may benefit more from less intensive programs.

Baillie et al. (2007) reviewed six randomized controlled trials of treatment for comorbid anxiety and SUD and concluded that for patients with more than moderate substance dependence there is clear and consistent evidence that standard treatment for SUDs leads to the best outcomes. The view is shared by other reviews. Treating anxiety first and "removing self-medication rationalizations" for drinking may be a rational approach in many dual-diagnosis patients

and may lead to a greater treatment compliance when focusing on alcohol. Special CBT approaches to reduce the expectancies for tension reduction from alcohol may help to reduce anxiety symptoms. Interpersonal group psychotherapy has not been studied in great detail in patients with comorbid psychiatric disorders and anxiety.

FUTURE PROSPECTS

While the epidemiologic evidence for a significant comorbidity between SUDs and anxiety disorders is robust, more longitudinal studies are necessary to fully understand the relationship. Only a few therapeutic and intervention studies have been published to date. For psychotherapy, more integrated treatment approaches should be developed and studied.

INTRODUCTION

Addiction and schizophrenia are both chronic disorders with serious complications, consequences, and costs for the individual and society at large. Schizophrenia most often has a chronic deteriorating course. The main component of schizophrenia is psychosis, defined as difficulty in distinguishing what is real from what is not real or impaired reality testing. This is manifested by positive symptoms such as hallucinations and delusions. Auditory hallucinations are common alone or in combination with hallucinations of the other four senses.

Other positive symptoms are delusions, which are fixed false beliefs. Persecutory (paranoid) delusions are quite frightening. Additional clinical manifestations are disorganized thoughts and behavior. Negative symptoms of profound deficits are often experienced during the residual phases of schizophrenia. Negative symptoms include alogia, avolition, and flattened affect. All of the negative symptoms disrupt interpersonal relationships and impair ability to function. Cognitive

deficits of schizophrenia are likely to contribute to the difficulty in treatment of addiction. Schizophrenia is one of the most expensive disorders in all of medicine. Even though it occurs in only 1% of the population it totals 2.5% of all the health care cost. It is estimated to cost \$26 000 per year per schizophrenia patient.

Although pharmacotherapy of schizophrenia with antipsychotic agents has achieved significant gains in positive symptom control, patients are often only partially treated and remain disabled by negative and cognitive deficits, poor treatment adherence, and lack of social and economic support. Management of this disorder is made much more difficult by the common association with comorbid substance abuse, which interferes with effective pharmacotherapy and efforts at rehabilitation, while adding the additional health-related and social burdens of the consequences of addiction. Thus, detection and treatment of addiction must accompany efforts to help patients with schizophrenia.

In addition to managing the two disorders simultaneously, careful diagnostic consideration is necessary in distinguishing first-episode schizophrenia from

FIGURE 53.1 Percentage of comorbid substance abuse in schizophrenia patients.

psychosis induced by substances of abuse since the two disorders often co-occur. The usual age of onset is late adolescence to young adulthood in both conditions. Two out of three patients diagnosed with first-episode schizophrenia, in retrospect, use drugs in the pre-morbid stages prior to the onset of psychotic symptoms.

If patients do not have substantial periods of sobriety, it is difficult to differentiate the clinical diagnosis of schizophrenia with certainty from substance-induced psychosis. Though drug use may trigger the clinical manifestation of schizophrenia, it is clearly not the cause. Likewise schizophrenia is not the cause of substance abuse.

EPIDEMIOLOGY

One percent of the population has schizophrenia and this percentage remains constant. However, substance abuse has significantly increased. Prior to the 1960s, concurrent schizophrenia and substance abuse were observed or at least described infrequently. Since then, the situation has changed dramatically. Deinstitutionalization is a factor since schizophrenia patients now have more access to drugs in their communities.

The lifetime prevalence of addiction in the general population is 16%. In contrast, the lifetime prevalence rate in patients with schizophrenia is about 47%. The only other Axis I Disorder that has a higher rate of comorbid addiction is bipolar disorder (61%). This issue exists in the United States and internationally (Australia, Switzerland, Italy, Germany, England). When nicotine is included, the rates are staggeringly high. Studies have shown that 75–90% of patients with schizophrenia smoke tobacco compared with 20% of the general population.

In special populations, such as among prisoners and the homeless, the rates of co-occurring schizophrenia and addictions are highest. Among prisoners, 90% of the patients who have schizophrenia abuse substances. In fact, schizophrenia patients with comorbid addiction are more likely to become violent and intertwined in the criminal justice system. Younger males are more likely to be afflicted with both disorders. In the homeless population, 70% of schizophrenia patients abuse substances.

There are geographic differences: cocaine is used more often in urban areas than rural areas.

In order of frequency, substances abused by schizophrenia patients include nicotine, alcohol, cannabis, and cocaine. Alcohol is three times more likely and other substances of abuse are five times more likely in schizophrenia than the general population. Two or more substances are often abused. There has been no reduction in tobacco use among schizophrenia patients in the last 40 years. Conversely, there has been a significant decline in the number of smokers in the general population. Patients with schizophrenia are less likely to abuse amphetamines, opioids, and sedative hypnotics than the aforementioned drugs (Fig. 53.1).

Abuse of substances in schizophrenia may go undiagnosed and undetected. Roughly half of patients with schizophrenia have a comorbid addiction problem. Evaluation of substance abuse needs to be assessed in every patient, and assessments need to be done throughout their lifetime. Table 53.1 shows the time period in which cannabis, cocaine, and opioids can be detected in urine.

NEUROBIOLOGY OF ADDICTION AND SCHIZOPHRENIA

Self-medication of schizophrenia with substances of abuse has been hypothesized. The idea is that substances are used to reduce symptoms. This hypothesis presupposes that substances selected would match the symptoms experienced. For example, schizophrenics would choose stimulants for negative symptoms. But this is not the case and most studies do not support this hypothesis.

Schizophrenics use what is more readily available and affordable. Reasons for use are similar to the general population, e.g. “to get high,” to decrease depression, to

TABLE 53.1 Time for Detection of Substances

Alcohol	< 24 h
Cocaine	3–7 days
Cannabis	4–7 weeks

relax, to increase pleasure, and to increase energy. The psychiatric symptom most associated with addiction among patients with schizophrenia is depression.

A more nuanced explanation of the neurobiology of addiction and schizophrenia involves mesocorticolimbic brain reward circuits. In schizophrenia, there is a postulated deficiency in dopamine-mediated mesocorticolimbic brain reward circuits. Substances of abuse ameliorate this deficit. Drugs such as alcohol, nicotine, cocaine may reinforce the reward system in the brain by increasing the level of dopamine in the nucleus accumbens of the limbic system.

In the mesolimbic regions and anterior striatum, deficiencies of dopaminergic neurons result in cravings. Therefore, schizophrenia patients are exquisitely vulnerable to addiction. When substances of abuse are introduced to schizophrenic patients, signal detection is modified. Then, negative effects of schizophrenia improve overall both with and without antipsychotic medications.

For example, nicotine affects the dopamine reward pathway. The dopaminergic and glutamatergic systems are involved in the etiology of schizophrenia. Nicotine binds nicotinic acetylcholine receptors in the midbrain during smoking. These neurons project from the ventral tegmental area to the prefrontal cortex and dopamine is released. Dopamine release in the nucleus accumbens leads to experiences of reward. This promotes impulsive, addictive behavior.

Hypofunction of dopamine in the prefrontal cortex mediates both cognitive deficits and negative symptoms. So by nicotine activating dopamine release in the prefrontal cortex, smoking is thought to decrease negative symptoms and cognitive deficits. This is correlated with the high rate of nicotine addiction in the schizophrenia patients.

Among the cognitive deficits in schizophrenia is visual-spatial memory. Hypofunction of cortical dopamine in the hippocampus of schizophrenics results in impaired performance in visual-spatial working memory. Smoking leads to improvement in tasks at least temporarily. Similarly in the prefrontal cortex of schizophrenia patients, attention, another cognitive dysfunction, is improved with smoking.

Abnormalities in emotion and motivation of schizophrenia patients are also attributed to dopamine system. Abusing cannabis doubles the risk of psychosis in schizophrenia patients. Also there is an earlier age of onset (17 versus 25) of schizophrenia patients who already have a history of cannabis abuse. Cannabinoid and dopamine receptor interactions in the prefrontal cortex, ventral tegmental area, and amygdala are thought to be vital in understanding the emotional associative learning difficulties in both addiction and schizophrenia.

There is an increase in risk of schizophrenia to 10% in first degree relatives and a 50% increased risk in monozygotic twins. But in terms of familial contributions in dual diagnosed patients, family history of schizophrenia does not correspond to substance use disorders in patients with schizophrenia. And substance use disorders are not associated with family members with schizophrenia.

COURSE AND CONSEQUENCES OF DUAL DISORDERS

Addiction is not the cause of schizophrenia and schizophrenia is not the cause of addiction. Rather, the effect of schizophrenia and addiction are bidirectional and each worsens the course of the other. Patients with addiction problems have an earlier age of onset of schizophrenia than patients without addiction. In addition, schizophrenia patients with comorbid substance abuse at the time of their first episode of psychosis are more likely to be men, with a longer duration of untreated psychosis, more severely ill, and be poor responders to antipsychotic medications. In short, substance abuse triggers and exacerbates psychosis that worsens the course of schizophrenia.

Moreover, schizophrenic patients who abuse drugs have an increased risk of suicide, are less compliant with treatment, often homeless, unemployed, violent, and frequently hospitalized (see Table 53.2). Substance abuse and violence are powerful predictors of acute psychotic episodes in patients with schizophrenia. In fact, schizophrenia patients who have a substance use disorder have twice the rate of hospitalization than those without substance disorders. Thus, these comorbid diagnoses occur more frequently among inpatients than outpatients. Up to 50% of readmissions for schizophrenia have been attributed to addiction.

Furthermore, addicted schizophrenia patients have significant medical complications. Rates of HIV, tuberculosis, hepatitis, and traumatic injury are higher in this population. They also have more smoking-related illnesses such as chronic obstructive pulmonary disease (COPD) and cardiovascular diseases. The rate of COPD in this comorbid patient population is 22.6% compared to 7.6% of the population at large. These illnesses

TABLE 53.2 Effects on Schizophrenia Patients Who Abuse Drugs

Stable living situation	↓	Homelessness	↑
Compliance with treatment	↓	Hospitalization	↑
Employment	↓	Suicide/Violence	↑

exacerbate costs and creates additional treatment burden. Both morbidity and mortality are increased in patients with comorbid schizophrenia and addiction.

However, smokers have reduction in antipsychotic drug-induced parkinsonism from the alteration in cholinergic and dopaminergic systems. Despite the negative impact substances have on course of illness, substances improve signal detection capability of the dopamine pathway, which leads to improvement in how patients feel subjectively which is powerful given the many negative consequences of drug use. Yet, patients abuse substances anyway.

INTEGRATED TREATMENT

As we do with all substance-abuse patients, we recommend addiction-specific psychotherapeutic techniques such as motivational interviewing and 12-step programs. Alcoholics Anonymous is the foundation of substance-abuse treatment. However, patients with schizophrenia report particular difficulties with these approaches that need to be addressed during treatment (see Table 53.3).

Since avolition is a core negative symptom of schizophrenia, it can be especially difficult to motivate them to set recovery-oriented goals. Patients with schizophrenia may never have attained particular goals such as obtaining a driver's license, job, property, or getting married. However, when schizophrenia patients are in group together with other dual diagnosis patients, who also discuss severe mental illness, they are better able to identify, engage, and benefit.

The best approach to treatment is to treat both disorders simultaneously. Sequential treatment of addiction first is no longer recommended. Antipsychotic medications enable patients to participate in psychosocial treatment which is the foundation of addiction treatment. Due to the chronic nature of schizophrenia, an integrated approach must be long-term and appropriately embedded within the context of psychiatric services. In this setting, there is less alcohol and drug use, better retention in treatment, and enhanced participation.

Since homelessness is prevalent in this patient population, support through residential treatment setting is

TABLE 53.3 Barriers to Psychotherapy Treatment of Addiction among Patients with Schizophrenia

Difficulty sitting still and restless in long meetings

No identification with social loss

Resent confrontation

important. Vocational rehabilitation is effective when available. For patients who have difficulty managing their funds or who typically spend much of their money on drugs or alcohol during the first few days of the month, a fiduciary can make a difference. Fiduciary arrangements could curtail the unnecessary admissions that occur when a patient is out of funds and has no place to sleep or eat. A fiduciary can assist in securing a living situation and paying expenses before releasing small amounts of money to the patient for discretionary spending (Table 53.4).

Typical antipsychotic medications have been observed to increase rate of smoking in patients who have schizophrenia. Nicotine is thought to counteract the extrapyramidal side effects of these first generation antipsychotic agents. Atypical antipsychotics are much less likely to generate extrapyramidal side effects and may have a particular role in treatment of schizophrenia patients with comorbid addictions.

Due to its alpha adrenergic blockade activity and weak blockade of dopamine receptors, clozapine is unique and superior for treatment of co-occurring addiction. Clozapine reportedly increases dopamine release in the prefrontal cortex and improves signal-detection capacity of the mesocorticolimbic dopamine-mediated circuitry.

Therefore, clozapine is thought to ameliorate or correct the mesocorticolimbic brain reward circuit deficiency that contributes to substance abuse in this patient population. But, quetiapine and olanzapine, and risperidone do not show these robust findings.

Nicotine

Schizophrenia patients are both more frequent and efficient smokers (taking more and deeper puffs). More frequent is defined as more than 25 cigarettes a day. Heavy smokers have an increase in hallucinations and delusions (positive symptoms) and fewer difficulties with flat affect, alogia, avolition (negative symptoms).

In addition tobacco, not nicotine, induces the cytochrome P450 isoenzyme CYP1A2 and this system also metabolizes some antipsychotic medications resulting in less available level of these medications. Therefore,

TABLE 53.4 Essential Components of Integrated Therapy

Supervised residential living

Case management

On-site treatment of addiction

Respect and empathy to foster strong therapeutic alliance, less confrontational

Collaborative goal setting

Psychopharmacology

smokers require higher dosages of antipsychotics exposing them to more cost and increase side effects. If smokers are able to quit, this may necessitate a decreased dose of medications. Likewise heavy caffeine use may also result in the induction of CYP1A2 and decrease the level of medications as well.

The combination of typical antipsychotics and nicotine replacement therapy (NRT) is safe and effective. Clozapine decreases negative symptoms and smoking. Therefore, treatment with clozapine is superior to the combination treatment of nicotine addiction.

Similar to the general population, bupropion can be helpful with smoking cessation in schizophrenia patients. Since bupropion has dopaminergic and noradrenergic effects, it has the potential to worsen psychosis. It also inhibits the CYP 450 2D6 system resulting in elevated levels of some antipsychotics. One must be mindful of this drug–drug interaction when prescribing these agents together.

Furthermore, cigarettes are a gateway to alcohol abuse and use of illicit substances. Smoking is present before alcohol dependence in virtually every patient. Tobacco dependence is basically a precursor to alcohol addiction among patients with schizophrenia

Alcohol

Thirty-seven percent of patients with schizophrenia abuse alcohol. Once diagnosed with schizophrenia, being a violent offender was the strongest predictor of alcohol use disorder. Alcohol worsens the course of schizophrenia.

Naltrexone is effective for alcohol addiction particularly in patients with family history of addiction. Naltrexone in addition to antipsychotic medications results in less alcohol cravings, less drinking days, and less heavy drinking days among the schizophrenia patients. Moreover naltrexone does not worsen psychosis.

Cannabis

There continues to be controversy regarding the therapeutic effects of cannabis in certain disease states. However, in schizophrenia use of cannabis has deleterious effects. Currently, there is no approved pharmacologic treatment of cannabis dependence for schizophrenia patients or for patients in general.

Cocaine

Schizophrenia patients are observed to use cocaine less often than nicotine, alcohol, and cannabis. Perhaps this is because cocaine is more difficult to obtain than the above three. Though reports show a role for clozapine in the reduction of cocaine use, risperidone does

not show reduction in cocaine use and olanzapine has equivocal effects.

Opioids

Schizophrenia patients are much less likely to abuse opioids compared with other drugs mentioned above. The treatment of schizophrenia patients, who abuse opioids, is the same as nonpsychotic patients. Treatment with methadone or buprenorphine has been found to be useful and safe.

CONCLUSION

There is an unusually high rate of addiction among patients with schizophrenia. Comorbid addiction and schizophrenia are highly associated in terms of neurobiology and worsening course of both individual disorders. Though substances of abuse have the immediate effect of increase in pleasure; they ultimately worsen the course of schizophrenia resulting in more frequent acute psychotic episodes.

The negative consequences affect society as a whole. The cost of cigarettes is approximately 27% of the monthly income of many patients with schizophrenia. Costs are elevated also because of increased health care expenses including additional medical burden, rehospitalization, and homelessness.

In patients who use chronically and are psychotic, it is beneficial to treat psychosis even in the face of addiction. Treatment of psychosis increases patient's engagement in addiction treatment, thereby helping to decrease substance abuse. This results in patients staying in treatment and reduction in psychotic symptoms. Treatment by the same clinician or clinical team is critical.

Substances of abuse are known to decrease compliance with treatment contributing to the number one reason of acute psychotic relapse. Both addiction and schizophrenia are chronic disorders that necessitate open-ended and continuous treatment. Likely recurrent interventions are required lifelong, since problems with addiction can occur during any phase of illness.

INTRODUCTION

In 1914, the Harrison Narcotic Act was created as opium and cocaine were previously unregulated, used liberally in the treatment of a variety of ailments, and became associated with criminal activity. In 1919, the Supreme Court ratified the Harrison Anti-Narcotic Act with the intention to regulate the importation, exportation, manufacturing, and distributing of opium and cocaine. Under this act addiction was not deemed a disease and physicians were restricted from prescribing maintenance opiate therapy to addicted patients. Those who prescribed opiates to addicts were censored, lost their medical license, and were incarcerated in some cases. Addiction was criminalized leading to resultant undertreatment of legitimate pain disorders causing undue suffering of pain patients. Over time through advocacy from the public and scientific

communities and published articles on the safety and efficacy of opioids in the treatment of pain, the intractable pain statutes reviewed by Joranson and Gilson in 1997 supporting opioid therapy for chronic pain including non-cancer pain were adopted.

Despite this evolution in philosophy regarding the therapeutic use of opioids, chronic pain remains a serious healthcare problem with associated economic burden. The person afflicted with pain can experience an array of problems including sleep disturbance, mood disorders, loss of work and family roles, sexual dysfunction, and diminished self-esteem all of which compromises quality of life. Delays in healing, changes in the central nervous system (neuroplasticity), depression, suicide, and opioid addiction (OA) can occur if pain is mismanaged or undertreated. Regardless of the enormity of the problem of chronic pain, growing concerns about addiction and diversion of opioids have contributed to the

inadequate treatment of pain, including acute episodes, end of life, and cancer pain, and especially in patients with chronic non-cancer pain (CNCP).

The individual struggling with both pain and co-occurring addiction is a particularly challenging case. Clinically, there are additional impediments in managing pain in this patient population as certain treatments such as opioid therapy are contraindicated or must be utilized judiciously and these patients carry added disease burden. Economically, patients with pain and addiction consume more healthcare resources. For example, White and colleagues in 2005 examined the database of medical and pharmacy claims from 16 health plans between 1998 and 2002 and classified opioid abusers by ICD-9-CM codes. A matched sample of non-abusers was also extracted for comparison. Results indicated that the prevalence of opioid abuse was low (eight in 10 000 persons), but the associated medical and pharmacy costs for abusers as compared to non-abusers were significantly higher. Abusers had a higher prevalence of nonopioid poisoning, psychiatric disorders, hepatitis (A, B, or C), and pancreatitis in contrast to non-abusers. Average annual direct healthcare costs for abusers were eight times greater than for non-abusers (\$15 884 versus \$1830) and mean annual drug costs were more than five times higher for abusers as compared to non-abusers (\$2034 versus \$386).

Prescription Opioid Abuse

Clinicians managing chronic pain patients (CPPs) are typically faced with the responsibility of providing the

appropriate standard of care to alleviate suffering, which includes chronic opioid therapy (COT) while not complicating recovery by exposing the vulnerable patient to the potential of opioid abuse and OA. It has been the position of many experienced pain clinicians and of organized pain societies such as the American Pain Society (APS) and the American Academy of Pain Medicine (AAPM) that the majority of individuals afflicted with chronic pain can be managed safely with opioids. However, there is ongoing debate regarding COT (3 months or longer) in the CPP population due to fear of diversion, addiction, and respiratory depression, as well as loss of efficacy due to tolerance. There is continuing discussion regarding the policy of moderate opioid prescribing in CPPs given the rising prevalence of prescription opioid abuse and OA in the country. For example, Substance Abuse and Mental Health Services Administration (SAMHSA) from the 2010 National Survey on Drug Use and Health (NSDUH) report the incidence of past month nonmedical use of pain relievers is substantially higher than that of stimulants, tranquilizers, or sedatives. In 2009, nonmedical use of pain relievers (2.2 million) was only slightly less common than the use of marijuana (2.4 million) for past year initiates among persons aged 12 or older (Fig. 54.1). Monitoring the future 2011 national results on adolescent drug use from Johnston and colleagues revealed that the use of narcotics other than heroin by 12th graders almost tripled from 3.3% in 1992 to 9.5% in 2004. From 2005 to 2010 the rate leveled between 8.7 and 9.2% (Fig. 54.2). Results from the 2010 SAMHSA Treatment Episode Data Set and the Drug Abuse Warning Network were also telling. Admission

rates to substance abuse treatment facilities for prescription opioid abuse increased from 18 300 in 1998 to approximately 105 680 in 2008. Between 2004 and 2009 there was a 98.4 increase in emergency department (ED) visits involving misuse or abuse of pharmaceuticals. Of the 1 244 679 ED visits in 2009 almost one half (595 551) were related to pain relievers. Sproule and colleagues in 2009 evaluated a sample of 571 opioid detoxification admissions over a 5-year period. The number of admissions related to controlled-release Oxycodone increased from 3.8% in 2000 to 55% in 2004. Legitimate prescriptions were the primary source of the opioids and the prescription opioid users reported higher levels of pain, comorbid substance use disorders (SUDs), and psychiatric symptoms. Excluding alcohol, tobacco, sedatives, and psychotropic drugs, opioid analgesics have become the common class of drugs associated with unintentional, fatal poisoning, greater than heroin, and cocaine.

SUDs are more common in many medical populations such as hospitalized patients, patients who have suffered major traumas and in patients treated for depression. Patients in these medical populations tend to develop acute and CNCP and, therefore, the prevalence of SUDs among these individuals treated for pain is high. Chronic pain is also common in patients seeking chemical dependency treatment.

The reported prevalence of OA in CNCP patients ranges from less than 1 to 40%. The wide range of

prevalence in different studies may be the result of the type of population sampled (primary care versus pain clinic) and whether patients were prescreened for history of SUD. A recent structured, evidence-based review of studies examining the abuse/addiction rate and aberrant drug-related behaviors (ADRBs) in patients receiving opioids for CNCP by Fishbain and colleagues in 2008 suggested that clinically significant abuse or addiction occurs in about 1/500 persons with no prior history of SUD and in about 3–4/100 of all persons prescribed COT for CNCP. Abuse/addiction rates appear to be highest in persons with history of SUD. ADRBs are more commonly observed than addiction and may reflect a range of issues including misunderstanding of instructions; self-medication of mood, sleep or other symptoms; elective use for reward/euphoria; or diversion for criminal intent and addiction. Urine drug screening (UDS) data were examined and revealed that 20.4% of CPPs had no prescribed opioid in the specimen. Illicit drugs were revealed in 12.7% of cases. The authors concluded that only a small percentage of CPPs exposed to COT will develop abuse or addiction.

The prevalence of “true” addiction in pain patients receiving prescription opioids is unknown in part related to confusion in terminology (addiction, tolerance, and physical dependence) and the population sampled. For instance, a pain clinic population would most likely have a higher proportion of patients with

co-occurring psychiatric disorders than a primary care population or a sports medicine clinic. A number of studies relied upon questionnaires and interview protocols that may have been inadequate or not sufficiently sensitive to render the diagnosis of addiction and had sample sizes that were typically small and unrepresentative.

RISK FACTORS FOR ADDICTION

Risk for addiction consists of a convergence of a number of factors related to the host (genetic predisposition and comorbid psychiatric conditions), environment (occupation, peer group, culture, and social stability), and the agent (availability, cost, speed of entering the brain causing euphoria, and the efficacy of the agent as a tranquilizer) (Fig. 54.3).

There is evidence indicating that risk for OA has considerable genetic origins. For example, one study by Tsuang and colleagues in 1998 demonstrated that 54% of the accountability for OA was due to genetic variance and that 38% of the accountability was explained by genetic variance specific to opioids. Other host factors include the extent of psychiatric comorbidities. Depression and anxiety disorders are common companions to chronic pain. Estimates of co-occurring depression in the pain population range from 30 to

over 80%. Anxiety disorders range from 7 to over 60%, and posttraumatic stress disorder (PTSD) ranges from 9 to 33% in patients attending pain clinics. Pain patients with psychiatric and SUD comorbidities have a propensity to use opioids for long term as compared to those patients without a documented history of mood disorders or addiction, and patients diagnosed with a psychiatric disorder are more likely to abuse/misuse opioids than those without a psychiatric disorder.

There is some evidence that healthy social support may reduce the vulnerability to substance abuse and reduce relapse. Inadequate social support may be an important environmental risk factor in the development and maintenance of addiction/abuse in pain patients receiving opioids. If behavioral health/substance abuse treatment resources are scarce, self-help groups such as Alcoholics Anonymous or Narcotics Anonymous may provide needed support to reduce the probability of relapse.

Availability of the agent is an important factor in the development of addiction. Over the past decade there has been an extraordinary increase in the retail sales of opioids (<http://www.deaddiversion.usdoj.gov/>). For example between 1997 and 2006 there has been a 196% increase in the retail sales of morphine, 274% increase in Hydrocodone products, 732% increase in Oxycodone, and over 1000% increase in methadone sales. The 2010 SAMSHA NSDUH report indicated in 2008–2009 among

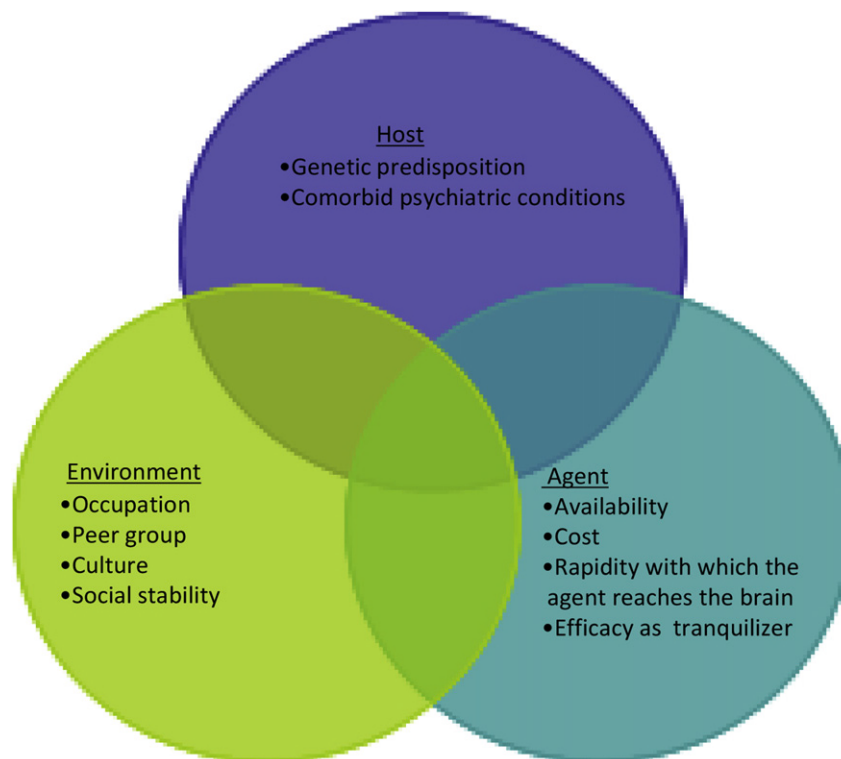

FIGURE 54.3 Risk factors for addiction.

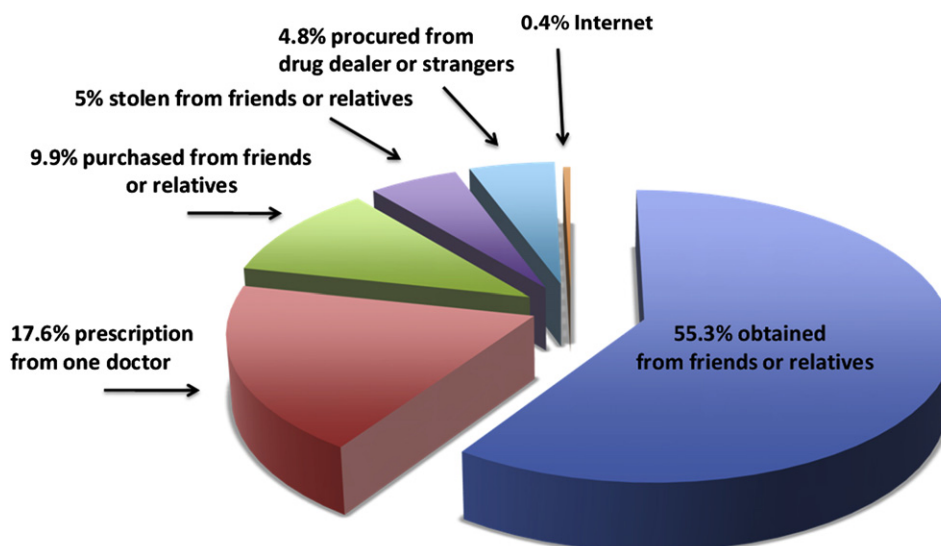

FIGURE 54.4 Source where pain relievers were obtained. *Substance Abuse and Mental Health Services Administration., 2010. Results from the 2009 National Survey on Drug Use and Health, vol. I. Summary of National Findings (Office of Applied Studies, NSDUH Series H-38A, HHS Publication No. SMA 10-4856 Findings). Rockville, MD.*

individuals 12 years or older who used pain relievers for nonmedical purposes 55.3% of this population acknowledged that they obtained the drugs most recently used from friends and family for free, 17.6% obtained the drugs from a prescription from one doctor, 9.9% purchased them from a friend or relative, 5% stole them from friends or relatives, 4.8% procured them from a drug dealer or stranger, and 0.4% bought them on the Internet (Fig. 54.4).

Other possible risk factors for opioid abuse include pain exaggeration, occult etiology for pain, poor function due to pain, age, psychological comorbidities, history of preadolescent abuse, cigarette dependency, PTSD, and family history of SUD. Cannabis use may also be a possible risk factor. Reisfield and associates in 2009 conducted a literature review of studies on COT, which included measures of ADRBs. Prevalence of cannabis use in patients prescribed COT ranged from 6.2 to 39% (5.8% in general US population). Cannabis use was significantly associated with present and future ADRBs.

The susceptible pain patient with genetic predisposition to addiction, undiagnosed or poorly treated comorbid psychiatric disorders, lacking social support, and having easy access to opioids may be especially at risk for the development of OA.

DIAGNOSING ADDICTION IN THE OPIOID-TREATED PAIN PATIENT

Considerable research has been devoted to identifying and assessing risk factors for addiction in pain

patients receiving opioids. Addiction is a chronic, neurobiological disease state produced by repeated exposure to a drug that activates the brain reward system leading to loss of control over drug use. Drugs with addictive qualities act through the “reward circuits” located within the mesocorticolimbic dopamine systems that include projections into the nucleus accumbens, amygdala, and prefrontal cortex. Addictive drugs produce reward, pleasure, or euphoria. Susceptible individuals repeatedly exposed to a drug with addictive qualities develop a biological adaptation or learning that leads to craving, compulsive use, and continuation despite physical or mental harm created by the drug.

Rendering a diagnosis of addiction in patients treated with opioids is complex and can be confusing due to the tendency to interchange the terminology of addiction and dependence. The World Health Organization (WHO) and the American Psychiatric Association (APA) adopted the term substance dependence, over what was historically termed drug addiction. The influential Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV-TR), published in 2000 established seven criteria for substance dependence (addiction). Only three criteria are required to make the diagnosis of dependence (addiction) (Table 54.1). As noted by Heit in 2003, five of these criteria are commonly experienced by the nonaddicted pain patient: tolerance, physical dependence/withdrawal, used in greater amounts or longer than intended, unsuccessful attempts to cut down or discontinue use, and considerable time spent obtaining the substance or recovering from use. Pain patients

TABLE 54.1 DSM-IV-TR Criterion for Dependence (Addiction)

- Tolerance
- Physical dependence/withdrawal
- Used in greater amounts or longer than intended
- Unsuccessful attempts to cut down or discontinue
- Much time spent pursuing or recovering from use
- Important activities reduced or given up
- Continued use despite knowledge of persistent physical or psychological harm

*3/7 required for diagnosis

***5/7 common in nonaddicted pain patients**

Heit, H.A., 2003. Addiction, physical dependence, and tolerance: precise definitions to help clinicians evaluate and treat chronic pain patients. *Journal of Pain and Palliative Care Pharmacotherapy* 17 (1), 15–29.

appropriately using opioids over time will develop tolerance and can experience withdrawal symptoms if a dose is missed or due to end-of-dose failure. These behaviors can be misinterpreted as reflecting the condition of addiction. Patients may also display ADRBs reflective of the development of addiction or possibly suggestive of misuse for purposes of self-medicating an untreated or poorly controlled mood disorder (chemical coping), inadequate pain control (pseudoaddiction), tolerance, or criminal intent (diversion).

A consensus panel from the APS, the AAPM, and the American Society of Addiction Medicine (ASAM) was convened in 2001 to develop less ambiguous definitions of dependence and addiction in the pain population to avoid stigmatizing the legitimate pain patient and causing the undertreatment of pain. Consensus recommendations included:

1. *Addiction* – “Addiction is a primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include one or more of the following: impaired control over drug use, compulsive use, continued use despite harm, and craving.”

This definition emphasizes the “four Cs” (adverse Consequences, Control, Craving, and Compulsivity) as critical markers of addiction. Physical dependence and tolerance are not required in formulating the diagnosis of addiction and are considered states that occur naturally when using prescribed opioids.

2. *Physical dependence* – “Physical dependence is a state of adaptation that is manifested by a drug class

specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.” Dependence often occurs in the abuse of highly addictive drugs, but not always such as in cocaine. Physical dependence is common in many classes of drugs that are used for long term such as beta-blockers, antidepressants, and corticosteroids, as well as opioids. The development of physical dependence in patients receiving opioid therapy can be mistaken as suggestive of addiction, for example when a patient reports withdrawal symptoms when missing a dose or due to end-of-dose failure or verbalizes concern to their physician about renewing opioid prescriptions on a timely basis to avoid withdrawal. If a patient develops withdrawal symptoms this may be viewed by an untrained clinician as a sign of addiction in the absence of other critical behaviors such as craving and compulsive use.

3. *Tolerance* – “Tolerance is a state of adaptation in which exposure to a drug induces changes that result in a diminution of one or more of the drug’s effects over time.” Patients receiving COT often require an increasing dose of the opioid to maintain the initial therapeutic response of analgesia and improved function. The opioid-tolerant patient will show a pattern of gradual increase in need for titration of dose. Tolerance and withdrawal symptoms are critical features of some addictions such as alcoholism but for prescribed medications such as opioids, these symptoms can be normal.
4. *Pseudoaddiction* – The consensus panel also added the term “pseudoaddiction” to describe an iatrogenic condition when relief-seeking behaviors occur if pain is undertreated. These behaviors may include clock-watching, doctor shopping, or drug seeking and even illicit drug use or engaging in deceptive acts to procure opioids all to alleviate pain.

The DSM-V is currently being developed. In this new version OA and dependence will be combined under the heading “opioid-use disorder” (Table 54.2).

The criteria for diagnosing opioid-use disorder are similar to DSM-IV except that tolerance or withdrawal “is not counted for those taking medications under medical supervision such as analgesics, antidepressants, anti-anxiety medications, or beta-blockers.” This change in taxonomy hopefully will aid in distinguishing addiction from tolerance and dependence in the patient legitimately using therapeutic opioids.

TABLE 54.2 DSM-V Opioid-Use Disorder

A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by two (or more) of the following, occurring within a 12-month period:

- Recurrent substance use resulting in a failure to fulfill major role obligations
- Recurrent substance use in situations in which it is physically hazardous
- Continued substance use despite having persistent or recurrent social or interpersonal problems
- Tolerance, as defined by either of the following:
 - A need for markedly increased amounts of the substance to achieve intoxication or desired effect
 - Markedly diminished effect with continued use of the same amount of the substance (*Note: tolerance is not counted for those taking medications under medical supervision such as analgesics, antidepressants, anti-anxiety medications, or beta-blockers*)
- Withdrawal, as manifested by either of the following:
 - The characteristic withdrawal syndrome for the substance (refer to Criteria A and B of the criteria set withdrawal from the specific substances)
 - The same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms (*Note: withdrawal is not counted for those taking medications under medical supervision such as analgesics, antidepressants, anti-anxiety medications, or beta-blockers*)
- The substance is often taken in larger amounts or over a longer period than was intended
- There is a persistent desire or unsuccessful efforts to cut down or control substance use
- A great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects
- Important social, occupational, or recreational activities are given up or reduced because of substance use
- The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance
- Craving or a strong desire to urge to use a specific substance

<http://www.dsm5.org>

GUIDELINES

Several guidelines were developed to promote “responsible practice” in prescribing opioids for chronic pain. The *“Model Policy for the use of Controlled Substances for the Treatment of Pain”* from the Federation of Medical Boards was published in 1998 and revised in 2004. *“Cautionary Guidelines for the Use of Opioids in Chronic Pain”* were proposed by the American Academy of Addiction Psychiatry (AAAP) in 2009 in response to

the “liberalizing” of opioid prescribing attributed to older guidelines from American pain societies. The APS and the AAPM commissioned an expert panel to systematically review the prevailing literature and developed the evidence-based *“Clinical Guidelines for the use of Chronic Opioid Therapy in Chronic Noncancer Pain.”* The “Model Policy” recommended completing and documenting medical history and physical examination (PE), written treatment plan, obtaining informed consent, and if the patient is at high risk for medication abuse or has a history of substance abuse a written treatment agreement should be used. The policy also suggested a periodic review of treatment goals and progress toward these goals, use of consultants particularly in high-risk patients, and outlined the content of appropriate medical records. The AAAP guidelines were enacted “to limit the over-prescription of opioids and problems associated with dependence and abuse.” The AAAP policies also encouraged obtaining a full medical history, completing a PE, and monitoring and risk assessment. The AAAP recommended against high doses of opioids and cautioned that chronic, high-dose opioid therapy might lead to opioid-induced hyperalgesia as well as risk of medical complications/adverse effects and deaths, particularly when opioids are used in combination with sedatives–hypnotics. If the patient’s pain appeared disproportionate to objective findings nonopioid therapies might be more appropriate and if the patient displayed any type of ADRBs the physician should consider detoxifying the patient from opioids.

The APS and AAPM guidelines are more expansive and were meant to be evidence-based, but most of the recommendations were based on expert consensus. Of the 25 recommendations from this panel, none were rated as supported by high-quality evidence, and only four could be supported by moderate-quality evidence. While also recommending conducting a thorough physical and history along with risk stratification and use of UDS, these guidelines provided more comprehensive and detailed strategies for patient selection, risk stratification, monitoring, informed consent, and specifics on initiation and titration of opioids and guidelines for discontinuation of opioid therapy. Nonopioid alternatives or co-interventions, both pharmacologic and non-pharmacologic and the management of opioid related adverse effects, and opioid rotation were addressed. “High-dose opioid therapy” was defined as greater than 200 mg daily of oral morphine or equivalent. It was advised that when this threshold is reached there should be heightened scrutiny regarding the appropriateness of opioid therapy. Lastly, the panel suggested that patients with a history of drug abuse, significant psychiatric comorbidities, or ADRBs may be considered for COT with the stipulations of increased monitoring and co-treatment with behavioral health or addiction specialists.

UNIVERSAL PRECAUTIONS AND RISK STRATIFICATION

There is limited and weak support for the efficacy and effectiveness of long-term opioid therapy in providing significant pain relief as indicated in a 2010 Cochrane review by Noble and colleagues. The APS/AAPM expert panel concluded that while the evidence was extremely limited, there was consensus that COT could be an effective treatment for carefully selected and monitored patients with CNCP. Prevailing evidence suggests that preselected patients treated with opioids have an extremely low prevalence of addiction. Deterring abuse of prescription opioids requires due diligence in risk assessment and stratification.

On the basis of time-tested concept of “universal precautions” developed for risk assessment in infectious disease, Gourlay, Heit, and Almahrezi in 2005 developed universal precautions in pain management (Table 54.3).

Applying these universal precautions the authors recommended that patients can be stratified into three different risk categories. Low-risk patients defined as having no personal or family history of SUD, no or minimal concomitant psychopathologies can be followed in a primary care setting. Moderate-risk patients having a past history of SUD, strong family history, and past/current psychiatric history should have specialist support. High-risk patients are those who are actively addicted and/or have unstable, major psychiatric comorbidities. These patients should be referred to specialty pain management centers that can provide the highest level of surveillance and integrated

TABLE 54.3 Universal Precautions

- Formulate diagnosis with differentials
- Psychological assessment including risk of addictive disorder
- Informed consent
- Treatment agreement
- Pre- and post-intervention assessment of pain level and function
- Trial of opioid therapy and/or adjunctive medication
- Reassessment of pain score and function routinely
- Regularly assess the “four A’s” (analgesia, activity, adverse affects, aberrant behaviors)
- Periodic review of pain diagnosis and the development of comorbid conditions including addictive disorders
- Documentation

Gourlay, D.L., Heit, H.A., Almahrezi, A., 2005 Mar–Apr. *Universal precautions in pain medicine: a rational approach to the treatment of chronic pain. Pain Medicine* 6 (2), 107–112.

treatment. Subsequently in 2006, Gourlay and Heit emphasized a patient-centered model promoting the assessment and management of treatable, concurrent disorders including pain, drug misuse/abuse, addiction, and other psychiatric disorders. This encourages patients being treated in a less stigmatizing, more humane manner, and enhancing the opportunity for diagnosing and treating complicating disorders such as addiction and psychiatric comorbidities.

MANAGING PAIN WITH OPIOIDS: MAXIMIZING BENEFIT AND MINIMIZING RISK

Chronic Disease Management and the Patient-Centered Medical Home

There is utility in considering both pain and addiction as chronic diseases, as this allows for the opportunity to employ a chronic disease management model that has been highly effective in other chronic disease states (diabetes, asthma, and heart disease) that are also highly prevalent and costly.

In managing chronic diseases, risk stratification is established and monitoring and modification of treatment is determined by the patient’s responsiveness to treatment as measured by certain markers (e.g. HbA1c, lipid levels, blood pressure readings, etc.). In the CPPs receiving opioid therapy these markers would include measures of ADRBs suggestive of misuse or abuse of opioids, pain intensity and measures of functionality and response to opioid therapy, and mental health screening. In patients with pain and co-occurring substance abuse, the level of surveillance and types of interventions would be determined by these various measures.

The basic elements of managing patients with opioids and chronic pain from a chronic disease management perspective include risk assessment, intervention, and monitoring.

Risk Assessment

Risk assessment includes the use of validated screening tools, UDS, and mental health screening.

RISK ASSESSMENT TOOLS

Genetic predisposition (family history), personal history of SUD, and the severity of psychiatric comorbidities have been postulated as the predominant risk factors for opioid abuse/misuse.

On the basis of known ADRBs a variety of screening tools have been developed for both prescreening patients being considered for opioid therapy and patients currently using opioids. Prescreening tools

include a Screener and Opioid Assessment for Patients with Pain (Butler and colleagues, 2004); Opioid Risk Tool (Webster and Webster, 2005); Diagnosis, Intractability, Risk, Efficacy (Belgrade and colleagues, 2006); and Drug Abuse Screening Test (Skinner, 1982). Assessments employed for monitoring patients currently on chronic opioids include the Pain Assessment and Documentation Tool (Passik and colleagues, 2004) and the Current Opioid Misuse Measure (Butler and colleagues, 2007). These assessment tools have methodological weaknesses including limited generalizability to other clinical settings, as they were mostly validated in pain clinic settings and concern regarding reliability in self-administered versus clinician-administered versions.

URINE DRUG SCREENING

UDS is commonly utilized to assess abuse potential and adherence in pain patients receiving opioid therapy. The APS/AAPM consensus clinical guidelines recommended that patients at high risk or who are engaged in ADRBs (strong recommendation, low-quality evidence) and patients at low risk (weak recommendation, low-quality evidence) have periodic UDS. A number of studies have demonstrated that a significant percentage of patients receiving prescription opioids have abnormal UDS. While an aberrant UDS may be suggestive of abuse or addiction, it does not diagnose addiction, physical, or psychological dependence. The absence of a prescribed opioid on UDS usually is considered to be an indicator of diversion. However, one must consider hoarding behavior for two additional reasons: the patient is fearful of not having access to opioids in the future or the patient is considering suicide.

MENTAL HEALTH SCREENING

A comprehensive risk assessment program should include mental health screening in light of the high prevalence of concomitant mood disorders in patients with chronic pain. Opioids have anxiolytic and possible antidepressant properties and may be used for purposes of chemical coping. Chemical coping refers to reliance on the opioid to promote emotional stability. There is also substantial literature on the risk of suicide in pain patients. Diagnosing depression in the pain population is complex as there is potential for symptom overlap between pain and depression, particularly in the somatic domain (sleep disturbance related to pain and opioid-induced inhibition of rapid eye movement (REM) and non-REM phases of sleep, weight, and appetite changes secondary to inactivity, change in libido, and/or energy related to opioid-induced hypogonadism) that may lead to misdiagnosis. There are a number of validated tools for assessing depression and anxiety which vary in length and specificity.

Effective risk assessment relies upon a combination of UDS and screening for ADRBs and mood disorders.

Interventions

Treatment decisions are determined by the initial risk stratification. On the basis of Gourlay and colleagues risk categories, patients at low risk can be followed in primary care with less intense monitoring (i.e. less frequent office visits) and more liberal dosing of opioids. Patients at moderate risk will require closer surveillance, more limited access to opioids initially, and co-treatment with other specialists (such as mental health practitioners and addiction medicine practitioners). Patients at high risk would benefit from referral to a specialty pain management program. However, in many instances, there is limited or no availability of specialty pain management especially in more rural areas.

Patients with high levels of depression and/or anxiety based on mental health screening would also benefit from referral to behavioral health. Rational pharmacotherapy targeting pain, sleep, and mood disorders, along with cognitive behavioral therapy and exercise is essential for all patients suffering from chronic pain independent of their risk profile.

In cases where the patients are actively abusing their medications, referral for substance abuse counseling and/or inpatient detoxification may be required. The screening, brief intervention, and referral to treatment (SBIRT) initiative was developed by SAMHSA and the Center for Substance Abuse Treatment (CSAT) as a comprehensive, integrated public health approach to facilitate early detection, intervention, and referral for treatment services for individuals with SUD. SBIRT is intended to be integrated into a system of services utilizing community resources. There is an SAMHSA sponsored web page that helps locate treatment providers and facilities in local regions (<http://findtreatment.samhsa.gov>). Utilizing the SBIRT service program patients referred for brief treatment or for specialty treatment self-reported a dramatic improvement in general health, mental health, employment, living situation, and criminal behavior.

Monitoring

Once risk stratification has been conducted and the intervention for the patient has been established, monitoring is crucial. In low-risk patients, who are responding effectively to the treatment interventions, the level of monitoring can be fairly infrequent. For patients at moderate or high risk for either abusing medications or experiencing high-levels of depression with a risk for suicidal ideation and/or attempts, the level of surveillance is more frequent until these conditions stabilize. At each monitoring, medical record audit

should be conducted to determine whether there have been any ADRBs (ED admissions for pain, frequent phone calls to the clinic, doctor shopping, etc.). The PE and repeat SUD/mental health screening is also an important part of responsible monitoring of patients being prescribed opioids for long term. Routine UDS is recommended, particularly for the patients at high risk for abusing their medications. There has been some dispute regarding the frequency and overall utility of UDS. Random UDS is reasonable in this patient population, but the clinician should take steps to be fully educated on the interpretation of UDS, and have a plan established when UDS is suggestive of diversion, hoarding behavior, or addiction.

Figure 54.5 outlines an algorithm of the basic principles of risk stratification, intervention, and monitoring.

Patient-Centered Medical Home

Theoretically complex cases of patients with chronic pain, co-occurring psychiatric disorders that are at high-risk for abuse would be treated in an integrated pain clinic with access to behavioral health and addiction specialists. In practice there is a paucity of these specialty clinics. The majority of these patients are managed in busy primary care practices that lack the needed resources to effectively manage this patient population. The Patient-Centered Medical Home (PCMH) was developed by primary care organizations in 2007 to promote comprehensive primary care that fosters a collaborative relationship between an individual patient and their personal physician, and when appropriate the family and community. The basic principles of PCMH include that each patient has a personal physician

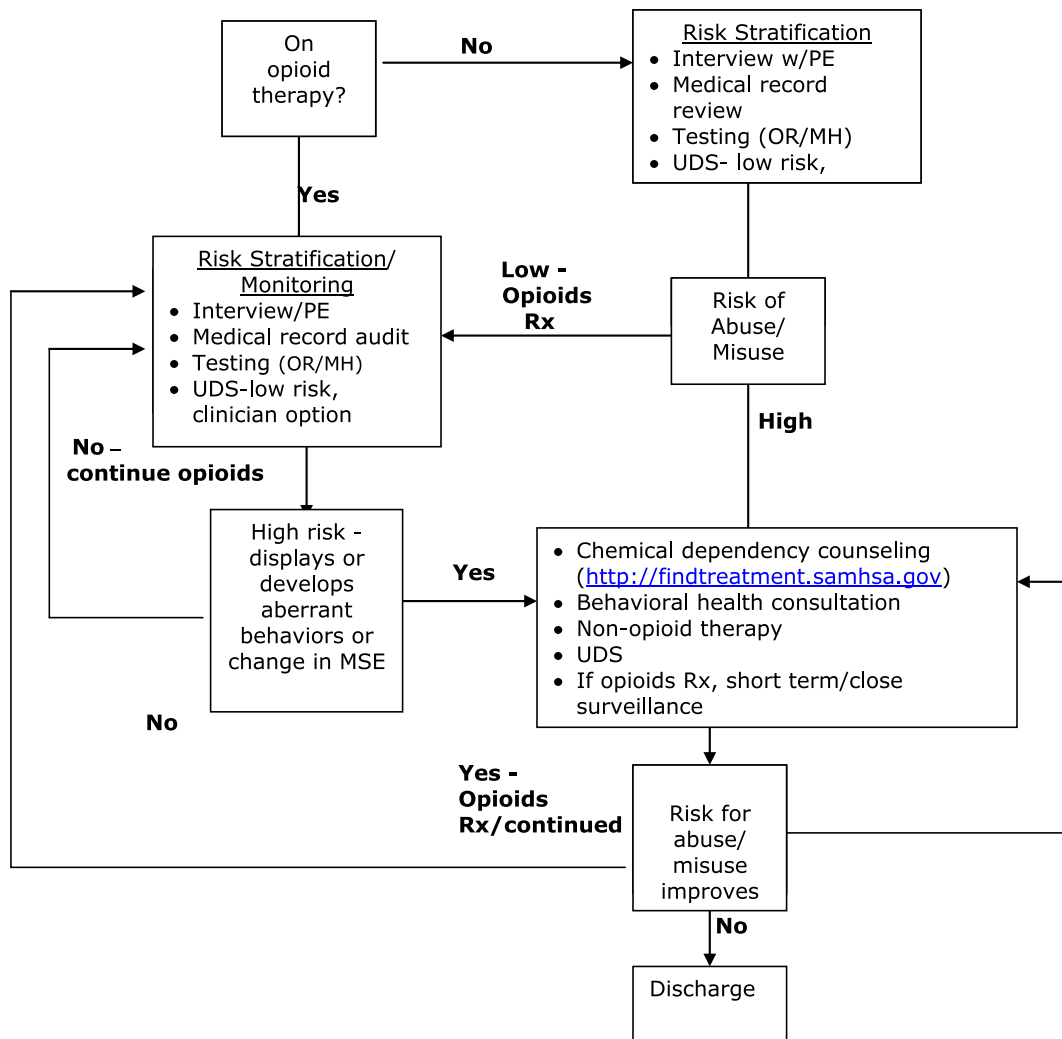

FIGURE 54.5 Algorithm for risk stratification, monitoring, and triage. UDS – urine drug screening, PE – physical exam, OR – opioid risk, MH – mental health.

directing medical practice through a team, is whole person oriented, provides coordination of care across a healthcare system, ensures quality and safety, promotes enhanced access to services, and reimbursement for PCMH reflects added value. SBIRT has been utilized in this model for substance abuse with promising results. The PCMH model has great potential in managing patients with chronic pain on opioid therapy and reducing the risk of abuse, addiction, and diversion.

STRATEGIES TO DETER OPIOID ABUSE AND DIVERSION

There have been a number of strategies developed in an attempt to deter misuse and abuse of prescription opioids and also to discourage diversion. These include changes in pharmacologic formulations, federal policy, and monitoring programs.

Abuse-Resistant/Abuse-Deterrent Opioid Formulations

Due to the substantial evidence of rising abuse and diversion of opioids, new formulations have been developed to dissuade abuse. These include: (1) abuse-resistant formulations that use a physical barrier mechanism such as a gel to reduce the ability to extract active opioids or alter a tampered capsule or tablet unusable for injecting or snorting; (2) agonist-antagonistic formulations combine an antagonist, typically Naltrexone, with the opioid such that if an opioid is crushed, chewed, or chemically altered the antagonist is released reducing euphoria and tendency for abuse; and (3) aversive agents such as niacin are released if the prescribed opioid is used in excess.

Prescription Monitoring Programs

A number of states have developed prescription monitoring programs (PMPs) to assist regulatory agencies and physicians in the detection of prescription drug abuse or diversion. Initially the objective of these PMPs was to detect and prosecute individuals involved in diversion, which is defined as unlawful transferring of a regulated pharmaceutical from legal means to the illicit marketplace. Data are collected from physicians who are prescribing the medications and pharmacies which fill the opioid prescriptions. The specifics and roles of the PMPs vary from state to state, including which schedule(s) of drugs is monitored, frequency of data collection, and which parties have access to the information (physicians, pharmacists, or Department of Justice).

While there are limited data on the success of the PMPs, it appears that these programs may be helpful in reducing abuse and diversion.

Risk Evaluation and Mitigation Strategy

The FDA amendments act of 2007 extended this agency's authority over drug products that have been demonstrated to carry risk for patients. Under this act the FDA has the authority to require pharmaceutical companies submitting certain drug approval applications to submit proposed risk evaluation and mitigation strategy (REMS) as part of the application. The FDA may require REMS when it's determined that there is a necessity to ensure that the benefit of a pharmaceutical outweighs its risk.

While the specifics of REMS for opioid analgesics are currently being debated, the possible elements of proposed REMS include specialty training and/or certification of both prescribers and persons dispensing the drug (pharmacists and hospital personnel), prescribers and dispensers are familiar with the educational materials on risk of the drug and conditions for safe use, a plan for communicating the risks of a drug, and an implementation system and developing a database of all enrolled entities (prescribers, pharmacies, practitioners, and healthcare organizations).

SUMMARY

There has been much deliberation regarding the prescription of opioids to patients with CNCP. The main focus of concern has been the potential of vulnerable patients exposed to opioids becoming addicted, thus complicating their care. However, there are a variety of risks involved when opioids are prescribed to this patient population. Types of risk include:

- *Addiction* – addiction in pain patients on opioid therapy is characterized by “four C’s” – continued use in spite of harm (adverse Consequences); impaired control over use (Control), compulsive use (Compulsivity), and preoccupation with the use for non-pain relief purposes (Craving).
- *Misuse* – patients misusing medications are not necessarily engaging in behavior reflective of addiction but may be chemically coping (i.e. using pain medications for mood modulation, disassociation in cases of PTSD) or in many cases attempting to remedy their sleep disorder.
- *Suicide* – patients with chronic pain have a high comorbidity of depression and in many of these cases engage in suicidal ideation. Patients with pain and depression are at high risk for potential suicidal

gestures. Patients may hoard their medications (evidenced by UDS indicative of no opioids being used) for purposes of self-harm.

- *Undertreatment of pain* – oftentimes patients are concerned about becoming addicted when prescribed opioids. In these instances, patients will under use their medications or refuse the use of opioids thus leading to poor pain control and suffering.
- *Diversion* – diversion is the transfer of a prescription drug from a legitimate to an illegitimate conduit of distribution or use.

Prevailing evidence suggests that addiction in patients on COT is relatively low, particularly in individuals with no current or past history of SUD and negligible psychiatric comorbidities. The incidence of misuse is unknown but most likely substantial given the high comorbidity of chronic pain and psychiatric disorders and the mood modulating effect of opioids. While practitioners are concerned about their patients becoming addicted to prescribed opioids or criminal diversion of opioids, many patients with chronic pain suffer from depression and pain may be an independent risk factor for suicide with drug overdose as a common plan. When dispensing potentially lethal quantities of opioids, mental health screening and monitoring should be a routine practice. A patient displaying evidence of moderate to severe depression which is unresponsive to appropriate antidepressant therapy or endorses suicidal ideation necessitates immediate referral to a mental health facility for co-treatment. Lastly, there is a great deal of stigma associated with CNCP patients receiving COT. Patients often feel overly scrutinized by their healthcare providers, pharmacists, friends, and family. The national attention devoted to concerns of abuse of prescription analgesics may fuel a legitimate patient's fear of becoming addicted to prescribed opioids. Low-risk pain patients that might otherwise benefit from opioid therapy may under use or refuse prescribed opioids. In these cases, additional patient education on the indications and proper use of opioids and addressing the patient's fear of becoming addicted is needed with special attention to defining the concept of addiction as compared to tolerance and physical dependence.

Recent guidelines on opioid prescribing have been published and there has been a great deal of research devoted to developing abuse-deterrent opioid formulations and risk assessment tools and utilizing medical informatics to reduce opioid abuse. When prescribing opioids due diligence includes not only assessing and monitoring for signs of addiction, but also evaluating and addressing the other potential risks (misuse, suicide, under utilization of opioids, and diversion). Employing a chronic disease management model that

includes risk stratification, intervention, and monitoring within a PCMH allows the clinician an opportunity for early detection of potential complicating conditions and corrective action.

INTRODUCTION

Insomnia has been diagnosed in prior literature using either the *International Classification of Sleep Disorders*, second edition (ICSD-2), or the *Diagnostic and Statistical Manual for Psychiatric Disorders*, version IV, third revision (DSM-IV-TR). The ICSD-2 criteria for insomnia includes a complaint of difficulty in initiating sleep, maintaining sleep or waking up too early, or sleep that is nonrestorative or poor in quality. This sleep difficulty occurs despite adequate opportunity and circumstances for sleep. In addition to the above, at least one or more complaints of daytime impairment are required, including fatigue or malaise, attention, memory or concentration problems, social or vocational dysfunction, mood disturbance or irritability, daytime sleepiness, poor motivation or energy, proneness for errors or accidents at work or while driving, tension, headache or gastrointestinal symptoms, and concerns or worries about sleep. These insomnia symptoms in substance

use disorders (SUDs) must be present for at least 1 month, with abuse or dependence on a drug that is known to alter sleep during intoxication or withdrawal. Further, this insomnia is not better explained by another sleep disorder, medical or neurological disorder, or mental disorder.

The DSM-IV includes a similar criteria for insomnia associated with an SUD. The sleep-related complaints include a difficulty initiating or maintaining sleep, or nonrestorative sleep. These insomnia symptoms may last for a month or more in duration and sufficiently severe to warrant independent clinical attention and is not better accounted for by a sleep disorder that is not substance induced. In addition, the disturbance should not occur exclusively during the course of a delirium, and there is evidence from clinical data that either these symptoms developed during or within a month of substance intoxication or withdrawal. In addition, the consequence of this sleep disturbance is clinically significant distress or impairment in social, occupational, or

other important areas of functioning. Despite the differing classification systems, the common elements include symptoms associated with difficulty with sleep at night, and/or the presence of unsatisfactory sleep quality, with associated impairment in functioning. Insomnia lasting more than a month has previously been termed as chronic insomnia.

The evaluation and treatment of the insomnia in SUDs are important from a treatment perspective for multiple reasons. First, insomnia in recovering alcohol-dependent patients may be associated with relapse back to alcohol use. Second, the presence of insomnia in alcohol-dependent patients may be an indication of an underlying comorbid and untreated psychiatric disorder, for example, a major depressive disorder that may impede the recovery process. Third, the insomnia symptoms may conversely mimic symptoms of depressive and anxiety disorders leading to an overdiagnosis and treatment of mood and anxiety disorders. Fourth, the presence of sleep continuity disturbance during recovery, especially in middle-aged patients with multiple medical comorbidities such as obesity and hypertension, should trigger an evaluation for underlying intrinsic sleep disorder like obstructive sleep apnea syndrome.

Insomnia is usually assessed with the use of subjective rating scales or objectively using an actigraph, or rarely using an in-laboratory polysomnogram. An actigraph is a wrist or ankle device that measures sleep indirectly, in the participant's domestic setting, based on the absence or presence of body movements during certain times of the day, in conjunction with the use of sleep logs. In addition to assessing for the presence of insomnia at home, the actigraph may be helpful to assess for sleep disorders involving a circadian mismatch, which may include sleep problems associated with going to bed too late or too early. Some of the subjective scales that have been used to assess for insomnia include the Pittsburgh Sleep Quality Index and the Insomnia Severity Index. An overnight polysomnogram, although a gold standard for the assessment of insomnia in research studies, is clinically useful only for evaluation of certain intrinsic sleep disorders such as obstructive sleep apnea syndrome and for research purposes.

The medications approved by the Food and Drug Administration (FDA) for insomnia include benzodiazepines, the newer non-benzodiazepine Gamma-amino butyric acid (GABA) receptor agonists, the melatonin receptor agonist ramelteon, and the histamine receptor antagonist doxepin. The medications in the benzodiazepine class include temazepam, triazolam, and flurazepam; those in the non-benzodiazepine GABA-receptor agonist class include zolpidem, zaleplon, and eszopiclone.

Despite the presence of multiple medications for the treatment of insomnia, there are some inherent problems associated with treatment of insomnia in those with SUDs. First, there may exist hesitancy on the part of many healthcare providers to provide medications for insomnia in sobriety. In a survey of 311 addiction medicine practitioners, Friedmann and colleagues found that 64% of the practitioners recommended medications to patients complaining of insomnia during recovery from alcohol abuse or dependence. Second, the use of benzodiazepine, as well as the non-benzodiazepine GABA-receptor agonists is usually avoided for the treatment of insomnia in addictive disorders. This practice is commonly used because of the concern over the risk of initiating dependence to these medications in these patients, a concept that needs further research. Thus, the interventions evaluated in prior research have included the use of other sedating and non-addictive psychotropic medications, melatonin, and light therapy. It is important to keep in mind that although some of these prescribed medications may be helpful for the insomnia, most of them have been prescribed on an "off-label" basis, that is, they are not approved by the FDA for this specific indication.

Behavioral therapies for insomnia are a current standard of care for chronic or psychophysiologic insomnia, as well as for insomnias comorbid with other disorders. Although these interventions may be ideally suited for insomnia comorbid with SUDs, unfortunately they have been inadequately investigated. With these considerations in mind, we will review the treatments for insomnia in the specific substance use categories.

METHODS

We reviewed the databases, Pubmed and ISI – Web of Science, for previous literature on treatment interventions involving insomnia in substance-abusing patients. Pubmed was chosen as a database, because of its extensive repository of literature. The ISI – Web of Science database was additionally selected because of its extensive indexing of pharmacologic literature.

The search criteria on Pubmed for the individual drugs consisted of the following: alcohol or alcoholism AND "sleep initiation or sleep maintenance disorder" (for alcohol abuse or alcohol dependence); cocaine and "sleep initiation or sleep maintenance disorder" (cocaine) or "cocaine" AND "Sleep"; "amphetamine related disorders" AND "sleep" (for amphetamines); "opiate related disorders" AND ("sleep" OR "sleep initiation or maintenance disorder") (for opiates); ("cannabis" OR "marijuana") AND "sleep", as well as, "marijuana abuse" AND "sleep initiation and maintenance disorders" AND "therapeutics" (for cannabis);

“treatment” AND “nicotine” AND “insomnia,”(nicotine); “lysergic acid dethylamide” AND “sleep” (for LSD); (“central nervous system depressants”) OR (“hypnotics and sedatives”) AND “abuse” AND “sleep initiation and maintenance disorder” (for sedative or hypnotic medications). The search criteria on the ISI web of science was similar, with the search pattern being treatment*insomnia*drug (ISI), where the drug was each individual category of drug, as mentioned above. All the studies were restricted to adult human subjects, for all the years existing in the database, and excluding animal studies.

RESULTS

Insomnia Associated with Alcohol Dependence

Insomnia has been associated with chronic alcohol dependence in one past epidemiological study. Active drinking in alcohol-dependent patients has been shown in prior studies to prolong sleep onset latency (SOL), decrease the total sleep time, and produce changes in the sleep architecture including a decreased rapid eye movement (REM) sleep duration. During withdrawal from alcohol after prolonged heavy use, there is a further increase in the SOL, with a decreased latency to onset of REM sleep. Delirium Tremens is an extreme form of alcohol withdrawal characterized by agitation, hallucinations, and arousal of the sympathetic system. Sleep disturbance during Delirium Tremens may consist of an increase in stage 1 sleep (light sleep), along with abnormalities of REM sleep. This acute withdrawal phase may last until 3 weeks, and with continued sobriety the patient enters abstinence. During abstinence, the prevalence of insomnia may range from 25 to 72% of the recovering patients and may persist for up to 3 years. This insomnia manifest with subjective complaints and polysomnographic abnormalities of an increase in the SOL, a decrease in the sleep efficiency, REM sleep abnormalities, and a decrease in the slow wave sleep duration.

The underlying biochemical abnormalities associated with prolonged alcohol use and withdrawal may cause or aggravate the insomnia symptoms, although this mechanism is incompletely investigated in humans. Alcohol modulates the excitatory and inhibitory neurochemical systems in the brain. Prolonged alcohol use is associated with an upregulation of the inhibitory GABA neurotransmitter system, and a compensatory downregulation of the excitatory glutamate (NMDA) neurotransmitter system. On cessation of heavy and/or regular alcohol use, alcohol withdrawal symptoms may be precipitated which may be associated with the unopposed activity of the excitatory glutamatergic

system. Medications in the benzodiazepine class are GABA mimetic, including lorazepam and are commonly used to treat alcohol withdrawal. These medications decrease the alcohol withdrawal symptoms and have been shown to improve sleep in some studies.

A range of interventions have been evaluated for the treatment of insomnia in these patients. Please see Table 55.1 for the list of medications that have been evaluated for the treatment of insomnia in this population. Most of these medications have harnessed a common associated adverse effect, i.e. sedation, to treat the insomnia. We will attempt to evaluate these interventions in more detail below.

Pharmacologic Interventions

1. *Anticonvulsant Medications:* Medications in this class are prescribed for multiple indications including seizures, pain, and headaches. Gabapentin and carbamazepine have been the most investigated medications in this class. Gabapentin is a medication prescribed for seizures and in certain pain

TABLE 55.1 Therapies Investigated in the Treatment of Insomnia in Alcohol Dependence

Therapies investigated
1. <i>Pharmacologic treatments</i>
A. Antidepressant medications
Trazodone
B. Mood stabilizer/anticonvulsant medications
Gabapentin
Carbamazepine
C. Antipsychotic medications
Quetiapine
D. Immunomodulator medications

E. Benzodiazepine medications
Triazolam
F. Other medications or compounds
Melatonin
L-Tryptophan
Acamprosate
Magnesium
Chlomechiazole
2. <i>Non-pharmacologic treatments</i>
Cognitive behavioral therapy for insomnia
Bright light

syndromes. This medication has been investigated during alcohol withdrawal and during sobriety, using a dose range of up to 1500 mg day⁻¹. Brower and colleagues evaluated the efficacy of gabapentin on insomnia in alcohol-dependent participants using a randomized placebo-controlled trial. Subjective and objective sleep improved in both the groups over the 6-week treatment duration. However, gabapentin, in comparison to placebo, over the 6-week treatment duration was associated with delayed onset of relapse to heavy drinking (Relative Risk = 0.25, $p = 0.04$). In another study, the relative efficacy of gabapentin and lorazepam on subjective sleep was assessed during a 12-day period, consisting of an initial 4-day treatment for alcohol withdrawal with either gabapentin or lorazepam, and a 8-day follow-up period subsequently. Then results did not show any difference in the efficacy between gabapentin and lorazepam during the treatment phase. However, in patients with a history of multiple previous detoxifications (≥ 2 detoxifications), gabapentin was more efficacious than lorazepam in improving the insomnia during and after the treatment phase. In another study involving patients in alcohol withdrawal, the same investigators evaluated the effects of carbamazepine and lorazepam for symptoms of mood, anxiety, and sleep quality. Results were significant for an improvement in the sleep quality and anxiety in the carbamazepine-treated patients (as compared to lorazepam-treated patients).

2. Antidepressant Medications: Trazodone, a serotonin reuptake inhibitor with H₁ antihistaminic and α_1 adrenergic antagonistic properties, is commonly prescribed on an "off-label" basis for insomnia associated with alcohol dependence in recovery. Friedmann and colleagues have shown that this medication is the hypnotic of choice in the majority (37.6%) of the addiction treatment providers for recovering alcoholic patients. The initial starting dose (mean \pm S.D.) for the providers in this study was 61.1 \pm 28.1 mg, and the duration of treatment (mean \pm S.D.) was 47.8 \pm 36.4 days. The efficacy of trazodone has been evaluated in two randomized placebo-controlled studies. In the first study conducted by Le Bon and colleagues, recently detoxified alcohol-dependent participants were assessed for objective sleep after 4 weeks of treatment. Trazodone as comparison to placebo, improved the continuity of sleep through the night, with a decrease in the wake time after sleep onset. In a larger study of alcohol-dependent patients with insomnia during the post-detoxification phase, the effect of trazodone on sleep was evaluated over 12 weeks, with a follow-up in 12 weeks after discontinuing the study medication.

Trazodone ($N = 88$), as compared to placebo ($N = 85$), improved the sleep quality at the 1-month and the 3-month follow-up assessments, with a moderate effect size between baseline and 1-month follow-up (Effect Size, Cohen's $d = -0.50$), and a large effect size between baseline and 3-month follow-up (Effect Size, Cohen's $d = -0.93$). However, no difference was seen in the sleep quality between the trazodone and placebo after stopping the medications for 12 weeks. Interestingly, trazodone treatment (as compared to placebo) was associated with a relatively lesser improvement in the proportion of days abstinent during the treatment phase, and an increase in the number of drinks per drinking day, during follow-up after completion of the treatment phase.

3. Neuroleptic Medications: These medications are primarily used to treat psychotic symptoms associated with schizophrenia or for psychiatric stabilization during a manic or a mixed episode associated with bipolar disorder. Among these medications, Quetiapine has shown the most promise for the treatment of insomnia. Quetiapine is a second-generation antipsychotic medication and an antagonist at the Dopamine (D₁), serotonin (5-HT₂), histamine (H₁), and alpha-adrenergic (α_1) receptors. This medication has shown some benefit in the improvement of sleep, mood, and craving for alcohol during acute residential rehabilitation addiction treatment in a case series conducted by Sattar and colleagues. In a retrospective study of data in alcohol-dependent Veterans in outpatient treatment, Monnelly and colleagues evaluated the effect on alcohol-related variables for patients prescribed quetiapine for improving sleep quality. Their results showed that quetiapine-treated Veterans (as compared to other medications) showed a higher number of days abstinent from alcohol, a lower number of hospitalizations, and with a trend toward significance for a higher number of days to relapse.

4. Benzodiazepine Medications: These medications are usually avoided in this population, with the exception of detoxification from alcohol use. In an open label study, the effectiveness of triazolam in treating insomnia was evaluated in 12 alcoholic patients after 5–15 days from their last drink, and with a median dose of 0.75 mg at bedtime. Subjective sleep with triazolam treatment (as compared to their baseline values) showed the following findings: an increase in the sleep depth and sleep duration and a decrease in the number of awakenings and anxiety levels. The most common adverse effect on the triazolam was grogginess and disorientation to time.

5. Etanercept: Prior studies have shown the presence of REM sleep abnormalities including, an earlier

onset, and architectural abnormalities during recovery and an increase in levels of acute inflammatory markers such as tumor necrosis factor-alpha (TNF- α). Etanercept, a protein that binds and inactivates the TNF- α in circulation, is FDA approved for the treatment of rheumatoid arthritis. Irwin and colleagues conducted a randomized, double-blind, placebo-controlled, crossover trial of 18 recovering alcohol-dependent participants. Results from this study showed that a single Etanercept dose (in comparison to placebo) was associated with a decreased amount of REM sleep; further, the percentage of REM sleep was inversely correlated with the circulating level of circulating levels of soluble TNF receptor II. The clinical consequence of this finding is currently unknown.

6. *Acamprosate*: Alcohol withdrawal symptoms may occur on cessation of prolonged alcohol use. These symptoms may be associated with unopposed activity of the excitatory glutamatergic system. Acamprosate, one of the FDA approved medications for the treatment of alcohol dependence, is a modulator of the glutamatergic system. In a randomized, placebo-controlled trial, Staner and colleagues investigated the effects of acamprosate on objective sleep during the immediate phase of alcohol withdrawal. Treatment with acamprosate (as compared to placebo) was associated with a decreased wake time after sleep onset, a higher amount of slow wave sleep, and an increase in the latency to REM sleep. However, there was no interaction between treatment groups and time.

7. *Melatonin and Its Analogs*: Melatonin is secreted from the pineal gland and has been used exogenously as a chronobiotic agent with minimal hypnotic properties. During alcohol withdrawal and early abstinence, decreased levels of the following indices have been seen: blood level of melatonin; a delay in the rise of the melatonin level; the peak level of melatonin in the blood at night. These findings may translate into a weaker drive to fall asleep and a tendency to fall asleep later in the night. Melatonin is freely available as a health food supplement over the counter in stores across the United States. There are no studies, to the best of our knowledge, which have evaluated the role of melatonin on sleep in the recovering alcohol-dependent patients. Ramelteon, a selective agonist at the Melatonin 1, and 2 receptors, is currently FDA approved for the treatment of insomnia. Brower and colleagues conducted a recent case series of five alcohol-dependent patients with insomnia during recovery, treated with ramelteon for 4 weeks, at a dose of 8 mg at nighttime. Results showed that ramelteon treatment was associated with an

improvement in the total sleep time and a decreased latency to falling asleep.

8. *Magnesium*: Magnesium is an ion that is involved in multiple integral functions in the body. In an open-label trial, Hornyak and colleagues treated 11 patients in subacute alcohol withdrawal with 30 mmol of magnesium daily for 4 weeks. Results showed that magnesium treatment was associated with a decrease in objective SOL, and an improvement in the sleep quality. A subset of 7 out of the 11 participants reported an improvement in their periodic limb movement index (PLMI) during sleep, while the other subset of 4 participants had an increase in their PLMI. Future studies will need to clarify the role of magnesium in sleep, if there is one.

9. *Clomethiazole*: This medication with hypnotic properties is commonly used in some European countries for the treatment of alcohol withdrawal symptoms. There is minimal data on clomethiazole's effectiveness in improving sleep in alcohol dependence. Further, clomethiazole has a narrow therapeutic index and thus may be fatal in an overdose.

Non-Pharmacologic Interventions

1. *Cognitive Behavioral Therapy for insomnia (CBTi)*: This treatment brings together multiple non-pharmacologic interventions for insomnia. According to Perlis and colleagues, the first line treatments are stimulus control therapy (SCT) and sleep restriction therapy (SRT), and education on sleep hygiene (SH) as an adjunctive treatment. The second line interventions include cognitive therapy and relaxation training. SCT attempts to strengthen the association between bedroom or the bed and sleep, a relationship that is problematic in patients with insomnia. This intervention can be implemented by using the bed for sleep or for sex, and discontinuing other non-sleep-related behaviors in bed or the bedroom. SRT attempts to initially contract the time in bed to the actual duration spent asleep in the bed at night, thereby reducing the time spent lying in bed awake. The sleep time is then gradually increased to levels optimal for the patient. The SH techniques include avoiding nicotine and caffeine prior to bedtime, and turning the clock away from line of vision. The *cognitive therapy* component consists of targeting the negative or dysfunctional thoughts and beliefs that lead to an increase in arousal around bedtime and thus interfere with sleep. *Relaxation techniques* are useful in patients with a high level of somatic arousal/anxiety at bedtime. They may include interventions such as diaphragmatic breathing and progressive muscle relaxation.

Behavioral therapy including CBTi with modifications for alcohol-dependent patients has been shown to be efficacious and is the recommended intervention for patients, whenever possible.

2. *Bright Light Therapy*: Another non-pharmacologic approach to the treatment of insomnia involves the use of this modality. Bright light therapy has primarily been used in the treatment of Seasonal Affective Disorders, as well as Circadian Rhythm Sleep Disorders. This non-pharmacologic treatment may improve sleep during withdrawal or initial phase of recovery, by improving the sleep quality and sleep architecture, and decreasing the SOL, as shown by Schmitz and colleagues. Further investigations including those comparing it to inactive interventions as well as studies with a larger sample size are needed to clarify the role of this intervention (Table 55.2).

Insomnia Associated with Cocaine Dependence

The emerging picture of sleep disturbance in cocaine dependence and withdrawal appears to be unique. Sleep disturbance investigated prospectively for 3 weeks of abstinence is significant for a mismatch between subjective and objective sleep measures. In one of the more comprehensive investigations involving a 23-day inpatient study, Morgan and colleagues investigated

sleep disturbance and its relationship with abstinence and cocaine binge sessions, using subjective and objective measures. Sleep evaluated between 14 and 17 days, showed a mismatch between subjective and objective measures. Specifically, participants rated their subjective sleep as the best, whereas the objective electrophysiological sleep measures were at their worst during this period. In addition, vigilance tests were seen to correlate positively with the electrophysiological sleep measures, and negatively with the subjective measures. They used the term “occult” insomnia for this phenomenon.

Modafinil is a wake-promoting medication, with a mechanism of action currently unknown, and is approved by the FDA for treatment of sleepiness associated with adequately treated obstructive sleep apnea, narcolepsy, and in shift work disorder. Modafinil has also been shown to be efficacious in promoting abstinence from use in cocaine dependence. In a recent placebo-controlled trial for 16 days, Morgan and colleagues evaluated the effect of modafinil treatment on subjective and objective sleep in cocaine-dependent participants. Modafinil (as compared to placebo) was associated over time with improved total sleep time, and stage 3 sleep at night. Subjective sleepiness was decreased in the morning and afternoon during the second and third weeks of the study.

In another human laboratory study, the differential efficacy between lorazepam and tiagabine (as compared to placebo) in improving sleep and sleep-related cognitive functioning was assessed. Tiagabine is an anticonvulsant medication with hypnotic properties, with possible mechanism of action through GABA reuptake inhibition into the presynaptic neurons. Lorazepam and Tiagabine were both helpful in improving sleep latency and sleep efficiency, although there were differences. In comparison to placebo, lorazepam use was associated with an increase in stages 1 and 2 of sleep, a suppression of slow wave sleep, a decreased sleep-dependent learning and increased impulsivity, as compared to Tiagabine; however, Tiagabine improved slow wave sleep.

TABLE 55.2 Medications Investigated for Insomnia with Use of Drugs Other Than Alcohol

Medications investigated
A. Cocaine
Modafinil
Lorazepam
Tiagabine
B. Other stimulants
Mirtazapine
Modafinil
C. Opiates
Quetiapine
Amitriptyline
Lorazepam
Buprenorphine
D. Cannabis
Mirtazapine
E. Nicotine
None

Insomnia Associated with Use of Other Stimulants

The insomnia associated with methamphetamine use or withdrawal has been minimally investigated. Medication interventions evaluated during methamphetamine withdrawal have included mirtazapine and modafinil. Mirtazapine is an antidepressant with hypnotic properties, which causes a central presynaptic α_2 -adrenergic receptor blockade, leading to a downstream increase in serotonin and norepinephrine. Modafinil on the other hand is a wake-promoting medication

prescribed for sleepiness associated with multiple intrinsic sleep disorders.

In a study conducted by McGregor and colleagues, treatment of methamphetamine withdrawal with modafinil ($N = 14$), in comparison to mirtazapine ($N = 13$) was associated with relatively lower sleep-related disturbances, and a lower severity of methamphetamine withdrawal symptoms.

Insomnia Associated with the Use of Opiates

A limited number of studies have investigated the sleep disturbance associated with the use of opiates, including use during methadone maintenance. In a double-blind crossover trial of 42 healthy adults, Dimsdale and colleagues evaluated the effect of sustained-release morphine and methadone on sleep architecture. Results showed that both the medications (as compared to placebo) were associated with an increase in stage 2 sleep, a decrease in slow wave sleep, and without any change in overall sleep efficiency. There was no difference between the two opiate medications.

Sleep disturbance is a common complaint in treatment-seeking opiate-dependent patients reporting to the clinic for addiction treatment. Sleep-related complaints that may occur during opiate withdrawal include a difficulty falling asleep, an inadequate sleep quality, or sleep quantity. In a human laboratory study evaluating the sleep in recently sober opiate-dependent patients, methadone treatment was associated with an increase in the deeper stages of sleep, a concomitant decrease in the superficial stages of sleep, and with a reversal of sleep architecture during detoxification. The sleep continued to improve over time during protracted abstinence. Predictors of sleep disturbance in patients maintained on methadone as seen in prior studies have included the following variables: benzodiazepine abuse, nicotine dependence, presence of psychiatric disorder, and bodily pain. Interestingly, 62% of the treatment-seeking opiate-dependent patients reported self-medicating themselves for their sleep disturbance in another study.

No specific treatment targeting the insomnia in opiate dependence was seen in the literature. Prior studies showed that treatment with Quetiapine or low doses of amitriptyline and lorazepam improved subjective sleep during opiate withdrawal. Wallen and colleagues have also shown that patients undergoing detoxification treatment with buprenorphine reported an improvement in their subjective sleep disturbance.

Insomnia Associated with the Use of Cannabis

The use of cannabis has been associated with an improvement in subjective sleep quality and ease of

falling asleep at lower doses, with deterioration of sleep measures at higher doses. On polysomnographic sleep studies, short-term use of cannabis has been associated with an increased slow wave sleep and a decreased REM sleep duration. Tolerance developed to the slow wave sleep effects on prolonged use over time. Changes seen in objective sleep during recent abstinence from heavy cannabis abuse may include an increase in the SOL, a decrease in the sleep efficiency, and a shorter latency to REM sleep. In one study conducted by Haney and colleagues, treatment with mirtazapine improved objective and subjective sleep measures during cannabis withdrawal, although mirtazapine use was associated with increased caloric intake.

Insomnia Associated with Nicotine Use or Withdrawal

Nicotine use or withdrawal is commonly associated with sleep-related disturbances including difficulty falling asleep, sleep fragmentation, a decreased sleep efficiency, and an increase in daytime sleepiness. Currently, no medication exists for the treatment of insomnia associated with active nicotine use or withdrawal from nicotine, to the best of our knowledge. To complicate this issue further, interventions used to treat nicotine dependence for example, nicotine replacement therapy, bupropion and varenicline may be associated with insomnia.

Recommendation for Management of Insomnia in Substance-Abusing Patients

To the best of our knowledge, no specific guidelines exist for the treatment of insomnia in the substance-abusing population. Many of the guidelines for the evaluation and treatment of chronic insomnia are applicable to the comorbid insomnia associated with the SUDs. These guidelines will be categorized into recommendations for evaluation and management.

Insomnia complaints in the substance population should prompt a thorough evaluation of the substances used, another intrinsic sleep disorder e.g. obstructive sleep apnea and circadian rhythm sleep disorders masquerading as insomnia, medical and psychiatric disorders. A sleep log or sleep diary should be used by the patient to document his/her sleep-wake patterns and naps, and the day-to-day variability in the sleep at home for at least the previous 2 weeks duration. Additional objective evaluation of the sleep-wake pattern for insomnia and circadian rhythm sleep disorders may be conducted using an actigraph. A polysomnogram is not usually recommended for the evaluation of insomnia routinely. A polysomnogram is usually

ordered to screen for an underlying intrinsic sleep disorder, e.g. breathing-related sleep disorders (obstructive or central sleep apnea), periodic limb movement disorder, or nocturnal seizures.

Inadequate sleep hygiene, which may be comorbid with insomnia in patients with addictive disorders, is best treated with behavioral therapy. Circadian rhythm sleep disorder as a comorbid disorder may present with insomnia and sleepiness and is best treated with a chronobiotic agent like melatonin, bright light therapy, or possibly behavioral intervention like chronotherapy. Breathing-related sleep disorders, including snoring and obstructive sleep apnea, which may be aggravated with the nasal congestion from the cigarette smoking, may mimic insomnia symptoms, and are best treated with weight loss, positive airway pressure therapy, and smoking cessation. Other understudied causes that may precipitate or perpetuate insomnia in this population are environmental and social factors, e.g. living in shelters, living alone, presence of high expressed emotions in the family during active use and recovery.

The aim of the insomnia treatment should be to improve the qualitative and/or quantitative sleep, along with any associated symptoms of sleep-related impairments. An initial approach for insomnia treatment should be behavioral, whenever possible. These behavioral approaches may include any one of the following: stimulus control therapy, sleep restriction therapy, relaxation therapy, or the above in any combination with cognitive therapy. The rules of good sleep hygiene should be independently recommended to all the patients presenting with insomnia. Pharmacological treatment when considered necessary should be considered for the shortest possible duration, with medications tailored to the patient's clinical profile, personal preferences and cost, or as an adjunct to behavioral treatments for the insomnia. Hypnotic agents without a known addiction potential like ramelteon may be a reasonable option. Over-the-counter medications like diphenhydramine are not recommended because of the relatively unknown efficacy. Further, the associated central anticholinergic side effect of medications like diphenhydramine, may place the patient at an increased risk of cognitive impairment. Medications in the benzodiazepine category are best avoided.

DISCUSSION

Insomnia is prevalent in the SUD population. Patients should be encouraged to remain abstinent or clean from substances of use. This insomnia may improve with sobriety or time spent remaining clean in many SUD

patients, while in others it may persist for longer periods of time, for reasons currently unknown and may be a risk factor for relapse in certain drug use disorder like alcoholism. The presence of persistent insomnia beyond the withdrawal phase and the first month of recovery may thus warrant treatment intervention. Literature exists predominantly for insomnia related to alcohol misuse, followed by cocaine, opiates, and nicotine. The complaint of sleep disturbance in opiate-dependent patients stabilized on methadone should trigger an evaluation for covert benzodiazepine use, the presence of comorbid psychiatric disorders, and an evaluation of underlying pain disorders which may interfere with sleep.

Other causes of insomnia may include inadequate sleep hygiene, circadian rhythm sleep disorders, sleep-related breathing disorder, restless leg syndrome, and periodic limb movements in sleep. This distinction is important as the treatment will differ by diagnostic category and may explain the lack of efficacy of standard hypnotic medications in certain participants.

The American Academy of Sleep Medicine (AASM) recommends an initial trial of behavioral therapy, with or without the cognitive component for chronic insomnia whenever possible. If behavioral therapy is not an option or has failed, pharmacotherapy may be attempted, tailored to the patient's individual clinical profile. However, none of the medications mentioned above have been approved by the FDA for the treatment of this comorbid insomnia and are currently used on an "open-label" basis. Most of the prior drug treatment studies for insomnia in addictive disorders have used small sample sizes or have not been replicated. In recovering alcohol-dependent patients, the most evaluated medications include gabapentin, quetiapine, and trazodone. However, the relationship of the improvement in insomnia with improvement in the alcohol use disorder is currently unknown. In cocaine-dependent patients, modafinil, a wake-promoting medication appears to have efficacy in improving sleep at night and sleepiness during the daytime; these findings may however need to be replicated. Medications in the benzodiazepine class are not recommended because of their abuse and dependence potential. The role of non-benzodiazepine class of hypnotic medications, e.g. ramelteon, zolpidem, or eszopiclone, in recovery is currently unknown. Future studies should assess in detail the other causes of insomnia mentioned above, the efficacy of cognitive behavioral therapy for insomnia in different populations of SUD, the safety and the role of non-benzodiazepine GABA-receptor agonists and ramelteon in insomnia associated with substance-abusing patients, and the role of combined behavioral and pharmacologic treatment.

List of Abbreviations

CBTi	cognitive behavioral therapy for insomnia
GABA	gamma-amino butyric acid
FDA	Food and Drug Administration
REM	rapid eye movement
SOL	sleep onset latency
SUD	substance use disorder
TNF-α	tumor necrosis factor-alpha

MEDICATION FOR CRAVING AND MOOD

Neurobiology of Cravings

Drug addiction or substance dependence is a chronic, relapsing disorder characterized by the following: (1) compulsion to seek and take the drug, (2) loss of control in limiting intake, and (3) emergence of

a negative emotional state when access to the drug is prevented. According to the United Nations International Drugs Control Programme and World Health Organization, "drug craving is a desire for the previously experienced effects of a psychoactive substance. This desire can become compelling and can increase in the presence of both internal and external cues, particularly, with perceived substance availability. It is characterized by an increased likelihood of

drug-seeking behavior or, in humans, drug-related thoughts.”

Craving is related to preoccupation/anticipation in the different stages of the addiction cycle driven by impulsivity with positive reinforcement and compulsivity with negative reinforcement and automaticity. The stages of addiction cycle include binge/intoxication, withdrawal/negative effect, preoccupation/anticipation (cravings), and transition to addiction. Craving has been difficult to measure in human clinical studies and has not always clearly correlated with relapse.

Animal models of craving can be divided into two domains. Type 1 craving is induced by stimuli that have been paired with drug self-administration, such as environmental cues. Type 1 craving is known as conditioned positive reinforcement in experimental psychology. In animal models, a cue previously paired with access to a drug can reinstate responding to a lever that previously has been extinguished. Type 2 craving occurs after a state of protracted abstinence in a drug-dependent individual. Type 2 craving is a state change characterized by dysphoria and anxiety. In animal models, this type of craving is described as residual hypersensitivity to states of stress and environmental stressors that lead to relapse and drug-seeking behavior.

It is in the extended amygdala that memories relating to drug abuse are transformed into craving to use a drug again. Chronic drug use and conditioning may bring about changes that can be detected by brain scans, and these changes might be reversible through medication and psychotherapy. The extended amygdala may link environmental stimuli to both the rewarding effects of drugs and withdrawal. Inactivation of the basolateral nucleus of the amygdala in rats disrupts the association of environmental stimuli with the rewarding effects of food, water, and sex. Neurobiological mechanisms and brain changes in the extended amygdala are likely associated with eating disorders, pathological gambling, and other behaviors driven by reward, withdrawal effects, and elements in the environment.

Animal studies suggest that drug-induced reinstatement (Type 1) is localized to the medial prefrontal cortex–nucleus accumbens–ventral pallidum circuit mediated by glutamate. For instance, craving and cues related to nicotine and cocaine can lead to activation of the prefrontal cortex and anterior cingulate gyrus per brain imaging studies. Cocaine craving is also associated with increased dopamine release in the striatum as well as opioid peptides in the anterior cingulate and frontal cortex. In a study using positron emission tomography (PET), regional cerebral blood flow (CBF) was measured in limbic and comparison brain regions of 14 detoxified male cocaine users and 6 cocaine-naïve comparison subjects during exposure to both nondrug-related and cocaine-related videos and during resting baseline

conditions. The cocaine video led cocaine users to experience craving and showed a pattern of increases in limbic (amygdala and anterior cingulate) CBF and decreases in basal ganglia CBF relative to their responses to the nondrug video. This response did not occur in the cocaine-naïve comparison subjects. These results show that limbic activation is one component of cue-induced cocaine craving (Figure 56.1).

Alcohol craving is associated with higher opioid peptide activity in the striatum but lower dopaminergic activity. According to brain imaging studies, there are baseline decreases in dopamine function (e.g. D2 receptors) and orbitofrontal function during chemical dependence; however, acute craving can lead to reactivation of dopamine function in the reward pathway. In summary, the prefrontal cortex, which includes the orbitofrontal, medial prefrontal, and prelimbic/cingulate, and the basolateral amygdala play a significant role in drug- and cue-induced craving.

Neuropharmacological and neurobiological studies using animal models for cue-induced reinstatement include the basolateral amygdala with a possible feed-forward mechanism through the prefrontal cortex system involved in drug-induced reinstatement. Neurotransmitters involved in cue-induced reinstatement are

FIGURE 56.1 PET scans reveal selective activation of brain circuits during cocaine craving. On the right, scans from volunteers who experienced cue-induced cocaine craving show activation of the dorsolateral prefrontal cortex (DL) and the amygdala (AM). When these volunteers were exposed to neutral (nondrug-related) cues, this activation was not seen. Adapted from Volkow ND, Wang GJ, Telang F, et al. (2006) Cocaine cues and dopamine in dorsal striatum: mechanism of cravings in cocaine addiction. *J Neurosci* 26: 6583–6588.

Neurochemical neurocircuits in drug reward

FIGURE 56.2 This sagittal section through a representative rodent brain shows receptors and pathways in the neurocircuitry of addiction. AC, anterior commissure; AMG, amygdala; ARC, arcuate nucleus; BNST, bed nucleus of the stria terminalis; Cer, cerebellum; C-P, caudate-putamen; DMT, dorsomedial thalamus; FC, frontal cortex; Hippo, hippocampus; IF, inferior colliculus; LC, locus coeruleus; LH, lateral hypothalamus; N. Acc., nucleus accumbens; OT, olfactory tract; PAG, periaqueductal gray; RPn, reticular pontine nucleus; SC, superior colliculus; SNr, substantia nigra pars reticulata; VP, ventral pallidum; VTA, ventral tegmental area. Koob, G.F., Volkow, N.D., 2010. *Neurocircuitry of Addiction. Neuropsychopharmacology Reviews* 35, 217–238.

characterized by glutamatergic projection from the frontal cortex to the nucleus accumbens that is modulated by dopamine activity in the frontal cortex. Cue-induced reinstatement involves dopamine modulation in the basolateral amygdala and a glutamatergic projection to the nucleus accumbens from both the basolateral amygdala and the ventral subiculum.

Stress-induced reinstatement of drug-related responses in animal models depends on the activation of both corticotropin-releasing factor (CRF) and norepinephrine in portions of the extended amygdala (central nucleus of the amygdala and the bed nucleus of the stria terminalis). Compulsive drug-seeking behavior is driven by the ventral striatal–ventral pallidal–thalamic–cortical neurocircuitry (Figure 56.2). Per alcohol dependence models, protracted abstinence involves overactive glutamatergic and CRF systems.

Due to acute and chronic neuroadaptation in the brain from addiction, craving can maintain addictive drug-seeking behaviors and lead to relapse even after a prolonged period of abstinence. Therefore, treatment that diminishes cravings (preoccupation/anticipation) of alcoholics and addicts can decrease the likelihood of relapse. In the future, neuroimaging studies may be used clinically not only to provide data on the reactivity of the neurocircuitry but also to correlate data with treatment efficacy and risk of relapse.

Future molecular targets for preoccupation/anticipation (craving) include activation of cystine–glutamate exchange (such as by *N*-acetylcysteine), which has been shown to prevent cocaine-induced escalation and behavioral sensitization as well as diminishing conditioned response to drug cues in humans.

MEDICATIONS FOR ALCOHOL CRAVING

- Disulfiram
- Naltrexone
- Acamprosate
- Combination therapy
- Emerging therapies
 - Topiramate
 - Ondansetron
 - Kudzu extracts

Alcohol dependence is a chronic relapsing disease that is treated using a combination of psychosocial and pharmacological treatments. Development of medications to treat alcoholism has focused on reducing craving and consumption of alcohol, treating withdrawal symptoms, preventing relapse, and treating associated psychiatric disorders. Animal models have provided the basic foundation of understanding alcohol-related drinking,

craving, dependence, and relapse. The alcohol-drinking behaviors are mediated through interactions of multiple neurotransmitter systems related to the reinforcing effects of alcohol. These systems affect the corticomesolimbic dopaminergic pathway, which is important in the rewarding effects of alcohol.

Disulfiram

Disulfiram is a form of aversive therapy that has been available since the 1940s. Disulfiram interferes with the metabolism of alcohol by irreversibly inhibiting aldehyde dehydrogenase, leading to the accumulation of acetaldehyde, which results in flushing, sweating, nausea, and tachycardia. Secondary mechanism of disulfiram is on the central nervous system to inhibit dopamine- β -hydroxylase from converting dopamine to norepinephrine, which potentially increases dopamine levels and may decrease cravings.

Serious adverse reactions include hepatotoxicity, optic neuritis, peripheral neuropathy, and psychotic reactions. Common side effects include metallic aftertaste, dermatitis, and transient sedation.

The efficacy of disulfiram is limited due to generally poor compliance when patients take it at their own discretion. Disulfiram is more effective when given in a monitored or witnessed setting for a highly motivated individual. Preliminary evidence shows that disulfiram may reduce alcohol cravings and increase consecutive days of abstinence among patients with alcohol dependence and comorbid psychiatric disorders.

Contraindications to disulfiram include use of alcohol-containing products or metronidazole. Relative contraindications include coronary artery disease, severe myocardial disease, and hypersensitivity to rubber (thiuram) derivatives.

Use disulfiram with caution in patients with hepatic cirrhosis or insufficiency, cerebrovascular disease or cerebral damage, psychoses (present or past), diabetes mellitus, epilepsy, hypothyroidism, and renal impairment. Disulfiram belongs to pregnancy category C. Patients must be reminded to carry a card to alert medical personnel in emergencies.

Disulfiram is available in oral daily dosing form at 250 mg daily (range 125–500 mg day⁻¹). Potential drug interactions of disulfiram include warfarin, isoniazid, phenytoin, and any nonprescription medication containing alcohol. Prior to prescribing disulfiram, the patient's liver function should be evaluated and subsequently monitored. Due to possible disulfiram–alcohol reaction, disulfiram should not be taken for at least 12 h and ideally 2 weeks after drinking alcohol. Patient needs to be instructed to avoid alcohol in the diet (vinegars and sauces), over-the-counter medications, and toiletries.

Naltrexone

Naltrexone has been shown to decrease drinking frequency and the likelihood of relapse to heavy drinking. The US Food and Drug Administration (FDA) approved naltrexone for the treatment of alcohol dependence in 1994. It is thought that the competitive antagonism of naltrexone to opioid receptors blunts the release of dopamine related to alcohol consumption, which results in decreased craving and diminishes the rewarding effects of alcohol use. According to animal models, naltrexone is thought to block the release of β -endorphins in regions related to alcohol reward.

Before and during treatment with naltrexone, liver function should be monitored. Take special precautions before starting naltrexone in patients with hepatic disease, renal impairment, and history of major depression or suicide attempts. Naltrexone is classified as pregnancy category C. In the event of emergency, patients should carry a wallet card to alert medical personnel that they are taking naltrexone. Common side effects of naltrexone include nausea, vomiting, decreased appetite, fatigue, somnolence, headache, anxiety, and dizziness.

Clinicians need to be mindful of the potential of naltrexone to precipitate withdrawal in patients with opioid dependence as well as inhibiting the effects of opioid analgesics for acute and chronic pain management. Patient should be free of opioids for 7–10 days before starting naltrexone. If there is a risk of precipitating opioid withdrawal, a naloxone challenge test can be performed.

Oral Naltrexone

Naltrexone is available in an oral 50 mg daily dosing. Alcoholics who are more greatly driven by reward craving experience increased level of stimulation while drinking alcohol and are more likely to respond to naltrexone. Variance of alleles in the μ -opioid receptor also affects the efficacy of naltrexone, such as seen in subjects of European descent on naltrexone with one or two copies of the 118G variant allele had lower rates of relapse and took longer to return to heavy drinking than those subjects who were homozygous for this allele; however, this has not been observed in all clinical trials. Alcoholics who have a family history of alcoholism seem to have a greater reduction in alcohol consumption compared those who have no known family history.

The efficacy of naltrexone has been proven in a meta-analysis of 27 randomized controlled trials (RCTs) that showed that short-term treatment with naltrexone decreased relapse (risk ratio of 0.64) with a number needed to treat (NNT) of 7.

The Combining Medications and Behavioral Interventions for Alcoholism (COMBINE) trial evaluated the

efficacy of naltrexone, acamprosate, or both, in comparison with each other and placebo, with health care provider-delivered medical management, and with or without a specialized alcohol counselor, delivered combined behavioral intervention. Patients who were treated with naltrexone plus medical management – or naltrexone, medical management, and combined behavioral intervention – had a greater percentage of days abstinent than those receiving placebo and medical management only. In addition, naltrexone reduced the risk overtime of heavy-drinking days.

However, not all clinical trials of naltrexone have seen significant improvements in drinking treatment outcomes. Per meta-analyses in 2002 and 2004, naltrexone has modest efficacy in preventing relapse to drinking. A recent multisite-clinical trial reported that a higher dose of naltrexone (100 mg day⁻¹) with medical management to increase compliance did significantly reduce alcohol use but with a small effect size.

Injectable Naltrexone

To increase compliance, a long-acting injectable naltrexone has been shown to decrease the event rate of heavy-drinking days (25% in 380 mg group versus 17% in 190 mg group). Compared with oral naltrexone, extended-release naltrexone reduces peak levels and fluctuations in plasma levels to minimize the side effects and elevates trough levels to improve efficacy. The administration of long-acting naltrexone along with psychosocial support has been associated with improvement in drinking outcome measures, especially among patients who are abstinent entering treatment.

The dosing of extended-release naltrexone is 380 mg given as a monthly intramuscular injection. It is important to monitor the muscle mass and skin of the injection site. Potential contraindications to injectable naltrexone include hemophilia and bleeding problems. There have been cases of reaction at the injection site, allergic pneumonia, and suicidal ideation with extended-release naltrexone.

Acamprosate

Acamprosate is thought to antagonize *N*-methyl-D-aspartate (NMDA) glutamate receptor sites or via modulation of glutamate neurotransmission at metabotropic-5-glutamate receptors to balance the gamma-aminobutyric acid (GABA) and glutamate neurotransmitter systems. These mechanisms of action are thought to reduce symptoms, such as insomnia, restlessness, anxiety, and depression, from protracted abstinence from alcohol. Acamprosate has been reported to reduce neuronal hyperexcitability during alcohol withdrawal. In a more recent animal clinical trial, the proposed

mechanisms of action by acamprosate on the neurotransmitter systems have not been observed in the therapeutic dose range used to decrease alcohol use. Acamprosate reduces responses to alcohol cues in alcohol-dependent animals.

Acamprosate has been shown in multiple European studies and in a meta-analysis in 2004 of 17 clinical trials to increase the proportion of dependent drinkers who maintain abstinence for several weeks to months. The results of the meta-analysis demonstrated that 36% of patients taking acamprosate were continuously abstinent at 6 months versus 23% of those patients taking placebo. However, two US clinical trials did not confirm efficacy of acamprosate. Secondary analyses in one of the trials showed possible efficacy in patients with baseline goal of abstinence. Differences between the European and US clinical trials include more severe alcohol dependence and longer period of abstinence prior to initiating acamprosate in the European studies. US clinical trials had a higher level of psychosocial interventions compared to European trials. A more recent meta-analysis of three significant European trials showed that the rates of complete abstinence as well as percent days of abstinence and time to first drink were significantly greater with acamprosate treatment.

Acamprosate is available in oral form at 666 mg three times daily dosing. Acamprosate is contraindicated in severe renal impairment with creatinine clearance less than 30 ml min⁻¹. Precautions need to be taken for patients with creatinine clearance 30–50 ml min⁻¹ (dose adjustment to 333 mg PO TID), depression, and suicidal ideation. Acamprosate is classified as pregnancy category C. There have been rare events of suicidal ideation and behavior related to acamprosate. Common side effects include diarrhea and somnolence. There are no known clinically relevant drug interactions.

Combination Therapy

The combination of naltrexone and acamprosate has been shown to be well tolerated and safe. However, the results of the combination have been mixed on whether it is superior to naltrexone alone. Some studies have shown superior efficacy; whereas, the COMBINE trial did not observe improved efficacy in combining naltrexone and acamprosate versus naltrexone alone.

Topiramate

Topiramate is an anticonvulsant that is not FDA approved for alcohol dependence but is an emerging therapy that has growing evidence to support its use for treating alcoholism. The mechanism of topiramate includes inhibition of extrasynaptic GABA_A receptors,

L-type calcium channels, voltage-dependent sodium channels; and antagonism of α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) and kainate glutamate receptors. Topiramate has been shown to reduce alcohol use in animal models.

Topiramate has been studied at doses of 200–300 mg day⁻¹ with efficacy in reducing the percentage of heavy-drinking days. In these studies, abstinence was not required prior to start of topiramate. There has also been evidence that topiramate is more effective than placebo and indistinguishable from diazepam for treatment of alcohol withdrawal.

The dosing range of topiramate is between 25 and 300 mg day⁻¹ with a target dose of ≥ 100 mg day⁻¹. Due to potential side effects, such as paresthesia, cognitive difficulty, taste distortion, and anorexia, topiramate should be titrated slowly, such as over several weeks to target dose. Less common adverse reactions include myopia, increased intraocular pressure, glaucoma, and nephrolithiasis.

Ondansetron

Ondansetron is a serotonin-3 (5-HT₃) antagonist used as an antiemetic. Preclinical trials support the off-label use of ondansetron based on evidence that 5-HT₃ receptors in the brain may affect the reinforcing effects of alcohol. Clinical trials in humans show that ondansetron reduces alcohol preference and desire to drink. Studies of ondansetron have shown decreased drinking behavior especially in the subpopulation of early onset alcoholics. Ondansetron has been studied at doses ranging from 1 to 16 $\mu\text{g kg}^{-1}$ with maximal efficacy at 4 $\mu\text{g kg}^{-1}$.

Kudzu

Kudzu is a Chinese herbal root. According to animal studies, extracts of kudzu, which contains a variety of isoflavones (e.g. puerarin, daidzein, and daidzin), have been shown to decrease alcohol consumption. In a small human naturalistic double-blind placebo-controlled trial ($n = 14$) for “heavy” alcohol drinkers (each subject served as their own control), there was a significant reduction in the number of beers consumed without a significant effect on the urge to drink alcohol for participants who received kudzu extract (puerarin) 1000 mg capsules three times daily for 1 week. There were no reported side effects of kudzu treatment.

The kudzu extract diadzein has been isolated as an aldehyde dehydrogenase 2 (ALDH-2) inhibitor, which has been shown in animal models to reduce excessive drinking. Synthetic versions of this selective ALDH-2 inhibitor are being investigated as potential medications to suppress relapse in abstinent alcoholics. More clinical trials will need to be conducted to better understand the

efficacy of kudzu extracts or synthetic variants for treatment of alcohol dependence.

MEDICATIONS FOR OPIOID CRAVING

- Opioid full/partial agonists
 - Methadone
 - Buprenorphine
- Naltrexone
- Emerging therapies

Understanding the neurobiological underpinnings of the endogenous opioid system as well as opioid addiction continues to be a rapidly evolving field in substance abuse treatment. Continued use of opioids is often reinforced through the euphoric effects (positive cravings) as well as the relief of withdrawal symptoms (negative cravings). Functional magnetic resonance imaging (fMRI) has demonstrated increased blood flow to regions of the orbitofrontal and inferior frontal cortex with projections from the mesolimbic dopaminergic system. This system in the brain is believed to play a large role in conditioning and reward processes. Single photon emission computed tomography has demonstrated decreased baseline dopamine type 2 receptors in the left caudate nucleus of opioid-dependent individuals compared to controls. Additionally, opioid-dependent individuals have higher levels of right putamen dopamine release in response to cue-exposure. This finding is significant because chronic craving and anhedonia have been positively correlated with dopamine release. Given the central role of craving in perpetuating opioid use, medications that target negative and positive cravings are commonly used.

Opioid Partial/Full Agonists

Opioid agonists have been used in the treatment of opioid addiction since the early 1960s. More recently, the partial opioid agonist buprenorphine has also gained an increased role within opioid maintenance. The main therapeutic effect of full and partial opioid agonists is relief of the physiological withdrawal symptoms associated with rapid discontinuation of opioids. These medications also serve to blunt the euphoric effects associated with illicit opioid use.

The most commonly utilized full agonist is methadone, a long-acting opioid, which acts as a high-affinity agonist at μ - and δ -opioids receptors as well as an antagonist at NMDA receptors. Methadone is rapidly and nearly completely absorbed in the intestines and accumulates in tissues throughout the body where it remains protein bound and is slowly released. It is extensively metabolized through the cytochrome P450 system before being excreted in the urine.

While general consensus supports the use of methadone as a safe and effective treatment for opioid-dependent individuals, there has been some disagreement about its effect on cravings for opioids. A review article in 2011 looking at the impact of methadone maintenance on heroin craving found 16 articles that met inclusion criteria. Among these articles, seven reported reduced opioids craving, four found continued risk of heroin craving, four found no effect on craving, and one study found that methadone could increase heroin craving.

Originally synthesized in 1974, buprenorphine acts as a partial agonist at the mu-opioid receptor and an antagonist at the k receptor. It was originally used in pain management but gained traction within addiction treatment during the 1990s. As a partial agonist at the k receptor, buprenorphine offers the advantage of a decreased risk of respiratory suppression while still controlling withdrawal symptoms. As a result of extensive first pass metabolism, buprenorphine has poor bioavailability when swallowed, but this is greatly improved when absorbed sublingually. Buprenorphine is lipophilic, highly protein bound within the serum and readily crosses the blood-brain barrier. It is primarily metabolized in the liver via the cytochrome P450 3A4 enzyme system and is eliminated in urine and feces.

In 2010, an article reviewing opioid agonist medications found six studies that looked at the relationship between subjective heroin craving and treatment with buprenorphine. While none of the studies used cue-elicited paradigms or neuroimaging, four studies found clinically significant reductions in subjective heroin craving. The remaining two studies found that low doses of buprenorphine (8 mg or less) may not be effective in craving reduction. However, these studies also found that higher doses of buprenorphine (greater than 8 mg) had a significant impact on craving reduction. This suggests that buprenorphine is effective in reducing opioid cravings at doses greater than 8 mg.

There is an excellent evidence supporting the efficacy of buprenorphine or the combination of buprenorphine and naloxone for the treatment of opioid withdrawal. Furthermore, opioid maintenance with buprenorphine is a safe and effective treatment for opioid dependence leading to rapid adoption of sublingual buprenorphine and naloxone or sublingual buprenorphine alone for the treatment of opioid dependence in real world clinical practice.

Naltrexone

Naltrexone is an opioid antagonist approved by the FDA in 1984 for the treatment of individuals with opioid addiction. It is available in oral form or as a long depot

injection and has a relatively lengthy duration of action. It has been found effective in treating specific groups of highly motivated individuals such as nurses, physicians, and prisoners in release programs, but this was believed to be independent of anti-craving effects. Traditionally, there has been little data to support the use of naltrexone in directly curbing opioid cravings. It may be due to the advantage of naltrexone over placebo stems from its use as a form of “behavioral pharmacotherapy” within an opioid abstinence program.

Recently, data for impact of naltrexone on opioid cravings have been mixed. Two studies using visual analog scales to rate subjective cravings found that naltrexone at 50 mg day⁻¹ did not reduce heroin craving. In contrast, Krupitsky et al. presented results in 2010 from a multicenter randomized double-blind placebo-controlled trial that looked at the effect of an extended-release naltrexone preparation compared to placebo in patients receiving biweekly drug counseling sessions. While it was not the primary outcome, the authors reported significant declines in subjective reporting of opioid cravings. Another study found that a very low dose of naltrexone (0.125 or 0.250 mg day⁻¹) administered during opioid withdrawal was effective in reducing subjective craving scores by 37% across days 1 through 6. Given the mixed results, further studies are needed to clarify the role of naltrexone in treating opioid cravings.

Emerging Therapies

Several other medications have been proposed for targeting craving among opioid-dependent individuals. While there is some preliminary data to support these medications, the research is still in its early phases and more data are required before they should be considered in the clinical treatment of opioid dependence.

Lofexidine is a centrally acting α -2 receptor agonist that reduces opioids cravings. The effect of lofexidine has been observed using a small (RCT) with a dosage of 2.4 mg twice daily in opioid-dependent individuals. It has been found that this agonist receptor, lofexidine, stabilized on combination with naltrexone for 4 weeks before being randomized to naltrexone plus lofexidine or naltrexone plus placebo. While the study only contained 18 individuals, it found an attenuated stress and drug cue-induced opioid craving response in the laboratory in patients who continued with lofexidine.

Given dopamine's role in the neurobiology of cravings, dopamine antagonists have been proposed as potential medications to target craving in opioid-dependent individuals. However, a study that included 17 detoxified heroin-dependent patients found that 2 mg of haloperidol daily had no effect on subjective craving.

In animals, rapamycin has been shown to inhibit the mTOR (serine-threonine kinase enzyme that controls cell growth) pathway. It has been postulated that inhibition of this pathway may interfere with synaptic plasticity and thus the memory formation and conditioning associated with heroin cue craving in addicts. Shi et al. (2009) found that a single-high dose of 5 mg rapamycin was effective in reducing the craving but not anxiety associated with drug-induced cues.

Memantine is a noncompetitive NMDA receptor antagonist used primarily in the treatment of Alzheimer's disease. In rodents, it has been shown to interfere with morphine-conditioned place preference. Studies in humans have demonstrated a slight decrease in cravings without impacting the reinforcing effects of heroin. These results were found using memantine at doses of 30 and 60 mg.

MEDICATIONS FOR STIMULANT CRAVINGS

- Modafinil
- *N*-acetylcysteine
- Stimulant Agonists
- Mecamylamine

While both cocaine and methamphetamine act by directly stimulating the ventral tegmental/nucleus accumbens reward pathway, they accomplish this in slightly different ways. Cocaine inhibits dopamine reuptake transporters resulting in increased synaptic dopamine levels. Similarly, methamphetamine inhibits dopamine reuptake but also acts on presynaptic neurons causing an increased release of dopamine. Stimulants have also been shown to impact norepinephrine, serotonin, glutamate, and GABA concentrations in the brain. While there are currently no medications with FDA approval for the management of stimulant-use disorders or cravings, trials continue to be performed on many promising agents.

Modafinil

One of the more promising medications for targeting cocaine cravings is modafinil, which has several mechanisms of action that overlap with the neurobiology of stimulant addiction. The mild stimulant properties may aid in reducing withdrawal symptoms while increased extracellular glutamate levels may serve to partially counteract glutamate depletion associated with chronic stimulant use. Additionally, modafinil decreases GABA activity and binds dopamine and norepinephrine receptors. Finally, there is some data suggesting that modafinil blocks the euphoric effects

of cocaine. Malcolm et al. conducted a small open label trial that found cravings for cocaine were significantly reduced in individuals treated with modafinil at 400 and 800 mg. Several other studies conducted in laboratory settings have also demonstrated decreased cocaine self-administration when modafinil was administered at 200 and 400 mg day⁻¹. Despite preliminary optimism, the results of initial outpatient RCTs have been mixed. A double-blind placebo-controlled trial conducted by Dackis et al. randomized participants to a single morning dose of modafinil 400 mg or matched placebo. They found a reduced percentage of cocaine positive urine drug screens but no improvement in craving, treatment retention or withdrawal.

The results are equally mixed for utilizing modafinil in the treatment of methamphetamine users. One RCT of methamphetamine-dependent HIV positive gay men found that 60% of the participants who finished the trial reduced their methamphetamine use by over 50%. Impact on cravings was not statistically significant. Conversely, another RCT looking at modafinil in methamphetamine users found no benefits over placebo among a number of measures including cravings. Given the mixed results, further RCTs are needed to evaluate the potential role of modafinil in stimulant misuse.

N-acetylcysteine

N-acetylcysteine (NAC) is a medication with preclinical trials and several pilot studies support its use in the treatment of cocaine users. NAC is believed to exert its effect by increasing extracellular glutamate by stimulating cysteine-glutamate antiporters. A double-blind crossover pilot study conducted on 15 participants looked at response to NAC 600 mg administered every 12 h or placebo during two identical 3-day hospital stays. The medication was well tolerated and resulted in a significant decrease in self-reported desire to use, decreased interest in response to cocaine slides and decreased time spent watching cocaine slides. While the results were relatively modest, they warrant further exploration with larger RCTs.

Stimulant Agonists

Several stimulant agonists have also been studied for the treatment of cravings. While some trials have shown reduced cocaine and stimulant use in individuals treated with methylphenidate or dextroamphetamine, the vast majority of these studies have either not reported impact on cravings or found no significant improvement compared to placebo. The added abuse potential associated with using agonist-like agents limits their clinical utility in the management of stimulant cravings (Table 56.1).

TABLE 56.1 Medications With Efficacy in Treatment of Cravings

	Medication	Mechanism of action	Typical adult dosage	Before prescribing	Side effects	Contraindications	Precautions	Evidence level*
Alcohol	Disulfiram	Inhibits aldehyde dehydrogenase and dopamine-β-hydroxylase	250 mg daily (range of 125–500 mg)	Evaluate liver function and warn patient to avoid alcohol in the diet, over-the-counter medications and toiletries	Common: sedation, dermatitis, metallic aftertaste. Serious: hepatotoxicity, optic neuritis, peripheral neuropathy, and psychosis	Absolute: use of alcohol-containing products or metronidazole. Relative: CAD, severe myocardial disease	Hepatic cirrhosis or insufficiency, cerebrovascular disease, psychoses, diabetes mellitus, epilepsy, hypothyroidism, and renal impairment. Pregnancy category C	Level C
	Naltrexone	Blocks opioid receptors	Start at 25 mg daily and increase to 50 mg daily after 4 days	Must be opioid-free for at least 7 days prior to initiating therapy. Consider naloxone challenge. Evaluate liver function	Common: nausea, decreased appetite, fatigue, and dizziness. Serious: precipitation of severe opioid withdrawal, hepatotoxicity	Ongoing opioid use, acute hepatitis or liver failure	Severe liver disease, renal impairment, depression. Pregnancy category C	Level A
	Injectable naltrexone	See above	380 mg injected once monthly	See above	See above. Also injection site reaction or infection, muscle and joint pain	See above. Also inadequate muscle mass	See above. Also bleeding problems	Level A
	Acamprosate	Unclear – affects glutamate and GABA neurotransmitter systems	666 mg three times per day. Reduce to 333 mg three times per day in patients with moderate renal impairment	Evaluate renal function	Common: Diarrhea, sedation. Serious: suicidal ideation	Severe renal impairment	Moderate renal impairment, depression. Pregnancy category C	Level C

(Continued)

TABLE 56.1 Medications With Efficacy in Treatment of Cravings—cont'd

	Medication	Mechanism of action	Typical adult dosage	Before prescribing	Side effects	Contraindications	Precautions	Evidence level*
Nicotine	Transdermal nicotine	Direct nicotinic-receptor agonist	Greater than 10 cigarettes per day: start 21 mg day ⁻¹ . Less than 10 cigarettes per day start 14 mg day ⁻¹ . Maintain at starting dose for 6 weeks and then titrate down, holding at each subsequent dose for 2 weeks	Evaluate for unstable angina or previous adverse reactions	Common: skin irritation, headache, heart palpitations, nausea, and insomnia	Severe arrhythmias, MI within 2 weeks, severe angina	Pregnancy category D	Level A
	Nicotine gum	Direct nicotinic-receptor agonist	Greater than 25 cigarettes per day: start 4 mg every 1–2 h. Less than 25 cigarettes per day: start 2 mg every 1–2 h. Maintain at initial dose for 6 weeks then taper down by increasing time between administration	Evaluate for unstable angina or previous adverse reactions	Common: headache, diarrhea, and nausea	Severe arrhythmias, MI within 2 weeks, severe angina	Pregnancy category unknown	Level A
	Nicotine lozenge	Direct nicotinic-receptor agonist	Greater than 25 cigarettes per day: start 4 mg every 1–2 h. Less than 25 cigarettes per day: start 2 mg every 1–2 h. Maintain at initial dose for 6 weeks then taper down by increasing time between administrations	Evaluate for unstable angina or previous adverse reactions	Common: headache, diarrhea, and nausea	Severe arrhythmias, MI within 2 weeks, severe angina	Pregnancy category unknown	Level A

Nicotine nasal spray	Direct nicotinic-receptor agonist	1–2 sprays per nostril every hour. Each spray delivers nicotine 0.5 mg. Maximum 80 sprays (40 mg day ⁻¹)	Evaluate for unstable angina or previous adverse reactions	Common: nasal irritation, rhinorrhea, headache, diarrhea, and nausea. Serious: bronchospasm	Severe arrhythmias, MI within 2 weeks, severe angina	Pregnancy category D	Level A
Nicotine inhaler	Direct nicotinic-receptor agonist	6–16 cartridges per day. Titrate to effect. Each cartridge designed to deliver nicotine 4 mg	Evaluate for unstable angina or previous adverse reactions	Common: cough, mouth/throat irritation, headache, diarrhea, and nausea. Serious: bronchospasm	Severe arrhythmias, MI within 2 weeks, severe angina	Pregnancy category D	Level A
Varenicline	Mixed agonist/antagonist at $\alpha 4\beta 2$ nicotinic acetylcholine receptors	Start 0.5 mg daily for 3 days then increase to 0.5 mg BID for 4 days then increase to 1 mg BID. If CrCl < 30, maximum dose is 0.5 mg BID. Treat for 12 weeks. May repeat treatment for an additional 12 weeks if unsuccessful.	Evaluate kidney function and psychiatric history	Common: nausea, vomiting, insomnia, headache, and vivid dreams. Serious: depression, agitation, suicidality, and Stevens–Johnson syndrome	None	History of psychiatric disorder, renal impairment. Pregnancy category C	Level A
Bupropion	Mechanism of action in smoking cessation unknown. Inhibits reuptake of norepinephrine and dopamine	Start 150 mg daily for 3 days then increase to 150 mg BID. Initiate 7 days prior to smoking cessation	Evaluate for MAOI use within 14 days, seizure disorder, bulimia or anorexia	Common: dry mouth, headache, nausea, anxiety, and insomnia. Serious: worsening depression, suicidality, psychiatric disturbance, and seizures	Seizure disorder, MAOI use within 14 days, anorexia, bulimia	Lowered seizure threshold, psychiatric disorders. Pregnancy category C	Level C

(Continued)

TABLE 56.1 Medications With Efficacy in Treatment of Cravings—cont'd

	Medication	Mechanism of action	Typical adult dosage	Before prescribing	Side effects	Contraindications	Precautions	Evidence level*
Opioid	Methadone	Full μ opioid-receptor agonist and NMDA antagonist	Schedule II controlled drug: prescriber must obtain separate registration as a narcotic treatment program. Initial dose not to exceed 30–40 mg. Titrate gradually against withdrawal symptoms. See local protocols for further guidance	Obtain baseline ECG, evaluate liver and kidney function	Common: sedation, constipation, nausea, and sweating. Serious: respiratory depression, QT prolongation, and cardiac arrhythmias	None	Reduce dose for hepatic or renal impairment. Caution in QT prolongation, pulmonary dysfunction or use of other narcotics. Pregnancy category C	Level A
	Buprenorphine	Partial agonist at the μ opioid-receptor and an antagonist at the κ receptor	Schedule III controlled drug: prescriber must meet qualification criteria and have a specific DEA number: 4–16 mg day ⁻¹ orally – see local protocols for further guidance	Make sure patient has not taken short-acting opiates for 12–24 h and methadone for greater than 48 h to avoid precipitating withdrawal	Common: sedation, constipation, nausea, sweating, and opioid withdrawal. Serious: respiratory depression, hepatotoxicity, and angioneurotic edema	None	Avoid abrupt cessation, caution with pulmonary problems or other narcotics. Pregnancy category C	Level A
	Naltrexone	Blocks opioid receptors	Start at 25 mg daily and increase to 50 mg daily after 4 days. Some evidence suggests low dose (0.125–0.250 mg day ⁻¹) is effective during withdrawal period	Must be opioid-free for at least 7 days prior to initiating therapy. Consider naloxone challenge. Evaluate liver function	Common: nausea, decreased appetite, fatigue, dizziness. Serious: precipitation of severe opioid withdrawal, hepatotoxicity	Ongoing opioid use, acute hepatitis or liver failure	Severe liver disease, renal impairment, depression. Pregnancy category C	Level B
	Injectable naltrexone	See above	380 mg injected once monthly	See above	See above. Also injection site reaction or infection, muscle and joint pain	See above. Also inadequate muscle mass	See above. Also Bleeding problems	Level B

* Evidence Level A: Systematic reviews (SRs) or large ($n > 200$) randomized controlled trials (RCTs); Evidence. Level B: Small ($n < 200$) randomized controlled trials (RCTs) or large ($n > 200$) RCTs with major methodological limitations; Evidence. Level C: Observational (cohort) studies, open label trials, case reports or small ($n < 200$) RCTs with major methodological limitations.

Note: cannabis and stimulants were not included, as data on treatment of cravings remains unclear.

Mecamylamine

Laboratory studies that demonstrated nicotine increases cue-induced cravings prompted exploration of mecamylamine, a nicotine antagonist, for the treatment of cocaine cravings. However, results of RCTs have been mixed and nicotine agonists are not currently used in the clinical management of cocaine cravings.

Emerging Therapies

Perhaps reflecting the paucity of effective pharmacologic treatments available for the treatment of stimulant-use disorders, a number of additional agents have been found to have limited or mixed benefit in treatment outcomes. At this time, none have demonstrated significant effect on cravings for stimulants.

MEDICATIONS FOR NICOTINE CRAVING

- Nicotine replacement therapy
- Combination therapy
- Varenicline
- Bupropion
- Alternative therapies

For those attempting to abstain from nicotine, relief from craving is among the most common reasons for seeking treatment from a health professional. Success in quitting can be predicted by the average intensity of cravings within the first days or weeks of abstinence. Additionally, intense acute cravings have been linked to an increased likelihood of relapse. Given the association between nicotine cravings and the odds of a successful quit attempt, pharmacologic interventions aimed at reducing cravings have received special attention in the treatment of nicotine dependence.

Nicotine Replacement Therapy

There are many forms of nicotine replacement therapy (NRT) including patches, gum, lozenges, nasal spray, and oral inhalers. These modalities have been shown to be effective and increase quit rates by 50–70% regardless of setting. While all forms of NRT work as direct nicotine agonists, different delivery systems result in variable pharmacokinetics and effects on cravings.

Transdermal nicotine patches supply a basal rate of nicotine release. They are available at doses of 7, 14, and 21 mg day⁻¹. The general recommendation is to initiate therapy with 14 mg day⁻¹ if patients are smoking less than 10 cigarettes per day and 21 mg day⁻¹

if patients are smoking 10 or more cigarettes per day. Patients are maintained on their starting dose for 6 weeks before being tapered down to each lower dose where they are maintained for 2 weeks. The most common side effects include nausea, heart palpitations, headaches, and local site irritation. While this strategy has been shown to reduce background craving, it has little effect on cue-induced craving.

The other forms of NRT result in acute peaks in serum nicotine that more closely mimic the effects of smoking. These modalities have been shown to reduce cue-induced craving and, to a lesser extent, background craving. Furthermore, the speed at which the nicotine is delivered correlates with the time to craving relief.

Combination Therapy

Combining NRTs to target background and cue-induced craving has also been studied. Combining NRTs is generally well tolerated and results in a clinically significant decrease in relapse. Schneider et al. compared four combinations of nicotine treatments: 2/4 mg gum + 15 mg patch, 2/4 mg lozenges + 15 mg patch, inhaler + 15 mg patch, and 10 + 15 mg double patch. They used the Smoker Anchored Withdrawal Grid to monitor craving and withdrawal over a 5-day period. This study in 2008 found that “urge to smoke” and “total withdrawal” scores increased from baseline in the double patch group but not in the combination groups. They also found that scores for “craving” and “miss a cigarette” did not rise in the lozenge/patch group but did in the other groups. While these results are suggestive of the efficacy of combination therapy, this study looked at short-term results and only included 27 participants. In 2008, Shah et al. conducted a large systematic review comparing therapy with patch alone to combined NRTs. They found the aggregated relative risks of abstinence using combination therapy were 1.42 (95% CI 1.21–1.67), 1.54 (1.19–2.00), and 1.58 (1.25–1.99) at 3, 6, and 12 months, respectively. The reported adverse effects were minimal. Doses varied among studies but this data supports the use of NRTs in combination.

Varenicline

Varenicline (Chantix in USA, Champix in Canada) is an orally administered agent that acts as a mixed agonist/antagonist at $\alpha 4\beta 2$ nicotinic acetylcholine receptors (nAChRs). Nicotine abstinence reduces dopamine release in the mesolimbic area of the brain resulting in withdrawal symptoms and cravings. Varenicline acts to stimulate dopamine release while simultaneously blocking nicotine receptors and has been shown to be significantly more efficacious than placebo for smoking

cessation. Gonzales et al. in 2006 conducted a double-blinded randomized control trial and found that a 26.3% greater chance of continuous abstinence from smoking after 9 weeks of treatment with varenicline at 1 mg twice per day versus placebo. As a secondary outcome, the study also found reductions in background cravings as well as withdrawal symptoms. This finding has been replicated in other studies; however, varenicline has not been shown to be effective in modulation of cue-induced cravings.

Of note, varenicline has a black box warning to monitor for serious neuropsychiatric events, such as behavior change, agitation, depression, and suicidality as well as worsening of preexisting psychiatric illness. The FDA announced in June 2011 that the use of varenicline might be associated with a small, increased risk of certain cardiovascular adverse events in patients who have cardiovascular disease. Further analyses need to be conducted to understand the full implications of this warning.

Bupropion

Several large clinical trials have demonstrated that bupropion is an effective treatment that improves the chances of successful quit attempts. Despite its efficacy in the treatment of nicotine dependence, its mechanism of action in smoking cessation remains unclear. There is some data suggesting that 300 mg day⁻¹ of bupropion might help to reduce nicotine craving and withdrawal. PET imaging has also demonstrated less metabolic activity in the anterior cingulate cortex of patients treated with bupropion relative to those who were not. However, among placebo-controlled trials, which account for the effect of abstinence, the preponderance of evidence suggests that bupropion does not impact nicotine cravings. Alternative explanations for the effectiveness of bupropion include treatment of depressed mood, irritability, difficulty in concentrating, and increased appetite.

Alternative Medications

Although not considered to be a first line agent, there is data supporting the use of clonidine in the treatment of nicotine dependence. Clonidine is believed to indirectly reduce cravings through the attenuation of withdrawal symptoms. However, its effects are dose-related and only achieve statistical significance when at least 300 mg day⁻¹ is administered. The side effects at this dose preclude common usage.

Nortriptyline also has a role in the treatment of nicotine dependence. While the exact mechanism of action for the effectiveness of nortriptyline is unknown, it does not appear to alter cravings.

MEDICATIONS FOR CANNABIS CRAVING

- Dronabinol
- Buspirone
- Divalproex
- Emerging Therapies

Marijuana (*Cannabis sativa*) is a plant whose psychoactive properties have led to widespread use throughout the world. Although it contains approximately 70 cannabinoid compounds, D⁹-tetrahydrocannabinol (D⁹-THC) acting on presynaptic cannabinoid receptors (CB₁), is thought to produce the mood alterations, feelings of euphoria and cognitive impairments associated with marijuana use. While not traditionally believed to be a substance resulting in true addiction, recent consensus has shifted. It is now known to activate the mesocortico-limbic system, a property common among all drugs of abuse. In addition, there is a well-described withdrawal syndrome associated with cessation of cannabis use. Cue-induced craving for cannabis has been studied using fMRI. This has demonstrated activation of the ventral tegmental area, thalamus, anterior cingulate, insula, and amygdala, which are the areas shown to play a central role in the neurobiology for cravings of other drugs of abuse. Despite its recent acceptance as a more traditional drug of abuse, there are currently no FDA-approved medications for the treatment of cannabis-use disorders.

Dronabinol

Dronabinol, oral D⁹-THC, acts as a direct cannabinoid receptor agonist. In human laboratory settings, doses of 60 mg day⁻¹ have been shown to modestly decrease cravings for marijuana while simultaneously easing symptoms of withdrawal. It was found to be particularly effective when combined with lofexidine, an α (2)-adrenergic receptor agonist. Lofexidine was administered at a dosage of 2.4 mg day⁻¹. While the combination was found to reduce cravings, this was a short-term study with marijuana withdrawal and relapse as the primary outcomes. Follow-up studies confirmed the effectiveness of dronabinol in outpatient settings among nontreatment-seeking individuals. However, the impact on cravings was not assessed. While these results are promising, further research is needed before dronabinol should be routinely used in the clinical management of cannabis-use disorders.

Buspirone

There is an early evidence to support the use of the anxiolytic agent buspirone in the treatment of marijuana

cravings. A 2006 open-label trial explored buspirone at flexible doses up to 60 mg day⁻¹ in 11 participants. While the study is limited by sample size and the open label design, there was a statistically significant reduction in frequency and duration of craving. There was also a 76.9% reduction in use reported by participants per the Time-Line Follow-Back method. A placebo-controlled trial of buspirone in individuals with cannabis dependence is needed before routine use is warranted.

Divalproex

Divalproex, an anticonvulsant and mood stabilizer showed preliminary promise in reducing cravings during abstinence among cannabis-dependent individuals. A study by Haney et al. (2004) looking at the effect of THC and divalproex on cannabis withdrawal found divalproex at a dosage of 1500 mg day⁻¹ reduced subjective cravings for marijuana. However, it also increased subjective reports of anxiety, irritability, and fatigue. Another blinded study using divalproex during abstinence found no significant difference from placebo. Based on these results, the use of divalproex for treatment of marijuana cravings is not indicated.

Emerging Therapies

While pharmacologic treatments for cannabis dependence are not as extensive as other substances of abuse, an increased understanding of the endocannabinoid system in the brain and recognition of the addictive nature of marijuana has resulted in a burgeoning area of research. Current preclinical studies have identified several compounds that warrant further study including the benzoflavone moiety from menthol extracts of *passiflora incarnate* Linnaeus, nicotinic $\alpha 7$ receptor antagonists and inhibitors of endocannabinoid-metabolizing enzymes. Any potential clinical use of these agents remains years away.

PET	positron emission tomography
RCTs	randomized controlled trials
5-HT ₃	serotonin-3

Glossary

Acamprosate *N*-methyl-D-aspartate (NMDA) glutamate receptor site antagonist used in the treatment of alcohol-use disorders.

Buprenorphine medication that acts as a partial agonist at the mu-opioid receptor and an antagonist at the k receptor used in the treatment of opioid-use disorders.

Bupropion antidepressant with efficacy in the treatment of nicotine dependence.

Bupirone serotonin 5-HT_{1A} receptor partial agonist.

Craving the desire for previously experienced effects of a psychoactive substance.

Disulfiram medication that inhibits aldehyde dehydrogenase leading to an aversive reaction to alcohol.

Dronabinol a direct cannabinoid receptor agonist.

Kudzu Chinese herbal root with an emerging efficacy in the treatment of alcohol-use disorders.

Lofexidine α 2-adrenergic receptor agonist.

Mecamylamine nicotine receptor antagonist.

Memantine a noncompetitive NMDA receptor antagonist.

Methadone direct opioid agonist used in the treatment of opioid dependence.

***N*-acetylcysteine (NAC)** medication believed to increase extracellular glutamate by stimulating cysteine-glutamate antiporters.

Naltrexone competitive-opioid receptor antagonist used in the treatment of alcohol- and opioid-use disorders

Ondansetron serotonin-3 (5-HT₃) antagonist with some efficacy in the treatment of alcohol-use disorders.

Rapamycin medication that inhibits mTOR, a serine-threonine kinase enzyme involved in regulation of cell growth.

Topiramate anticonvulsant used in the treatment of alcohol-use disorders.

Type 1 craving a craving induced by stimuli paired with drug administration.

Type 2 craving dysphoria and anxiety following protracted abstinence.

Varenicline mixed agonist/antagonist at α 4 β 2 nicotinic acetylcholine receptors (nAChRs).

INTRODUCTION

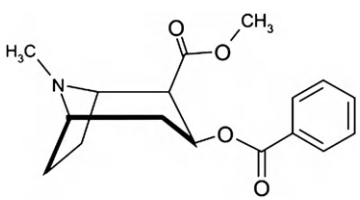

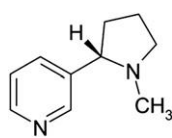

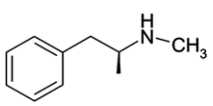

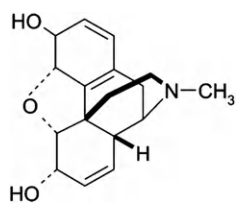

Every individual is composed of unique biological and physiological characteristics, which govern the individual's drive to eat and drink and do other things for stimulation or pleasure. The use of opium, wine and beer, coca leaves, and tobacco has been well documented in human history. In the case of morphine and cocaine, the active drug substances were extracted from plants in 1803 and 1855 respectively, and subsequently prescribed as a temporary relief for acute pain and local anesthesia. As time passed, these drugs began to be used illegally for nonmedicinal recreational purposes.

Generally, drugs of abuse can be delivered by various routes such as smoking, nasal or oral ingestion, or intravenous injection. From the peripheral blood circulation, a drug is distributed to various organs of the body and is metabolized with a specific plasma half-life (e.g. about 60–90 min for cocaine, see Table 57.1). During this period a portion of the drug also rapidly crosses the blood–brain barrier (BBB) and enters the central nervous system (CNS). Since drugs

of abuse are small lipophilic molecules (with a molecular weight <500 Da) that may have a chemical structure similar to that of neurotransmitters (such as dopamine), they bind and activate various receptors. This leads to overstimulation of neural circuits, resulting in strong signals to the brain's reward pathways that give a relaxed sensation of pleasure or escape from reality, driving some individuals to more frequent drug intake and addiction to the drug of abuse. Such substance abuse eventually boomerangs as the addict starts to suffer from the escalating socio-economic and health problems caused by the abuse. (For any further details concerning the addiction of these drugs please refer to Heroin Addiction, Cocaine Addiction, and Methamphetamine Addiction.)

Current medications, such as methadone for heroin addiction, as well as addiction treatment programs are widely available in developed countries, but they are often not sufficiently effective in reducing drug intake, even for the motivated patient who is dependent on a drug. (Further details can be referred in Methadone Maintenance, Antagonists for the Treatment of Opioid

TABLE 57.1 Summary of Chemical Structures of Common Substance Abuse

	Cocaine	Nicotine	Methamphetamine	Morphine
Structure				
Molecular weight	333	162	149	303
Bioavailability	33% oral, 60–80% smoking	20–40% Oral	63% Oral, 100% iv	25% Oral, 100% iv
Half-life (h)	1	2	9–15	2–3
Metabolism	Hepatic	Hepatic	Hepatic	Hepatic 90%
Excretion	Renal	Renal	Renal	Renal 90%, biliary 10%
Active metabolites	–	–	Amphetamine, 4-hydroxyamphetamine	Morphine-6-glucuronide
Inactive metabolites	Ecgonine, benzoylecgonine	Cotinine	–	Morphine-3-glucuronide
Binding receptor	Dopamine transporter	Acetylcholine	NMDA	Opioid
Clinical status of vaccines	Phase I, Phase IIa, Phase IIb completed	Phase I, Phase II, Phase IIb	Preclinical	Preclinical

Dependence, Buprenorphine for Opioid Dependence, Medications to Treat Addictions: Nicotine Replacement, Non-nicotine Medications, Pharmacotherapy of Cocaine Dependence, Agonist-Like (Substitution) Treatment for Cocaine and Other Stimulant Dependence, Medication Development for Amphetamine Dependence) In addition, the pharmacological antagonists used against drugs of abuse may enter the CNS and create unwanted side effects. Recent vaccine strategies for specific drugs can produce either active antibodies directly in humans or monoclonal antibodies through cell cultures, which are then passively administered to humans. These specific antibodies in the peripheral circulation can sequester an abused drug in the bloodstream and reduce its entry to the brain. Antibodies are large molecules that cannot cross the BBB unless there is inflammation or the presence of a specific binding receptor at the BBB to deliver the antibody by receptor-mediated transcytosis. Therefore, immunotherapy has been proposed as a safe and viable approach for treating addictive disorders. Though passive administration of humanized or chimeric monoclonal antibodies against such drugs could be used, patients would need frequent injections to maintain a sufficiently high concentration of antibodies in the peripheral circulation to sequester the drug. In

addition, this treatment strategy would involve some risk of developing an immune response to the administered antibody, as well as being cost-prohibitive for delivery of monoclonal antibodies at sufficiently high concentrations. Improved vaccination therapy has the potential to be a promising and cheaper alternative to address many of the treatment problems for drug addicts.

VACCINE CONSTRUCTION

An initial and repeated systemic exposure to foreign antigens will usually result in the adaptive immune system detecting and clearing them away. However, addictive drugs are too small to provoke any immune response. The goal of antidrug vaccines is to stimulate the immune system to produce antibodies that recognize only the specific drug or selected metabolites and to create enough high-affinity circulating antibodies to bind and thereby prevent drug entry into the brain. The optimal development of a vaccine construct involves the covalent linkage of a representative drug of abuse (the hapten) through a spacer (linker) arm to a suitable high molecular weight immunogenic carrier molecule (see Fig. 57.1). Generally, nonhuman proteins

FIGURE 57.1 Preparation of immunogens by covalently coupling a hapten with an immunogenic carrier molecule.

such as bovine serum albumin (BSA), ovalbumin, or Keyhole Limpet Hemocyanin (KLH) have been initially used as immunogenic carrier proteins in small animals. For human vaccines, proteins such as cholera toxin B and tetanus toxoid, which are approved by the FDA, have been used.

There are many linkers available, but drugs of abuse are generally small with few functional groups (see Table 57.1), thereby limiting the options. Ideally, the attachment of a linker to a hapten should allow retention of the stereochemical and electrostatic properties of the drug molecule. When a successful hapten-protein construct is made, the immunogen is injected after being mixed with an adjuvant such as alum. It is expected that the covalently linked drug will be taken up by antigen presenting cells for display to B cells and T-helper cells, so as to activate the humoral response and produce high levels of specific antidrug antibody.

ANTIBODY THEORY AND EXPECTATIONS

When a conjugate vaccine elicits an immune response, the immune system produces polyclonal antibodies against the hapten molecules. Antibodies will also be elicited against epitopes from the carrier protein, and sometimes against the linker, which will not contribute to the antidrug effects of the vaccine. Immunoglobulins (Ig) M and G are the two common antibody isotypes produced during the typical systemic polyclonal response. Initially, the immune system produces large 900 kDa pentameric IgM molecules with 10 antigen-binding sites, but subsequently, IgG antibodies dominate the response. The 150 kDa IgG protein is a Y-shaped molecule having two light and two heavy chain components giving two antigen-binding sites on the two arms of the Y structure. To understand the quantitative and qualitative properties of antibodies against haptens, a simple 1:1 binding equation can be written as shown below, treating the human body as one closed

compartment where $[Ab]_{\text{free}}$ and $[D]_{\text{free}}$ correspond to the concentration of the specific antibody-binding sites and the concentration of abused drug present in the serum (excluding the distribution to various organs for simplicity). Both entities have their own input and elimination half-life.

$$[Ab]_{\text{free}} + [D]_{\text{free}} \xrightleftharpoons[k_d]{k_a} [Ab - D]_{\text{bound}} \quad \text{Eq. 1}$$

A differential equation can be written for the association and dissociation of the complex $[Ab - D]_{\text{bound}}$ where k_a and k_d are the association and dissociation rate constants, respectively.

$$\frac{d[Ab - D]_{\text{bound}}}{dt} = k_a [Ab]_{\text{free}} \times [D]_{\text{free}} \quad \text{Eq. 2}$$

$$\frac{d[Ab - D]_{\text{bound}}}{dt} = k_d [Ab - D]_{\text{bound}} \quad \text{Eq. 3}$$

$$\text{Affinity} : K_D = \frac{k_d}{k_a}$$

To block the pharmacological effects of the drug, the vaccine needs to stimulate the production of drug-specific antibodies at a higher concentration $[Ab]_{\text{free}}$ than the drug-intake antibodies $[D]_{\text{free}}$. The drug plasma concentrations ($[D]_{\text{free}}$) vary based on the dose amount, dose frequency, route of administration, and pharmacokinetic elimination profile. Most abused drugs show pharmacological activities in the range of 0.5 μM plasma concentration, which is equivalent to 0.25 μM of specific IgG antibody (two binding sites per molecule that interact independently with a small molecular weight drug), or $\sim 37.5 \mu\text{g ml}^{-1}$ of IgG. This is substantially higher than the amount of antibody elicited by ordinary vaccines against various microbiological pathogens and toxins such as influenza and tetanus. For example, only $\sim 1\text{--}2 \mu\text{g ml}^{-1}$ of specific antibody is sufficient to prevent tetany.

Besides large quantities of specific antibody, a fast rate of complex formation (k_a) is required to capture

the drug in peripheral blood circulation before it can enter into the brain. The often misunderstood dissociation constant (K_D) is an equilibrium, time independent dissociation constant equaling the ratio of the rate constants expressed as $k_d/k_a [M]$, and higher antibody affinity means lower values ranging from 10^{-6} to 10^{-12} M. Since the dissociation constant (K_D) is indirectly proportional to k_a , it is expected that an optimal antibody has a strong ability to bind to the drug rapidly (high k_a), and to hold the drug firmly for a long time (low k_d). With the understanding of these qualitative properties of antibodies coupled with the quantitative information from a variety of species, such as $[Ab]_{free}$, $[D]_{free}$, $[Ab-D]_{bound}$ that can occur when the drug enters a body, it is possible to derive a mathematical model to determine the antibody response goal for vaccines to treat drug abuse. Though such thorough studies with polyclonal antibodies have not yet been performed to our knowledge, we have performed some simulations to understand how much antibody needs to be produced to achieve different levels of drug binding. Based on this about $20\text{--}40 \mu\text{g ml}^{-1}$ high affinity antibody is required to bind 50–90% of $0.5 \mu\text{M}$ drug.

The rationale of developing vaccines for abused drugs has been understood for a long time, but only recently has the field made some significant progress toward transferring the use of this concept from the bench to the patients. The rest of this article will focus on reviewing the vaccine development and clinical status of some of the common drugs of abuse such as morphine, methamphetamine, cocaine, and nicotine.

MORPHINE AND HEROIN

Morphine is a narcotic alkaloid drug isolated from the opium poppy, which led morphine and similar drugs to be known as opioids. Traditionally, morphine has been widely used as an analgesic to relieve acute pain and induce deep sleep, but its overconsumption can lead to addiction. Morphine can be synthetically diacetylated to form heroin, which is a similar but more potent drug due to its rapid uptake by the CNS. Both heroin and morphine are regulated in the United States as Schedules I and II controlled substances,

respectively. Heroin, being more lipophilic, is rapidly absorbed into different organs, and it has a higher permeability into the CNS than morphine. These drugs bind to several opioid receptors and alter the synaptic levels of dopamine neurotransmitters. Morphine is metabolized into morphine-3-glucuronide or morphine-6-glucuronide by glucuronosyltransferase and the 6-metabolite still retains the narcotic activity of the parent morphine. The first antidrug vaccine was developed in the early 1970s against morphine. The preferred site for covalent modification of morphine turned out to be the 6-hydroxyl group. The 6-succinyl-morphine conjugate vaccines produced antibodies that recognized both heroin and morphine, as heroin is rapidly hydrolyzed in circulation and in the CNS to the active 6-acetyl form as well as to morphine itself. Rabbits and one rhesus monkey were successfully vaccinated against morphine and heroin, but until recently these efforts were not taken any further, due to the successful introduction of methadone and other pharmacological antagonists for opiate addiction in developed countries. However, there has been a dramatic increase in the abuse of heroin in the Far East and Russia in recent years, with the concomitant spread of blood-borne or sexually transmitted diseases such as HIV/AIDS. This socioeconomic threat, along with the high cost of methadone and other treatment programs that are not affordable for many abusers, eventually reenergized the enthusiasm for opiate vaccine development.

Recently, Anton and Lef of the Laboratory of Molecular Neurobiology and Addictive Neurochemistry in Mexico attained high polyclonal antibody levels in rodents using 6-succinylmorphine attached to a derivative of tetanus toxoid as a carrier protein. These antibodies were able to bind both morphine and heroin at high-dose levels. Similar studies in our laboratory have demonstrated that morphine conjugate vaccines are able to elicit high levels of antibodies that inhibit the nociceptive action of morphine as measured by hot-plate and tail-flick assays in mice.

METHAMPHETAMINE

Methamphetamine is a highly addictive human-made stimulant drug that induces euphoria. A 2008 survey by The National Institute of Drug Abuse (NIDA) reports that 850 000 Americans aged 12 and above had abused methamphetamine at least once in the previous year and several law enforcement agencies in the United States of America noted that methamphetamine abuse may be their greatest drug threat. Though methamphetamine can be prescribed at very low doses, it is abused at higher doses by routes such as oral,

snorting, or injection. The small and lipophilic nature of methamphetamine allows it to easily cross the BBB and block the monoamine transporters, thereby increasing dopamine concentration in the CNS as well as blocking dopamine reuptake from synaptic vesicles. It is primarily excreted by the kidneys unchanged, but is also metabolized to amphetamine, which is itself a powerful stimulant, and to the inactive 4-hydroxyamphetamine. In contrast to many other abused drugs, both methamphetamine and its metabolite amphetamine have long-lasting plasma half-lives of about 9–15 h. In addition, they are both optically active molecules with the *dextro* isomer (right handed) being biologically more potent than the *levo* one (left handed). Hence, in designing immune conjugates it is imperative to retain the correct stereochemistry to provoke the immune system to produce appropriate antibodies. Since the presence of methyl groups and chiral carbons are important for the biological properties of methamphetamine, the phenyl group of methamphetamine has been a major site for covalent modification for optimal hapten development.

Most of the work on methamphetamine has been in preclinical animal studies and currently there are no active vaccine formulations or human clinical trials in progress. Owens and colleagues at the University of Arkansas developed a vaccine by conjugating a methamphetamine hapten with a six carbon spacer group at the para position of the phenyl ring (S-(+)-4(5-carboxypentyl)methamphetamine) to KLH. The vaccine elicited methamphetamine-specific antibodies in rats and it was shown that repeated administration of methamphetamine did not affect the generation of antibodies. In subsequent studies, the same group raised monoclonal antibodies (mAbs) against methamphetamine and demonstrated that passive administration of these mAbs reduced self-administration behavior and locomotor activity in rats. Currently, this group is actively involved in developing a humanized version of their successful animal mAbs, particularly focusing on the mAbs with slow dissociation constants for passive immunization of methamphetamine abusers. Many other groups also continue to work to optimize an effective vaccine formulation, in order to initiate the first human clinical trials against methamphetamine abuse.

COCAINE

Cocaine (*benzoylecgonine*) is a bicyclic alkaloid extracted from the leaves of *Erythroxylum coca* and it is a psychoactive substance (see Table 57.1) listed as a Schedule II agent by the Drug Enforcement Agency. In 2008, over 5.3 million Americans aged 12 and older abused cocaine, leading to many chronic health

consequences and criminal activities. It is commonly consumed as the hydrochloride salt by inhalation or injection or as the free base (crack) by smoking. Immediately after direct absorption to the systemic circulation, cocaine rapidly distributes to the peripheral system, and subsequently a small fraction reaches the CNS. Cocaine binds to the dopamine transporter, inhibiting reuptake of dopamine and artificially elevating signaling from this messenger system. In the periphery, it is metabolized primarily in the liver, where the methyl ester is hydrolyzed by human carboxylesterase (hCE1), which hydrolyzes the methyl ester of cocaine, whereas the benzoyl ester is either hydrolyzed by hCE2 in the liver or by butyrylcholinesterase in plasma, leading to the major inactive metabolites, benzoylecgonine (BE), ecgonine methyl ester, and ecgonine that are excreted by the kidneys. The *N*-methyl group can also be removed to produce norcocaine. Both the methyl and benzoyl esters of native cocaine are essential for the drug's activity. Hence, it is desirable that the antibodies produced by vaccination recognize native cocaine and do not bind significantly to the inactive metabolites.

In 1993, a viable cocaine vaccine was developed by the Janda group at Scripps Research Institute. They first attached a six carbon linker to the carboxylic group of BE without altering its stereochemical properties and then coupled it to the carrier protein KLH using carbodimide chemistry. When rats were actively immunized with this construct, they produced cocaine antibodies with about 1 μM affinity, and locomotor activity (restless movement from place to place) and stereotyped behavior (repetitive meaningless gestures or movements) ordinarily induced by cocaine injection were suppressed. In addition, reduced cocaine levels in the brain tissues were observed in the immunized rats following acute administration of cocaine. Later, in 2001, the same group developed a more stable immune conjugate by altering the labile ester group to an amide, which increased the hapten-protein stability for sustained production of antibodies. Even though an initial blockade of cocaine levels in the brain was obtained using this vaccine, the low antibody titer values in the range of 12 800–25 600 were not sufficient to reduce cocaine entry to the brain following repeated doses.

In another effort in 1996 led by Barbara Fox from ImmuLogic Pharmaceuticals, a conjugate vaccine was developed by coupling 20–27 molecules of a cocaine derivative (succinyl norcocaine) per molecule of BSA. This elicited high antibody titers ($>100\,000$) to cocaine derivatives for up to 4 months and showed that 0.7 mg ml^{-1} of antibodies was sufficient to bind 8.7 μM cocaine. Interestingly, their data from competition enzyme-linked immunosorbent assay showed that the antisera also bound the pharmacologically active metabolites norcocaine and cocaethylene (a toxic derivative

produced when ethanol is consumed with cocaine) but showed a minimal recognition of pharmacologically inactive metabolites such as ecgonine methyl ester and benzoylecognine. However, these studies did not answer whether the addicted animal learned to compensate for the immunization by taking more drugs or if vaccination discouraged cocaine intake even if more drug were readily available. These questions were partly addressed in 2000 by the same group by passively administering anti-cocaine mAb in a rat self-administration model (1 mg kg^{-1} training dose). The addicted behavior for cocaine intake was significantly reduced only when the drug-specific mAb levels were greater than $50 \mu\text{g ml}^{-1}$. In the same study, 2 weeks after addicted rats ($n = 8$) were given a vaccine consisting of succinyl norcocaine conjugated to recombinant cholera toxin B (TA-CD), they produced serum antibodies against cocaine in the $80\text{--}700 \mu\text{g ml}^{-1}$ range, and antagonism of cocaine self-administration was apparent in the animals whose antibody levels were high enough. A similar study by the Janda group using the vaccine they had developed came to essentially the same conclusions. In an active vaccination study performed by Landry (Columbia University) on three Rhesus monkeys of mixed age and sex, a correlation was reported between the increased titer values of anti-cocaine antibodies and the proportional degree of antagonism of cocaine behavioral effects with no serious adverse consequences, suggesting the potential efficacy of anti-cocaine vaccination for humans.

Based on these preclinical findings, both Phases I and II human clinical trials were carried out using the TA-CD vaccine. The phase I study was carried out on 34 cocaine abusers with three injections over 2 months to assess the immunogenicity and safety of the vaccine in humans. As noted in preclinical animal studies, the human subjects tolerated the vaccine with no serious adverse effects and produced anti-cocaine antibodies at levels that correlated with the vaccine dose. Later, to determine the optimal dosing requirements, a 14-week Phase IIa study was carried out in 18 cocaine abusers at two different dose levels ($100 \mu\text{g} \times 4$ injections, or $400 \mu\text{g} \times 5$ injections). It was found that the patients who received a total dose of $2000 \mu\text{g}$ had a significantly higher antibody titer after 6 months. In Phase IIa studies carried out with a group of 109 cocaine abusers of a heterogeneous outpatient population who were enrolled in a methadone treatment program had no immune deficiency. They were chosen because their methadone treatment schedule meant that fewer patients would be lost because of noncompliance. After five vaccinations, 98% of subjects produced anti-cocaine antibodies, and about 38% of the subjects produced antibodies at $\geq 43 \mu\text{g ml}^{-1}$. The high responders had significantly more cocaine-free urine samples than the

rest of the subjects once the antibody levels were high enough. It is not clear why the rest of the subjects were unable to produce the required antibody target level, and unfortunately few of the subjects reached the primary end point of abstinence from cocaine for three consecutive weeks. Nevertheless, the use of cocaine vaccines will be more promising if high persistent levels of antibodies can be reached by improvements in vaccine construction and better adjuvants.

NICOTINE

Nicotine is an addictive alkaloid drug found in *Solanaceae* plants such as tobacco. It is commonly consumed through cigarette smoking and causes about 90% of lung cancer cases in the United States of America and about 10% of overall deaths in the world. Though adults are legally allowed to smoke despite the known health consequences, nonsmokers are also affected through secondary smoke. As a result of smoking one cigarette, about 1–2 mg of nicotine is absorbed in the mucosal surfaces of the respiratory tract of the smoker. From there it enters the bloodstream and rapidly distributes to other organs including the brain. In the brain it binds to the nicotinic acetylcholinergic receptors and causes the release of many chemical messengers such as acetylcholine, epinephrine, and dopamine. With a half-life of 2 h in the human body, nicotine is primarily metabolized in the liver by the enzyme cytochrome P450 to the pharmacologically inactive molecule cotinine, which has a plasma half-life of about 16 h. Nicotine is a small optically active molecule with two rings and an asymmetric S-configuration. It lacks suitable functional groups for direct conjugation (see Table 57.1), and hence an appropriate linker must be added carefully to avoid altering the stereochemical properties of native nicotine.

In 1973, a group led by Langone at Brandeis University reported the first nicotine-protein vaccines by synthesizing 3-succinylmethylnicotine and adding it to large carrier proteins. Immunizing rabbits with these conjugates along with complete Freund's adjuvant generated antinicotine antibodies. Though the initial aim was to raise antinicotine antibodies suitable for use in quantitating nicotine and its metabolites by radioimmunoassay in tissues and biological fluids, later efforts were focused on the development of nicotine vaccines. Several other groups have continued developing nicotine derivatives with different linker sizes and linker attachment sites. Additionally, various carrier proteins (KLH, recombinant cholera toxin B, *Pseudomonas* exoprotein A, virus-like particles formed from the bacteriophage Qb) have been exploited to optimize nicotine vaccines. Studies have been successfully performed on rodents with these various constructs that

demonstrated the elicitation of endogenous antinicotine antibodies with different titer values. These studies showed that the nicotine concentration was significantly higher in the serum than in the brain compared to the unvaccinated control mice and furthermore demonstrating that the antinicotine antibodies retained the nicotine in the peripheral circulation without permitting it to enter into the CNS.

At present, there are three pharmaceutical companies that have completed Phases I and II human clinical trials for nicotine vaccines: NicVAX from Nabi Inc. (USA), NicQb from Cytos AG (Switzerland), and TA-NIC from Celtic Pharma (UK). All three vaccines were sufficiently immunogenic and were well tolerated in Phase I clinical trials without any cross reactivity with endogenous neurotransmitters. In a large Phase IIb double-blind placebo-controlled clinical trial of NicVAX with 301 heavy smokers (average of 24 cigarettes per day), the vaccine was effective in promoting and sustaining continuous abstinence from smoking at 12 months after vaccination in only 18% of subjects as compared to 6% in the placebo group. Interestingly, the successful quitters from the trial were predominantly those who produced high levels of antibodies against nicotine and its metabolites. Similarly, in a 6-month NicQb Phase II trial with 341 smokers, 57% of NicQb-vaccinated subjects mounted high-level antibody responses and quit smoking from the second until sixth month as compared to 31% of placebo subjects. Similar results were obtained with TA-NIC, which clearly demonstrates that the effectiveness of active immunization against nicotine is directly proportional to the amount and persistence of antinicotine antibodies.

BENCH TO PATIENT TRANSITION

Vaccination for addictive disorders is primarily seen as a treatment to block the entry of drugs of abuse into the CNS. Novel vaccine formulations for different drugs of abuse have been successfully developed, and proof of concept data has been obtained in preclinical animal studies showing successful production of antidrug antibodies and significant reductions in drug-promoted behavior in the animals. The TA-CD vaccine against cocaine has completed the Phases I and IIa clinical trials and advancement to a Phase III trial is in progress. The vaccine was shown to be safe without significant side effects, but the efficacy of vaccination was limited and dependent on the magnitude and kinetic parameters of the antibodies elicited. In the recent Phase IIa TA-CD clinical trial only about 38% of patients produced high anti-cocaine antibody titers and efficacy was also limited to 2 months in terms of a reduction in cocaine use. Similar observations have been documented from the

clinical trials of nicotine. Since a single cigarette contains a relatively lower dose of nicotine than the usual single doses of other abused drugs, the required level of antinicotine antibody to prevent relapse from a one-time exposure may be lower than for other drugs. Several preclinical animal studies have shown efficacy with a moderate level of antibodies even with a large excess of a single drug administration. However, recent human clinical trials showed only a moderate efficacy with a large variability in the magnitude of the immune response and it remains unclear why some subjects produced more antibodies than others. Currently, the field is focused on trying to unravel the biological and genetic variations behind the addiction. Recently, using a rat animal model for addiction, the teams of Pier Vincenzo Piazza and Olivier Manzoni, at the Neurocenter Magendie in Bordeaux, demonstrated that in addicted rats, the transition to cocaine addiction permanently impairs long-term depression of the neuronal response in the nucleus accumbens (a center in the brain associated with addiction behavior) and thereby disturbs the synaptic plasticity between the neurons. In contrast, the nonaddicted rats, which received similar cocaine doses, the long-term depression of the neuronal response was reversible. It will be interesting to see whether the vaccination of addicted animals can encourage recovery from the loss of long-term depression.

Recent advances in adjuvant research in finding improved immunostimulants for suitable drug conjugate vaccine formulations hold high promise to help achieve sustained high-level production of antidrug antibodies. However, inclusion of any novel adjuvants for humans apart from the currently approved agents can be expected to delay the vaccine applications as safety and other regulatory concerns have to be addressed. Despite the dramatic high throughput technological inventions with various bioanalytical platforms, there is still a limitation on the ability to investigate and understand the biophysical properties of antibodies, such as kinetic parameters, produced by human subjects or in preclinical animal models. There is also not much information available regarding the influence of the number of haptens covalently linked per carrier protein and its variability in the vaccine formulations between different laboratories.

In contrast to pharmaceutical companies that produce small drug molecules and therapeutic proteins, only a few pharmaceutical companies have the resources and expertise to produce any new vaccine product that could meet the demanding regulatory requirements. The vaccine process development includes transferring the technology from basic research laboratory to a good manufacturing environment to produce each and every vaccine dose precisely equivalent and safely transportable. With the recent progress on addiction

vaccines for cocaine and nicotine toward larger clinical trials, other drug vaccines in the field will have to address such manufacturing issues as well. While nicotine and cocaine are the two major drugs of abuse advancing rapidly toward clinical use, other drugs such as heroin, morphine, and methamphetamine are still in the preclinical phase. We have recently initiated a larger six-site Phase III clinical trial with the TA-CD cocaine vaccine. In addition, NIDA has funded \$10 million grant to Nabi pharmaceuticals for conducting Phase III clinical trials on NicVAX.

It is difficult to speculate regarding the implications of the progress with cocaine and nicotine vaccines for heroin, morphine, and methamphetamine vaccines, which are all still in the preclinical stages. However, it is interesting to note that the majority of the cocaine and heroin are degraded by hydrolysis with a serine hydrolase enzyme carboxylesterase 1 (hCE1), which is readily available in liver, kidney, and small intestines and by butyrylcholinesterase in the bloodstream for quick degradation. This is not the case in other drugs discussed here (see Table 57.1). The enzyme hCE1 hydrolyzes the methyl ester of cocaine to benzoylecgonine and methanol, and the hCE2 hydrolyzes the benzoyl ester of cocaine to ecognine methyl ester and benzoic acid. In the case of heroin, hCE1 and hCE2 hydrolyze the acetyl groups of heroin to 6-monoacetylmorphine. However, only hCE2 hydrolyzes 6-monoacetylmorphine to morphine, which is the parent molecule still having high BBB permeation. In the case of methamphetamine, the presence of methyl group increases the lipophilicity for high BBB permeation and also makes it less susceptible for enzymes such as monoamine oxidase, which keeps the drug intact with a long circulation half-life. In addition, its demethylated metabolite amphetamine is another active stimulant with a long circulation time of about 9 h. In a successful scenario for addiction vaccine development, it remains challenging for the vaccine community to design an immunogen to perturb the immune system to produce antibodies capable of binding all forms of native and active metabolites.

Transfer of active immunotherapeutic strategies from bench to clinic for treating and/or preventing addictive disorders may also present many complicated ethical decisions involving the addicted patients or their family members, government, and other social welfare organizations as well. It is important to realize that the current immunization strategies attenuate the effects of abused drugs for a few to several months unlike typical preventive vaccines against viruses or bacteria. Improved vaccines may have much more prolonged therapeutic efficacy. Addressing the safety and efficacy of active immunizations, particularly in the context of preventive efforts with more persistent

vaccine responses could be cumbersome and time-consuming.

In brief, the development of vaccines for substance abuse was hypothesized in the early 1970s that and only in the recent years has the field moved from laboratory bench into patients. However, it is unlikely that any treatment in this field will work for everyone unless we completely understand the biological basis of addiction. Until then the vaccines for addictive disorders will still be a work in progress.

Glossary

Adjuvant	a chemical or mixture of agents that activates immune cell signaling nonspecifically to enhance immune responses.
Affinity	a measure of the strength of antibody binding to an antigen or epitope of a target molecule to a single binding site.
Avidity	a measure of overall stability of an antigen-antibody complex, which is governed by the intrinsic antibody affinity to the antigen to a single binding site and valency (number of binding sites) of the antibody and the geometric arrangement of the interacting components.
Blood-brain barrier	a complex physical barrier that protects the brain from the entry of unwanted chemicals from the blood into the brain. The efflux and influx transport of various chemicals across

the barrier is tightly regulated by the brain capillary endothelial cells.

Carrier protein attachment of molecules too small to elicit an immune response by themselves (Haptens) to these proteins allows the immune recognition of these structures.

Epitope the chemical structure of a molecule that physically and specifically interacts with the binding site of an antibody or other immune recognition molecule.

Hapten these are small molecules (e.g. drugs of abuse), which are molecules too small to elicit an immune response by themselves.

Neurotransmitters these are endogenous signaling molecules, which communicate between the neurons by activating specific receptors.

INTRODUCTION

Pathological gambling, kleptomania, trichotillomania (TTM), pyromania, and intermittent explosive disorder (IED) are all formally recognized by the Diagnostic and Statistical Manual of Mental Disorders – 4th Edition (DSM-IV) as impulse control disorders (ICDs) Not Elsewhere Classified. Although compulsive buying, compulsive sexual behavior (CSB), Internet addiction,

and pathological skin picking (PSP) are not formally recognized by the DSM, they are generally included as ICDs Not Otherwise Specified. The hallmark characteristic of an ICD is an inability to resist urges to engage in behaviors that are excessive and harmful to oneself or others. ICDs are fairly common among both adults and adolescents. A study of 791 college students found that 82 (10.4%) met criteria for at least one lifetime ICD, demonstrating the common nature of these disorders in

the general population. ICDs generally have the following features in common: (1) repetitive or compulsive engagement in a behavior despite adverse consequences; (2) diminished control over the problematic behavior; (3) an appetitive urge or craving state prior to engagement in the problematic behavior; and (4) a hedonic quality during the performance of the problematic behavior. These features have led to a description of ICDs as “behavioral addictions.” Some of the ICDs (pathological gambling, kleptomania, pyromania, compulsive buying, CSB, and internet addiction) seem to fit the conceptualization of behavioral addictions better than other ICDs (TTM, PSP). In particular, IED may in fact have even less in common with other ICDs. The degree to which ICDs overlap in terms of clinical, genetic, phenomenological, and biological characteristics is not completely understood. Future research should help clarify whether only certain ICDs share a common pathophysiology or whether only certain individuals with certain ICD share the same pathophysiology. See Table 58.1 for summary of double-blind treatment studies for ICDs.

PATHOLOGICAL GAMBLING

Clinical Characteristics

Pathological gambling (PG) is characterized by persistent and recurrent maladaptive patterns of gambling behaviors. Approximately 0.4–1.6% of Americans meet criteria for a PG diagnosis. Gambling often starts in adolescence or young adulthood and develops into a problem several years later. The gender ratio of males to females with PG appears to be 2:1. Women tend to develop PG at a quicker rate than men, while men begin gambling at a younger age. Male pathological gamblers appear more likely to report problems with strategic or “face-to-face” forms of gambling, for example, blackjack or poker. Female pathological gamblers tend to report problems with nonstrategic, less interpersonally interactive forms of gambling, for example, slot machines or bingo. High rates of bankruptcy have been linked with PG. In addition to financial problems, impaired functioning, decreased quality of life, marital problems, and legal problems are associated with PG. If left untreated, PG appears to be a chronic, recurring condition.

Individuals who struggle with PG may also be dealing with another psychiatric condition. Common lifetime comorbid disorders include mood (20–55.6%), substance use (35–76.3%), and other ICDs. Suicide attempts are also common in PG with one study reporting attempts in 58 (17%) of 342 individuals. Studies have also found high rates of co-occurring personality disorders.

Pharmacological Treatments for Pathological Gambling

Opioid Antagonists

Mu-opioid receptor antagonists inhibit dopamine release in nucleus accumbens and ventral pallidum through the disinhibition of gamma-aminobutyric acid (GABA) input to the dopamine neurons in the ventral tegmental area. The hypothesis underlying the use of opioid antagonists was that decreased dopamine in the nucleus accumbens and motivation circuit would dampen excitement and cravings related to gambling behavior. Although modulation of drive and subsequent behavioral output by dopamine, endorphin, and GABA have been investigated, the specific mechanisms remain incompletely understood, particularly as related to pathological gambling.

Two opioid antagonists have been investigated in the treatment of pathological gambling: naltrexone and nalmefene. Two of the three double-blind studies of naltrexone (studies randomized 45 and 77 subjects into a 12-week and 18-week study, respectively) found that subjects significantly improved on measures of gambling behaviors and urges when compared to placebo. A study randomizing 52 subjects to receive naltrexone or placebo for 11 weeks in addition to cognitive behavioral therapy (CBT), however, found that groups did not significantly differ in measures of gambling frequency or expenditures.

Nalmefene was found to be effective in reducing PG symptoms in two double-blind studies. A 16-week study found that nalmefene produced significantly greater reductions in gambling symptoms than placebo in 207 gambling subjects. Another larger study of 233 PG subjects treated for 12 weeks found that overall nalmefene was not superior to placebo. However, with analyses limited to subjects taking 40 mg of nalmefene daily, results indicated that the active medication group reported significantly fewer gambling urges compared to those on placebo.

Antidepressants

The hypothesis underlying the examination of antidepressant medications for PG is based on its hypothesized neurobiology. Low levels of the serotonin metabolite 5-hydroxyindole acetic acid (5-HIAA) and blunted serotonergic response within the ventromedial prefrontal cortex (vmPFC) have been associated with impulsive behaviors. Individuals with PG show relatively diminished activation of the vmPFC during a simulated gambling task, and severity of gambling problem correlated inversely with signal intensity within this brain region. Decreased serotonin function within vmPFC may therefore engender disinhibition and contribute to pathological gambling. Thus, drugs

TABLE 58.1 Double-blind Treatment Studies of Impulse Control Disorders

Double-blind treatment studies	Number enrolled	Duration (weeks)	Outcome
Pathological gambling			
<i>Opioid antagonists</i>			
Naltrexone (ReVia)	45	12	Naltrexone group significantly improved compared to placebo
Naltrexone (ReVia)	77	18	Naltrexone group significantly improved compared to placebo
Naltrexone (ReVia)	52	11	Naltrexone group did not significantly differ from placebo
Nalmefene (Revex)	207	16	Nalmefene resulted in significant improvement compared to placebo
Nalmefene (Revex)	233	12	Nalmefene did not result in significant improvement compared to placebo in an intent-to-treat analysis; 40 mg resulted in significant improvement when only those who reached target dose were analyzed
<i>Antidepressants</i>			
Fluvoxamine (Luvox)	15	8*	Fluvoxamine superior to placebo
Fluvoxamine (Luvox)	32	24	Fluvoxamine not statistically significant from placebo except in young males
Paroxetine (Paxil)	45	8	Paroxetine group significantly improved compared to placebo
Paroxetine (Paxil)	76	16	Paroxetine and placebo groups with comparable improvement
Escitalopram (Lexapro)	4	8	Significant improvement for escitalopram subjects while placebo group had a relapse of gambling symptoms
Sertraline (Zoloft)	60	24	Sertraline did not significantly differ from placebo
Bupropion (Wellbutrin)	39	12	Bupropion did not significantly differ from placebo
<i>Mood stabilizers</i>			
Lithium carbonate SR (Lithobid SR)	40	10	Lithium produced significant improvement in reducing PG symptoms and severity compared to placebo
<i>Atypical neuroleptics</i>			
Olanzapine (Zyprexa)	21	7	Olanzapine did not significantly differ from placebo
Olanzapine (Zyprexa)	42	12	Olanzapine did not significantly differ from placebo
<i>Glutamatergic agents</i>			
N-acetylcysteine (NAC)	27	6	59.3% of subjects were rated as responders in the OL. In the DB, 83.3% on NAC still met responder criteria at study endpoint compared to 28.6% on placebo
Kleptomania			
<i>Antidepressants</i>			
Escitalopram (Lexapro)	15	17	Escitalopram produced no significant differences compared to placebo
<i>Opioid antagonists</i>			
Naltrexone (ReVia)	25	8	Naltrexone was statistically superior to placebo in reducing stealing behavior
Compulsive buying			
<i>Antidepressants</i>			
Fluvoxamine (Luvox)	37	13	Fluvoxamine and placebo groups with comparable improvement
Fluvoxamine (Luvox)	23	9	Fluvoxamine and placebo groups with comparable improvement
Citalopram (Celexa)	15	9	63% were rated as responders in the OL. In the DB, 63% of the placebo group relapsed compared to none of those on citalopram

(Continued)

TABLE 58.1 Double-blind Treatment Studies of Impulse Control Disorders—cont'd

Double-blind treatment studies	Number enrolled	Duration (weeks)	Outcome
Escitalopram (Lexapro)	17	9	73% of OL sample were rated as responders. 67 and 63% from the placebo and active medication group, respectively, relapsed during the DB phase after being rated as an OL responder
Compulsive sexual behavior			
<i>Antidepressants</i>			
Citalopram (Celexa)	28	12	Citalopram significantly reduced desire for sex, masturbation frequency, and weekly hours of pornography use compared to placebo. Sexual risk decreased in both groups, but no significant difference was found between groups
Trichotillomania			
<i>Antidepressants</i>			
Clomipramine (Anafranil) Desipramine (Norpramin)	13	5*	Significant improvement with clomipramine compared to desipramine
Clomipramine (Anafranil)	16	9	67% of the clomipramine group were rated as 'very much improved' on the CGI compared to none assigned to placebo. This difference only approached significance
Fluoxetine (Prozac)	15	6*	Fluoxetine failed to show significant improvement compared to placebo
Fluoxetine (Prozac) Clomipramine (Anafranil)	12	10*	Fluoxetine and clomipramine produced similar positive results
Fluoxetine (Prozac)	23	12*	Fluoxetine produced no significant improvement compared to placebo
<i>Opioid antagonist</i>			
Naltrexone	17	6	Naltrexone produced significant improvement only on one measure of symptomology compared to placebo
<i>Atypical neuroleptics</i>			
Olanzapine (Zyprexa)	25	12	Olanzapine resulted in significant improvement compared to placebo
<i>Glutamatergic agents</i>			
N-acetylcysteine (NAC)	50	12	NAC was statistically superior to placebo in reducing TTM symptomatology
Pathological skin picking			
<i>Antidepressants</i>			
Fluoxetine (Prozac)	17	10	Fluoxetine produced significant improvement compared to placebo
Fluoxetine (Prozac)	8	6	53.3% were rated as responders based on the YBOCS-PSP in the OL. In the DB, fluoxetine maintained positive results while the placebo group returned back to baseline severity
Citalopram (Celexa)	45	4	Citalopram was not statistically superior to placebo on a visual analog scale
<i>Mood stabilizers/Anticonvulsants</i>			
Lamotrigine (Lamictal)	35	12	Lamotrigine did not significantly differ from placebo. Lamotrigine responders had impaired cognitive flexibility and delayed reach times at baseline compared to lamotrigine nonresponders
Intermittent explosive disorder			
<i>Antidepressants</i>			
Fluoxetine (Prozac)	100	14	Fluoxetine demonstrated superiority to placebo
<i>Mood stabilizers/Anticonvulsants</i>			
Divalproex sodium (Depakote)	116	12	Significant changes were seen only in IED subjects who had a Cluster B personality disorder
Levetiracetam (Keppra)	40	10	Levetiracetam was not superior to placebo

* indicates subjects were put in each agent for x number of weeks.

targeting serotonin neurotransmission may be effective in the treatment of pathological gambling.

The majority of double-blind pharmacologic treatment studies for PG have assessed the efficacy of antidepressants with mixed results. While a 16-week, cross-over study of 15 pathological gamblers found that the fluvoxamine group had significantly greater improvement of gambling symptoms compared to placebo, a 6-month study of 32 pathological gamblers found fluvoxamine to be no more effective than placebo. In the latter study, however, high treatment discontinuation (90.6%) and placebo response rates (59%) complicated study findings. Mixed results have also been found for paroxetine. Paroxetine was found to significantly decrease gambling urges and behavior in 45 pathological gamblers participating in an 8-week study. In contrast, results from a larger study of 76 participants with PG indicated that paroxetine was not superior to placebo on any outcome measure in a 16-week trial. These negative findings, however, may be due to a high placebo response rate. Of those randomized to placebo, 48% responded compared to a 59% response rate in the treatment group.

Research has found escitalopram to be a superior treatment to placebo. A 12-week, open-label study investigating escitalopram in pathological gamblers with co-occurring anxiety disorders found that of the four subjects who were responders during the open-label phase (6 of 13 subjects, 46.2%, with PG and high levels of anxiety responded to escitalopram during the open-label portion) and randomized into the 8-week, double-blind discontinuation period, three subjects randomized to active medication continued to maintain improvement in both gambling and anxiety symptoms. The one subject assigned to placebo returned to baseline levels within 4 weeks.

In contrast, other studies have found sertraline and bupropion, a nonserotonergic antidepressant, were not superior to placebo in treating pathological gambling. Researchers found that sertraline and placebo yielded similar response rates in 60 pathological gamblers participating in a 6-month study. Seventy-four and seventy-two percent of those randomized to sertraline and placebo, respectively, were rated as responders.

In the only study examining a nonserotonergic antidepressant, 39 PG subjects were randomized into a 12-week, flexible dose study of bupropion. The study found no significant differences between subjects assigned to bupropion compared to those assigned to placebo in terms of gambling behaviors and thoughts, or time or money spent on gambling per week.

Mood Stabilizers

Only one randomized, placebo-controlled trial of a mood stabilizer has been performed in PG. In

a double-blind, placebo-controlled study of 40 PG subjects with bipolar spectrum disorders (bipolar type II, bipolar not otherwise specified, or cyclothymia), sustained release of lithium carbonate was shown to be superior to placebo in reducing PG symptoms during 10 weeks of treatment. Although a majority (83%) of subjects in the treatment group displayed significant decreases in a clinical rating of gambling urges, thoughts, and gambling behaviors in the past week, no differences were found in self-reported amount of money lost, episodes of gambling per week, or time spent per gambling episode.

Atypical Neuroleptics

Olanzapine, an atypical neuroleptic, was investigated in two double-blind studies. A 7-week trial of 21 subjects with PG found that there were no significant differences in gambling urges or behaviors when comparing active treatment to placebo groups. Similarly, olanzapine failed to demonstrate statistical significance compared to placebo in a trial of 42 individuals with PG enrolled in a 12-week trial.

Glutamatergic Agents

Positive results have been found with *N*-acetylcysteine (NAC) – a glutamatergic modulator. Statistical analysis of an 8-week, open-label trial of NAC followed by a 6-week, double-blind discontinuation phase with 27 subjects revealed that those randomized to receive NAC had significantly reduced gambling thoughts and behaviors and an improved level of functioning. Furthermore, approximately 83% of individuals on NAC were rated as ‘responders,’ compared to 30% assigned to placebo.

Treatment Summary

Several findings emerge from these pharmacological studies:

1. Although several different classes of medication appear to show some efficacy in treating PG, only opioid antagonists have demonstrated the successful replication of a positive, randomized, placebo-controlled study. Based on the present data, opioid antagonists should be considered first-line pharmacological treatment for PG.
2. Data for the glutamatergic modulator, *N*-acetylcysteine, and for lithium are encouraging and should be further investigated.
3. Although the majority of pharmacological studies have focused on antidepressants, the results have been inconclusive. Escitalopram, however, may be effective for pathological gamblers with high levels of anxiety.

4. Atypical antipsychotic treatment studies suggest that these medications provide no greater benefit than placebo.
5. An exploration of the clinical characteristics of pathological gamblers in which a specific pharmacological treatment is advantageous is necessary to assess reasons as to why some agents are efficacious in some individuals with PG and not in others.

There are also numerous limitations to the current knowledge regarding pharmacological treatment of PG. No comparison studies of medications have been performed in a randomized, placebo-controlled design. No studies have examined which intervention (pharmacotherapy versus psychotherapy) is more effective or whether combination treatment is more beneficial. In addition, no study has examined whether certain individuals with pathological gambling would benefit more from medication or from psychotherapy.

KLEPTOMANIA

Clinical Characteristics

Individuals who struggle with kleptomania repetitively and uncontrollably steal items that are not needed for personal use and may hoard, give away, return, or throw away the stolen items. Although epidemiological research has found that 11.3% of individuals have shoplifted at least one time in their life, no studies have examined the prevalence of kleptomania in the population. One study of 791 college students, however, found that 3 (0.38%) met DSM-IV criteria for kleptomania. Studies of individuals arrested for shoplifting have suggested that 3.8–24% may meet criteria for kleptomania. The majority of individuals with kleptomania appear to be female. Typically, onset of kleptomania is during adolescence. Individuals with kleptomania report significant guilt over their behavior, and the majority have been apprehended at some time due to their stealing.

Studies have found that psychiatric comorbidity with affective disorders, substance use, and anxiety disorders is common among individuals with kleptomania. Additionally, individuals with kleptomania often meet criteria for another ICD. Family studies have found that first-degree relatives of individuals with kleptomania have higher rates of alcohol use disorders compared to control groups.

Pharmacological Treatments and Recommendations

Although research has only recently explored pharmacologic treatment for kleptomania, these studies have

shown a similar response between substance use disorders and kleptomania. Historically, the use of serotonergic medications for substance use disorders has not been impressive. Similarly, a recent controlled study of a serotonergic medication (escitalopram) in the treatment of 24 patients with kleptomania was largely unsuccessful in reducing stealing behavior. After 7 weeks of open-label treatment, escitalopram reduced shoplifting urges in 19 (79%) of the participants. Fifteen responders were then randomized to a 17-week, double-blind discontinuation phase where they received either active medication or placebo. At the end of this portion of the study, no significant differences were seen between active medication and placebo, that is, 50% of those on placebo and 43% on active medication maintained their improvement from the open-label portion of the study.

There are no medications currently approved for the treatment of kleptomania, but medications that have shown promise in treating substance use disorders have also shown promise in treating kleptomania. Given their ability to modulate dopaminergic transmission in the mesolimbic pathway, opioid receptor antagonists (naltrexone) have also been investigated in the treatment of kleptomania.

A recent double-blind, placebo-controlled study evaluating the efficacy of naltrexone in the treatment of kleptomania demonstrated its benefit in reducing stealing urges. As in the case of substance use disorders, naltrexone appears to target urges in kleptomania. Twenty-five subjects with kleptomania were enrolled. Significantly better results were observed for those assigned to naltrexone on the primary efficacy variable. Remission of kleptomania symptoms was seen in eight naltrexone subjects (66.7%) and one (7.7%) placebo subject. Although the study was only 8 weeks in duration, a naturalistic outpatient study demonstrated that subjects treated with naltrexone monotherapy for up to 3 years continued to report overall improvement.

There is limited treatment research on kleptomania and future research needs to continue to investigate possible pharmacological treatments for kleptomania. Future research investigating kleptomania and its relationship to substance use disorders holds significant promise in advancing prevention and treatment strategies for addiction in general.

COMPULSIVE BUYING

Clinical Characteristics

It is estimated that about 5.8% of US adults report shopping or spending behavior that could be classified as compulsive buying. Although there are no agreed upon diagnostic criteria, core features of the disorder

are a preoccupation with buying, spending more than one can afford on unneeded items, or shopping for longer durations of time than originally intended. Most individuals with compulsive buying are women with an onset of the behavior during late adolescence or early adulthood. Items typically are unused, given away, or returned to the store. Compulsive buying regularly results in large amounts of financial debt, marital or family disruption, and even legal consequences.

Pharmacological Treatment and Recommendations

Antidepressants are the only pharmacological therapy investigated for the treatment of compulsive buying, and the effectiveness of medications has been examined in four double-blind, randomized, placebo-controlled trials. In the first of two double-blind studies, 37 subjects were treated with fluvoxamine for 13 weeks. Only 9 (45%) of 20 patients assigned to medication were responders, and this rate did not differ significantly from that in the placebo group (8 of 17 were responders). In the second double-blind study, 23 subjects were treated with fluvoxamine for 9 weeks following a 1-week placebo lead-in phase. No differences in response rates were observed between the groups treated with active drug or placebo.

The third controlled study was a 7-week open-label study of citalopram that randomized the responders to 9 weeks of double-blind medication or placebo. Subjects taking active citalopram demonstrated statistically significant decreases in terms of the frequency of shopping as well as the intensity of thoughts and urges concerning shopping.

The final double-blind study found that escitalopram was not effective for the treatment of compulsive buying. Seventeen participants were randomized into a 9-week, discontinuation period after being rated as responders in a 7-week, open-label study. During the discontinuation phase, 63% and 67% of the escitalopram and placebo groups, respectively, relapsed.

There is only scant evidence concerning effective treatments for compulsive buying. Based on available data, citalopram appears promising for this disorder. It is unclear why citalopram may be effective while other selective serotonin-reuptake inhibitors (fluvoxamine, escitalopram) fail to demonstrate benefit.

COMPULSIVE SEXUAL BEHAVIOR

Clinical Characteristics

CSB is characterized by recurrent and intense sexual fantasies, urges, or behaviors and clinically significant

distress or impairment in functioning associated with sexual fantasies, urges, or behaviors. The prevalence rate of CSB in the general population is unknown; however, one study of college students found that 3.7% reported symptoms consistent with CSB. The gender distribution of CSB is unknown, but the majority of treatment-seeking individuals with CSB are males with an onset during late adolescence. The sexual urges and behaviors are often distressing and uncontrollable, triggered by certain mood states (most commonly sadness or depression), and result in a negative mood state and feelings of shame.

Psychiatric comorbidity may also be an issue for individuals struggling with CSB. Studies have found that individuals with CSB often have co-occurring substance use disorders. Family history of addiction is also common with one study indicating that 40% of individuals with CSB had at least one chemically dependent parent.

Pharmacological Treatments and Recommendations

Although a variety of medications have been examined in case reports (e.g. naltrexone, antidepressants, and mood stabilizers), only one double-blind, placebo-controlled study has been published. Compared to placebo, citalopram significantly reduced the desire for sex, frequency of masturbation, and hours of pornography use per week in 28 gay and bisexual men randomized in a 12-week study. High-risk sexual behavior did not differ between groups.

Treatment recommendations are difficult to make given the extremely limited amount of information regarding pharmacotherapy for CSB. There is a substantial need for more systematic studies of the treatment of this disorder.

PYROMANIA

Pyromania is characterized by deliberate and purposeful fire-setting on more than one occasion. The frequency of pyromania within the United States is not well established but one study found pyromania in 1% of college students. A review of 282 arsonists' hospital records found that about 24% who had committed other nonviolent crimes and about 12% who had committed other violent crimes met criteria for pyromania. Within a psychiatric population, studies have found that approximately 6% and 3% meet lifetime and current criteria, respectively, for pyromania. A clinical study of 102 psychiatric inpatient adolescents observed that 6.9% met criteria for current pyromania. Pyromania in

adults appears to be more common in males. Although many individuals with pyromania report pleasure while setting fires, the majority feel severe distress after setting a fire.

No double-blind studies for pyromania have been published. Medications described in case reports that have been demonstrated to be beneficial in the treatment of pyromania include topiramate, escitalopram, sertraline, fluoxetine, lithium, and a combination of olanzapine and sodium valproate. An equal number of medications, however, have failed to show benefit: fluoxetine, valproic acid, lithium, sertraline, olanzapine, escitalopram, citalopram, and clonazepam. Another case report, illustrating the treatment of an 18-year-old male with pyromania, described the use of a combination of topiramate with 3 weeks of daily CBT.

Pyromania is a largely unrecognized disorder that causes significant psychological, social, and legal repercussions. Because few individuals volunteer information regarding their fire-setting, it is important that clinicians recognize the disorder and screen patients appropriately. Various treatments have been helpful in case studies but more research examining etiology and treatment is needed.

INTERNET ADDICTION

Clinical Characteristics

Internet addiction is characterized by excessive preoccupations, urges, or behaviors regarding Internet use resulting in impairment or distress. Internet addiction appears to have three subtypes: excessive gaming, sexual preoccupations (cybersex), and text messaging. The estimated international prevalence rates of Internet addiction is 1.5–8.2%. Within the United States, prevalence rates range from 0.3 to 6%. These rates, however, are derived from studies using a variety of methodologies and, thus, may not correctly reflect the true prevalence of the disorder.

Neuroimaging studies suggest that online gaming cravings activate areas of the brain implicated in substance use disorders. Personality may also play a role in the development of Internet addiction, such as tendency toward novelty seeking and harm avoidance. A recent study in China found that being male, drinking behavior, family dissatisfaction, and recent stressors are predictive of Internet addiction in adolescents. Several cross-sectional studies have found high rates of affective disorders, anxiety disorders, and attention deficit hyperactivity disorder within this population.

Pharmacological Treatments and Recommendations

Although there are no double-blind, placebo-controlled pharmacotherapy studies in the medical literature, two open-label treatment studies have been published. One study examined methylphenidate in 62 children with Internet addiction and co-occurring attention deficit hyperactivity disorder. After 8 weeks of treatment, frequency of Internet use and duration of use both decreased significantly. In another open-label study, escitalopram treatment resulted in a significant decrease in the number of hours spent on the Internet.

With no available placebo-controlled trials, medication treatment recommendations are not possible at this time. Double-blind, placebo-controlled trials are needed.

TRICHOTILLOMANIA

Clinical Characteristics

Approximately 0.5–3.9% of people in the United States have TTM, a disorder characterized by the repetitive, intentional pulling of hair causing noticeable hair loss and resulting in clinically significant distress or functional impairment. TTM is more common in females (~90%) and typically starts in early puberty (11–13 years old). Hair may be pulled from any area of the body but is most commonly pulled from the scalp and eyebrows. One epidemiological study of 1697 individuals with TTM found that about 80% reported that their hair-pulling caused social anxiety, and of those who scored high on a hair-pulling severity measure, about 49% avoided social situations and 35% claimed hair-pulling interfered with daily occupational tasks. Hair-pulling is often hidden from family, friends, and treatment providers and people with TTM may go to great lengths to disguise their problem, such as having an elaborate hairstyle or wearing wigs and makeup.

Pharmacological Treatment

In comparison to the other ICDs, there are a number of controlled pharmacological trials that have been performed in TTM. Five of the eight double-blind pharmacological studies examined antidepressants. One study examined clomipramine compared to desipramine in a 10-week double-blind, cross-over (5 weeks for each agent) design (following 2 weeks of single-blind placebo lead-in). Twelve of thirteen subjects had significant improvement on clomipramine. In contrast to the previous study, clomipramine did not yield a significantly greater response to treatment when compared

to CBT and placebo in 16 subjects randomized into a 9-week, placebo-controlled, parallel-treatment study. Although clomipramine resulted in a greater decrease in symptoms compared to placebo, these differences were not significant. CBT, however, resulted in a significantly greater reduction of TTM symptoms compared to clomipramine.

Study of Fluoxetine in Three Randomized Trials with Conflicting Results

In one study, fluoxetine (doses ranged from 20 to 80 mg day⁻¹) was compared with placebo in an 18-week double-blind cross-over study (with a 5-week washout period between treatment arms; 6 weeks on each agent). No significant differences were found between fluoxetine and placebo on measures of hair-pulling urges, frequency, or severity. In a study comparing fluoxetine with clomipramine (mean dosage of 75 mg day⁻¹ for fluoxetine and 200 mg day⁻¹ for clomipramine), a 2-week placebo lead-in was followed by a double-blind, randomized 20-week crossover design (10 weeks on each agent). Both clomipramine and fluoxetine demonstrated a similar positive treatment effect. A third controlled study used a double-blind, placebo-controlled crossover design with 16 subjects treated with 12 weeks of each agent (taking up to 80 mg day⁻¹ of fluoxetine) separated by a 5-week washout period. Fluoxetine failed to show significant improvement compared to placebo.

In a study of the opioid antagonist, naltrexone was compared to placebo in a 6-week randomized, double-blind parallel study. Of 17 subjects who completed the study, 10 received placebo and 7 received naltrexone 50 mg day⁻¹. Significant improvement was noted for the naltrexone group on one measure of TTM symptoms. Two other measures of symptom improvement, however, showed change in the anticipated direction for the naltrexone group but failed to reach statistical significance.

The atypical neuroleptic, olanzapine, was examined in a double-blind, placebo-controlled study of 25 subjects treated for 12 weeks. Those on active medication had significantly greater improvement on measures of TTM severity compared to placebo, and 85% on active medication (compared to 17% on placebo) were rated as full responders.

In the largest pharmacological study of TTM, *N*-acetylcysteine, a glutamatergic agent, was examined in a 12-week, placebo-controlled study of 50 subjects with TTM. The study found that subjects receiving *N*-acetylcysteine had significantly greater decreases in TTM symptoms and a greater percentage of subjects (56%) assigned to NAC were rated as much or very much improved compared to placebo (17%).

Treatment Summary and Recommendations

Data regarding effective pharmacological treatments for TTM are rather sparse. There is some hint that *N*-acetylcysteine and the atypical neuroleptic olanzapine may have some benefit for TTM, but there is conflicting data supporting the use of serotonin-reuptake inhibitors. Naltrexone may offer some promise in treating TTM, but further research is needed in this area before clear recommendations can be made regarding pharmacological interventions.

PATHOLOGICAL SKIN PICKING

Clinical Characteristics

Individuals with PSP repetitively or compulsively pick their skin, resulting in tissue damaging. The area usually picked is the face, but any body part can be a focus. Prevalence rates of PSP are not well established. A large epidemiological study of 2513 individuals found that between 0.2 and 1.4% of US adults satisfied criteria for PSP; however, a smaller community sample found a prevalence rate of about 5%. Typically, PSP is more common among females. Picking may consume a significant portion of time and frequently leads to infections and significant scarring. Individuals with PSP often have a co-occurring psychiatric condition. Lifetime substance use (38%), affective (28.6–36.4%), and obsessive-compulsive disorder (15.2–19.0%) are common.

Pharmacological Treatment and Recommendations

Only four placebo-controlled, double-blind studies have been completed for PSP, and three of the studies have used selective serotonin-reuptake inhibitors. One study of fluoxetine in 21 subjects with PSP found that, among the 17 completers (6 fluoxetine, 11 placebo), the fluoxetine group improved significantly more than the placebo group after 10 weeks of treatment. However, subjects responded on only one of the three measures in the intent-to-treat analysis and full remission was not observed.

In a second fluoxetine study, 15 subjects were given 6 weeks of open-label fluoxetine followed by a 6-week double-blind discontinuation phase for responders (classified as 30% improvement from baseline severity scores). At the end of the 6-week open-label treatment phase, eight subjects (53.3%) were considered responders. The four subjects randomized to fluoxetine maintained their improvement during the double-blind discontinuation phase while the placebo group returned to baseline levels of picking severity.

In a double-blind study of 45 PSP subjects treated with citalopram for 4 weeks, scores on the Yale-Brown Obsessive Compulsive Scale modified for PSP decreased significantly for the citalopram group but not for the placebo group. However, there was no significant medication effect on the primary outcome measure – a visual analog scale of picking behavior.

One placebo-controlled, double-blind study has evaluated the anticonvulsant, lamotrigine, and found that it was not superior to placebo on any measure of PSP severity in 35 subjects randomized in a 12-week study. Detailed analysis, however, indicated that lamotrigine responders demonstrated impaired cognitive flexibility and delayed reaction times at baseline compared to lamotrigine nonresponders. This suggests that there may be different cognitive subtypes of PSP and that lamotrigine may be effective only in a certain type of PSP.

Although limited, the published pharmacological studies suggest that serotonergic antidepressants may be effective for treating PSP but the overall benefit appears limited.

Further research on this treatment and others is needed for more conclusive results. The lamotrigine study suggests that improved understanding of the pathophysiology of PSP may result in more targeted treatment strategies.

INTERMITTENT EXPLOSIVE DISORDER

Clinical Characteristics

It is estimated that about 4–7.3% of people in the United States have IED, a disorder characterized by recurrent, significant outbursts of aggression resulting in assaultive acts against people or property that are disproportionate to outside stressors. Clinical studies have found that the majority (77–88%) of individuals with IED are male. The first outburst typically occurs in early adolescence with individuals usually meeting IED criteria between ages 14 and 18 years. In general, outbursts last about 30 min and people with IED report significant psychosocial impairment resulting from their behavior and describe their behavior as distressing and problematic. Less than 30% of people with IED, however, have ever received treatment.

In a national survey of 9282 US adults, of the 7.3% who met a lifetime diagnosis of broadly defined IED (having at least three attacks within a lifetime and at least one in the past 12 months), about 82% of individuals with IED have co-occurring lifetime psychiatric disorders, most commonly any mood (37.4%), anxiety (58.1%), and substance use disorders (35.1%).

Pharmacological Treatment and Recommendations

Although there have been several treatment studies of aggression, only three placebo-controlled double-blind pharmacological studies of IED have been published. One study of 100 subjects with IED treated for 14 weeks found that fluoxetine reduced frequency and severity of impulsive aggression and irritability.

A 12-week study of divalproex sodium – a mood stabilizer – in 96 subjects with Cluster B personality disorder, 116 with IED, and 34 with posttraumatic stress disorder found that divalproex had no significant influence on aggression in the subjects with IED.

A third study found that levetiracetam – a mood stabilizer – was not superior to placebo on measures of aggression, hostility, or patient-rated improvement in 40 subjects with IED randomized in a 10-week, variable dose study.

Fluoxetine appears to be a potentially effective treatment option for IED. Given the paucity of treatment studies for IED, however, no clear treatment recommendations for IED can be offered.

CONCLUSIONS

Relatively little is known about behavioral addictions compared to other psychiatric illnesses. Most research has focused on PG, but research concerning clinical and biological/genetic characteristics of all types of behavioral addictions is greatly needed to better inform researchers, clinicians, and the general public. Large, randomized, placebo-controlled studies are especially needed to gain knowledge about beneficial treatments. Taken as a whole, pharmacological treatment studies have suggested that opioid antagonists may be useful for some behavioral addictions (PG, kleptomania), while serotonergic antidepressants may be useful for others (such as IED, PSP, CB, and CSB); however, the data are limited and results should be interpreted with caution. Data from glutamatergic agent studies warrant further research in their use for the treatment of PG and TTM. Further exploration of atypical antipsychotics for the treatment of TTM is also needed. Data regarding lithium, antiepileptic, and stimulant medications are extremely limited and inadequate to reach any clinical judgments. Closer examination of the heterogeneity across and within these disorders and how that heterogeneity impacts pharmacological treatment is an area for further research. Advances in these areas will hopefully increase public awareness of these disorders, serving to improve the lives of those both directly and indirectly affected by behavioral addictions.

Glossary

Atypical neuroleptic a drug used to treat psychiatric conditions, such as schizophrenia and bipolar disorder, which block receptors in the brain's dopamine pathway.
Comorbid the presence of one or more diseases in addition to a primary diagnosis.
Double-blind a research technique in which neither the subject nor the researchers administering the treatment condition know if the subject is receiving the active treatment or the placebo and is done to eliminate biased results.
Glutamatergic agent a drug that modifies glutamate activity in the brain.
Impulsivity an innate tendency toward reacting in a hasty and spontaneous way to internal or external stimuli with a lack of consideration to negative consequences.
Open-label a research method in which subjects and clinicians know which medication the subjects are receiving.

Opioid antagonists a drug that interferes with the binding of opiates to the brain's opioid receptors.

Placebo an inert medication given to a subject that functions as a control to the medication being tested.

Serotonin-reuptake inhibitor a drug that functions as a neurotransmitter uptake inhibitor on the brain's serotonin receptors.

INTRODUCTION

Throughout most of the world in the twenty-first century, governments are involved with multiple aspects of the administration of health care and the financing of health care delivery. Thus the breadth and depth of health care available and accessible in a given setting reflect public policy in that setting. Public policy, in turn, is a reflection of national politics, the evolutionary pattern of legislation, and societal values which guide choices between alternatives.

In the United States, health care policy has emerged rather haphazardly, with a largely *laissez faire* environment dominating up until the first half of the twentieth century when a host of demographic and technological changes transformed health care possibilities and

expectations. Beginning after World War II, concern over reform and reorganization of health care entered the political arena. A bifurcation emerged, centering around the possibility of the Federal government as a single payer for health care, an idea to which its opponents promptly and effectively attached the term, "socialized medicine." Some version of proposed expansion of Federal financial and administrative control of medical care has been represented in a long sequence of proposals and changes that have occurred over the past 70 years.

Historically, the treatment of addiction has had little relation to changes in health care policy. The treatment of substance use disorders (SUDs) in the US is a relatively new entry into the medical care arena, having undergone many transitions and changes since its

inception in the 19th century. From the nineteenth century onward, psychoactive substance use has been seen as a public matter affecting the public good. As such, it has been the target of a series of legislative actions and public policies that have been very specifically addressed to psychoactive substances, including their distribution, use, and resultant needs for interventions directed at some users. Such interventions have combined various forms of treatment and punishment.

SUBSTANCE USE DISORDERS AND THE CONTEMPORARY US MEDICAL CARE SYSTEM

The linkage between SUDs and the medical care system has tightened considerably over the past four decades. Coincidentally, in the twenty-first century reform of the overall US health care system appears to be underway on a potentially large scale. This coincidence of increased medicalization of SUDs and health care reform has led to the possibility of a major transformation of the treatment of SUDs in the US. The main vehicle is the passage and implementation of the Patient Protection and Affordable Care Act of 2010, generally known as the Affordable Care Act (ACA). Despite its Congressional passage and being signed into law, the ACA is presently threatened by a number of court challenges as well as both legislative and state level efforts to slow or prevent its complete implementation.

It is however very unlikely that all of the changes underway will be completely reversed. These unknowns may not be fully resolved for more than a decade, and may undergo constant change as the US social system responds to internal demographic and technological change as well as external pressures created by a globalized economy, and completely unpredictable transformations in world politics and the physical environment.

Intended outcomes of this transition for SUDs treatment in the US is the expansion in the availability and accessibility of treatment and a distinctive integration of SUDs treatment into the American health care system such that it achieves the long-aspired goal of being addressed as “a disease like any other.” Thus, while most of the attention to this wave of health care reform is upon policy specifics, America may indeed experience a major symbolic and definitional transition regarding SUDs.

The specific provisions of ACA increase Medicaid coverage, which is presently a large-scale payer for treatment of SUDs, but within a much lower income range than that mandated by ACA. Further, the provision of mandatory health insurance of nearly the entire population substantially broadens the potential target

population who may be treated for SUDs without substantial out-of-pocket payment. Under the provisions of the law, group health insurance plans must include “mental health and substance use disorder services, including behavioral health treatment,” along with nine other categories of care.

Finally, many different provisions of ACA mandate the integration of all medical services, drawing together much of what is currently “specialty care” (which includes treatment for SUDs), with one of the ideals being the “medical home” where all care is coordinated, duplication eliminated, efficiency in service delivery enhanced, reduced demands for patient skills at “navigating the system,” and reduction of futile referrals for needed care through “hand-offs” are ineffective. But far and away the most significant aspect of ACA for the treatment of SUDs is the fact of its specific inclusion in the legislation, and what this means as the culmination of the long struggle for the treatment of substance dependency as “a disease like any other.”

PARITY LEGISLATION

A unique force in the projected future of the SUDs treatment specialty must be added to considerations of the impact of health care reform. Shortly before the ACA legislation was passed, Congress enacted and the President signed into a law the Mental Health Parity and Addiction Equity Act of 2008, also known as the Wellstone-Domenici Act. The purpose of this Act, referred to here as WDA, is to require that employers who offer health insurance coverage for mental health and SUDs provide coverage that is no more restrictive than coverage for medical and surgical problems.

This legislation complements the broadened coverage and integrative prescriptions of the ACA, with parity of coverage also reinforcing SUDs as “diseases like any other.” In contrast to the ACA, there are at present no predictions of legal challenges to the parity law, although there are few specific tools for guiding its implementation and enforcement. But regardless of the fate of the ACA in the courts or in legislatures, it is difficult to conceive of the reversal of mandated parity in financial coverage for SUDs (as well as psychiatric disorders).

For the treatment of SUDs, the greatest significance of both the ACA and the WDA lies in the fact that these are the first pieces of major Federal legislation that have included mention and discussion of SUDs as an integral part of the health care arena. According to A. Thomas McLellan, Director of the Treatment Research Institute and former Deputy Director of the White House Office on National Drug Control Policy, in the formulation of ACA, treatment of SUDs was not only made normative,

but was seen within the frame of cost savings whereby early interventions in SUDs prevent or reduce needs for later medical care investments. Within WDA, the platform for articulating the concept of parity in coverage was the comparative costs of other medical care. These "firsts" represent a major step toward the institutionalization of treatment for SUDs as a standard expectation within all relevant medical care settings.

THE HISTORICAL PLATFORM FOR SUDs IN TODAY'S HEALTH CARE REFORM

Discussing these projected changes in isolation could be accomplished simple description of the technical provisions of the ACA, but this is likely to be quite meaningless without considering the sociohistorical and political context. Understanding the significance of these reform actions takes us across American history to examine the precursors of today's health care reform in terms of earlier social policies that defined the social impacts of psychoactive substance use and SUDs. An important dimension of this history is that while those involved in the treatment of SUDs have long urged for parity and have been constantly challenged by the imbalance between perceived need for treatment of SUDs and the actual utilization of treatment, there has not until recently been internal pressure to "desegregate" or integrate specialty care for SUDs into mainstream medical care. There is substantial experience with both payment problems and the relative quantity of treatment delivery, but integration is involving and will continue to demand the charting of new territory and the facing of unexpected challenges.

This history begins in Colonial America where psychoactive substance use was initially outside the purview of social concern and beyond the reach of social policy, except for issues related to taxation of production and distribution of beverage alcohol. Drug users were unknown and those whose drinking was viewed as problematic was largely limited to persons who were nonproductive and became wards of the community. A physician and American Founding Father, Benjamin Rush of Pennsylvania, might be counted as a first advocate for "health care reform" for alcoholism by his articulation of a disease conception of the apparently uncontrolled use of distilled liquor. While invariably documented today as the "founding" of modern addiction treatment, there is little evidence of Rush's influence on this score among his own contemporaries.

The next phase saw a slow but soon-to-be dramatically escalated wave of social concern about the dangers and social costs of alcohol use, culminating in National Prohibition, a distinctive social policy almost completely eliminating the legal manufacture or distribution of

beverage alcohol. During the nineteenth century, three "reform" movements highlighting treatment have been documented, none of which yielded lasting effects. First was the invention in Boston of a self-help effort for chronic inebriates who would "take the pledge," and who came to refer to themselves as "Washingtonians." This group established a hospital-like setting for those most devastated by their alcohol consumption. Remnants of that institution still survive today.

Their practices have some clear parallels with the twentieth century technology of Alcoholics Anonymous, but there is no evidence of a connection. Second, activists in New York State developed a major publicly supported sanitarium for chronic inebriates that operated briefly, but which failed as a reform movement when the State Legislature specifically concluded that it was a waste of public dollars to support treatment for this self-indulgent and indolent behavior. Third, a specific residential treatment program for both alcohol and opiate dependence was launched in the 1890s by a physician, Leslie Keeley, which evolved quickly into a "chain" of treatment centers, said to have treated a total of 300 000 patients. The regimen, typically viewed as chicanery by contemporary historians, involved a combination of a secret medication, group discussions, and posttreatment mutual support follow-up in local Keeley Clubs. The Keeley Institutes survived only a short time after Leslie Keeley's death, apparently due more to organizational and financial issues than to perceived failure of the treatment. While no heritage of this effort is claimed, it was remarkably similar in structure to treatment efforts that were to dominate the second half of the twentieth century. Combined treatment of both alcohol and opiate problems in the same setting is especially notable.

Social policies about other psychoactive substances have followed pathways both different and parallel to those directed at alcohol. During the Temperance Movement, moderate concerns about the quasi-medical use of opiates and cocaine led to modest social reactions in the late nineteenth century that is a source of scholarly debate as to whether this "wave" sprung from the widespread use of opiates and other drugs to treat injury and disability resulting from the Civil War. It is noteworthy that Leslie Keeley, who offered opiate-dependence treatment, had been a Civil War surgeon, and likely a substantial number of his patients were veterans of that conflict.

Another brief emergence of medically based treatment (but far from a health care reform was the use by physicians of morphine and heroin (a 1890s invention) as treatments for what was essentially morphine addiction in the late nineteenth and early twentieth centuries. This substitute treatment was eventually forced out of existence by the 1914 Harrison Act,

motivated by the spread of opiate addiction away from the white middle class and into marginalized minority and immigrant populations. This Act ended open traffic in opiates and cocaine, even though programs offering morphine treatment to addicts persisted until 1920 in a few relatively isolated settings. This essentially began the American Drug Prohibition experiment which remains very much alive in the twenty-first century, with efforts and investments that dwarf the earlier prohibition of alcohol.

During the 1920s and 1930s, all forms of medically oriented treatment for all SUDs were essentially defunct, save for some isolated and low visibility private sanatoria. About 20 years after the initiation of Drug Prohibition, the constitutional amendment that had established Alcohol Prohibition was repealed. American culture was placed in limbo about the meaning of alcohol, for the Repeal process was not based on alcohol's safety or the benefits of its use, but on the uncontrollability of its manufacture and distribution. Eventually, the idea of the dangers of alcohol to all users slowly became supplanted by rediscovery of an earlier idea of "alcoholism," its adoption being greatly facilitated by the coincidental invention of an apparently successful "treatment" that became the program of Alcoholics Anonymous (AA).

THE BEGINNINGS OF PARITY FOR SUDs TREATMENT

The overview of the history of health reforms related to SUDs proceeds most clearly from this point if reforms related to alcohol and drugs are viewed separately for most of the twentieth century. The initial drive for the inclusion of alcoholism within health care cannot be labeled as a call for health care reform, but indeed as oriented to inclusion and a very simple form of "parity." Stemming from recently formed (and recently named) AA and reflecting its commitment through its traditions to avoid public involvement, the National Council on Alcoholism Education (NCAE) emerged as a public relations arm of AA, but totally without formal connection or identification. As a potent alternative, it was identified and affiliated from its founding with the Yale Center on Alcohol Studies, bringing credibility and respectability through this Ivy League connection. NCAE was launched in 1944 by Mrs Marty Mann, one of the first women to recover through AA (subsequently renamed the National Council on Alcoholism (NCA) in 1957 and given the expanded label of National Council on Alcohol and Drug Dependence (NCADD) in 1990). Mann had a previous career in public relations and was a deft and effectively aggressive leader of the organization for over 30 years.

Promoting medical parity for the treatment of alcoholism in the 1940s and 1950s was remarkable in several respects. First, its revolutionary nature must be recognized, in that NCAE was formed only 11 years after the repeal of National Prohibition. The revolutionary aspect lies in its redefinition of the alcohol problem as being something other than alcohol itself, but a disease affecting an apparently limited number of people. This contrasted with the official vision of 1933 and before held by the Federal and state governments that beverage alcohol endangered the life of anyone who consumed it. At the same time, the activities of NCAE and its descendant organizations began what was a successful movement to construct a substantial but segregated treatment system for SUDs.

This movement for "parity in recognition" lacked substance in that few if any specific treatments for alcoholism were being promulgated to the medical community by NCAE. The only treatments within its armamentarium were detoxification and AA. The process pursued during this period might be accurately labeled as destigmatization. NCAE's mechanisms were centered on public visibility through the establishment at the community level of local committees or councils, with a core of local AA members encircled by nonalcoholic representatives of the local clergy, physicians, other professions, and often local government.

Much of the publicity centered on the possibilities of recovery, but steered away from specific recruitment to AA. Through the councils' membership and the staging of public presentations, the middle class and respectable nature of the people involved was implicitly emphasized, contradicting the entrenched image of the alcoholic as a "Skid Row" public inebriate without employment, family or even a stable residence.

An early effort to counter this image while creating a new platform for identifying alcoholics began through NCAE as "industrial alcoholism programming." Leaders of the Yale Center of Alcohol Studies had developed "The Yale Plan for Business and Industry" as a means for providing assistance to employees with alcohol problems (largely through AA affiliation) before their behavior led to job termination, a colorful history that has been described by social historians Harrison Trice and Mona Schonbrunn. Between 1948 and 1958, Yale and NCAE employed a colorful and charismatic consultant, Ralph "Lefty" Henderson, who crisscrossed the country as a speaker at local NCAE councils, and visitor to workplaces in an effort to implement Yale Plan strategies. Adoption by workplaces was modest, but became the target of substantial publicity, sometimes accompanied by the endorsement of corporate executives who were willing to be identified as recovered alcoholics. The focus upon the employed alcoholic was a dramatic symbolic

opportunity to reconfigure the national image of the “typical alcoholic” as someone like one’s neighbors and friends, not the smelly panhandler in the central city. At the same time, the well-being of communities’ public inebriates was on the agenda of NCAE. The goal was toward some form of rehabilitation or betterment, first addressing the decriminalization of public intoxication. Instead of public inebriates passing repeatedly through the “revolving door” of the local jail, local communities were urged to establish treatment centers and halfway houses for these individuals wherein opportunities for AA attendance and affiliation were among the offerings. Other than AA, a sharply distinctive treatment technology was not evident.

The movement for official decriminalization spurred through Federal legislation became for a time a centerpiece in the 1950s and 1960s of what was now NCA. This can be viewed as a deliberate effort at health care reform in that it essentially eliminated jail sentences as the societal “cure” for repeated public drunkenness and instead moved toward rehabilitation as the target (Beauchamp, 1980). There was however no suggestion of integration of this treatment with the broader health care community. It was a continuation of a pattern that led to the construction of a substantial but segregated treatment system for SUDs.

To a degree, local law enforcement agencies reacted positively to the removal of their responsibility for public inebriates in their jails. It is unlikely however that decriminalization offered a substantial contribution to a new view of “alcoholism as a disease like any other.” This legislative action did not construct a new or potent constituency that would advocate for NCA’s goal for “recognition parity.”

FORMALIZING TREATMENT FOR SUDs

Two developments that enhanced a broader base for advocacy were the “Minnesota Model” of treatment delivery and a modest but visible success in the development of workplace alcoholism programming. The Minnesota Model can be viewed as a specific step toward a health care “reform” in that it provided a very specific example of the kind of treatment that was being advocated, and at the same time provided for a very tight coupling of the AA model into a professional treatment regimen. Because of the centrality of AA principles within the Minnesota Model, this also set the stage for substantial involvement of recovered alcoholics in the treatment process, which might be viewed as a long-term latent goal of NCAE activity.

A parallel emphasis on medical involvement can be seen in the technology of industrial alcoholism programs.

As mentioned, these had diffused modestly, but following Henderson’s work, a specific workplace-oriented department was established within the national offices of NCA, which served the purpose of facilitating the diffusion and implementation of workplace programs at the level of local NCA councils. As the social historians Trice and Schonbrunn describe, these programs had a “reform” and “mainstreaming into medical care” element through the standard placement of the industrial alcoholism program within the company medical department, and program implementation required the full endorsement and active involvement of the company’s medical director.

The innovative nature of this placement is not obvious unless one considers obvious alternative placements in universally present safety or labor-relations units, which would have cast totally different images over these programs than that garnered by medical department placements. A further near-universal feature of the workplace program was the employment of a recovered alcoholic as the day-to-day program coordinator, usually drawn from company ranks. NCA’s activities in the promotion of workplace-based programs culminated in 1968 in a widely publicized announcement at the 28th World Congress on Alcoholism in Washington DC that the US Federal Government was initiating an employee alcoholism program for all of its civilian employees.

On the last day of 1970, President Nixon reluctantly signed what was called (after the late Senator Harold Hughes of Iowa) the Hughes Act, which established the National Institute on Alcohol Abuse and Alcoholism (NIAAA) within the National Institute of Mental Health, in turn within the National Institutes of Health (NIH). Beyond establishing a modal NIH research institute, this legislation eventually led to what was relatively massive funding for the Federal support of treatment and prevention activities. Included was the national program to advance the diffusion of employee alcoholism programs, and resources were promptly marshaled to support a national campaign that would succeed in mandating health insurance coverage for alcoholism treatment.

THE ORGANIZATIONAL BASIS FOR INTEGRATION OF SUDs INTO MEDICAL CARE

NCA’s activism at the national and local levels can be credited with this massive reform. Beyond the many steps necessary to pass this legislation through both branches of Congress, a cherished story is the personal influence used on Nixon by several leading industrialists who were NCA activists and also in

recovery. The ingredients of “having a seat” at the NIH, funding for treatment, and insurance coverage for treatment that could be tapped via referrals from workplaces all contributed to a solid platform for institutionalization of alcoholism treatment in American society that was not to be reversed, although its support would suffer multiple setbacks in the decades that followed.

The 1970s and 1980s were marked by large-scale growth in alcoholism treatment and an apparent success at destigmatizing alcoholism. One of the main mechanisms was for famous figures to come forward and announce their successful recovery to the public, eventually including Betty Ford, the wife of the President.

It was however another President, Ronald Reagan, who succeeded in a first setback for this apparently successful health care reform movement by transferring most of the funding authority for the support of SUD treatment from the Federal Government to the states. This change, along with what proved to be a temporary removal of NIAAA from NIH, was implemented throughout the 1980s. Most of the alcoholism treatment was centered on the 28-day Minnesota Model, which proved to be highly vulnerable to a confrontation with newly emergent “managed care” in the late 1980s and early 1990s. With employers clamoring for a reduction in what were believed to be externally mandated increases in health care costs, managed care found funding for alcoholism treatment to be a “sitting duck” for cost-cutting. Among its vulnerabilities was the lack of data to support the need for the 28-day inpatient experience, in contrast to briefer and less expensive outpatient care. Further, the absence of differential diagnoses of alcohol problems coupled with the prescription of the 28-day regimen for practically everyone proved indefensible. Thus the second setback to the earlier “reform” was a sharp reduction in the availability of Minnesota Model treatment, the promotion of a relatively vague alternative of brief outpatient treatment, and sharp limits on reimbursement for alcoholism treatment.

At this point in history, the 1990s, the permanent merger of alcohol and drug treatment interests began, initially fitful and with some resistance (particularly from those identified with alcoholism treatment who likely foresaw downward mobility for themselves and increased stigmatization for their target disorder), but from then to the present, the closest approximation of a “single voice” across alcohol and drug treatment interests has emerged. Before turning to those developments and their role in health care reform, a brief review of drug treatment developments during the twentieth century is in order.

TOWARD INSTITUTIONALIZING TREATMENT FOR ILLEGAL DRUG DEPENDENCE

The use of science to discover effective treatment for opiate addiction began in earnest in the late 1920s, and its limited visibility came with the post-World War II establishment of the US Public Health Service Hospital in Lexington, KY. This hospital served as a prison for addicts who had been arrested in venues across the country and as a research laboratory pursuing two goals: establishing the safety of newly invented pharmaceuticals through using the addicts as experimental subjects, and searching for a nonaddicting substitute for the treatment of opiate addiction. Many other research studies on addiction-related phenomena were conducted, and the Lexington laboratories became the precursor of the research laboratories presently operated by the National Institute on Drug Abuse. The establishment of this “treatment” center (and a sister “hospital” in Fort Worth), eventually included experiments at group therapy and a therapeutic community. “Lexington” brought intentional medical labels to the programs, but not necessarily to the clients. Records of publicity from that era clearly describe a dark and ominous (and not necessarily hopeful) medium-security prison setting.

By the 1960s, increased diffusion of “drug panic” related to heroin use in northeastern urban settings set the stage for what might be seen as a dramatic reform, the emergence of methadone treatment for heroin addicts. Other than self-motivated abstinence preceded by “cold turkey” detox, this was a clearly articulated medical means for addicts to become patients and to become abstinent from opiates. Because it continues an opiate addiction, methadone maintenance has never found strong societal acceptance. However it distinctively introduced “treatment” with physicians and nurses. There were however no serious suggestions of a reform that would “mainstream” methadone maintenance into the health care system.

During this period, two other treatment technologies were present, but of low visibility. These were Narcotics Anonymous, a self-help program in many ways identical to AA, and therapeutic communities, which were partly descended from the controversial Synanon organization, and which had a distinctive set of procedures for rehabilitation within a nonmedical and notably non-spiritual residential setting of up to 2-years-duration. While offering alternatives to methadone maintenance, neither of these programs attempted any kind of integration with the broader health care system.

During the 1970s, National Institute on Drug Abuse(-NIDA) emerged in 1974 as a parallel organization to

NIAAA, with the same authorities for the distribution of funds to support treatment. The activities did not overlap however, for much of the NIDA supported activity within drug treatment occurred close to the criminal justice system, and new treatment centers came to be dependent upon referrals from criminal justice. By contrast, NIAAA was struggling to disengage itself from the formerly criminal Skid Row public inebriates, to the point of initially labeling its workplace programming efforts "Project 95" to describe its targeting of the 95% of American alcoholics who are not on Skid Row. Thus, while there was little of the "medicalization fanfare" accompanying the low-key establishment of NIDA, its presence within NIH was a step toward an institutionalized presence in the mainstream health care enterprise that would not be reversed.

The 1970s also saw the explosion of marijuana and psychedelic drug use among middle class youth, as well as the partly-phantom crisis of opiate addiction and other drug abuse among returning Vietnam veterans. This greatly increased the public consciousness and confusion about nonalcohol psychoactive substances. Various forms of emergency care for overdoses and "bad trips" were evident, but there was no surge toward increasing treatment capacity for SUDs on the basis of this highly visible experimentation or veterans' addiction. Instead it shaped public sensitivities in the direction of support for increased social control and surveillance, and the vigorous reemergence of the War on Drugs in the 1980s.

NIDA experienced with NIAAA the disappearance of its treatment funding authority, but gained new prominence through the highly aggressive actions toward drugs encouraged by President Reagan. In addition to the great waves of interdiction on all borders and throughout the world, drug users in the workplace became specific targets through "drug-free workplace" legislation. Mandatory drug testing, particularly of job applicants, diffused very rapidly and served to undermine the constructive orientations in employee programs that had been initiated and supported by NIAAA. Exclusion and punishment rather than treatment became the bywords of the War on Drugs, but the presence of NIDA ironically allowed for spillover opportunities of increased funds that actually ended up supporting SUD treatment.

CREATION OF A SCIENTIFIC FOUNDATION FOR TREATING SUDs

Bringing together the alcohol and drug strands of reform history in the 1990s, it has been mentioned that the two specialty interests merged, precipitated by the

establishment of a merged Federal block grant and other treatment grant support within the new Substance Abuse and Mental Health Services Administration, merging of alcohol and drug "authorities" at the state level, and eventually, providing the range of services for all drug dependence in the same centers, partly driven by the observation that most clients abused multiple substances. This in turn created a "spillover" of therapies that had been developed for alcohol problems such that the predominant treatment model became a substance-free, 12-step orientation model with the goal of long-term abstinence. There is now a single SUD treatment industry, but it is not unified and in fact lacks a unifying professional or trade association or other organizational mechanism that would allow for collectively addressing the challenges of the ACA.

During the 1990s, SUD treatment has been significantly transformed, with several events that can be seen as setting the stage for integration with the broader medical community. These include the evidence-based practice (EBP) movement, medication-assisted treatment of SUDs (especially buprenorphine), the chronic brain disease definition of SUDs, wraparound service adoption and Screening, Brief Intervention and Referral to Treatment (SBIRT)

The essential necessity of adopting EBPs was presented to the specialty in a unilateral fashion following a 1998 commissioned report from the Institute of Medicine. This report made clear that there was a very poor information transfer from treatment research to SUD treatment practice, not unlike other branches of health care where the emphasis upon EBP has become institutionalized. Part of the solution for the SUD specialty was the creation by NIDA of an extensive Clinical Trials Network (CTN) that recently celebrated its 10th anniversary. Utilizing 12 university centers and more than 140 SUD treatment organizations, the CTN conducts intensive clinical trials of treatment technologies either unique to or adapted to SUD treatment and endeavors to diffuse resulting new practices through "blending products" and through a Substance Abuse and Mental Health Services Administration (SAMHSA) supported network of organizations, the Addiction Technology Transfer Centers. The CTN has the potential as both an internal integrative mechanism for the SUD treatment specialty, as well as being an external integrative mechanism into broader health care. It was modeled in part after several mechanisms implemented by the National Cancer Institute, and without doubt serves to legitimize SUD treatment within the broader medical community represented at NIH.

Of the EBPs that have been subject to trials by the CTN and other researchers, the set that offer the most

mainstreaming potential are medications developed and refined for the treatment of SUDs. Here medical management of both alcohol and opiate dependence through naltrexone and detoxification/maintenance for recovery from opiate addiction with buprenorphine are notable links to mainstream medicine, both required supervision by a physician. Using “medication-assisted treatment” to address SUDs may prove a critical link for commonality with the broader medical community.

A Federal initiative launched in 2000 that has specifically established that linkage is the structure within which buprenorphine is delivered to opiate-dependent patients. Rather than adding this to treatments available within methadone clinics, a structure was established that essentially mandates integration with mainstream medicine (particularly primary care) as a precondition for buprenorphine treatment. The intent is to increase utilization of medication-assisted treatment through providing privacy and confidentiality within typical office treatment that may not be available in a methadone clinic. Physicians must be certified by SAMHSA following a training course before they are licensed to distribute buprenorphine (or other drugs for opiate detoxification or maintenance). In order to avoid “pill mills,” each physician was initially limited to 30 patients simultaneously, a number later increased to 100 patients. It is expected that counseling will accompany buprenorphine administration. Physicians working within SUD treatment programs can of course use this setting for buprenorphine treatment, although the intention of these regulations was to maximize involvement of the broader medical community.

MECHANISMS FOR MAINSTREAMING AND INTEGRATION OF SUDs INTO MEDICAL CARE

Mainstreaming SUDs into medical care also involves labels. Accompanying the use of medications in treatment has been a pervasive emphasis in publicity about SUD treatment that addiction is a chronic brain disorder, affecting individuals through their lifetimes, and characterized by relapse. Steady promotion of this concept as if it were unequivocally grounded by research findings is a major dimension of an effort (especially within NIDA) to characterize SUDs for legitimate inclusion within general medical care. This description as a chronic disorder also increases the necessary scope of treatment. While earlier discussion described the promotion of alcoholism as “a disease like any other,” this is much more specific and perhaps medically compelling. However such discussion, regardless the apparent authority of the source, does not necessarily transform the substantial attitudinal residue among

both the public and medical professionals that alcohol and drug dependence are bad habits, describe individuals’ moral weakness, or an engrained pattern of self-medication for an underlying psychiatric disorder.

Another mechanism for integration is embedded in a widely adopted wraparound services that are found in some form in most SUD treatment programs. This concept originated with the Addiction Severity Index developed by Thomas McLellan and his colleagues at the University of Pennsylvania. The fundamental idea is that among SUDs, opiate addiction in particular is characterized by a deterioration of the overall social ecology of the addict’s life, with the SUD embedded in medical, psychological, financial, legal, familial, educational, residential, and employment problems. Without addressing the complex of these other issues, treatment of the SUD will have a minimal impact and any success at abstinence will likely be short lived. Inclusion of medical problems as a wraparound service need is a clear bridge to integration with broader health care.

Perhaps the most prominent mechanism geared toward integration is SBIRT. This concept originated with the work of Michael Fleming and others at the University of Wisconsin that produced the dual findings that primary care physicians could effectively identify alcohol problems within their routine practices, and a brief intervention accompanying such identification could have a useful impact on drinking behavior. The SBIRT mechanism now includes a further step of referring to specialty SUD treatment those patients whose problems clearly extend beyond a brief intervention. A somewhat different version of SBIRT uses the brief intervention as a motivator for referral to specialty treatment without the identifying agent attempting an intervention to address the SUD. True to its invention, the heaviest emphasis at present centers on the SBIRT mechanism and its implementation in primary care practice, with reimbursement now available when the full procedure is utilized. This involvement of primary care physicians is a strong example of an integrative bridge of SUD treatment into general medical care.

Other SBIRT implementation settings include emergency rooms and general hospital treatment settings. Research has demonstrated substantial presence of untreated SUDs in both of these settings. Success in primary care and general hospitals rests on the skills of the physicians or nurses in motivating either behavior change or referral action. SBIRT implementation in emergency rooms offers multiple challenges between delivering the immediately needed treatment and the engagement for effective delivery of treatment for SUDs for patients who may be short-term, or who end up in care in some unit well beyond the scope of the emergency service.

Despite some efforts that have not received Federal support, there has been minimal progress in integrating SBIRT into the workplace. Extending back to the early efforts of NIAAA, potential platforms for the use of SBIRT are possible within some forms of employee assistance programs (EAP) where self-referred employees undergo diagnostic interviews with adequately credentialed personnel. SBIRT might also be successfully implemented within wellness programs that are common in larger workplaces. Epidemiological data confirm that the majority of those with untreated alcohol use disorders are gainfully employed, yet the implementation of SBIRT in these settings is yet to become a priority interest in the overall effort toward integrating SUD treatment into general medical care.

BARRIERS TO THE INTEGRATION OF THE TREATMENT OF SUDs INTO MEDICAL CARE

Having reviewed the changes and initiatives that have formed bridges for integration of SUD treatment into mainstream health care, the issue to be addressed is the manner in which the ACA will affect the treatment of SUDs. In this section, examples of problematic areas for integration are considered, including workforce issues, “co-occurring disorders,” and acceptance and engagement by physicians and nurses in SUDs treatment.

Is the current treatment workforce eligible for integration into mainstream medical care? Parts of the ACA appear to address this, stressing the need for credentials that extend beyond the training of a substantial minority of the SUD treatment workforce. At the same time, within social work, clinical psychology, nursing, and medicine, there is very little in terms of in-depth training that could either be made available to the current workforce or adequately train a new workforce, which in turn would be expected to be attracted to the engagement in SUD treatment. Thus the current workforce may not be able to meet the requirements of practice within an integrated setting where they likely will be required to deal with multiple medical situations not seen in current specialty SUD treatment. At the same time, no strategic plan appears to be in place to either upgrade their training or train and attract a replacement workforce.

An ongoing example of a facet of integration within the currently segregated SUDs treatment specialty is what is commonly labeled as “co-occurring disorders.” At first blush, this would appear to encompass consideration of any ongoing medical problem that is a “preexisting” condition or perhaps even extends to physical and psychological disabilities. However, it refers in fact only to psychiatric disorder that is believed to exacerbate the

SUD. This topic is typically addressed separately from the wraparound services discussed previously.

Attention to this limited set of problems is implicitly viewed as a feature of modern, evidence-based treatment in contrast to the 12-step-dominated treatment of the past. Within the unwritten but potent cultural lore of 12-step programs, depression and anxiety, sometimes in severe forms, are viewed as part of the process of recovering from a SUD. The implicit belief is that these problems are the result of the long process of deterioration accompanying the development of the addiction, and that they are natural and to-be-expected experiences for many. As one sustains abstinence and moves toward sobriety through the steps, these conditions will “fall away” and thus do not need ancillary treatment.

The new science-driven treatment dismisses these assumptions as foolish and dangerous, perhaps typical of the outmoded past. Today these co-occurring problems must be addressed in treatment plans. It is argued that either successful treatment of the “other” condition must precede addressing the SUD, or that treatment of both conditions must occur simultaneously. This of course raises complex challenges for the competencies that are available in a treatment setting, leading in many cases to the need for external referral. The issue of third-party coverage for such care may also be complicated, although within the lore of the treatment specialty, it is often observed that the diagnosis of co-occurring disorder is a boon for payments in that the psychiatric diagnosis may create eligibilities for reimbursement that are more extensive than those available to cover the treatment of the SUD. Alternatively, a dual diagnosis may also for an extension of treatment after payments for the treatment of the SUD have been exhausted.

Ideally, this reimbursement problem may be resolved by full implementation of parity legislation. Beyond that resolution, however, the current segregated SUD treatment specialty is not sanguine about its success in addressing what it has called co-occurring disorders. Not surprisingly, comparative data often reveal the worst prognoses for those with these dual diagnoses. Thus there is little argument that within the context of segregated treatment, the limited definition of co-occurring disorders has produced operational and logistic problems that are not yet even close to resolution.

Integration of treatment as outlined by ACA is however a definite challenge to this operational definition of disorders that “co-occur” with SUDs. Without a complete cataloging, it is evident that a multitude of disorders may co-occur with SUDs, particularly closely linked problems such as diabetes, stomach ulcers, circulatory problems, and respiratory issues. It has long been a contention of the SUDs treatment community that the broader medical care community, particularly primary

care physicians, will readily treat the physiological and disabling consequences of substance abuse and addiction, but will not address, diagnose or treat the abuse or addiction itself. Integration and medical home concepts supposedly will bring this bifurcation to an end. Addressing these as co-occurring conditions with SUDs has not been addressed. One can speculate about the need for treatment teams bridging the skills needed for these co-occurrences, the issues of authority in such teams, matters of priority, and the braiding or unraveling of reimbursement.

One of the greatest challenges for the integration of SUDs treatment into mainstream health care under ACA is the engagement of the entire health care workforce, but especially physicians and nurses. Medical and nursing education is completely inadequate in its past and present coverage of SUDs. There has long been evidence of negative attitudes toward SUDs among physicians and nurses, not only sharing negative stereotypes with the general public but having had negative socialization experiences where patients with SUDs have been recalcitrant, resistant to treatment, and chronic relapsers. It is clear that within integrated systems of care such as medical homes, leadership positions will go to physicians and nurses. Without their active support and involvement, adequate and appropriate attention to SUDs may be at risk. Most of these professionals currently lack any in-depth training in the nature of SUDs or the effective technologies of SUDs treatment. This is perhaps the most threatening artifact of the decades of segregation of SUDs treatment from mainstream medical care. There appear to be no plans whatsoever for the training of these populations or for the supplementation of medical and nursing education to include adequate coverage of SUDs.

CHALLENGES IN THE IMPLEMENTATION OF HEALTH CARE REFORM AND THE TREATMENT OF SUDs

As a concluding set of observations, it is important to reverse the focus and consider some potential ways in which the integrated treatment of SUDs might affect mainstream health care, including the concept of wrap-around services, long-term follow-up, and the recovery movement.

As more acute diseases are successfully contained, the fact emerges that most of the American population will eventually cope with a chronic illness, in many cases leading to death. Through its concept and implementation of wrap-around services, SUD treatment has valuable lessons to transfer to the care of other chronic disorders. There is ample documentation of the life

difficulties that all sorts of patients experience in attempting to sustain the gains from treatment. As SUD treatment becomes integrated into general medical care, the logic of wrap-around services can be transferred to those with other chronic conditions whose problems in their life ecology can undermine treatment gains. Wrap-around services do not require added services beyond skilled selection and referral to external agencies specializing in meeting these needs.

The principle of investing in long-term follow-up originates with AA, has long been accepted among SUD treatment specialists, and today is incorporated into most of SUD treatment. Among the very few changes observed in the AA culture over the decades was a transition from the use of the term "recovered alcoholic" to "recovering alcoholic." The positive idea of continuous growth in ongoing 12-step participation is intermingled with the subtle warning that changes in lifestyle and other transitions can lead to relapse. The fit with the nature of chronic disease is obvious, almost all of which have a lifestyle change component associated with maximizing long-term health. Among those who have experienced SUD treatment, continuous recovery experiences can lead to a positive "recovery" identity which can be supported and encouraged by medical personnel without requiring their active involvement in added therapy.

Over the past decade, the long-term recovery concept has been broadened and investments in treatment by SUD specialists have been enhanced by a new "recovery movement." Partly consistent with the model of SUDs as lifelong chronic diseases, the recovery movement emphasizes the need for involvement in communities of others in recovery in order to sustain gains. While building upon and to a degree incorporating some of the concepts of 12-step programs, the recovery movement attempts to be nondoctrinaire and totally inclusive of persons with a wide range of treatment experiences. Spreading this notion to other chronic diseases could be a very low cost means of mobilizing community-based interests and resources that sustain the investments made in the gains accomplished by treatment.

List of Abbreviations

AA	Alcoholics Anonymous
ACA	Affordable Care Act
CTN	Clinical Trials Network
EBP	evidence-based practice
NCA	National Council on Alcoholism
NCAE	National Council on Alcoholism Education
NIAAA	National Institute on Alcohol Abuse and Alcoholism
NIDA	National Institute on Drug Abuse
NIH	National Institutes of Health

SAMHSA	Substance Abuse and Mental Health Services Administration
SBIRT	Screening, Brief Intervention and Referral to Treatment
SUDs	substance use disorders
WDA	Wellstone-Domenici Act

Glossary

Affordable Care Act it is believed that the ACA will reinforce the parity law, ensuring that all Americans are able to get the SUD care that they require.

Mental Health Parity and Addiction Equity Act of 2008, also known as the Wellstone-Domenici Act under this Federal law, insurance companies will not be able to limit benefits for the treatment of substance use disorders. This bill was a major legislative project of the late Senator Paul Wellstone and former Congressional Representative Jim Ramstad, both of Minnesota, and both publicly announced recovering alcoholics. It was the only amendment attached to the history-making \$780B “bailout” bill passed by Congress to stimulate the American economy.

Parity equality, parity is the recognition of substance use disorders as equivalents to physical illnesses. Historically, many health insurers have limited benefits for SUDs and psychiatric disorders to a much lower level than those available for physical conditions. Consequently, many people choose not to seek treatment, and brief therapy becomes the only option for those who do get help.

IMPROVING THE QUALITY OF ADDICTION TREATMENT

Treatment for alcohol and drug use disorders varies. Addiction treatment is the product of tens of thousands of practitioners with idiosyncratic approaches to counseling; most counselors practice without professional licensure and receive little supervision. For decades, the primary training for many alcohol and drug counselors has been personal experience in recovery rather than professional training in graduate schools. Most counselors work in independent not-for-profit corporations that specialize in treating alcohol and drug use disorders. The 13 000–14 000 specialty clinics in the United States tend to be small with a median daily caseload of 30 patients. Services are not standardized across clinics or within clinics

across counselors. Treatment outcomes, moreover, appear to be relatively unpredictable and outcomes tend to be similar when examined by treatment modality, level of care, and patient attributes. Addiction treatment's reliance on counselors without professional licensure practicing in small independent specialty clinics with little supervision and few standardized practices contributes to concern that quality of care is uncertain. From an external perspective, the delivery of addiction treatment appears to be haphazard. It is not surprising that many observers are skeptical of the value of addiction treatment and demand evidence of treatment effectiveness. Persistent skepticism challenges the field of addiction treatment to document the quality and effectiveness of care, and to demonstrate the personal and social value of investments in addiction treatment.

Improving the quality of care is a challenge. There is a need for quality treatment but typical approaches to quality assurance are reactive – licensure, accreditation, credentialing, and practice standards. Recent approaches to treatment quality emphasize strategies to continuously improve treatment processes. Examples of process improvement from the Network for the Improvement of Addiction Treatment (NIATx) and related initiatives illustrate the application and impacts of quality improvement. Performance measurement becomes the hurdle – program management must identify useful measures of performance that link to patient outcomes. The environment for addiction treatment is changing rapidly. In 2025, addiction treatment may be more fully integrated with primary care, use population measures of health, and rely on emerging electronic technology.

NEED FOR QUALITY ADDICTION TREATMENT

In the United States, about 23 million individuals 12 years of age and older meet diagnostic criteria for alcohol and drug use disorders. The estimated cost of untreated addiction sums to more than \$180 billion a year (i.e. lost productivity, law enforcement costs, health care expenses, and entitlement payments). In addition to the financial costs, untreated addiction increases medical risks and death, family and social problems, and reduces quality of life. Conversely, individuals who initiate and maintain stable recovery benefit through improved health, increased employment, and enhanced well-being. Society benefits through reductions in crime and the burden of caring for individuals and their families disabled by addiction. For all of these reasons, it is incumbent upon the field to deliver the highest quality treatment.

STRATEGIES TO PROMOTE QUALITY CARE

Quality of addiction treatment has been a concern since states began building addiction treatment systems in the 1960s and 1970s. Quality assessment has evolved from a focus on licensure to accreditation and credentialing to development of practice standards and, more recently, to the use of process improvement.

Licensure

States license professions and services to protect consumers. The enabling legislation that created state programs for alcohol and drug treatment typically includes licensure requirements and strengthen

community confidence in the credibility and quality of addiction treatment services. Licensure regulations specify health and safety standards (e.g. screens for windows, width of door ways), and staffing requirements (e.g. staff to patient ratios, hours of staff training, and supervision). Because state licensure regulations typically date to the 1970s, they reflect the dominant models of care at that time (i.e. residential and inpatient care and the use of staff with personal experience in recovery and without professional graduate education). States typically license addiction treatment programs and facilities rather than practitioners. Practitioner licensure is a relatively new development for addiction treatment professionals. State standards are idiosyncratic to each state and there is little consistency across states. State licensure sets minimum standards to operate a business in the state.

Accreditation

Because of the variability in state licensure requirements, trade groups established service standards that were consistent across the membership and more stringent than state licensure requirements. Accreditation offers consumers increased confidence in the credibility and quality of the services provided, and may offer a competitive advantage over nonaccredited services. Accreditation requires organizations to meet specific standards of care and business operations (e.g. treatment services provided and documentation required, facility requirements, human resources, safety and infection control, patient rights, and performance improvement). Survey teams of professionals from other accredited organizations conduct site visits to determine if applicant organizations meet the accreditation standards. Organizations are typically visited every 2 or 3 years in order to maintain accreditation.

In the behavioral health field, the most prominent accreditation organizations include the Joint Commission (the Joint Commission on Accreditation of Health Care Organizations) and CARF International (formerly the Commission on Accreditation of Rehabilitation Facilities). The Joint Commission dates its efforts to standardize hospital services to the founding of the American College of Surgeons in 1913 and the subsequent creation of the Joint Commission on Accreditation of Hospitals in 1951; accreditation of mental health and addiction treatment services began in 1972. CARF International began in 1966.

The 2007 National Survey of Substance Abuse Treatment Services (N-SSATS), an annual census of addiction treatment facilities, reports that the Joint Commission accredited 21% of the nation's 13600 addiction

treatment facilities and CARF International accredited 20%. A handful of facilities reported accreditation from the Council on Accreditation (5%) and the National Council on Quality Assurance (3%). The Joint Commission accredited more facilities operated by federal agencies (80%), general health care organizations (67%), and mental health programs (36%) than free-standing addiction treatment centers (17%). Similarly the Joint Commission was more likely to accredit inpatient services (79%) than methadone (33%) and outpatient services (20%). CARF dominated the accreditation for methadone (51%). Overall, 95% of the addiction treatment facilities responding to N-SSATS reported being licensed or accredited.

Credentialing and Privileging

Health care organizations usually verify that the practitioners they hire are appropriately trained and qualified. Background checks confirm that practitioners completed training in accredited professional programs and have professional licenses. Without appropriate credentials, practitioners cannot be granted practice privileges within the health care organization. Addiction treatment organizations, however, may be less likely to complete formal verification of counselor training because many of the counselors they hire are not licensed to practice independently.

Practice Standards and Clinical Guidelines

Clinical guidelines and practice standards usually emerge from professional trade organizations to establish standards of care and promote consistency across practitioners in the delivery of care. The American Psychiatric Association, for example, developed guidelines for the treatment of alcohol and drug use disorders.

The most important standard of care may be the *National Voluntary Consensus Standards for the Treatment of Substance Use Conditions: Evidence-Based Treatment Practices* issued by the National Quality Forum in 2007. The recommendations, applicable to all members (national consumer advocacy groups, health professional trade associations, health systems, health plans, groups that purchase health plans, pharmaceutical companies, and research institutes), identify four domains (and sub-domains) of expected services for addressing addiction: (1) identification of substance use conditions (screening and case finding, diagnosis and assessment); (2) initiation and engagement in treatment (brief intervention, promoting engagement, and withdrawal management); (3) therapeutic interventions to treat substance use illness (psychosocial interventions and pharmacotherapy); and (4) continuing care management of substance use illness. As a result of the National

Quality Forum's standards, health care plans and health care organizations are expected to screen for alcohol and drug disorders, initiate care, and use evidence-based practices for the treatment of addiction. The standards specifically recommend pharmacotherapy for adult patients with no medical contraindications and diagnosed with opioid, alcohol, and/or nicotine dependence; the standards stipulate that medication should be provided in combination with psychosocial treatment. If fully implemented, the standards could facilitate the integration of addiction treatment into general medical care.

Process Improvement

Quality assurance through the use of licensure, accreditation, credentialing, and practice guidelines tends to be a reactive process. When systems fail to meet standards, corrections are made. Quality improvement is a proactive process that shifts the focus from correcting errors and mistakes to preventing errors and mistakes. Systems are developed to minimize the potential for error and seek continued improvements in the quality of care (fewer mistakes). Quality improvement also shifts perspective from organizational needs (i.e. maintain accreditation) to consumer needs (i.e. how do we serve patients more efficiently and effectively) and requires attention to patient expectation and satisfaction. Quality improvement is now an important facet of accreditation and a central part of quality care.

QUALITY IMPROVEMENT AND HEALTH CARE

The Institute of Medicine's Committee on the Quality of Health Care in America challenged the US health care system to improve health care delivery systems, prioritize patient needs, implement evidence-based decision making, continue efforts to improve patient outcomes, and reduce inefficiencies. Their report, *Crossing the Quality Chasm*, encouraged the US health care system to adopt six aims to guide quality improvement efforts: (1) safe care – avoids injuries to patients from the care intended to help them; (2) effective care – provides services based on scientific knowledge to all who could benefit and refrains from providing services to those not likely to benefit; (3) patient-centered care – is respectful of and responsive to individual patient preferences, needs, and values and ensures that patient values guide all clinical decisions; (4) timely care – reduces waiting time and sometimes harmful delays for both those who receive and those who give care; (5) efficient care – avoids waste, in particular waste of equipment, supplies, ideas, and energy; and (6) equitable care – consistent high

quality across gender, ethnicity, geographic location, and socioeconomic status. A 2005 Institute of Medicine report extended the *Crossing the Quality Chasm* structure to alcohol, drug, and mental health treatment and recommended efforts to (1) promote patient-centered care, (2) foster the adoption of evidence-based practices, (3) develop and use process and outcome measures to enhance the quality of care, and (4) mandate the use of quality improvement measures.

The Institute of Medicine reports catalyzed the application of process improvement within US health care systems. Systems of care are expected to collect data that document the effectiveness of care delivery and use the data to proactively manage care so that processes of care become more efficient and more effective. These expectations are generalizing slowly to the delivery of behavioral health care and to treatment for alcohol and drug use disorders.

IMPROVING THE DELIVERY OF ADDICTION TREATMENT

The Institute of Medicine's six dimensions of quality care apply to treatment for alcohol and drug use disorders. Delayed care is less effective; delays reduce rather than improve motivation for treatment. Treatment systems and providers should identify and address disparities in access and retention so that underserved groups have equitable access to care. System changes can promote the adoption of evidence-based practices including the use of behavioral and pharmacological therapies. Enhanced retention reduces no-show rates and improves counselor productivity and efficiency. Attention to patient needs leads to changes from systems that benefit practitioners (e.g. 50-min sessions between the hours of 9:00 and 5:00 on weekdays) to more accessible services (e.g. early morning and evening services including weekends). Despite the promise of process improvement, the application to addiction treatment remains novel. NIATx is helping addiction treatment organizations and systems improve the quality of care.

NIATx

In 2003, the Center for Substance Abuse Treatment (CSAT) and the Robert Wood Johnson Foundation (RWJF) collaborated to bring quality improvement to addiction treatment. Their aims included improved access and retention, and as a result, improved efficiency and effectiveness. The vehicle for their initiative was the NIATx at the University of Wisconsin – Madison. NIATx provides training to participating agencies in implementing a simplified version of the Institute for Health Care Improvement's hospital improvement support

system. NIATx combines the process improvement tradition of Deming and Juran with four quality improvement aims: (1) reduce waiting time to treatment (timeliness); (2) reduce the number of clients who make first contact but do not come in for assessment (no-shows); (3) increase the number of clients admitted to treatment (admissions); and (4) retain clients in treatment (continuation).

NIATx uses five principles which evolved through a review of product innovation and process improvement research. The first principle is "Understand and involve the customer." Customer-oriented organizations involve those they serve in developing and assessing improvements, confirming that improvements meet expectations. Customers in the substance abuse treatment realm are not limited to clients; this principle extends to the families of clients, staff working at the site, and even the surrounding community. The second principle, "Fix key problems," links organizational change to agency goals by directing change agents to focus on processes that are critical to the organization. Specific targets vary. Agencies are encouraged to link changes to salient organizational objectives such as reduced staff turnover or improved client retention and, in turn, enhance the agency's business case. The third principle, "Pick a powerful change leader" addresses how to select individuals who will lead change cycles and coordinate change teams. These leaders must have adequate authority and respect from staff to build and motivate change teams. They must also be able to promote buy-in by having a clear vision that is attractive clinic-wide. The fourth principle, "Get ideas from the outside," encourages organizations to seek input from outside their field. In fact, the process improvement movement within the health care field draws heavily on continuous improvement models initially developed to improve manufacturing processes. Change teams are encouraged to seek out creative ideas from other organizations' successes including business practices from other domains such as the transportation and hospitality industries. The last principle is "Use rapid-cycle testing."

Participants use rapid Plan-Do-Study-Act (PDSA) cycles to identify organizational problems and generate solutions (Plan), implement new processes (Do), measure and assess the outcomes (Study), and institutionalize the change or make additional changes (Act). Ideas for change projects can be self-generated by a change team or the result of a "walk through." Walk throughs involve a staff member role-playing as a client in order to gain a customer perspective. For example, during a walk through the staff member will call for an appointment and document what kind of an experience it was and ways to improve it. Another example is arriving for the intake appointment and observing

how they were greeted, how long the intake process took, any redundant paperwork, etc. On the basis of this information, changes are proposed and piloted to assess feasibility and initial effects. Participating agencies strive to use these observations to remove inefficiencies that delay admissions and contribute to missed appointments and early dropout. Strategies include but are not limited to (1) paperwork reduction, (2) motivational interviewing, (3) reminder calls, (4) improved transitions between levels of care, (5) contingency management, and (6) counselor-specific feedback. A cross-site evaluation of NIATx participants found a 37% reduction in days to treatment from 19.6 to 12.4 days across all levels of care. Retention in care also improved; the proportion of clients who completed a first session of care and returned for a second and third session of care increased 18% between the first and second session (72–85%) and 17% between the first and third session of care (62–73%).

NIATx Case Study: Acadia

Acadia Hospital, a freestanding psychiatric hospital in Bangor, Maine, participated in the initial cohort of NIATx members. In 2003, 25% of the clients who called for outpatient care at Acadia attended their assessment appointments, typically 4 days passed between first call for treatment and intake appointment, and only 19% entered treatment. Acadia formed a walk through team and recorded experiences, timelines, and questions encountered from a client perspective. The walk through identified barriers to admission in Acadia's intake procedures; clients were required to place daily calls to the assessment center to schedule appointments to "demonstrate their interest in treatment." Acadia used the NIATx process improvement approach to reduce the time between a first call for service and admission through a series of changes: (1) not requiring patients to call during the waiting period and (2) introducing first-come, first-served walk-in assessments. As a result of the changes, 65% of the approximately 225 clients a month who called for treatment came in for assessment (compared to the 25% baseline) and 52% of the clients (instead of 19%) entered treatment. Other changes, including creating a pool of clinicians to accommodate heavy intake days and expanding the number of hours per day, staff could evaluate clients led a reduction in time to treatment from 4.1 to 1.3 days. Now that Acadia served more clients, they added staff and increased revenue by 56% over 2 years.

NIATx 200

NIATx 200 tested the structure of NIATx. A randomized trial of 201 agencies examined the effectiveness of

four combinations of services for adopting and sustaining organizational improvements: (1) *learning sessions* – biannual meetings where change teams convene to learn and gather support from each other and to receive technical assistance and guidance from outside experts on how best to adopt innovations; (2) *interest circle calls* – monthly teleconferences where agency change leaders discuss change-related issues and progress (participants share and discuss strategies to improve timeliness, continuation, admissions, drop-outs, and transitions); (3) *coaching* – coaches use site visits, monthly phone conferences, and e-mail to help agencies address key issues, offer process improvement training, and promote appropriate innovation; and (4) all three services (learning sessions, interest circle calls, and coaching). The NIATx 200 website (<http://www.niatx200.net>) provides useful process improvement tools including (1) a catalog of change ideas and case studies, (2) a toolbox providing just-in-time training on topics such as walk throughs and key innovations, (3) online tools to assess organizational (or project) readiness for and ability to sustain change, and (4) links to relevant process improvement websites.

STAR-SI

The Strengthening Treatment Access and Retention – State Implementation (STAR-SI) program was funded by the Substance Abuse and Mental Health Services Administration's (SAMHSA) CSAT and the RWJF. STAR-SI extends NIATx principles to state-level process improvements and improves delivery of substance abuse treatment. System barriers and broken administrative procedures can often only be addressed at the state level. STAR-SI encouraged states to leverage their position of purchasers of addiction treatment services states to improve practice. Nine state-provider partnerships in Florida, Illinois, Iowa, Maine, New York, Ohio, Oklahoma, South Carolina, and Wisconsin received funding to implement process improvement strategies targeting fiscal, regulatory, and policy changes. An important component of STAR-SI includes designing and testing methods states and other payers use to engage with each other and with providers. The case of Oklahoma provides some insight into STAR-SI's success.

STAR-SI Case Study: Oklahoma

The Oklahoma Department of Mental Health & Substance Abuse Services (ODMHSAS) began its work with six providers to review state processes that impede delivery of care. After identifying issues such as complicated certification rules, contract requirements, and

miscommunication between the state and providers, the partnership used process improvement methods to ameliorate these problems. As a result, redundant paper was eliminated, waiting times to treatment were reduced, and continuation rates increased. Jennifer Glover, director of ODMHSAS reported that the key was changing the nature of the relationship: "Historically, providers have seen the single state agency as an enforcer, rather than as a partner." The collaborative use of change cycles invited provider input in a way that had never occurred before, bringing about a commitment to a "culture of change." In fact, soon after the initiative's success was reported, the governor signed state legislation which required providers to perform "walk throughs," a component that fosters a customer-centered approach to process improvement.

Advancing Recovery

Advancing Recovery was an RWJF initiative using process improvement strategies and system change to promote the adoption of evidence-based practices for addiction treatment. Twelve states or cities (Alabama, Arkansas, Baltimore, Colorado, Dallas, Delaware, Florida, Kentucky, Maine, Missouri, Rhode Island, and West Virginia) formed partnerships with addiction treatment centers to facilitate the use of behavioral and pharmacological therapies through changes in regulation, financing, interagency collaboration, treatment processes, and customer input. Comparing the first and last quarters of the year, Colorado, Dallas, Maine, Missouri, and West Virginia reported a collective 163% increase in the use of medication-assisted treatment and Alabama, Arkansas, Baltimore, Colorado, Kentucky, and Rhode Island increased the use of continuing care 28%. Advancing Recovery illustrates the application of process improvement to system changes for addiction treatment and the potential to leverage change and strengthen the use of evidence-based practices.

A common characteristic of process improvement strategies is the attention to performance measures. Collection and analysis of valid and reliable data can be used to guide and evaluate efforts to promote improvements in the quality of care. Data managers, policy makers, and researchers are increasing attention to data system development to enhance tracking of service quality measures.

PERFORMANCE MEASUREMENT

Process improvement implementations rely heavily on collection and analysis of data. To measure and improve delivery of care, systems must be able to collect information, measure change, and provide feedback.

The Health Care Effectiveness Data and Information Set (HEDIS) (a set of performance measures used to compare and evaluate health plans), for example, includes performance measures developed by the Washington Circle to assess the initiation of treatment for drug and alcohol disorders (the percent of patients diagnosed with a drug or alcohol problem who begin care within 14 days of the diagnosis) and engagement in care (percent of those who initiate care who receive two or more units of care within 30 days). The data suggest that health plans have weak showings on these measures. The percent of patients in commercial plans who initiate care has declined from 46% (2004) to 43% (2009) and the percent who engage in care (16%) is disappointing.

Barriers to Performance Measures

Data systems in addiction treatment programs are typically underdeveloped, underfunded, underutilized, and poorly maintained. A key challenge in the assessment of substance abuse treatment is the development of systems and measures to accurately monitor quality indicators. Innovations to improve data system infrastructure are critical for informing decision makers about quality measures. The same innovations seen in the medical field for reducing errors and improving outcomes can be applied in the addiction field. Challenges associated with these improvements include the cost of the technologies and workforce training.

Small numbers are a critical impediment to implementing electronic health records within substance abuse treatment systems: the median number of clients in outpatient treatment is 30, so the per patient costs associated with computerizing records is an economic challenge. In addition, many addiction treatment agencies do not intrinsically value data collection and data-driven decision making; therefore, there may be few perceived benefits to the treatment center other than completing state and federal reporting requirements. In an examination of program use of data for quality improvement, agencies struggled to accurately and consistently provide client-level data that would inform them of their progress on their process improvement goals. Primary barriers to the use of data include lack of expertise and system complexity. In NIATx many counselors had difficulty understanding appropriate outcome measures or did not collect appropriate baseline data. Moreover, data collection was unreliable due to data collection staff turnover and position vacancies. Accurate data collection of measures at the agency is critical to track the progress agencies are making with clients prior to their discharge. Also of interest is what happens to clients after they leave treatment. Does

treatment and improved agency processes have an impact on clients post-discharge?

Quality Improvement and Client Outcome Measures

Efforts to track clients after leaving treatment are costly and impractical. A critical public policy issue for studying the quality of substance abuse treatment, nonetheless, is to provide evidence on treatment effectiveness by linking process quality measures with enhanced treatment outcomes.

Improved data reporting through electronic health records and standardized measures is a step toward automated quality monitoring. At present, however, tracking systems generally cannot provide data on outcomes beyond treatment discharge. Research documents the relationship between treatment and improved social outcomes such as reduced criminal activity and health care costs, but little is known of how improvements in the delivery of drug treatment influence these relationships over time. This barrier to progress in the field can be addressed by leveraging technology to link across disparate state administrative databases that capture data on health care utilization, employment, and criminal justice involvement. State data systems offer valuable yet underutilized methods of monitoring provider performance and client outcomes.

Linking state administrative systems facilitates analyses of access to and utilization of addiction treatment services, treatment outcomes, and societal economic impacts. The ability to link records across systems becomes an important source of information to evaluate the longitudinal impact of an intervention. In order to develop appropriate research protocols, researchers working with state administrative datasets need to identify and select the appropriate data sources, determine how to obtain the required data, and understand the advantages and challenges of the selected data sources. Client outcomes are of particular interest to program administrators and state legislators responsible for treatment funding decisions and long-term planning.

ADDICTION TREATMENT QUALITY IN 2025

The addiction treatment system in the United States is likely to change rapidly in the next generation. Efforts to reform health care and to integrate addiction treatment into primary care will change the delivery of care and the assessment of treatment quality. There will be more focus on population measures of effectiveness and greater reliance on electronic technology.

Traditionally, substance use conditions are treated primarily in specialty clinics, separate from general medical practice. Communication about client conditions and status between treatment providers and general health care practitioners is nonexistent and routine screening for substance use disorders is atypical. When health care providers identify problems, moreover, the patient may simply receive a referral, with no follow-up. While treatment has generally occurred outside primary and other health care settings, creative models for integrated care are being developed and may change the assessment of treatment quality.

Integrated Treatment and Parity

In the United States, two federally sponsored studies have increased support for the integration of services. The first, *Integration of Mental Health/Substance Abuse and Primary Care*, was sponsored by the Agency for Health Care Research and Quality as part of its Evidence Report/Technology Assessment Series. This report found that integrated care led to better outcomes for those with alcohol use disorders and documented that complex, multi-plan payment schedules were an impediment to the implementation of this integrated model.

The second report, *Reimbursement of Mental Health Services in Primary Care Settings*, was sponsored by the SAMHSA. The goal was to respond to the 2003 President's New Freedom Commission on Mental Health, *Transforming Mental Health Care in America*, which called for improved integration of physical and mental health. SAMHSA collaborated with the Health Resources and Services Administration, and the Centers for Medicare & Medicaid Services (CMS) to document Medicaid/Medicare barriers to reimbursement of mental health services within primary care. It also detailed recommendations for ameliorating these barriers. Though its focus was on mental health, the barriers to reimbursement for integrated treatment for substance use disorders are similar.

Policy makers have taken note of these and other reports and studies. For example, the Wellstone and Domenici Mental Health Parity and Addiction Equity Act of 2008 increased health plan coverage for addiction treatment: financial co-pays and limits on amount of care for behavioral health services must be similar to those provided for medical care. Enhanced utilization of addiction treatment is likely to amplify concerns about the quality and effectiveness of care. Because the act eliminates barriers to the use of services for substance and mental health disorders, some have expressed concern that these changes may increase health plan costs due to increased service utilization. These fears may be unfounded: a study of the implementation of parity in the plans of federal employees

found only a slight increase in costs to the health plan. Health care reform initiatives may have more extensive impacts.

Health Care Reform

The Patient Protection and Affordable Care Act is reforming health care in the United States. The Act attempts to better control the health care expenses, enhance the quality of health care, and reduce the number of uninsured. When fully implemented in 2014, economists estimate that an additional 30 million individuals will have Medicaid health insurance. It has the potential to catalyze substantial change in the financing of addiction treatment. SAMHSA anticipates that Medicaid and other health plans will be the primary payer for most addiction treatment services. As a result, resources such as the federal block grant could be used to support Medicaid, replacing the current system that directs grants to and contracts with freestanding specialty addiction treatment centers. Health plans are typically selective in their purchase of service contracts and screen for indicators of quality care. Business models for addiction treatment programs are likely to change dramatically; programs that provide evidence of quality care are likely to have competitive advantages. Additionally, treatment organizations and practitioners may be required to meet Medicaid eligibility standards and these standards are likely to require individuals with graduate degrees and professional licensure. This could have a dramatic impact on the workforce in a field where only about 50% of the counselors have graduate degrees.

As the Affordable Care Act impacts the delivery of health care, the organization and financing of addiction treatment services are adapting. Policy makers tout and test pay-for-performance. Providers and practitioners who generate higher rates of sustained recovery will be more competitive in the market. There is likely to be less attention to the quality of treatment processes and more attention to the quality of stable outcomes. Services may shift from an acute care model with a beginning (admission) and end (discharge) for each episode of care to chronic care strategies that emphasize retention in care over prolonged periods of time so that symptoms are monitored continuously and care is intensified as needed. Integration with medical care will be more common. Use of pharmacological therapies will be expected. Medicaid is likely to become the dominant payer for publicly funded addiction treatment. State Medicaid plans increasingly capitate health plans to deliver all required care including treatments for alcohol and drug use disorders. Health plans will be selective in who they contract with and are likely to restrict reimbursement to licensed professionals. With more reliance

on professional licensure to identify qualified practitioners, concerns about the quality of treatment may dissipate and attention to the quality of outcomes will increase. Market forces, therefore, are likely to push the addiction treatment system toward the development of outcome monitoring systems. Policy makers are also likely to realize the need to adapt to population perspectives to reduce the prevalence of alcohol and drug disorders.

Population Quality Strategies

Alcohol and drug control policies are enacted to control the supply or demand for drugs and alcohol. A seminal monograph entitled *Alcohol Control Policies in Public Health Perspective* was one of the first to highlight the influence of national and international governments and agencies on prevention and treatment. Today, substance abuse treatment policies vary widely across the globe. In some countries such as Sweden, substance abuse treatment is outside the health care infrastructure. Other countries, such as the Netherlands, allow for injection rooms for the consumption of prescribed heroin. With the wealth of scientific evidence available today, policy makers can make informed decisions to build public health strategies that reduce alcohol and drug problems. There is no single policy measure that is able to ameliorate all drug and alcohol problems. Most countries are finding that good strategies include incorporating a range of measures.

Drug and alcohol policies include (1) population-based policies, (2) problem-directed policies, and (3) direct interventions. The first group includes actions such as taxation and legal restrictions, education, and media campaigns. Problem policies target alcohol and drug-related problems like drinking and driving. Direct interventions include policies for individual users such as treatment, brief interventions, and harm reduction strategies. Effective policies require strategies to promote efficiency in the organization and delivery of care and enhance the capacity to serve more patients.

E Technology Quality

Patients, policy makers, and other stakeholders expect addiction treatment to keep pace with the latest innovations and trends to deliver quality care. Use of e-technology, for example, may enhance counselor productivity, improve efficiency, and develop the quality of clinician-delivered treatment. Internet applications are emerging for screening, brief interventions, continued monitoring of patients, and delivery of clinical training in evidence-based practices for addiction treatment providers. For instance, online counseling and technology-assisted interventions can improve treatment

and engagement using e-mail communications. Cognitive behavior therapy seems especially amenable to computer-based therapy. Electronic applications available on the web may also reach users at earlier stages in their disease, reaching subgroups whose pathology has not progressed to more advanced stages. Computer and Internet-based interventions and self-help options have the potential to close the treatment gap, reaching groups that do not seek traditional methods of treatment. Future advances in the delivery of treatment policy should promote the use of such programs into practice, and replace outdated and ineffective modes of treatment. Current policies, however, require face-to-face contact for billable services. Pay-for-performance and performance-based contracting are emerging strategies to alter the financing of addiction treatment services. As addiction treatment services become more integrated with primary care, demands will increase for effective and efficient service delivery.

DISCUSSION

For some who struggle with alcohol and drug use disorders, addiction is a chronic relapsing illness and critics question the effectiveness of the current treatment system. Health care costs substantially increase over the life of individuals with substance use disorders, especially for those with comorbid conditions. Substance use conditions complicate treatment of other medical conditions such as diabetes. Screening and early intervention can prevent substance use problems from escalating. These concerns are advancing to a more holistic and integrated approach to treatment. There is a growing recognition that the field of addiction treatment must document the quality and effectiveness of care. The substance abuse treatment field has reached a critical juncture: new ways of thinking are changing treatment for substance use disorders and, as a result, the organization and delivery of care. The ultimate goal remains improving the quality and effectiveness of addiction treatment.

STUDY DESIGN CONSIDERATIONS

In this section, we discuss several study designs and the specific issues associated with use of each design.

Randomized Controlled Trial Study Designs: "The Gold Standard"

Historically, substance use treatment efficacy was demonstrated by examining outcomes achieved in controlled research experiments where the observed effects could be attributed to a particular treatment rather than some other confounding factor. More specifically, randomized controlled trial (RCT) has been the favored study design utilized to assess treatment efficacy. In this approach, research participants are randomly assigned to either a treatment condition or one or more comparison condition(s). Common comparison conditions include treatment as usual, a wait list control group,

or some other form of treatment. RCTs are perceived to maximize internal validity, that is, the outcomes that occur can be attributed to the treatment and not to other factors. Evaluating the efficacy of a treatment without randomization is difficult and potentially prone to errors. For example, if we evaluate the efficacy of a treatment program by comparing individuals who decide to attend a treatment program to those who decide not to attend a treatment program, we are at risk of confounding. Specifically, individuals who choose to attend a program or who are nonrandomly assigned to attend a program might differ from those who choose not to attend. These potential differences might therefore determine the outcomes that occur, rather than the differences in the treatment that was received by the two groups. The advantage of randomization is that we know that, on average, the groups assigned to the treatment and comparison condition groups do not differ on these kinds of preexisting characteristics.

Using rigorous experimental designs, such as RCTs, has been emphasized as a necessary step in demonstrating treatment efficacy according to stage-based approaches to behavioral substance use treatment development. Stage-based approaches have been adopted by the US-based National Institutes of Health (NIH) as a strategy to guide research in behavioral treatment development. Utilizing this approach, Stage 1 typically involves piloting and testing the feasibility of a treatment with the aim of understanding the process of the treatment. Stage 2 focuses on evaluating the treatment efficacy by using a rigorous experimental design. After one RCT has demonstrated a treatment's efficacy, the execution of additional RCTs conducted by researchers independent from the treatment developers can help strengthen the evidence for a treatment's efficacy. In Stage 3, treatments that have been shown to be feasible and effective are evaluated to determine if they work in typical treatment settings to demonstrate treatment effectiveness, which indicates that results achieved in the RCT can generalize to typical treatment settings and populations. Tests of effectiveness allow researchers to address the external validity of the treatment, that is, the ability to generalize the study results to other settings and populations.

In response to stage-based approaches to treatment development, there has been a growing emphasis on balancing the need to address internal validity as well as accounting for external validity early on in treatment development and efficacy testing. This has been the result of the recognition that conditions under which many RCTs have been conducted to demonstrate efficacy may not bear much resemblance to real world treatment settings. Therefore, the treatment may not achieve the same outcomes in typical treatment delivery settings. For example, RCTs typically utilize strict inclusion and exclusion criteria that result in the treatment being tested with a small sample of individuals who may be very different from the individuals who are typically treated for substance use problems. For example, many individuals seeking help for substance use problems may have multiple co-occurring conditions that may exclude them from participating in an RCT. In addition, RCTs may also involve treatment delivery using highly skilled clinicians with intensive supervision, which does not always reflect the realities of typical treatment delivery. RCTs with stringent inclusion and exclusion criteria and closely monitored treatment delivery may enhance internal validity by ensuring that the treatment is being tested among a homogenous client population and delivered as intended; however this affects external validity.

Recent work has therefore begun to emphasize blending elements from efficacy and effectiveness designs so that the research findings are more clinically

meaningful and the treatments are applicable for delivery in real world treatment settings. For example, many RCTs are now being conducted in real world delivery systems rather than in controlled academic laboratory settings. Other variations of this design include utilizing "real world" treatment staff to deliver the intervention, rather than researchers or highly trained clinical staff who are unlikely to be employed in these settings. Treatments are also being designed to more adequately reflect resources available in typical delivery settings. This has led to a focus on briefer interventions, treatments delivered in group rather than individual formats, and using technology, such as the Web, rather than in-person staff to deliver the intervention.

It is also important to note that RCTs have limitations that do not necessarily ensure internal validity. For example, randomization (and thus internal validity) can be undermined by differential rates of refusal or treatment drop-out. Another threat to RCT internal validity is contamination. In this case, participants do not adhere to their assigned treatment and instead use the treatment provided to participants in the comparison group. Though RCTs are designed so that no systematic differences are expected between participants assigned to the treatment and control groups, it is possible for participants in the treatment and control groups to differ on preexisting, observed characteristics in the sample. When this occurs, different statistical adjustments can be made. Statistical adjustment strategies such as risk, case mix, or covariate refer to methods that are commonly used to account for observed baseline or pretreatment differences between individuals in the assigned study conditions.

Individual versus Cluster Randomized Designs

An approach that preserves the benefit of randomization in real world settings where individual randomization is not feasible is the cluster randomized trial (CRT). A canonical example is when an intervention involves changing the therapeutic environment of a clinic, school, or other higher level unit, such as a public health intervention. In this case, individuals are assigned to the condition based on the group they currently belong to; thus, CRTs have the advantage of greater external validity.

CRTs may also be employed when there is a risk of contamination across conditions. For example, if a trial of an educational intervention is carried out, which involves providing educational materials to participants in an intervention group, and providing different (or no) materials to participants in a control group, then there is a risk that materials may be shared across the groups if there is communication between individuals across

conditions. Similarly, if a trial is carried out to investigate the efficacy of an intervention that is freely available to the public, members of the control group may see their peers using the intervention and choose to use the intervention themselves – one example may be the use of nicotine patches to aid in the cessation of smoking. Thus, CRTs are necessary when an intervention needs to be applied to a group of individuals simultaneously and may be advantageous when there is a risk of contamination.

Researchers conducting and interpreting CRTs must be aware of two issues. The first issue of cluster randomization is the threat of nonrandom assignment at the individual level. In an individually randomized trial, a person is recruited to the trial and is then assigned to a condition. In a CRT, a group is recruited to the trial and then persons are assigned to a condition based on the group (clinic, school, etc.) to which they belong. In this case, allocations are known prior to recruitment. Cluster-specific variation, such as differences in the patient populations across clusters, may therefore unbalance the comparison conditions on important characteristics. Further, in some cases, it may be difficult to conceal the treatment assignment to participants and treatment providers, which can threaten validity. For example, a clinician who is very enthusiastic about a particular treatment that is available in his/her cluster might put particularly strong effort into recruiting participants into the trial. The second issue is the necessity for considerably larger sample sizes because outcomes of individuals within clusters are nonindependent.

Quasi-experimental Study Designs

Quasi-experimental study designs involve the comparison between two or more groups where the assignment to the treatment and comparison groups is not randomized. Quasi-experimental designs are typically done when random assignment is not feasible for practical or ethical reasons. These designs may help inform treatment efficacy but are susceptible to bias due to confounding of characteristics of intervention assignment with the intervention effect. It is important to employ risk adjustment strategies when evaluating treatment efficacy in such studies given the lack of randomization.

Systematic Reviews: Generalizing from the Existing Evidence

A broader assessment, or summary of evidence, can be conducted when a particular treatment has been tested multiple times in various settings. In this approach to evaluating treatment efficacy, a systematic review may be conducted of existing studies to determine the evidence for a particular treatment's outcomes. One approach to

determining efficacy quantitatively through a systematic review is called meta-analysis. In this approach, a common set of metrics across a relevant set of studies is used to gauge the magnitude of a treatment's impact.

Summary

When considering design features for treatment efficacy studies, it is relevant to consider both internal and external validity to best inform the field about what works for substance use treatment. The recent research in the field of treatment efficacy recognizes the importance of balancing internal and external validity in developing and testing behavioral treatments to address substance use. Although randomized controlled study designs are still the gold standard because of their compelling nature to conclude cause and effect, other designs may provide valuable insight into treatment efficacy when an RCT is not feasible.

ANALYTIC METHODS TO EVALUATE TREATMENT EFFICACY

In this section, we discuss common analytic methods used in the substance use treatment field to evaluate treatment efficacy.

Researchers frequently assess treatment efficacy by examining the intention to treat (or sometimes intent to treat; ITT) effect. The ITT effect summarizes the effect of treatment assignment on outcomes by comparing responses from individuals assigned to receive the treatment to individuals assigned to the comparison group(s), regardless of what treatment they actually received. The importance of the ITT effect is typically assessed through statistical testing. The most common testing approach is to specify two hypotheses: a null hypothesis that the outcomes for participants assigned to the treatment and comparison condition(s) are equal and an alternative hypothesis that outcomes across treatment conditions differ from one other. In the case of individual-level RCTs, the simplest statistical analysis that might be appropriate for the data would employ a bivariate test such as a *t*-test or a test of proportions to compare treatment and comparison conditions. However, it is often necessary to conduct more sophisticated statistical analyses to accommodate different study design features or data complications. We highlight some of these below.

Drop-out and Noncompliance to Treatment

One threat to the internal validity of a treatment study is drop-out from treatment and noncompliance. That is, individuals who are assigned to a treatment choose not

to take up or complete treatment, despite it being offered and available. For example, in Project Choice, a voluntary after-school intervention, treatment was taken up by approximately 15% of those to whom it was available. In addition, if individuals are randomly assigned to either some form of therapy or a waiting list control, there is a chance that those assigned to therapy may drop out, whereas it is not possible to drop out of a wait list control group because no actual treatment is being provided. This is a problem because drop out might be related, for example, to level of substance use – those who drop out may be functioning less well and finding it difficult to keep appointments and maintain the therapy.

The ITT effect reflects not just the effect of the intervention effect but also the appeal and practicality of the intervention. For example, a high level of noncompliance might suggest that the intervention lacks appeal for its intended target population. The intervention might need to be altered or barriers to its uptake removed. Thus, the ITT effect differs from the effect of the intervention itself. In the presence of noncompliance and drop-out, it may be tempting to analyze the data based on the treatment received – that is, those individuals who were compliant with an intervention would be analyzed as an ‘intervention’ group, with the ‘control’ group either remaining the same or including individuals from the treatment group who were noncompliant. However, such an analysis will provide a biased estimate of treatment efficacy because, unlike an RCT, those who decide to take up the treatment versus those who do not would no longer be expected to be balanced on pretreatment characteristics, including unobserved characteristics, which could then induce bias into the assessment of treatment efficacy. Thus, using an ITT approach risks bias in a conservative direction, with the effect of the treatment being underestimated, whereas using a treatment received approach risks overestimating the size of the treatment effect. Researchers would rather underestimate than overestimate effects; hence the ITT approach is preferred.

Yet, researchers often want to estimate treatment efficacy when all clients are compliant with their treatment assignment in order to address the scientific question of the efficacy of the intervention as it was designed. Such an estimate would complement the ITT effect by indicating whether removing barriers to treatment uptake might hold promise for the intervention’s efficacy. An alternative treatment-effect estimate that addresses this issue is the complier average causal effect (CACE), which is the estimate of treatment efficacy for those who comply with their treatment assignment. A major challenge with CACE estimation is that complier status for each individual is unknown; someone who is assigned to the intervention condition and receives the intervention could be a treatment complier or someone who always takes up

the intervention, whereas someone who is assigned to the comparison condition and does not use the intervention could be a complier or someone who might never take up the intervention. Thus, several assumptions must be made in order to estimate the CACE such as treatment assignment is random; the outcomes of each individual are not affected by the intervention assignment of any other individuals; some individuals who are assigned to receive the intervention will comply with their treatment assignment and the treatment will only affect outcomes for compliers; and there are no ‘defier’ individuals who will always do the opposite treatment of what they are assigned.

Covariate Adjustment

For studies that lack balance of observed pretreatment characteristics across comparison groups – regardless of whether or not those studies are RCTs – covariate (or risk or case mix) adjustment of treatment-effect estimates are crucial. Traditionally, the most frequently -used method of covariate adjustment was regression adjustment (i.e. enter risk adjustment variables as predictors into a regression of an outcome of interest on the treatment group indicator). The strengths of covariate adjustment include the ease of incorporating covariates into any regression-based model (e.g. cross-sectional or longitudinal models, or models that account for hierarchical (multilevel) data such as in CRTs). Limitations of covariate adjustment are that covariates are assumed to be related to the outcome in the manner specified by the model (i.e. usually linearly), that the relationship between covariates and treatment outcomes is assumed to be equal in both treatment and control groups, and that there is also a danger of including too many covariates in the model relative to the sample size (over-fitting) if there are numerous covariates of interest.

Propensity Score Adjustment

Propensity score adjustment techniques can avoid some of the limitations of covariate adjustment. The propensity score is the probability of an individual being assigned to a particular treatment condition based on a set of covariates, which are typically pretreatment characteristics in treatment efficacy studies. Recent methods address propensity score estimation for studies with multiple treatment arms; however, for illustration we focus on estimating the conditional probability of treatment assignment for two-arm studies because this study design reflects the vast majority of applications of propensity scoring. The propensity score is estimated by modeling assignment to treatment (versus control) as a function of pretreatment characteristics. Statisticians

have shown that adjusting for the propensity score produces balance between treatment and control conditions with respect to pretreatment characteristics.

Propensity scores can be incorporated into the analysis in several different ways. Early papers on propensity score estimation advocated creating strata according to the quintiles of the propensity score estimates, estimating the treatment effect within each quintile, and averaging results across quintiles to estimate the overall treatment effect. More modern approaches include using functions of the propensity scores as weights in analyses or conducting matched-pairs analyses by matching treatment and control individuals who have similar propensity scores. The latter approach is particularly attractive when one can draw comparison of individuals from a large pool (such as from a large administrative database), but can be more limited for modestly sized treatment-effect studies.

A limitation of both covariate and propensity score adjustment that is especially relevant for nonrandomized studies is that these approaches only control for observed differences between treatment groups, therefore unobserved differences could still exist between groups that are being compared. In such cases when one suspects unobserved yet important differences exist between comparison groups, methods used to estimate CACE, econometric approaches such as instrumental variables, or sensitivity analysis to examine the robustness of treatment efficacy estimates to unobserved bias can be utilized.

Group Treatment

Group treatment is a frequently employed modality for substance use. Participants typically enter group treatment under a rolling (or “revolving” or “open”) admissions policy. Treatment groups with rolling admissions (“rolling groups”) continuously enroll new participants into the group as space permits. This is in contrast to “closed” groups, in which the same participants are expected to jointly attend group treatment sessions without the addition of new group members. Recent research underscores the importance of accounting for the interrelatedness (correlation) of outcomes for participants attending group treatment, regardless of how participants are admitted into the group. Failure to account for this correlation could lead to biased statistical tests and incorrect conclusions about the effectiveness of the treatment.

The analytic methods necessary to model the correlation among participant outcomes for participants attending closed groups are straightforward compared to what is required for rolling groups. For closed groups, standard implementations of hierarchical (or multilevel) modeling that are widely available in popular statistical

software packages allow the user to specify to which closed group participants belong and to specify random effects terms to model the correlation of outcomes among participants attending the same treatment group. In contrast, rolling admissions induces a far more complex pattern of interrelatedness among participant outcomes because the set of participants in the group can change from session to session. For example, suppose 10 participants attend the first session of a treatment group, and one of these 10 participants is very disruptive and leaves the group after the first session. Then, another participant enrolls at session two after the disruptive participant’s departure. Even though these two participants never met, the second participant’s outcomes could still be correlated with the disruptive participant’s outcomes if the disruptive participant altered the group climate sufficiently enough to affect the group experience for the remaining nine participants, who then interact with the new participant in the second session.

One recent method for rolling group studies is to use multilevel models that capture the overlapping participant attendance across sessions with random session effect terms that are allowed to be correlated. Techniques for modeling correlated random effects include conditionally autoregressive priors, which are frequently employed in the analysis of geographic (spatial) data. In the context of rolling groups, the analyst would specify the closeness of each pair of random session effects. For example, sessions attended by the same 10 participants might be considered very close relative to sessions sharing fewer participants. This method is flexible enough to be applied to data collected either during the course of group treatment or to post-treatment outcomes and to incorporate other application specific concerns, such as concerns about whether treatment efficacy differs for participants who drop out of treatment early or have different patterns of group treatment attendance.

Accounting for Cluster-Level Treatment Assignment

When the unit of treatment assignment is a cluster rather than an individual on whom outcomes are examined, testing for treatment efficacy requires accounting for the fact that individuals within cluster have nonindependent outcomes. This means that there is less information in the data compared to an individual-randomized trial in which outcomes for the same number of individuals could be assumed to be independent from one another. This reduction in information due to cluster-level randomization is called the design effect, or variance inflation factor (VIF), which is approximately equal

to $1 + (m - 1)r$, where m is the number of individuals per cluster and r is the intraclass correlation, which is the proportion of variance in individual outcomes that is attributable to cluster membership. The effective sample size is equal to the raw sample size divided by the VIF. The effective sample size represents the sample size of an individually – randomized trial that would have an equivalent amount of information about the difference between intervention and comparison conditions. Even for small values of r , the VIF will be large when m is large, thereby increasing the numbers of individuals necessary for the cluster randomized study relative to an individually randomized RCT. Thus, the effective sample size is frequently considerably less than the raw sample size. In the worst case scenario, the effective sample size is equal to the number of clusters. Multilevel (or hierarchical or random effects) regression modeling is one analytic approach to account for the nonindependence of outcomes for individuals within the same cluster. Multilevel modeling allows a researcher to estimate the treatment effect at the cluster level, thus aligning the treatment-effect description with the cluster-level targets of the intervention.

Meta-analysis and Study Pooling

Meta-analysis is a statistical technique that allows researchers to pool the results from multiple studies that set out to test the same hypotheses. Consider an example of 10 RCTs that have been carried out to investigate the efficacy of motivational interviewing for substance use. If each of these hypothetical trials contained 100 participants, we could pool the results of each of these trials to create an effective sample size of 1000 participants. Such a pooled analysis would then result in a larger sample size, which leads to greater power, and a more precise estimate, and also incorporates a wider range of individuals, enhancing the generalizability of the estimates. When studies are pooled, a test of heterogeneity of effect is carried out. This tells us if the variation in effect sizes across studies is greater than would be expected by chance if the studies were sampled from the same population. If heterogeneity exists, this suggests that there are differences between the studies, which means that the intervention was found to be more effective in some of those studies compared to other studies. Heterogeneity can then be investigated through the use of meta-regression analyses, in which study characteristics are used as predictors of study-level outcomes. For example, we might investigate whether trials using motivational interviewing approaches are more effective in adolescents than in adults by using a meta-regression approach. It should be noted that meta-regression approaches are indirect tests of

a hypothesis. Therefore, these meta-regression approaches do not provide the same level of evidence as a well-designed RCT that includes both adolescents and adults and compares efficacy. However, if a meta-analysis shows that a treatment is efficacious, it typically shows that the treatment under study is effective across multiple studies. In this way, the results from a meta-analysis may provide stronger evidence regarding the efficacy of a particular treatment than the results from a single RCT.

HOW TO INTERPRET RESULTS

Over the past decade, literature has focused more on interpretation of treatment findings. Although the typical metrics for substance use are externally valid and easy to interpret, for example, the percentage of days abstinent, well-described efficacy studies typically address whether differences are both statistically and clinically meaningful. However, it is important to note that many substance use outcomes that are studied, such as “recovery” and “relapse,” have been defined in a number of different ways in the literature and therefore a consistent definition does not currently exist. In this section, we discuss how to interpret results from treatment efficacy studies.

Sample Size Considerations

Sample size can affect a researcher’s ability to draw clear conclusions about the outcomes of a study. Determination of sample size should occur before the study begins. Several factors should be taken into account when determining sample size. One factor is the expected size of the treatment effect to be detected by the study, which is called the hypothesized effect size. The hypothesized effect size should represent the difference between the treatment and comparison group(s) that would be meaningfully large enough to influence clinical practice. The number of participants in the study should be sufficiently large to reduce the variation in the treatment-effect estimate so that if there is a difference between study conditions, it can be detected. A second factor that influences the choice of sample size is the form of the treatment-effect estimate. For example, detecting practically meaningful difference between treatment conditions on a difference in proportions in a dichotomous outcome would require a greater sample size than comparing means for a continuous outcome since continuous measures provide more detailed information about an outcome. A third factor that influences sample size is the significance level of the test of treatment efficacy (also called the Type I error), which is often

denoted by the alpha level (α). A significance level of $\alpha = 0.05$ implies that when the null hypothesis is true (no evidence of a treatment effect), one can expect the test of significance to erroneously reject the null hypothesis 5% of the time. A fourth factor is the statistical power of the hypothesis test. The power of a test is the probability of not rejecting the null hypothesis when in fact the alternative is true, which is called a Type II error. Since the Type I and Type II error rates are related, increasing one typically decreases the other, so investigators need to weigh the relative costs of erroneously rejecting the null hypothesis when the null hypothesis is true versus failing to reject the null hypothesis when the alternative hypothesis is true.

The Meaning of Statistical Significance

Determining whether an effect is statistically significant depends on at least two things: the size of the effect and the number of individuals being studied. Consider an example of an intervention that is able to reduce substance use from 10 to 5%. Given exactly this reduction in every study, a randomized trial with 20 people in each group would give a probability or p -value of 1.000, giving no evidence of any effect. A trial with 200 people in each group (and exactly the same result) would give a p -value of 0.086, providing weak evidence of an effect. With 400 in each group, the result would be statistically significant at $p = 0.010$, and with 800 in each group, $p < 0.001$. A naive interpretation of these results would be that the statistically significant results were more important. This is not the case; the more significant results provide better evidence for the effectiveness of the intervention due to having a larger sample size in this case.

If a statistically significant result is not found, we cannot conclude that the null hypothesis can be accepted as the statistical tests used only allow us to conclude that we have failed to reject the null hypothesis. For example, if a study found no effect of an intervention, we cannot conclude that the intervention is ineffective, we can only conclude that we have not found evidence that the intervention is effective. When we search for a needle in a haystack, if we don't find a needle, we can only conclude that we didn't find a needle – not that there is no needle to be found. In other words, if we find a statistically significant result, we have obtained evidence against the null hypothesis (i.e. there is no treatment effect). If we do not find statistical significance, we can only conclude that we have failed to reject the null hypothesis, not that the null hypothesis is true.

Effect Size and Clinical Significance

Statistical significance indicates the probability associated with the null hypothesis, but it does not

determine whether the result is important, meaningful, substantive, large enough to care about, or clinically significant. To interpret the effect of an intervention in terms of whether it is sufficiently large to be termed clinically significant, we must describe the magnitude of the effect of the intervention.

Some outcome measures can be summarized by a mean, which allows us to simply calculate an average value for individuals in two groups. Because people can examine their data in different ways, however, we must understand the baseline from which we start to determine a treatment's effect. For example, if we expected that treatment would increase service use, we might find that the mean number of days of service use for a control group was 25, and the mean for the treatment group was 45. We can represent the size of this effect as the difference between these two groups by using days, stating that treatment increased service use by 20 days. Alternatively, we can express the effect of treatment as a ratio, stating that the effect of the treatment was to increase service use by 80% ($45/25 = 1.80$ or an 80% increase). There is not a one-to-one correspondence between the two measures. In another example, a reduction of 1 drink per drinking day can represent a 17% reduction, relative to a control group which is consuming, on average, 6 drinks per drinking day, but a 50% reduction relative to a control group that consumes, on average, 2 drinks per drinking day. Thus, the baseline from which we start can affect how we evaluate the effectiveness of our intervention.

Effects are often reported using standardized measures. For example, when a difference between two groups with respect to a continuous outcome measure is examined, one might standardize the difference by dividing by the standard deviation (this might be a pooled standard deviation or the standard deviation of the control group). This standardized effect size measure is known as Cohen's d . An effect size measure such as Cohen's d allows one to make comparisons across different continuous measures. Specifically, if one study has evaluated a treatment in terms of days in treatment, but a second study has evaluated a treatment in terms of an Alcohol Use Disorders Identification Test (AUDIT) score, the effects of these studies could be compared through the use of Cohen's d . A second use of Cohen's d is that it allows one to quantify the size of an effect using a unit-free measure. Cohen applied labels to different effect sizes for Cohen's d , calling 0.2 a small effect, 0.5 a medium effect, and 0.8 a large effect. If a study evaluates a treatment effect and finds an AUDIT score change of 4 units, this is difficult to interpret for anyone unfamiliar with the AUDIT scoring system, but if we are also told that the Cohen's d effect size is 0.5, we can interpret the size of the effect and have a somewhat better understanding of the clinical significance

of the study. However, Cohen's d and similar effect size measures have some disadvantages. The first is that the units of the measure are lost when any effect size measure is standardized. Learning that an intervention doubled the number of days in treatment might be more interpretable than $d = 0.5$. A standardized effect size measure alone cannot therefore convey clinical meaningfulness. Another problem with standardized effect size measures is that they are determined not only by the size of the effect, but also by the amount of variance in the data. For example, a difference in the number of days in treatment of 1 would result in an effect size of 0.5 (medium) if the standard deviation were equal to 2, but only 0.2 (small) if the standard deviation were equal to 5. These concerns also hold for other types of standardized effect size measures for noncontinuous outcomes.

Another measure of effect size that can be used for either categorical or continuous outcomes (but we will limit this discussion to categorical outcomes) is the number needed to treat or NNT. The NNT is the number of people who need to be treated with the intervention, rather than the control condition, in order that one person sees a benefit. The NNT is considered to be a useful indicator for policy decisions, as it describes the impact at a level of individuals affected. The NNT is calculated as $1/(\text{risk difference})$. If the risk of relapse is 60% (or 0.6) in the control group and 40% (or 0.4) in the treatment group, the risk difference is $0.6 - 0.4 = 0.2$. The NNT is $1/0.2 = 5$. Thus, if five people were treated with the intervention, rather than the control condition, we would expect one additional individual to cease use who would not have otherwise ceased use.

Substantive Significance

Just because a treatment shows a statistically significant effect does not mean that is likely to be useful or that policy should change to use that treatment. First, and most obviously, the change in the outcomes associated with the intervention should be sufficiently large – the appropriate effect size should be calculated and presented. Second, determining how large an effect should be to be clinically meaningful is challenging, and other features of the intervention must be taken into account beyond simply the effect size. For example, the costs (both financial and societal) of an intervention as well as of the condition being treated should be taken into account when determining the substantive significance of an intervention. If an intervention had a small effect but could be implemented at low cost and easily, such an effect might be substantively important, or if a condition has very large financial and societal costs, interventions with relatively small effects might result in a large

cost saving dollars-wise. In general, researchers have found that every additional dollar invested in substance use treatment saves taxpayers \$7.46 in societal costs (crime, violence, loss of productivity, etc.). Health economists use sophisticated modeling techniques to determine the cost-effectiveness of treatments. For example, the UK Alcohol Treatment Trial (UKATT) compared two treatments: in one group social behavior therapy and network therapy were employed; this was compared with motivational enhancement therapy. No statistically significant differences were found between these two treatments, but analysis of the costs showed that both therapies saved approximately five times as much as they cost, taking into account health, social, and criminal justice services. In addition, the authors concluded that there was a 58% chance that motivational enhancement therapy was more cost effective than social behavior therapy, and a 42% chance that social behavior therapy was more cost-effective than motivational enhancement therapy, thus helping policymakers conclude which treatment is more likely to be cost-effective. In another study conducted in the United States, targeting cannabis use among adolescents, a brief five-session treatment called Motivational Enhancement Treatment/Cognitive Behavioral Therapy-5 or MET/CBT-5 was found to be equally efficacious and more cost-effective compared with other four adolescent treatments that were at least twice as long (MET/CBT-12, Family Support Network therapy, Adolescent Community Reinforcement Approach, and Multidimensional Family Therapy).

CONCLUSIONS

The development of efficacious treatments for substance use requires the use of rigorous analytical methodologies to provide reliable information to guide clinical practice. The use of randomized study designs is typically preferred over nonrandomized designs and there are analytic techniques that can be used to adjust for preexisting differences among comparison groups. When randomization at the individual level is not feasible, cluster randomized designs offer another option to testing treatment efficacy. Blending components from both traditional efficacy and effectiveness studies has increased in the last decade in recognition of the need to build treatments that are appropriate for delivery in real world treatment settings. As the number of research studies increases, the use of systematic review methods, such as meta-analyses, is useful in informing the field about treatment efficacy. Continued use of the aforementioned methods along with further innovation in these areas will help to improve the quality of evidence of treatment approaches to address substance use.

Glossary

Alpha level in statistical testing, the probability of rejecting the null hypothesis given it is actually true. It is the cutoff that is selected for determining whether a p -value associated with a test statistic is small enough (less than the alpha level) to reject the null hypothesis.

Alternative hypothesis in general, the proposition that the null hypothesis is false. In a typical treatment efficacy study, the alternative hypothesis is that the true (or population) means on some outcome measure for the treatment and control groups is unequal.

AUDIT Alcohol Use Disorders Identification Test.

Case mix adjustment a statistical procedure used to identify and adjust for variation in participant outcomes that stem from observed differences in participant characteristics (or risk factors).

Cluster randomized trials (CRTs) a randomized trial where units composed of multiple individuals (i.e. a set of providers, institutions, schools, or communities) are randomized rather than individual research participants to study conditions.

Cohen's d a measure of effect size, calculated as the difference between two means divided by the pooled standard deviation.

Complier average causal effect (CACE) the treatment effect for those who comply with their treatment assignment.

Confounding failure to control for the effects of a third variable in an experimental design.

Contamination when an individual assigned to one intervention receives a different intervention.

Covariate adjustment see Case mix adjustment.

Design effect see Variance inflation factor.

Effect size an effect size is a value that represents the strength of a relationship between two variables in a population (or a sample estimate of that relationship).

External validity the degree to which the results of an experiment can be generalized to the population of interest.

Intention to treat (ITT) an analysis where data from participants are analyzed according to the study condition to which they were assigned, regardless of the treatment actually received.

Internal validity the certainty with which results of an experiment can be attributed to the treatment under study rather than to some other variable.

Intraclass (intracluster) correlation coefficient (ICC) a statistic used in cluster randomized trials that describes how strongly outcomes are correlated for units assigned to the same cluster.

Meta-analysis a systematic procedure for statistically combining the results across many different studies.

Null hypothesis the hypothesis that the treatment has no effect in the study population.

Number needed to treat (NNT) an estimate of how many persons need to receive a treatment before one person would experience a beneficial outcome.

Propensity score the probability of being assigned to a study condition as a function of observed covariates.

Quasi-experimental design a type of design that approximates the control features of a true randomized experiment (RCT) to infer that a treatment under study has its intended effect.

Randomized controlled trial (RCT) a type of experiment in which participants are assigned to a study condition (i.e. treatment or control) using a random process.

Risk adjustment see Case mix adjustment.

Sample size the number of participants in a study.

Statistical power the probability, on the basis of observed data, to correctly reject the null hypothesis given a certain effect in the population. Power is expressed as $1 - \beta$, where β is the probability of a Type II error.

Statistical significance rejection of the null hypothesis when an outcome has a low probability of occurrence (typically 0.05 or less) if in fact the null hypothesis is correct.

Study design a methodology that is used to investigate a treatment-effect relationship.

Systematic review a critical assessment and evaluation across many research studies that address a particular clinical issue. May or may not include a quantitative assessment across studies (meta-analyses).

Treatment effectiveness how well a particular treatment works as demonstrated in "real world" conditions.

Treatment efficacy how well a particular treatment works as demonstrated in an experimental controlled research setting.

Type I error an incorrect decision to reject the null hypothesis when it is true.

Type II error an incorrect decision to fail to reject the null hypothesis when it is false.

Variance inflation factor (VIF) a measure used to determine the extent to which the group assignment in a cluster randomized trial (CRT) has increased the variance of the estimate. It is calculated as $(m - 1) ICC$, where m is the mean cluster size and ICC is the intracluster correlation coefficient.

Wait list control a comparison condition used in experimental studies where participants are assigned to (wait to) receive treatment after the experiment is completed.

ECONOMIC ANALYSIS

A major goal of the science of economics is to determine how society can best allocate its scarce resources to produce the array of goods and services that maximize the welfare of the people in that society. Costing, economic evaluation, and cost-function analysis are three types of economic analysis that have been conducted both to inform and to understand the effects of allocation decisions in the addiction treatment field.

The fundamental assumption of economics is that resources, such as raw materials, workers' time, and equipment, used to produce goods and services are limited whereas society's need and desire for those goods and services are not. This means that choices have to be made, either implicitly or explicitly, about what will be produced and how. Under certain conditions a market allocation mechanism, in which individuals make decisions such as what they want to purchase and how much they are willing to pay, how many hours they choose to work in return for wages or salaries, and how to invest their savings to receive the desired rate of return, leads to the optimal array of

goods and services being produced in the most efficient manner possible. The array is optimal in the sense that there is no additional transaction, such as a purchase, investment, or employee hire that can make one person better off without making someone else worse off. Production is efficient because it requires the fewest resources possible, maximizing the amount that can be produced and therefore getting as close as possible to fulfilling society's needs and desires.

The market allocation mechanism can achieve this optimum automatically only in what are known as perfectly competitive markets. In perfectly competitive markets, all individuals involved have complete and accurate information on which to base their decisions, firms can freely enter an industry in which there is excess demand for a product and leave one for which there is excess supply, no buyer or seller is large enough to affect the price of the good or service they produce, and only a single, homogeneous, product is produced. Health care markets in general, and the market for addiction treatment in particular, seldom meet those conditions. Economic evaluation and cost-function analysis have been used to better understand the effects of

these deviations from perfect competition and to help society take actions, through, for example, public policies and purchasing decisions that maximize welfare.

Economic evaluation, which has been conducted frequently on treatment interventions and programs, encompasses cost-benefit analysis (CBA), cost-effectiveness analysis (CEA), and cost-utility analysis (CUA). Broadly speaking, these types of analyses help determine whether the benefits of a particular intervention, program, or practice are worth the resources needed to produce it. Cost-function analysis, which has been conducted less frequently on addiction treatment programs but extensively on other health care providers, seeks to characterize the production process – how inputs such as labor and equipment are combined to produce outputs – and to investigate whether or not the process is efficient. In either case, the first step in conducting these analyses is to determine how much it costs to produce treatment. In the addiction treatment field, this is generally done using costing studies.

COSTING STUDIES

Addiction treatment providers generally have not been subject to the same types of financial oversight as other health care providers, in part because they often have been funded by state agencies through grants that allocate a certain number of treatment slots rather than relying on service-based reimbursements from payers such as Medicare. As a result, there is no standard chart of accounts or other generally accepted mechanism by which addiction treatment providers commonly categorize and report their expenses. In addition, any accounting records they do have likely do not include volunteer services, donated space, or other nonpaid inputs used in the production of addiction treatment, or the resources expended by a parent organization, if there is one, that contribute to the production of treatment in an individual program. Although these inputs may not be paid by the treatment program, the time volunteers spend, the space that programs occupy, and the administrative services provided by the parent organization could be used to produce other goods and services that society values, thereby enhancing welfare. It is also essential to account for these costs because others wishing to implement the same program elsewhere may not have access to the volunteers, donations, or parent organization support and would need to pay for them. Some research suggests that these “opportunity costs” may add as much as 15% to the total cost of treatment programs, although that estimate is far from definitive. The lack of a standard chart of accounts and concerns about adequately capturing all relevant costs has led economists studying addiction treatment

programs to rely on de novo data collection, often using instruments such as the Data Treatment Cost Analysis Program (DATCAP), the Substance Abuse Services Cost Analysis Program (SASCAP), the Treatment Cost Analysis Program (TCAT), or methods such as micro-costing (described below).

The DATCAP is a standardized instrument that can be used by researchers, ideally individuals with a bachelor’s or higher degree in economics, to interview program directors or financial officers and to extract information from financial records to ascertain the yearly costs of production. Information is gathered on a comprehensive list of inputs, such as personnel costs, the costs of contracted services such as laboratory services, building and facilities costs, supplies and materials, miscellaneous costs such as staff travel, as well as volunteer and donated inputs. In addition, information on the number of clients and their average length of stay is captured so that per-week estimates and episode costs can be computed. The DATCAP has been used in numerous studies, often to collect cost data for economic evaluations. The DATCAP is from a family of instruments including one used to assess the costs incurred by patients in treatment (Client DATCAP) and the costs incurred by parents and other caregivers of those in treatment (Caregivers DATCAP).

Another tool for determining the economic costs of treatment programs is the Treatment Cost Analysis Tool (TCAT). The TCAT is a Microsoft® Excel-based workbook that allows researchers as well as program directors to enter and analyze cost data. It collects annual cost information on a comprehensive set of inputs, including volunteer labor and donated goods, used to produce addiction treatment, but in somewhat greater detail than the DATCAP. For example, although the DATCAP collects information on depreciation costs for the facility as a whole, the TCAT captures it for some individual items such as computer equipment. The TCAT also explicitly captures overhead costs from facilities that are part of larger parent organizations. The TCAT workbook contains comparison values that can be used for quality control in the data entry process as well as for analysis by program directors. This relatively new tool has been fielded in more than 70 programs nationwide.

The other major instrument for collecting cost data on addiction treatment providers is the SASCAP, which combines a cost survey similar to the DATCAP that obtains annual program cost data from program directors, and a labor allocation survey that collects data from a key informant on how staff members spend their time. These instruments can be administered by individuals without specific economic or accounting training, lowering the costs of data collection compared to the DATCAP. The information can be combined to provide

not only data on the annual costs of the entire treatment program, but also the costs of distinct services, such as initial assessment and treatment planning, initial medical services, and group counseling, within that program. The SASCAP has been used in a number of treatment programs, including a major study of methadone treatment programs. Work is underway to develop and test a Web-based version, which, if successful, should further reduce the costs of administering the instrument.

The DATCAP, TCAT, and SASCAP all compute treatment costs for the program as a whole or for specific services, the averages of which can be used for a variety of purposes including studies of the costs of the treatment program as well as costs of interventions that are the subject of economic evaluations. Another costing method that is increasingly being applied in addiction treatment intervention studies is microcosting; this method can be especially useful in capturing the full cost of a specific treatment intervention, particularly a new one, and for analyzing the variations in costs across patients. Microcosting entails determining exactly what and how many inputs were used to treat each patient in a study. Although the list of inputs is similar to those identified in other costing methods (e.g. personnel hours, office space, supplies), inputs are tracked for each patient through methods such as activity logs and other detailed data-collection efforts.

This brings more accuracy to the cost estimates and allows better estimates of the variability of those costs across patients. Generally, however, microcosting studies are more expensive than other types of cost studies and can be more intrusive. No studies have yet compared the outcomes from the two approaches in addiction treatment studies to determine how much the results differ and under which conditions.

Table 62.1 displays estimates of the costs of treating clients in US addiction treatment program from selected studies using these methods. Studies using the DATCAP, SASCAP, and TCAT used data from convenience samples; therefore, the reported findings are neither generalizable nor comparable. Only one study to date has provided national estimates of treatment costs, the 1996–97 Alcohol and Drug Services Study Cost Study (ADSS), but that did not use a comprehensive cost-assessment instrument, although the instrument that was used was the basis for the TCAT. Published cost estimates from the ADSS study, which have been inflated to 2002 dollars, are presented for comparison purposes.

The results displayed in Table 62.1 suggest that there are substantial variations in treatment costs across providers. The sources of those variations are poorly understood. Studying such variations is the subject of cost-function analysis, which will be discussed below, following the discussion of economic evaluation.

TABLE 62.1 Illustrative Results from Selected Costing Studies of Addiction Treatment Programs (Standard Deviation in Parenthesis When Reported)

Type of Treatment	DATCAP (2006 US dollars)*	TCAT (2006 US dollars)**	SASCAP (2000 US dollars)***	ADSS (2002 US dollars)§
Regular outpatient	\$2325/episode (2138)	\$882/episode		\$1433/admission
Intensive outpatient	\$4271/episode (5057)	\$1310/episode		
Adolescent outpatient	\$2954/episode (2678)			
Mixed regular and intensive outpatient		\$1381/episode		
Methadone maintenance	\$7409/episode (4747)		\$4176/patient/year (2560)	\$7415/admission
Adult residential	10, 228/episode (11,354)			\$3840/admission
Therapeutic community	\$21 404/episode (14 125)			
In-prison therapeutic community	\$1747/episode (1078)

ECONOMIC EVALUATION

There are several types of economic evaluation, but three commonly used ones to examine addiction treatment programs are CBA, CEA, and CUA. Although these analyses appear to be very similar, the theoretical basis for them differs, as do the conclusions that can be drawn from them. In addition, the science of each continues to evolve both broadly and within the addiction treatment field, leading to a variety of approaches and continued debates as to the best way to conduct these analyses. Given the state of the science and the quality of the data available to conduct them, these analyses can best be thought of as mechanisms to promote a careful delineation of the costs and benefits associated with programs and interventions. The results of these analyses provide an important piece of evidence that decision makers, such as individuals, third-party payers, program directors, and governments, can use in determining how to invest their scarce resources in purchasing, providing, or funding addiction treatment.

Cost–Benefit Analysis

A CBA involves identifying and valuing in monetary terms all the resources used to produce a good or service and the resulting benefit. It involves the computation of one of two summary statistics, either the benefit–cost ratio or the net benefit. The benefit–cost ratio divides the monetary value of the benefits of the program by the monetary value of the costs. The resulting ratio reveals how much society gains (or loses) in monetary terms from a unit of expenditure on the program. A net benefit ratio simply subtracts the costs from the benefits. Either a benefit–cost ratio greater than one or a positive net benefit signal that society should consider allocating resources to this program, depending on the other possible uses of those resources (which may be even more cost-beneficial).

The results from CBAs are thought by most economists to lead to decisions on resource allocation closest to those that would be made under perfect competition and can therefore be said to be welfare enhancing. This, of course, assumes that the analysis contains values and characterizes all of the major costs and benefits appropriately. Although it sounds simple enough, numerous controversies remain in this field. For example, there is a continuing debate as to whether or not the analysis should include the reduction in goods and services that results because an individual in ill health is not working or is not working up to his potential, because in most economies there are unemployed individuals who could take the job.

Although generally it is possible to delineate and value the costs of producing addiction treatment, it may be more difficult to accurately delineate the other cost implications of the activity (e.g. future treatment utilization) and some of the benefits (e.g. reduced pain and suffering of family members), given available data and methods to elicit those values, although innovations in that area are continuing. Another issue is the length of follow-up. Most studies in the addiction field estimate the benefits of an acute episode of treatment over a relatively short period of time. One study, however, found that allowing for the chronic nature of addiction and modeling the life course yielded cost–benefit ratios that were significantly higher than those of a single treatment episode.

Cost-Effectiveness Analysis

Although it sounds very similar, CEA is quite different from CBA and only yields information leading to welfare-enhancing decisions under certain rather strict conditions, such as that all costs are included in the calculations and that everyone is willing to pay the same amount for an extra unit of benefit. In CEA, the costs of a program contain elements similar to those in a CBA, but only one benefit, such as a specific outcome variable, is examined. Furthermore, that benefit is not expressed in monetary terms but rather in its natural units such as, for example, the longest duration of continuous abstinence measured in weeks. Finally, CEAs usually are done comparing two or more programs or interventions, or a given program and an enhanced version. It is seldom appropriate to say that a particular program or intervention is cost-effective in and of itself. It is only cost-effective in comparison with alternative uses of the resources used to produce it that achieve the same outcome. Many CEAs in the addiction treatment field have been conducted alongside clinical trials that compare a new treatment to treatment as usual, or that compare an existing treatment and its enhancement.

The result from a CEA is also presented as a ratio, called the incremental cost-effectiveness ratio (ICER), which can be interpreted as the extra costs for an additional unit of benefit. This is an important piece of information when one program has better outcomes but higher costs than another program. If one program has both better outcomes and lower costs, it is said to dominate the other program.

Although CEA can be a useful tool to aid narrow decisions about which from among like interventions should be undertaken to most efficiently achieve a specific outcome given a specific program budget, it

can be problematic when applied to addiction treatment because of the multiple outcomes that addiction treatment can affect. Although a single measure for use in economic evaluations of addiction programs based on Addiction Severity Index data has been developed, it has not been adopted widely. In addition, it is difficult to use the results of a CEA to compare alternative uses of the same resources for very different purposes with different outcome goals. Finally, although it seems that CEA might be preferable because it does not require placing a value on the benefit of a health care organization, that actually is not the case. When the decision maker is presented with a finding that, for example, prize-based contingency management would cost an extra \$258 over the costs of usual care for a 1-week increase in the longest-duration abstinent, the decision maker must decide whether or not the extra week is worth \$258, thereby valuing the outcome.

Cost-Utility Analysis

CUA overcomes one of the identified shortcomings of CEA, the fact that it can be difficult to compare interventions with different outcomes. CUA is the same as CEA except that the benefit is measured in terms of quality adjusted life years (QALYs). A QALY is a year of life adjusted for the quality or value based on health status. Quality is assessed across the physical, social, and somatic domains, and weights are assigned to the various dimensions. A year in perfect health is assigned a QALY value of 1. A year of less than perfect health is assigned a value below 1. Theoretically, all manner of programs and interventions can be compared based on their ability to increase QALYs. There are several ways to arrive at the weights that quantify the decrement in quality of life experienced among individuals in less than perfect health.

Among the controversies in this line of analysis are whether these weights should be assigned using a generic preference weighting scheme or a disease-specific weighting scheme, and who should do the weighting. Many of the addiction studies conducted to date have used a generic survey instrument, such as the EQ-5D, administered to individuals in the study population. The EQ-5D asks individuals about problems they are having with items such as physical functioning, pain, emotional distress, and social functioning, and then asks them to rate how good or bad their health is based on a 100 point scale. The information is summarized for different health states and used to create weights for use in the economic evaluation. However, the recognition that drug abuse treatment can affect quality of life beyond the domains measured in generic

instruments has spurred the development of a few disease-specific instruments, although they have not been widely used.

Another purported benefit of CUA is that a commonly accepted threshold can be used to determine whether or not it is worth investing in a specific intervention or program; values of between \$50 000 and \$100 000/QALY have traditionally been used as threshold values in addiction treatment and other studies. This range is based on the costs of an additional QALY for patients receiving dialysis, which is viewed as an appropriate benchmark because of the US Medicare Program's decision to cover this intervention for all who need it. However, recent work has called into question the appropriateness of this threshold and debate continues.

A Note on Perspective

One of the design considerations when planning an economic evaluation of a treatment program or intervention is the perspective from which it will be conducted. In other words, whose costs and benefits should be included in the analysis? Given that the main goal of the science of economics is to examine the allocation of resources across society, economic analyses require the use of a societal perspective. This involves accounting for the costs and benefits of an intervention or program regardless of who incurs or receives them whether the payer, provider, other health care providers, the social services system, the patient or family members, the criminal justice system, and so forth. Others argue that it is more appropriate to consider only the provider or payer perspective because they are the ones who decide which programs to offer or reimburse, and, therefore, what interventions and program models will be used in practice. However, limiting the perspective to only one actor can lead to suboptimal choices when, for example, treatments are chosen that minimize the cost to the provider or insurer but transfer costs to others such as patients or the social welfare system. Conducting the analysis from a societal perspective and then reporting the results from that and the other relevant component perspectives, which are encompassed in the societal estimate, is a preferred course of action.

Communicating Uncertainty

Estimating and communicating the variation inherent in the ICER – which is the ratio of two estimated variables – is a relatively new feature in the reporting of economic evaluations of addiction treatment programs and interventions. It is an important methodological advance, however, because it enhances our

understanding of the variation in costs and individual responses to programs and interventions, and provides important information about the strength of the evidence. In the addiction literature this has been done in a number of ways. One example is to estimate a confidence interval around the estimate of the ICER. Another is to generate an acceptability curve, which displays the probability that a given intervention is cost-effective at different levels of the decision makers' willingness to pay for a unit of benefit. It is also possible, when comparing two interventions or programs, to plot the joint distribution of the incremental costs and effects, to get a sense of how dispersed they are.

Also popular is the use of sensitivity analysis to determine the effect of varying key assumptions in the analysis on the results. Each of these methods has its strengths and weaknesses. It is often advisable to report several of these ways of communicating uncertainty, which, taken together, can appropriately characterize the precision of the estimate, the strength of the evidence, and the potential consequences of making the wrong choice.

Study Designs

Economic evaluations of addiction treatment programs have been of two main types: ancillary studies to effectiveness or efficacy trials or outcome studies and simulation studies. Each can provide valuable evidence to inform decisions about the allocation of resources. Those evaluations done alongside clinical trials have the benefit of randomization and of allowing for a very accurate and detailed assessment of the costs of the program or intervention at the time it is being provided to the patient. If conducted early enough, they can also inform the future development of the intervention or program to reduce costs so that it will be more likely to be adopted if it is found to be effective. Results from these studies, however, are limited in the sense that they can be difficult to generalize beyond the types of patients and settings used in the trial. In addition, results may not accurately reflect how the intervention or program would be implemented outside of a trial setting, much like the clinical results from the trial.

Dynamic simulation studies can be useful for examining the long-term effects of interventions and programs, for analyzing the results at the population level, and for including a large number of variables in the analysis. In the addiction field, these have been used for all three types of economic evaluation described here. The types of simulation models used to study addiction treatment interventions and programs typically start with a data set, which may come from survey or administrative data, containing

a variety of variables on the individual person at a specific point in time. At that point in time, each individual in this data set can be in one of a limited number of comprehensive and mutually exclusive states, for example, using a drug and not in treatment, using a drug and in treatment, not using a drug and not in treatment, and not using a drug and in treatment. Each state is associated with a variety of costs, such as the costs of treatment, the consequences of drug use, including criminal justice involvement and other health care utilization. Mathematical equations, combining information on the individuals within the data set (such as their age, gender, drug use history, and treatment utilization, with information, often from the literature, on the probabilities of transitioning among these states over time as a function of these characteristics) are used to develop a path across time of the individual's movement into and out of these states. The estimated trajectories of those who receive treatment are compared with the trajectories of those who do not receive treatment to generate the costs and benefits of the treatment program or intervention.

Results of Economic Evaluation Studies

Table 62.2 displays information on several recent economic evaluation studies of addiction programs and interventions. CBA studies tend to find that addiction treatment is cost-beneficial. CUA studies tend to suggest that effective addiction treatments and improvements to those treatments cost modest amounts per increase in QALYs, although recent studies incorporating uncertainty estimates reveal that the results are often imprecise. This is often because the analyses are conducted on clinical trial samples that may not have been powered for the economic evaluation, but also because of the heterogeneity of costs and outcomes observed across patients. Some of the studies in Table 62.2 also reveal that the analyses yield different results based on perspective. Further work is needed to improve methods, such as assuring that power analyses are conducted to determine the adequacy of the sample size for the economic analysis and to standardize the reporting of studies, including design, perspective, costing methods, and uncertainty estimation, to make the results as useful as possible.

COST-FUNCTION ANALYSIS

As is apparent from the costing study results presented in Table 62.1, the costs of producing addiction treatment vary substantially. This variation may be due to a variety of factors, including differences across

TABLE 62.2 Selected Economic Evaluations of Addiction Treatment

Subject	Method	Findings
Publicly funded addiction treatment programs in California*	CBA based on a pre-post study design on data on patients from 43 addiction treatment programs. Benefits, including reductions the costs of medical care, mental health services, criminal activity and transfer payment programs, and increases in earnings, were collected using Addiction Severity Index (ASI) data and administrative data. Direct treatment program costs were estimated using the DATCAP.	Over the 9-month period of the study, treatment cost approximately \$1583 on average while the benefits to society were \$11 487, for a 7:1 ratio of benefits to costs. Sixty-five percent of the total benefit was from reductions in crime costs.
Methadone treatment over the lifetime**	CBA based on a simulation model of the progression of heroin use and treatment, as well as employment, criminal activity, incarceration, and health care use, over the lifetime of a cohort of individuals from 18 to 60. Data are from a variety of national surveys and from published sources.	The benefit–cost ratio for the initial treatment was \$4.86 per dollar spent. Treatment over the lifetime returns approximately \$37 per dollar spent.
Prize-based contingency management plus usual care versus usual care alone for increasing longest-duration abstinent (LDA), negative urines, and length of stay***	CEA based on results from a US RCT of 415 stimulant abusers. Costs were estimated from a provider perspective using a microcosting approach and uncertainty assessed using sensitivity analysis and acceptability curves.	On average, CM cost \$258 for each 1-week increase in LDA, \$146 for each additional stimulant-free urine, and \$398 for each 1-week increase in length of stay. The acceptability curve analysis reveals that CM has a 90% probability of being cost-effective at a willingness-to-pay threshold of \$325 per additional week of LDA.
Motivational interviewing (MI) versus usual care for smoking cessation and relapse prevention [§]	CEA and CUA based on results from a US RCT of 302 low-income pregnant women in Boston. Costs were estimated from a societal perspective using microcosting methods, and QALYs were derived from the published literature.	MI was dominated by usual care for smoking cessation; for relapse MI cost \$851 per life year saved and \$628 pre additional QALY.
Nine treatment regimens for alcohol dependence: Medical management (MM) plus placebo, MM plus naltrexone, MM plus acamprosate, MM plus placebo plus a combined behavioral intervention (CBI), MM plus naltrexone plus acamprosate, MM plus naltrexone plus CBI, MM plus acamprosate plus CBI, MM plus naltrexone plus acamprosate plus CBI, and CBI only ^{¶, †}	CEA using data on 1383 participants in the US Combined Pharmacotherapies and Behavioral Interventions (COMBINE) clinical trial. Outcomes were percentage of days abstinent, avoiding heavy drinking, and achieving a good clinical outcome (abstinent or moderate drinking without problems). Per-patient costs were estimated from the provider perspective based on the number and types of services received, times the cross-site medians of the labor, space, laboratory costs for each service, plus the cost of the medication. Per-patient costs were also estimated from the patient perspective, including time, out-of-pocket, and medication costs. Acceptability curve analysis and sensitivity analysis were used to assess uncertainty.	The treatment regimen that had the highest probability of being cost-effective varied across willingness-to-pay thresholds. From the provider perspective, MM plus naltrexone was most likely to be cost-effective for lower thresholds, while MM plus naltrexone plus acamprosate was most likely to be cost-effective at higher thresholds. Patients had the same ranking, but the threshold at which MM plus naltrexone plus acamprosate had the highest probability of being cost-effective was much lower than that of the provider (\$1500 versus \$7000 per patient with a good clinical outcome).
Twelve-week buprenorphine-naloxone treatment (up to 24 mg day with 1-week taper – BUP) versus brief detoxification treatment using buprenorphine-naloxone (up to 14 mg day tapered to zero on day 14 – DETOX) [‡]	CEA and CUA based on results from a US RCT of 152 adolescent subjects. Costs were estimated from the payer and societal perspectives using the SASCAP, and QALYs were elicited from clients using the EQ-5D instrument. Uncertainty was estimated using acceptability curve analysis.	BUP cost \$1376 per extra QALY and \$308 per extra opioid-free year from the payer’s perspective, although the chances of it being cost-effective were only 86%. Point estimates suggest that BUP may be cost-effective from a societal perspective, but the results were statistically imprecise.

Subject	Method	Findings
Varenicline plus physician counseling versus physician counseling alone for smoking cessation [#]	CUA using a simulation model based on Japanese epidemiological data, and effectiveness and transition probability information from expert opinion and the literature. Costs were measured from the perspective of the health care system and were based on patient and provider surveys, as well as administrative data.	Varenicline was dominant overall and for men, and cost about \$3000 per QALY (in 2007 dollars) for women, although there was considerable uncertainty around the estimates.

programs in their size, the types and scope of services they produce, local costs of doing business, the types of patients treated, and the efficiency of production. Cost-function analysis, which has just recently begun to be applied to addiction treatment programs, offers a way to examine the causes of this variation. It can also provide important information to policymakers and payers about the appropriate amount to reimburse programs, as well as the optimal size and configuration of these programs.

Derived from the standard neoclassical theory of the firm, cost-function analysis is a type of regression analysis that regresses variables such as the volume of output (e.g. the number of clients treated) and costs of inputs such as wage rates for various types of staff and rental space costs, on the total cost of production. Coefficients on the variables provide an estimate of the effect of a small change in the value of those variables on costs.

Understanding the cost structure of an industry, such as whether or not it displays economies of scale or scope, can inform payment, antitrust, and licensing policies as well as industry production practices. An industry is said to experience economies of scale if the average or per-unit cost of production is lower in firms with higher output levels than it is in firms with smaller output levels. In industries with strong economies of scale, it may be appropriate for policymakers to encourage the formation of a few large firms rather than many small ones, for example, through payment or licensing policies. An industry is said to experience economies of scope if firms that produce multiple products can

produce those products at a lower average cost than would be achieved if different firms produced each product separately. If economies of scope are present in the addiction treatment field, it may be appropriate for policymakers to consider changing regulatory requirements where necessary to make it easier for firms to produce several different types of treatments under the same roof. Also important is understanding another facet of the cost structure of the industry, whether efficiency can be improved by altering the mix of inputs used in the production process. This can be ascertained by examining the coefficients on the input price variables.

Other variables are included in the analysis both to improve the estimates of industry structure coefficients and to understand the effects on costs of those variables. These other variables, which can include information on the types of patients the program treats, its location in a high-cost or low-cost area, or whether or not it is part of a parent organization, may be especially important if the results from these studies are used to determine payment rates or to compare firms on the basis of their efficiency. Failure to account in the analysis for factors that legitimately affect cost differences and that society values can lead to erroneous conclusions and policy actions.

Two studies grounded in economic theory have been conducted on addiction treatment programs, one using data on a nationally representative sample of outpatient nonmethadone facilities from the ADSS study and the other using a large sample of methadone treatment facilities. The outpatient nonmethadone study examined

TABLE 62.3 Findings from Economic Cost-Function Analyses

Study	Findings
Study of a nationally representative sample of 222 outpatient nonmethadone treatment programs. Explanatory variables included number of admissions, wages (counselor, clerical, and senior administrative), office space, percentage of patients who were white, black, Hispanic, other race, percentage referred by the criminal justice system, percentage who had both drug and alcohol disorders, percentage who injected drugs, percentage who received Supplemental Security Income (SSI) or Social Security Income (SSDI), facility ownership (private for-profit, private nonprofit, government), whether or not the program was part of a larger organization, location in an urban area, and how many special services the facility reported offering.*	A 10% increase in the number of treatment admissions resulted in a 6.7% increase in total costs, suggesting economies of scale. Facilities with higher proportions of clients with SSI and SSDI had higher total costs.
Study of 159 methadone treatment programs from several states that participated in the Center for Substance Abuse Treatment's Evaluation of the Methadone/LAAM Treatment Program Accreditation Project.**	A 10% increase in patient days resulted in an 8.2% increase in total costs, suggesting economies of scale.

** Dunlap, L.J., Zarkin, G.A., Cowell, A.J., 2008. *Examining variation in treatment costs: a cost function for outpatient methadone treatment programs*. HSR: Health Services Research 43, 931-950.

economies of scale only, while the methadone study examined both economies of scale and scope. The results, shown in Table 62.3, suggest that there are economies of scale in both types of treatment programs but little support for the presence of economies of scope in methadone treatment. Few other variables were significantly related to treatment costs.

Although these studies are informative, they do not adequately control for two factors that could affect costs, the omission of which might affect the estimates of economies of scale and scope because of omitted variables bias, but which are also important in their own right: client casemix and the quality of care provided. Casemix

measures are needed to objectively control for differences in the resources that may be required to treat different types of clients. Failure to include such information when using cost-function results to set payment rates, for example, could lead programs to stop admitting clients they believe will cost more to treat, reducing access to those who might need treatment most. Failure to include quality measures could lead programs to use methods that are less costly but not as effective, leading to worse outcomes and lowering the value of society's investment in treatment.

Although Table 62.3 shows that the studies did include indicator variables that might capture some differences in casemix, the field has not carefully conceptualized, developed, or tested a comprehensive measure or set measures for this purpose. The field is also lacking in quality of care measures appropriate for this purpose. Although length of stay often is considered a proxy for quality in addiction treatment, its use in cost-function analysis is especially problematic because a longer length of stay could also reflect inefficiency in the production of treatment. Research designed to fill both of these gaps would enhance the utility of cost-function and other economic analyses, as well as the ability to compare programs for other purposes such as pay-for-performance schemes.

SUMMARY

The basic insight from economics – that limited resources must be allocated carefully to maximize welfare – has led to the development of a variety of analytical approaches to inform allocation decisions. These approaches, including costing studies, economic evaluations, and cost-function analyses, have increasingly been applied to study addiction treatment programs and interventions, and the methods and data available to conduct them continue to improve. Addiction treatment is often found to be cost-beneficial, and effective enhancements to addiction treatment are often shown to improve outcomes or increase QALYs at costs that many would consider reasonable. Studies to date suggest that there is substantial variation in the costs of producing addiction treatment, but the sources of that variation are poorly understood. Although other factors, such as equity and access, should certainly be considered when deciding what addiction treatments to purchase, provide, or fund, careful accounting of the costs of a proposed activity and the outcomes or benefits it produces need to be a cornerstone of any such decision.

Economic analyses, like all analyses, should have clearly defined goals, employ methods and data that are most appropriate to meet those goals, and be

reported in a way that accurately, clearly, and objectively states what was done and what it means. CEAs and CUAs, for example, may be most useful when considering novel treatment interventions or enhancements to existing interventions. They can help identify interventions that are unlikely to be of high value as proposed and point to ways to improve their value. A high-quality analysis would involve determining the most appropriate outcome or outcomes to measure and how to best measure them, assuring adequate statistical power, clearly describing the comparator condition, carefully costing (identifying, quantifying, and valuing) all of the societal resources incurred in the production and participation in each of the treatments and how they vary among patients, and assessing and communicating the statistical significance of the ICER and, in the case of QALYs, its relationship to the chosen threshold value. Theoretically, microcosting is the preferred method for assessing the costs of interventions for CEAs and CUAs, but research is needed to determine if the additional accuracy warrants the significant research resources required to conduct such studies in the addiction field. Studies examining other health care sectors suggest it may not. Simulation analyses that can estimate the effects on ICERs of changes in the model parameters – for example, reduction in the price of pharmaceutical interventions that might be possible when a generic becomes available – can be used to avoid the problem of nipping the diffusion of a promising intervention in the bud because it appears too costly. To enhance the quality and comparability of such studies, research is needed to identify clinical endpoints or other outcomes that could be implemented across studies and in developing a nationally representative cost database that could be used to value treatment inputs.

CBAs may be most appropriate as an aid to determining which of a variety of cost-effective treatments or other interventions to implement given limited budgets. Careful accounting of the costs and benefits that accrue to the entire society is essential in making this determination. Again, results can be reported for different perspectives, but spillovers must be identified and accounted for in the main result. For these types of analyses to fulfill their promise, investments need to be made in understanding and quantifying the nature of the disorder, the long-term consequences of drug use among the treated and untreated populations, and the long-term effects of treatment for diverse populations. Such data currently are lacking.

Undergirding each of these studies needs to be cost data that adequately captures and converts into currency terms the resources used to produce treatment. In the absence of government- or market-mandated reporting requirements such as those that exist in other

industries, it falls to researchers to capture those data using *de novo* data-collection methods such as the ones described above. Ideally, such data would be pooled to provide industrywide averages that could be used across studies, and that could support careful examinations of the industry's structure and ways to make it as efficient as possible.

INTRODUCTION

The treatment of drug addiction can involve a range of pharmacological and psychosocial approaches. Pharmacological treatment of drug dependence can be divided into three broad categories: detoxification (supervised withdrawal from the drug of addiction), relapse prevention (prophylaxis against relapse), and maintenance or substitution treatment programs (supervised provision of the drug of addiction or a similarly acting drug (its agonist)). Psychosocial treatments involve cognitive behavioral therapy, therapeutic communities, or social support, and may or may not be provided in conjunction with a pharmacological treatment. Some treatment programs such as needle

and syringe programs (NSPs) do not aim to reduce or stop drug use, but to reduce the harm that drug use causes. These types of treatment are of an approach referred to as *harm reduction*.

The aims or desired outcomes of each of these treatments can vary widely. Treatment may differ in the length of intervention (e.g. short-term detoxification to longer-term relapse prevention, substitution, or maintenance), the requirement of abstinence from addictive drug use, and the degree of clinical engagement. The strengths and weaknesses of each approach to addiction treatment differ but the ethical principles that supervene on the treatment of addiction hold irrespective of the treatment aim or modality.

ETHICAL PRINCIPLES AND SOCIAL FACTORS INFLUENCING THE TREATMENT OF ADDICTION

The treatment of drug dependence should observe the minimum requirements for ethicality of any form of medical or psychosocial treatment. These have often been expressed in four influential ethical principles: respecting the *autonomy* of persons who are being treated, avoiding harm (*nonmaleficence*), doing good (*beneficence*), and providing a fair distribution of costs and benefits of drug treatment and drug policy (*distributive justice*). These four ethical principles also form the basis of important statements of human rights, such as the World Medical Association's Declaration of Helsinki and similar statements by United Nations Organization.

Treatment of drug dependence can involve the use of the coercive powers of the state and the denial of liberty and autonomy because the behavior of drug-dependent people adversely affects others (e.g. criminal acts to finance illicit drug use, violence, or dangerous driving while intoxicated). Treatment of drug dependence also often involves the coordination of several different social systems – the medical or health care system, public health, and criminal justice – which often requires careful justification and balancing of the rights of addicted individuals and the community in developing treatment policy.

Most would agree that individuals should be respected and treated fairly. However, consensus often proves elusive in the case of treatment of drug dependence because of disagreements about what these ethical imperatives require us to do, and where the balance of effort and responsibility lies. These disagreements are often largely driven by different answers given to the following questions: What is the nature of addiction? How does addiction affect those with the disorder? How much autonomy do drug-dependent persons have? To what extent are they able to make decisions about their drug use, consent to enter treatment, choose not to use drugs, be involved in decisions regarding their treatment, and take responsibility for their actions? What are they capable of and responsible for? What are the respective rights and responsibilities of society and drug-dependent individuals?

AUTONOMY AND THE DRUG-DEPENDENT INDIVIDUAL

For most of the last century, drug-dependent persons were seen as autonomous, self-governing individuals who willfully, knowingly, and voluntarily engaged in criminal and immoral behavior (i.e. illicit drug use).

However, in the last decade, the autonomy and responsibility of addicted individuals were called into question by genetic and neuroscientific research on addiction. In 1997, Alan Leshner, the then director of the National Institute on Drug Abuse (NIDA), declared addiction to be a “chronic, relapsing brain disease” caused by the repeated self-administration of drugs that produced enduring changes in brain neurotransmitter systems and left addicted individuals vulnerable to relapse.

Brain imaging studies have shown how prolonged drug use produces long-lasting changes in brain structure and function that undermine voluntary control. These studies have specifically shown that chronic drug use produces a significant decrease in dopaminergic activity that is involved in the disruption of limbic and prefrontal regions. Adaptations in limbic regions emphasize the rewarding effects of drugs and make addicted individuals less sensitive to the rewarding effects of everyday rewarding activities, such as food, work, and relationships. Disrupted functioning in the prefrontal regions focuses addicted individuals' attention on drug use and impairs their ability to control their drug use for months after they become abstinent. Addicted individuals also display cognitive deficits in decision-making tasks.

An explicit aim of advocates of the brain disease model of addiction is to change the way that society deals with addiction. The hope is that public acceptance of addiction as a brain disease will lead to less reliance on punitive measures and more effective and humane medical treatment of addiction. It is also hoped that reduced social stigma would encourage more individuals to seek treatment early and increase funding for medical research and interventions. Despite a decade of the chronic, relapsing brain disease model of addiction, relatively little has changed in societal responses to addiction.

Some social scientists are concerned that the brain disease model of addiction may be used to justify greater discrimination against those with an addiction. If individuals with an addiction are seen as suffering from a brain disease where their behavior was neurobiologically determined, addicted individuals might be deemed incapable of making decisions regarding their drug use. On this view, those with an addiction lack the capacity to make autonomous decisions, and more coercive forms of treatment or invasive interventions with serious risks or side effects could be justified. Such an interpretation could lead to reliance on only mildly effective pharmacological or neurological treatments at the expense of cheaper, more effective social policies that aim to minimize the effects of drug abuse. An uncritical acceptance of this view might also encourage the promotion of expensive and invasive “cures” of addiction of doubtful efficacy to a vulnerable and desperate population.

The ability, or lack thereof, of the drug-dependent individuals to control their drug use is central to ethical debates regarding the treatment of drug dependence. These arguments hinge on whether these individuals are compelled to use drugs. While arguments for compelled behavior can stem from both biological and social causes, arguments for compulsive behavior more often involve appeals to biological causes. Genetic and neurophysiological explanations of compulsive drug use are much more compelling and have the appearance of material fact. The presence of “addictive genes” and pictures of “addicted brains” possess the allure of truth and are easily misrepresented or misunderstood. Results of this kind are often used to portray the addicted person as someone who is “internally coerced by an irresistible force” and therefore lacks autonomy with regard to drug use.

Some bioethicists have used the chronic, relapsing disease model of addiction to argue that people with an addiction lack the autonomous decision-making capacity about drug use. According to these ethicists, addicts are unable to make rational decisions about whether to accept offers of drugs in experimental or clinical research studies. Such arguments would also raise similar doubts about the capacity of addicted individuals to provide free and informed consent to enter any form of treatment that involves maintenance on an agonist drug, such as methadone or buprenorphine: two of the most effective pharmacological treatments available to opioid-dependent individuals.

Such interpretations ignore the limitations of what the neuroscience of addiction is able to tell us. For addiction to completely override autonomy in drug-dependent individuals, the forces of addiction must be demonstrably irresistible and absolute. Observational studies show that this is not the case and evidence from the neuroscience literature is not as clear as some bioethicists suggest. Neuroimaging and cognitive studies show that addicted individuals, as a group, are more likely to show disruptions in brain function, which is thought to be associated with a reduced ability to control drug use and make appropriate decisions. They do not, however, demonstrate an absolute lack of control that undermines decision-making capacity in all addicted individuals.

Many addicted individuals succeed in stopping drug use without further assistance. Others can become abstinent for varying periods as a result of social pressure. The problem with the disease model of addiction, and any of the “lifestyle diseases” such as obesity and diabetes, is that nearly any kind of abnormal behavior will be accompanied by biological changes in the brain that can be detected or measured. Finding such differences does not indicate that they comprise a disease of biological origin. By contrast, those who claim that

addiction is a self-serving excuse for willful and bad behavior ignore the biological correlates of addiction.

The nature of addiction is a much more complex phenomenon than either partial perspective allows. Disease models need to acknowledge that people with drug dependence still maintain a level of autonomy in making decisions about their drug use. Skeptics need to acknowledge that disrupted brain neurobiology does impair the ability of some drug-dependent people to make decisions about their drug use and may indicate the need for pharmacological interventions to support abstinence.

PERSONAL HEALTH AND THE PUBLIC GOOD

The treatment of drug dependence, particularly illicit drug dependence, is motivated by mixed personal, public health, and public order goals that complicate and sometimes compromise treatment. Drug-addicted individuals often enter treatment under some form of coercion, whether it be from friends or family, or as a result of an encounter with the criminal justice system as an alternative to imprisonment. Many drug-dependent persons are unable to pay the costs of their treatment, which is often provided by the government. Taxpayer-funded addiction treatment is usually justified because it is more cost-effective than imprisonment in reducing crime and public disorder.

Treatment often involves interactions between personal and public health systems and the criminal justice system. These different areas (e.g. law enforcement, clinical staff, and public health) have different aims and approaches to health care, with different professional ethical imperatives, that can lead to conflicts in the provision of treatment. Clinical or personal medicine focuses on the treatment and cure of individual patients while public health medicine aims to understand and ameliorate the causes of disease and disability in a population. While the physician–patient relationship is the focus of medicine, public health involves interactions and relationships among professionals and members of the community, as well as government agencies. The involvement of the criminal justice system in coercing patients into treatment and the competing goals of drug treatment of different agencies amplifies opportunities for conflict. The tensions between these goals must be managed by all forms of treatment, including abstinence-oriented treatment, but they present special issues for programs that provide pharmacological treatment of opioid dependence.

Pharmacological treatments, agonist maintenance in particular, can have negative effects on society if drugs for treatment are diverted to the black market. As

a result, treatment requires the imposition of restrictions to protect public welfare. Public ambivalence about the ethical acceptability of maintaining “addicts” on “drugs” often leads to restrictive rules and regulations on pharmacological treatment. Some regulations are intended to minimize the risk of nonaddicted persons entering treatment (e.g. by demanding evidence of an extensive history of dependence and documented failure at abstinence treatment). Other regulations aim to prevent diversion of pharmaceutical opioids to the black market where they may result in harm (e.g. overdose deaths, new cases of addiction). Program regulations may also include regular urine testing, punishment for patients who provide a certain number of dirty urine samples (e.g. exclusion from the program), limits on the length of treatment, or an insistence upon achieving a goal of abstinence from all drugs within some arbitrary period (e.g. 1 or 2 years). These regulations may have unintended effects such as decreased program retention, discouraging drug-dependent persons from seeking treatment until their condition is chronic, or forcing stable patients to withdraw from treatment and return to illicit drug use. Ethical treatment of addiction requires program rules and regulations that balance patient and community safety while permitting patients to remain in and benefit from treatment.

DISTRIBUTIVE JUSTICE: BALANCING THE BURDEN OF DISEASE AND TREATMENT

The public benefits that treatment for drug dependence brings are important in obtaining public support, but there is a danger that policies that benefit the majority may impose unfair burdens on a vulnerable minority. An important ethical goal of drug-dependence treatment is ensuring that public policies do not *unfairly* burden or discriminate against a vulnerable minority to serve the public good.

Distributive justice is a difficult and emotively charged issue in the case of addiction because drug use has negative effects on society, and drug policies that aim to discourage drug use may adversely affect dependent individuals. This raises important questions about where the burden of responsibility lies for society and the addicted individual in dealing with drug dependence. For a treatment to be ethical, it is necessary to show that (1) it is effective in reducing negative outcomes for both society and the individual and (2) that the social and political policies that produce and respond to addiction do not unfairly burden the minority who become addicted. The first condition is necessary but not sufficient: it would be unethical, for

example, to use effective pharmacological treatment of opioid dependence to compensate for social policies that fail to address social disadvantage, family history of violence and drug use, and presence of comorbid psychiatric disorders, all of which increase vulnerability to opioid addiction.

Those who receive publicly funded or subsidized treatment arguably have a reciprocal responsibility to engage in a reasonable treatment program, to meet its aims, and to avoid behavior that adversely affects the community. Society is justified in expecting that drug-dependent individuals, who engage in treatment, adhere to treatment and not act in ways that adversely affect society. For example, while methadone maintenance treatment has been shown to be relatively safe and effective in reducing opioid use, it can lead to overdose if methadone is diverted to opioid-naïve users. In the United Kingdom during the 1990s, poorly regulated methadone programs led to the diversion of methadone onto the black market, resulting in fatal methadone overdoses of persons who were not in treatment. Risks such as these highlight the importance of delivering treatments in ways that protect both those receiving it and the broader society.

Treatment responses and regulations used to ensure that those who enter treatment meet their obligations must be informed by a broad set of ethical principles. To be ethical, they must

1. not unduly violate privacy and autonomy of individuals;
2. scale responses to individual lapses to their relative importance in achieving overall treatment goals;
3. be mindful and consistent with the ability of individuals to meet their obligations (including actively helping individuals to do so); and
4. be sensitive to the situation of the individual, with regard to both internal (neurophysiology and neuropsychology) and external (social) circumstances.

Based on the ethical analysis presented, we believe that the treatment of drug dependence should meet the following ethical guidelines:

1. Drug-dependent persons should have equitable access to safe and effective forms of treatment. That is, they should not be discriminated against by virtue of their condition nor should the illegal status of their actions prevent them from access to safe and effective treatment.
2. There should be rigorous evidence that the treatment be safe and effective. New pharmacological or neurological treatments for drug dependence need to have their safety and efficacy rigorously assessed before they are widely used.

3. Treatment should be provided safely in well-structured, well-resourced, and well-managed treatment programs.
4. Treatment should ideally be individualized to the patient. Addicted persons differ in many ways and addiction is a dynamic process. Different individual's needs will therefore vary and may change over time and circumstances. It is accordingly important that treatment flexibly meets patients' changing needs.
5. Treatment staff need to emphasize the importance of the client–carer relationship in providing ethically adequate treatment that respects the autonomy of patients, their privacy, and the confidentiality of information that they provide, and ensures that individuals provide free and informed consent to participate in treatment (see below).
6. Treatment should be motivated by an intention to treat the individual. Ideally, treatment that accords with the ethics of personal medical care is also the most successful in meeting the aims of a public health care program because good individual treatment will ensure good program retention and maximize the benefits to the individual and the community that funds his/her treatment.
7. Good relationships between clients and staff are important in successful treatment. Attitudes of staff toward clients and their relationship with clients have been found to be the critical factors in determining the success of methadone maintenance treatment.
8. Conversely, treatment programs should be regulated in such a way that protects society from further harm. These rules and regulations should be understood by clients and be administered in a fair and reasonable way that aims to protect society and are not used to unfairly punish clients. Drug-addicted individuals should not bear a disproportionate social burden in accepting treatment.

ENTERING TREATMENT FOR ADDICTION

Informed consent is the process by which individuals agree to enter treatment in the full knowledge of its possible risks and benefits, and in the absence of duress or coercion. Informed consent requires that the individual (1) has the capacity to understand treatment and communicate his/her wishes, (2) is free to make decisions (i.e. is not internally or externally coerced), (3) is fully informed of the risks and benefits of the treatment as well as those of other treatment options, and (4) has reasonable access to all effective forms of treatment, where treatment is appropriately operated and resourced.

When drug-dependent individuals enter treatment, they are often in a desperate state. They may be willing to agree to almost anything to get into treatment (e.g. to end their withdrawal symptoms or avoid the negative social consequences of their addiction). For these reasons, individuals in this situation should not be asked to provide detailed consent to a treatment program, apart from indicating their acceptance of the immediate offer of assistance. Clients can only begin to think about detailed requirements of treatment after they have been stabilized in pharmacological maintenance treatment or have completed supervised withdrawal.

When choosing a treatment, it is important that the client understands its effectiveness, benefits, and risks, as well as the requirements of the treatment program. The treatment that is chosen should reflect the aims of the individual rather than those of the staff or the wider community. The staff member's responsibility is to ensure that the client is well-informed about the treatment options that are available, their goals, risks, and benefits, and what the expectations are in entering the program. Ensuring this understanding requires discussions about the pros and cons of abstinence versus maintenance treatment goals, as well as an honest appraisal of the risks and the likelihood of benefiting from both types of treatment (see [Table 63.1](#)).

Informed consent to a detailed treatment contract will state the rules and regulations of treatment and an individual's obligations. This may include information on drug testing regimes, responses to positive urine samples, intended length of treatment, costs, where and how often drugs are to be dispensed, other treatment requirements, involvement of the criminal justice system, and rights to privacy and confidentiality, including informing participants of the limits of confidentiality (e.g. that it is mandatory to report child abuse or homicide). Rules and obligations such as this should

TABLE 63.1 The Minimum Requirements for Acquiring Free and Fully Informed Consent to Addiction Treatment

Minimum requirements for informed consent to addiction treatment, include providing information to clients about

1. Clinical characteristics and diagnosis
 2. Treatment recommendations
 3. Risks and benefits of treatment
 4. Costs of treatment
 5. Program rules – rights and obligations
 6. Alternative services and interventions
 7. Freedom to choose and refuse treatment
-

be aimed at the treatment of the individual, while still protecting society from harm.

COERCED TREATMENT OF ADDICTION

There is reasonable evidence that persons who enter treatment for drug abuse will benefit from the treatment and that the longer they remain in treatment, the better off they will be. The fact that many drug-dependent persons are ambivalent about entering treatment has led to the use of various forms of formal and legal coercion to encourage treatment entry and retention that vary in the degree to which they contravene an individual's liberty, freedom, and autonomy.

Mild informal coercion, such as social pressure from friends and family to enter treatment, can be effective motivation for addicted persons to enter and complete treatment. Formal, noncriminal coercion by employers and other nongovernmental agencies, such as Employment Assistance Programs, is negotiated between agencies or employers and the individual.

Informal social coercion and formal noncriminal coercion arguably raise few ethical issues in the treatment of drug dependence. In both these cases, the drug-dependent person is *relatively* free to agree to treatment or suffer the threatened consequences (such as loss of employment or relationship). The coercive pressure in these situations does not deprive them of their liberty or deny their autonomy. Legal coercion, or the forced or coerced treatment of addicted individuals by the state, does raise a number of ethical concerns.

The Case for Legally Coerced Treatment

Legally coerced treatment most often involves the use of the criminal justice system to enforce entry to treatment on pain of imprisonment. A major justification for legally coerced treatment is that treating offenders' drug dependence will reduce the likelihood of their re-offending. Studies from both the United States and Australia have shown that treatment for drug addiction significantly reduces criminal and violent behavior by addicted subjects while they remain in treatment. The use of drug treatment programs as an alternative to incarceration has also been motivated by the failure of prison terms to reduce drug use and drug-related crime among drug-dependent people who are overrepresented in prisons.

The advent of HIV/AIDS has provided an additional argument for treating addicted persons who engage in injecting drug use. Keeping injecting drug users (IDUs) out of prison reduces the transmission of infectious diseases such as HIV and hepatitis C virus (HCV). The ethical, correctional, and public health arguments for drug treatment under coercion are reinforced

by the economic argument that it is less costly to treat offenders who are drug dependent in the community than it is to imprison them.

Legal coercion covers a wide range of strategies for getting individuals into treatment programs. The form of legal coercion that has become increasingly popular within the criminal justice system is the use of diversionary programs that offer drug-dependent persons treatment as an alternative to imprisonment at various stages in the criminal justice process. Legally coerced treatment is most often advocated for persons charged with or convicted of an offense to which their drug dependence has contributed. It is generally offered as an alternative to imprisonment to have legal sanctions deferred, reduced, or lifted, or as a condition of parole. Suspension of legal sanctions is usually made conditional upon successful completion of a treatment program, with the threat of imprisonment if the person fails to comply.

When Is Coerced Treatment Ethical?

Careful consideration of ethical issues is critical when the state uses the threat of imprisonment to encourage drug-dependent persons to seek treatment. Coerced treatment of addiction must operate within a constitutional and legal framework that protects the civil liberties of the people being coerced into treatment. It is important that treatment does not override an individual's basic human or civil rights to achieve broader social goals.

Coerced treatment for drug addiction may be justified by appealing to either of two ethical principles: *paternalism* or *the public good*. Addiction is a harmful behavior in which to engage; it adversely affects an individual's health and social welfare and significantly increases mortality and morbidity. Coerced treatment of drug addiction could therefore be justified for *paternalistic* reasons: that is, on the grounds that it is in the best interests of the individual. This would involve coerced treatment for an addicted individual's "own good."

Two forms of paternalism can be distinguished on the basis of the degree of coercion involved. Treatment that is provided against an individual's wishes, where the individual is deemed competent in making this decision is referred to as *hard paternalism*. When an individual is deemed incapable of making a competent decision, treatment is imposed because it is argued that their condition prevents them from making informed decisions on their own behalf. Coerced treatment of this type is referred to as *soft paternalism*. It is soft paternalism that is most likely to be used to justify coerced treatment in the case of addiction.

In many countries, people with serious mental illnesses can be compelled to accept treatment under certain circumstances, usually after some form of judicial review. While there is a strong beneficent

justification for providing treatment, respect for an individual's liberty to make their own decisions about treatment generally overrides the beneficent drive to intervene. This would prevent the use of coerced treatment under hard paternalistic justification.

The second principle that can be used to justify coerced treatment of drug dependence is to protect the social welfare or the *public good*. The public good claim for the use of coerced treatment depends on the negative effect of drug-addicted individuals on society (e.g. via drug dealing and other criminal activity to finance their drug use). The justification of coerced treatment to protect the public good therefore becomes a distributive justice issue: that is, providing a fair distribution of the costs and benefits of drug use and drug treatment. This analysis arguably creates an obligation on society to provide treatment, and an analogous obligation on drug-dependent individuals to accept treatment under certain circumstances. This is the most commonly used justification for coerced treatment of addiction.

Some authors reject any form of treatment under coercion for drug addiction. Radical libertarians argue that drug use is always voluntary. Others accept that drug dependence exists, but oppose compulsory drug treatment on the grounds that it does not work. If treatment under coercion was ineffective, then there would be no ethical justification for providing it.

A consensus view on coerced drug treatment prepared for the World Health Organization (WHO) concluded that it was legally and ethically justified only if (1) the rights of the individuals were protected by "due process" (in accordance with human rights principles) and (2) if effective and humane treatment was provided.

Some proponents argue that offenders should be allowed two "constrained choices." The first would be whether to participate in drug treatment. If they declined to be treated, they would be dealt with by the criminal justice system in the same way as anyone charged with the same offense. The second choice would be given to those who agreed to participate in drug treatment: this would be a choice of the type of treatment that they received. There is some empirical support for these recommendations in that there is better evidence for the effectiveness of coerced treatment that requires some degree of "voluntary interest" by the offender.

The requirement of constrained choice of treatment has three implications. First, pharmacological treatments, including substitution or maintenance approaches, should be included in the options that are offered. There has been a tendency for coerced treatment programs to offer only "drug-free" abstinence-oriented treatments that prevents coerced addicted individuals from accessing the forms of treatment that are most likely to benefit them. Second, pharmacological

treatment options should not be the only options available. A range of drug-free treatment options should be available for those who do not wish to use pharmacological treatment. Third, the safety, effectiveness, and cost-effectiveness of whatever forms of treatment are offered should be rigorously evaluated.

Is Compulsory Addiction Treatment Ethically Acceptable?

Compulsory treatment – the unconditional, forced treatment of addicted individuals who have not committed a crime – does not offer a drug-dependent individual any choice. Coerced treatment of this type involves an extreme violation of an individual's autonomy and liberty. Mandatory treatment has generally involved the confinement of individuals in specialized drug-treatment facilities or prison hospitals, usually with the goal of attaining abstinence. Failure to comply with any condition of the program usually results in being readmitted to a secure inpatient facility.

As compulsory treatment involves a maximal deprivation of liberty, it requires a correspondingly greater ethical and legal justification than other forms of coerced treatment. Arguably, this includes stronger evidence that this form of treatment is effective and that the consequences of not treating the person are significant and likely to occur. Given the poor outcomes of compulsory treatment, it is difficult to justify its use for either paternalistic or public good reasons. Importantly, compulsory treatment programs override the autonomy of the individual and arguably constitute a violation of civil liberties in a manner that contravenes the United Nations Declaration of Human Rights. Coercive diversion strategies, by contrast, are less restrictive because they involve constrained choices in which a choice not to enter treatment leaves the person to face the judicial system with their civil and human rights intact.

Ethical Issues in Providing Coerced Addiction Treatment

Ethical issues in coerced addiction treatment also arise from the interaction between the correctional and medical treatment systems. A major problem is the conflicting expectations of correctional and treatment personnel about the effectiveness of drug treatment and their understanding of each other's roles and responsibilities.

Treatment staff regard the drug offender as a client: someone who should be involved in treatment decisions and whose personal information should be confidential. Treatment staff also expect that their clients will have relapses to drug use, which should be dealt with therapeutically rather than punitively. Correctional and

judicial personnel, by contrast, often expect treatment to produce enduring abstinence. They see treatment as something directed by the court and hence regard drug use in treatment as a breach of a court order that treatment staff are legally obliged to report. When these expectations of treatment effectiveness are not met and there is little communication between courts and treatment services, judges and magistrates may become skeptical about the value of coerced treatment and reduce their use of it.

The effective and ethical use of coerced drug treatment accordingly requires a shared understanding of the likely benefits of treatment and a clear statement of the roles of correctional and treatment staff. The latter should include agreement on their respective responsibilities for monitoring and reporting on an offender's progress in drug treatment. These issues should be addressed in written protocols that govern interactions between courts and treatment personnel.

TREATMENT OF VULNERABLE POPULATIONS

Addiction Treatment in Prisons

Few prisons in developed or developing nations provide effective treatment for addiction. When addicted individuals enter prison, they more often than not receive little or no treatment for their condition. Consequently, many are forced to undergo unsupervised detoxification, or "cold turkey." Given the high rates of imprisonment among drug-dependent (in particular opioid) persons, more should be made of the opportunity to offer them treatment while in prison. At a minimum, we should avoid the current practice in many prison systems of compulsory unassisted detoxification. Basic human rights include access to good pharmacological management of withdrawal symptoms on prison entry. A good case can also be made for providing substitution (e.g. methadone or buprenorphine) treatment and other harm reduction programs (e.g. NSPs) in a prison setting with the aims of both benefiting opioid-dependent prisoners and contributing to the good management of prisons. A reduction in blood-borne virus (BBV) transmission within prisons and BBV transmission and relapse to heroin use after release may therefore represent an additional benefit.

The lack of adequate addiction treatment can lead to the use of drugs within prisons, increasing the risks of drug overdose, and HIV and HCV infection. As a UN report noted, by entering prisons, prisoners are imprisoned for their crimes; they should not be condemned to HIV and AIDS by being denied access to effective addiction treatment. Forced detoxification can also

lead to overdose if individuals with no opioid tolerance relapse to opioid use in prison or on release, as many do.

Few prisons provide access to sterile injecting equipment for IDUs. This is despite high rates of HIV (10–20%) and HCV (30–40%) infection occurring in prisons. Approximately one-third of the prisoners report injecting drugs while incarcerated and a high proportion share injecting equipment. These individuals are at a very high risk of contracting HIV or HCV. Failure to provide prisoners with the means to avoid these diseases arguably denies them access to health measures available to the rest of society, violating the "principle of equivalence" (the obligation to provide equivalent care to prisoners as available to the general population) and the right to health.

Human Rights in the Treatment of Addicted Pregnant Women

Substance abuse during pregnancy can have adverse effects on both the mother and the developing fetus and may increase the risk of medical complications during birth. Individuals born to substance-using mothers often suffer from significant structural brain abnormalities (e.g. significant neuronal loss and smaller brains) and lifelong cognitive and behavioral deficits for the abuse of drugs such as alcohol (e.g. fetal alcohol syndrome), cocaine, and methamphetamine.

The treatment of substance abuse or addiction during pregnancy raises the challenging ethical issue of balancing the interests of the fetus and the freedom of the mother. Society often imposes limits on the autonomy of individuals when their behavior affects others, such as overriding a competent patient's refusal of treatment to prevent the spread of an infectious disease. However, the case of overriding the autonomy of drug-abusing pregnant mothers to protect the fetus from harm is complicated by the uniquely interdependent relationship between the mother and fetus, and the uncertain legal status of the fetus.

There are two arguments against state-sanctioned coercive treatment and detention of pregnant mothers: (1) the stress and anxiety associated with forced detention or medical intervention, or the experience of intense withdrawal symptoms, can have serious adverse effects on the mother and fetus; and (2) the threat of compulsory treatment programs may deter women from presenting themselves early for prenatal care and preterm health checks to avoid compulsory detention or intervention. Both of these outcomes would adversely affect the health and welfare of the child and mother in ways that may offset any benefits of coerced treatment.

Increasing access to addiction treatment for consenting addicted mothers is a preferable option. Given the

potential harm from enforced addiction treatment for pregnant women, treatment programs should rely on less restrictive and coercive forms of treatment that do not override the mother's autonomy. Alternative options may include improving engagement with clinicians and education, reinforcing abstinence using vouchers, offers of free prophylactic support to prevent relapse, less punitive responses to positive drug tests, and offers of effective and safe substitution treatments.

CONCLUSION

Drug addiction is a condition that not only causes significant harm to those who suffer from it but also adversely affects society. It is a condition that also raises questions about our ability to control our own actions. If opioid addiction is seen as a failure of individuals to control their behavior, it can lead to a moral condemnation of those who suffer from it. This may affect how we as a society deal with it and in turn may lead to adverse consequences for both the individual and society. Drug addiction often requires a response from many governmental agencies, both medical and judicial, that can affect how treatment is provided and how effective it is.

It is important that the treatment of drug dependence be governed by the primary aim of treating the individual suffering from it. Most of the obstacles to effective treatment are the result of different understandings of the nature of drug addiction and confusion over the aims of treatment. Often the regulations and policies that guide treatment are aimed at controlling and even punishing the individual. Not only are such approaches ethically unsound – in that they violate the individual's right to safe and effective treatment – they are also ineffective from the utilitarian ethical perspective that often motivates the provision of treatment for drug dependence. Treatment that aims to produce a therapeutic benefit for the individual is more effective if it engages the patient in treatment and encourages an individual to change, within the constraints of preventing further harm to society.

INTRODUCTION

Substance abuse treatment practices have evolved independent of the mainstream health care community. Traditional health care facilities, like hospitals, were unable to adequately treat addictive disorders, leaving a gap in the treatment. Recovering addicts filled this gap by implementing a peer treatment system. Even as the disease model was applied to addiction, treatment perspectives did not change. Especially since there was little evidence available to determine which practices were effective.

Currently, the field of addiction is experiencing a transition from the use of subjective evidence to a focus on objective evidence. In the past, treatments were designed

based on subjective opinions of what worked best. As the wealth of scientific evidence increases, we are better able to make scientifically informed decisions as to which treatments to employ. In addition, policy factors can also influence treatment decisions. Increasingly, treatment programs relying on government funding are being required to demonstrate that the programs they fund incorporate evidence-based practices.

Evidence-Based Treatments (EBTs) are approaches that have been found to improve patients' functioning after rigorous scientific testing. Through the use of EBTs, we can ensure patients get the best possible services. The use of EBTs combines research with clinical expertise, and takes patient characteristics into consideration when selecting the best interventions.

However, there are barriers to the adoption of EBTs. Many programs have different treatment approaches, and providers may use different treatments within the same clinic. Sometimes providers are committed to their particular treatment models, believing the methods they have used for years to be correct. There is also the tendency to fall back on what we know out of comfort, rather than trying something new and unfamiliar.

In this chapter, we will describe different types of evidence and how it is evaluated to determine whether or not a treatment is evidence based. In addition, we will highlight important methodological issues that arise, describe findings from key studies, and the current state of EBT. Future directions for the field are also presented, focusing on increasing the dissemination and adoption of EBTs.

EVIDENCE-BASED TREATMENT

What Constitutes Evidence for a Particular Treatment?

How is a treatment deemed to be evidence based? There are several methods of evaluating treatments, such as randomized-controlled trials and meta-analyses, which will be described in more detail later in the chapter. Working within the population of substance users, EBTs have been found to be more successful in reducing patients' alcohol and drug use relative to a comparable treatment. Consensus exists, based largely on published studies, that several treatments (e.g. motivational interviewing, cognitive-behavioral therapy, contingency management) are evidence based. As a result, lists of EBTs have been generated by multiple sources. The EBTs included on these lists vary, and treatments that are not deemed evidence based are absent from such lists. There are overarching concerns about the generation of lists of EBTs. It is suggested that treatments be subject to ongoing testing and lists of EBTs should reflect the latest evidence. While scientific evidence is a key component in evaluating treatments, the role of clinical judgment and patient characteristics has also been cited as important factors.

Evaluating Evidence for EBT

Over the years, the EBT movement remains focused on empirical evidence as a guiding force in addiction treatment, but the nature and scope of the relevant evidence continue to evolve. Early conceptions of EBT placed a great deal of emphasis on randomized-controlled trials as the only form of methodological evidence worthy of inclusion and limited the use of

treatments to only those that had been validated by a randomized-controlled trial, the gold standard of evaluation research. In recent years, other methods have begun to gain acceptance. Efficacy and effectiveness studies, pharmacological studies, and meta-analyses are common types of studies used as evidence for EBTs, and several key contributions of these types are summarized below. When evaluating the validity of these types of studies there are several areas of focus including treatment fidelity, inclusion criteria of the sample, assessment issues, cost-effectiveness, and treatment acceptability. These areas will be discussed in detail.

Efficacy and Effectiveness Studies

In behavioral research, randomized-controlled trials, sometimes called efficacy trials, have become gold standards against which to evaluate treatments. These trials randomly allocate individuals to treatment condition in order to control for factors that could potentially confound study results. There are several benefits to employing a randomized study design. By randomly assigning participants to each group, one can reduce potential confounding factors related to participant characteristics, self-selection processes, or the context in which the intervention is implemented. Randomizing participants can help the researcher better understand if the treatment is causing a behavior change. Recently, however, critics have questioned whether the findings of such tightly controlled studies will translate into routine clinical practice. Instead, many researchers are suggesting effectiveness trials that test interventions in real-world settings, with the patients and providers that are likely to be using the intervention. This design choice consequently limits intervention studies to those that can be realistically administered given staff preferences, time, and resources.

Pharmacological Studies

In pharmacological research, clinical trials also vary in their applicability to real-world settings. The National Institutes of Health identifies four phases of research, each with its own methodological advantages and drawbacks (see Relevant Websites). This type of phased research is typically conducted only after a particular intervention shows preclinical promise in laboratory or animal studies. Within this system, Phase I research involves testing a medication with a small sample. Phase II trials test the intervention with a larger sample to further monitor safety. In Phase III, the drug is tested with an even larger population and compared to another treatment or control condition to determine its comparative efficacy. In Phase IV research, a drug that is already being routinely administered is evaluated for

effectiveness and safety in real-world settings, and the long-term effects are assessed. The findings of such research may be more meaningful given their greater likelihood of being administered in real-world settings.

Systematic Reviews and Meta-Analyses

In recent years, a greater focus has been placed on systematic reviews and meta-analyses. Early on in substance abuse research, researchers synthesized groups of studies by reading the literature and making inferences about overall effectiveness using a narrative style. Those methods sketched the big picture for a particular treatment, but sometimes they lacked scientific rigor and were prone to the biases and preconceptions of the authors. In a more recent development, methodologically driven reviews were conducted that provided more objective summaries of the literature base. One such strategy uses a box tally method, counting the numbers of positive and negative findings published in scientific journals for a particular intervention, and producing a cumulative evidence score either for a given treatment or against a given treatment. Sometimes the box tally method is enhanced by differentially weighting studies based on factors like their methodological quality.

Meta-analysis is a more sophisticated approach to synthesizing multiple studies. The different outcome variables of a group of studies are statistically combined to produce standard measures of effect. These effect sizes can allow researchers to compare different treatments and are less influenced by the bias that can result from having an insufficient number of participants in significance testing. Meta-analysis offers a common metric (i.e. effect size) that can be used as a standard to compare different interventions. Meta-analysis, however, has its own difficulties. For one, outcome studies in substance abuse research use a variety of outcome variables (e.g. abstinence, quantity of use). Statistically combining these diverse measures can be misleading. In addition, there is a bias in research known as the file drawer problem, to leave negative findings in the file drawer and publish only positive findings, resulting in an optimistic picture of effectiveness. Nonetheless, meta-analyses are important tools. An international network of researchers, known as the Cochrane Collaboration (see Relevant Websites), conduct reviews of substance use behavioral and pharmacological treatments.

Treatment Fidelity

An important factor to consider when evaluating EBTs is that of treatment fidelity. Treatment fidelity describes the degree to which treatments are delivered competently and as intended. Poor treatment fidelity can reduce our ability to attribute symptom changes to

the intervention and to replicate and disseminate treatments. Treatment fidelity is particularly important when comparing a novel treatment intervention to treatment-as-usual. Without evidence of treatment fidelity, it can be difficult, if not impossible, to understand differences between treatment conditions. One approach to increasing treatment fidelity is the development of treatment manuals that can be used during implementation. Although treatment manuals can improve treatment fidelity and make implementation easier, there is risk of serious misapplication when the treatments and disorders are highly context dependent and highly variable through time, as they often are in the substance abuse areas. Treatment fidelity is rarely monitored outside of randomized-controlled trials due to the cost associated with supervision, feedback, and fidelity monitoring. Assessing treatment fidelity is further complicated by recent evidence, which suggests that there is little to no correlation between provider self-report and objective evaluation of providers' behaviors.

Sample Characteristics

One of the most important factors to consider when evaluating evidence for EBTs is the sample under study. Most randomized-controlled trials have strict eligibility criteria for inclusion and can exclude participants who present with complex issues, such as psychiatric disorders, noncompliance, co-occurring medical disorders, and homelessness. Such exclusion criteria may increase the likelihood of a study being successfully conducted, but may also have the unintended consequence of reducing a study's ability to generalize its findings to those individuals who seek treatment. Rates of comorbidity in both clinical and community samples suggest that single-disorder presentations are the exception rather than the rule, and by limiting the inclusion of these individuals into clinical trials we are limited in our ability to say what treatments work for them. A similar argument can be made for the inclusion of women and ethnic minority participants into clinical trials. For a study to have adequate external validity, that is the ability to generalize the study's findings to other populations and settings, the study sample should be similar to the target population. Keeping these issues in mind when evaluating evidence is vital to ensure even the most marginalized populations receive the most effective treatments.

Issues Related to Assessment

When evaluating the evidence presented in research studies, several issues related to the assessment of outcome variables should be taken into consideration. Research studies are usually funded for limited periods of time and logistical and monetary issues make it difficult to follow participants after implementation to

evaluate the long-term impact of the intervention. As a result, few intervention studies provide evidence of sustained effects. In addition, some studies only measure specific outcome variables and may not assess the variables a provider or treatment program are interested in. For example, a research study evaluating the efficacy of motivational interviewing for reducing drug use in prisoners may not assess how the intervention impacts recidivism or familial relationships. In combination, not having information about sustained effects and important outcome variables can make it difficult to evaluate which treatments would be the best for a particular patient.

In addition, research studies often require participants to complete extensive assessment batteries prior to receiving treatment. Assessment interviews typically query patterns of alcohol and drug use, as well as potential consequences of use. An unintended consequence of these lengthy interviews is a reduction in substance use by research participants, prior to receiving any treatment. This assessment reactivity is an important consideration when evaluating treatment outcome studies.

Cost-Effectiveness

In recent years, there has been an increased focus on the cost-effectiveness of EBTs. Cost-effectiveness analysis compares a new treatment strategy with current practice and calculates a cost-effectiveness ratio based on several factors including substance use, medical visits, employment, and imprisonment. If a strategy is “cost-effective” it means that the new strategy is a good value. In other words, the new treatment has a greater impact on disease burden, or costs less to achieve the same reduction in burden, and is therefore more cost-effective than the older treatment. Unfortunately, cost-effectiveness studies are costly themselves, so few studies occur. Cost-effectiveness information can be helpful in the evaluation of EBTs, but these studies occur later in the process. Only after an intervention has proven to be effective (usually through a randomized-controlled trial) cost-effectiveness analyses are undertaken.

Acceptability

An important factor to consider when evaluating EBTs is that of acceptability to the providers in the field, to policy makers making funding decisions, and to the patients. Providers are at the frontline of implementing EBTs in clinic settings, and gaining their support is important to assure the success of implementation (*see* Dissemination of Evidence-Based Treatment into Practice to learn more about dissemination of EBTs). Communicating information about EBTs to clinical staff through colleagues rather than from research articles or books tends to increase acceptability. When evaluating the appropriateness of an

EBT for implementation, understanding resistance that might arise is vital. Even where systems are in place to help with the implementation of an EBT, providers may be skeptical in regard to the use of such practices perceived to come from the culture of research, or when imposed by mandate. Treatment manuals can improve treatment fidelity, though perceived rigidity by treatment staff and patients may reduce treatment acceptability. Policy makers are also important to consider when it comes to the acceptability of treatments. Often, there are mandates that require the use of EBTs in clinics receiving state and federal funds and policy makers may wish to decide which EBTs are used and fund clinics accordingly. The treatment to patient match is another important factor to take into account. Finding treatments that are acceptable to patients and fit with the patient’s goals can increase the likelihood that patients will stay in treatment long enough to benefit from the EBT.

Having an informed approach to the evaluation of evidence of EBTs that selects and evaluates research methods in service of a given research question – and not the other way around – is essential for promoting an interdisciplinary approach to addiction science. An approach that establishes whether and how a treatment performs under tightly controlled conditions, and if it does, whether it is effective and cost-effective in the usual clinical setting and in a variety of cultures and settings using pragmatic trial designs. Keeping in mind that establishing treatment efficacy with randomized-controlled trials is an appropriate use of method to answer a research question, but there are other questions relevant to improving the reach and effectiveness of practice that are better addressed with non-experimental designs and methods, or that require a combination of the two approaches. In the next section, we will describe key studies that have been used as evidence for EBTs in the field of addictions. These include multi-site clinical trials, meta-analyses, and reviews.

EXAMPLES OF KEY STUDIES AND FINDINGS

Multi-Site Clinical Trials

Several large, multi-site, randomized clinical trials have revealed a good deal about treatment efficacy in the addictions. These studies are typically of high methodological quality. A drawback of the rigorous methodological features, such as having extensive exclusion criteria, can limit generalizability to real-world clinical settings. Several multi-site clinical trials have been particularly informative to the field of substance use and dependence. Five of these flagship studies are described in more detail below: Project Matching Alcoholism Treatments to Client

Heterogeneity (MATCH), Combining Medications and Behavioral Interventions (COMBINE), the Cannabis Youth Treatment study, the Marijuana Treatment Project, and the Clinical Trials Network.

Project MATCH was a collaborative, multi-site trial sponsored by the National Institute on Alcohol Abuse and Alcoholism (NIAAA). The study tested matching hypotheses, which predicted that patients with certain characteristics would fare better in a particular treatment. Participants were assigned randomly to one of three treatments (cognitive-behavioral treatment (CBT), motivational enhancement therapy (MET), or 12-step facilitation (TSF), and their outcomes were compared based on 10 variables. At a 12-month follow-up, participants from all three treatments had more days abstinent and drank fewer drinks per episode when compared with baseline assessments. However, few of the matching hypotheses were supported. Findings indicated that CBT, MET, and TSF were equally effective in improving alcohol outcomes (see Relevant Websites).

The COMBINE study built on the findings of Project MATCH to learn whether combining medications for alcohol dependence (naltrexone and acamprosate) would improve the effectiveness of behavioral interventions. A combined behavioral intervention was created that incorporated aspects of the three treatments used in Project MATCH. In addition, COMBINE tested a Medication Management (MM) intervention, a less intensive treatment that provided support and encouraged medication compliance. Participants in the study were randomly assigned to one of nine treatment combinations. Results from the COMBINE Study showed that adding a brief intervention (MM) to naltrexone could be a cost-effective way of treating alcohol dependence and that a combination of medication and behavioral treatment was more effective than *medications* alone. The implication of these results is that, via the use of a variation of MM combined with naltrexone, it may be possible to treat alcohol dependence more effectively in primary care settings.

The Cannabis Youth Treatment study aimed to compare the effectiveness and cost-effectiveness of five treatments in real-world settings. Adolescents in the study were randomly assigned to one of five group therapies (MET/CBT 5 sessions, MET/CBT12 sessions, the Adolescent Community Reinforcement Approach (ACRA), Multi-dimensional Family Therapy, and Family Support Network). Results revealed that participants in the five treatments showed significant improvements but the most cost-effective approaches included MET/CBT5, MET/CBT12, and ACRA (see Relevant Websites).

The most recent and largest controlled trial of marijuana treatment in adults (the Marijuana Treatment Project, see Relevant Websites), compared a 9-session combined cognitive behavior treatment with

motivational enhancement and case management to a 2-session motivational enhancement treatment and found that the extended CBT intervention was more effective than brief motivational therapy.

Clinical Trials Network

Multi-site randomized clinical trials can be conducted with high internal validity, but they do not always apply readily to clinical practice. Rigid restrictions in participant inclusion criteria, for example, with administration of interventions by highly trained practitioners (following standardized treatment protocols) can increase our ability to show that a treatment actually caused changes, but these tight procedures decrease the generalizability of findings to community treatment centers. In those settings, patients often have multiple and more severe problems, and providers may have relatively little training. To address the limitation or relevance to the community treatment system, the National Institute on Drug Abuse (NIDA) formed the Clinical Trials Network (CTN). The CTN provides a setting where treatment providers and researchers exchange information and develop research together. Research protocols are tested in front-line clinics, making results more generalizable to community settings. Since its inception, CTN has funded nearly 50 large clinical trials to determine the most effective treatments for drug dependence, testing a variety of interventions (behavioral treatments, medications, telephone support), and in different languages. Dissemination of effective treatments is a principal goal of the CTN. A dissemination library serves as a forum from which dissemination can occur (see Relevant Websites). To facilitate dissemination, the CTN developed the Blending Initiative which is designed to blend resources, information, and expertise in order to encourage the use of current EBT interventions in the drug abuse treatment field.

Meta-Analyses and Reviews

The Mesa Grande (great table) project was an influential review of 361 clinical trials of treatments for alcohol use disorders conducted by researchers at the University of New Mexico's Center on Alcoholism, Substance Abuse, and Addictions (see Relevant Websites). Results showed equal effectiveness for brief interventions, social skills training, community reinforcement approach (CRA), behavior contracting, behavioral marital therapy, and case management in treating alcohol use. Some medications were among the supported approaches, including opiate antagonists (naltrexone, nalmefene) and acamprosate. Confrontational counseling and mandated Alcoholics Anonymous were judged to be ineffective.

When it comes to drug use, contingency management, relapse prevention, CBT, and treatments that

combine CBT and contingency management are all found to be effective. In comparing effect sizes across treatments contingency management interventions showed the greatest effect. There are also differences in effectiveness depending on drug of choice, with marijuana use being the easiest to treat and poly-substance use the most difficult.

To assist addiction treatment professionals and program planners, the Substance Abuse and Mental Health Administration (SAMHSA) has a website that can be searched to identify interventions thought to prevent or treat mental illness or substance abuse. The National Register of Evidence-Based Programs and Practices (NREPP) contain results of a periodic, systematic review of these interventions, and it categorizes approaches into three levels: promising, effective, or model programs. Promising programs may be effective but lack the requisite research. Effective programs are both promising and have sufficient comparative research trials that show that they accomplish their objective related to mental health or substance use. Model programs are both effective and are ready for dissemination, based on both materials and training being available (see Relevant Websites).

Dodo Bird Effect

A common finding in comparative clinical trials, reviews, and meta-analyses in substance abuse is that the treatments being tested all perform equally well. Some have used an analogy between treatment outcome research and the Dodo Bird's race in *Alice in Wonderland*, in which the Dodo bird enthusiastically declares that "everyone's won and all must have prizes". Although some treatments have been found to be ineffective in comparative studies of addiction treatments, most theoretically based or manualized behavioral treatments perform equally well when tested in the field. The findings of equal effectiveness are especially surprising considering that so many treatments have vastly differing assumptions about the recovery process.

EBT IN PRACTICE

In this section, we will briefly discuss a structured approach to applying EBTs in clinical practice. These five steps (Ask, Search, Appraise, Apply, and Evaluate) can help providers interested in determining which EBT would be the most appropriate for implementation. The first step is to formulate a question (ASK), based on the presenting problem of the patient. For example, if a 25-year-old male Caucasian patient presents with methamphetamine dependence and a history of trauma, an

appropriate question would be: Which treatments have been found to be effective to address methamphetamine use for male Caucasian patients with trauma symptoms? A more specific question will help with the remaining steps. For example, determining if the patient is interested in setting a harm reduction or abstinence goal, or whether or not he was interested in outpatient treatment, would help further specify the question. It may be necessary to go back and modify the primary question.

After formulating a question, the second step of the process is to search the literature (SEARCH) and identify articles and other evidence-based resources that answer the question. As was described earlier in the chapter there are Internet resources available (e.g. NREPP), meta-analytic reviews (e.g. Cochrane Collaboration), or large multi-site trials (e.g. Project MATCH) that can help with this step. More examples of EBTs are described in the next section. Once resources have been gathered the third step is to critically appraise the evidence and assess its validity (APPRAISE). Specific considerations for evaluating evidence were discussed earlier in this chapter. After reviewing the available evidence in the fourth step EBT is applied (APPLY). It is through the application of an EBT that practitioners can determine which parts of the treatment, if any, are appropriate and acceptable to both the practitioner and the patient. This is done in the fifth step. The fifth and final step of the process includes reevaluating the application of evidence and areas for improvement (EVALUATE). After applying the treatment you can then go back and reevaluate the effectiveness of the treatment, and then make changes accordingly (Table 64.1).

The practical application of these five steps (Ask, Search, Appraise, Apply, and Evaluate) will vary depending on who employs them. In some clinics, administrators and not providers choose the treatments that will be used with the patients in the clinic. In these situations Appraise, Apply, and Evaluate can still be used by providers to determine if the treatment they have been asked to use is the most appropriate for their patient. At the administrator level, each of the steps can be used to determine which treatments will be used in the clinic. At this level the first step (ASK) will be focused on a large sample instead of an individual (e.g. which treatments have been found to work in outpatient settings to reduce stimulant use?). These steps can be of use in a variety of settings and with providers from different organizational levels.

EXAMPLES OF EVIDENCE-BASED TREATMENTS

As an addictions provider or policy maker it is essential to have at least a cursory knowledge of which treatments have support for their effectiveness. In

TABLE 64.1 Evidence-Based Treatment in Practice

Step 1: Formulate a question (ASK)	Based on the presenting problem of the patient determine which question you wish the Evidence-Based Treatment to address. A more specific question will help with the remaining steps. It may be necessary to go back and modify the primary question.
Step 2: Search the literature (SEARCH)	Identify articles and other evidence-based resources. Types of resources include Internet resources, meta-analytic reviews, or large multi-site trials.
Step 3: Critically appraise evidence and assess validity (APPRAISE)	Specific considerations for evaluating evidence include methodological quality, treatment fidelity, inclusion criteria, outcome measures used, cost-effectiveness, and acceptability.
Step 4: Apply evidence-based treatment (APPLY)	Use the evidence-based treatment with your patient. Through the application of an evidence-based treatment you can determine which parts of the treatment will work to address your formulated question.
Step 5: Reevaluate applied evidence (EVALUATE)	After applying the treatment you go back and reevaluate the evidence taking into account patient and practitioner preferences.

this section, we briefly describe several treatment approaches broadly considered to be evidence-based.

Cognitive-Behavioral Therapy

Cognitive-behavioral approaches start with the belief that learning processes play a vital role in the development and maintenance of addictive behaviors. These are among the most extensively studied of substance abuse treatments. Acknowledging the substantial research that has been conducted on cognitive-behavioral therapy as an empirically supported treatment and that few differences are found when comparing CBTs (see Mesa Grande review above), researchers have recommended that effective elements across cognitive-behavioral approaches be integrated into treatment approaches.

Motivational Interviewing

Motivational interviewing (MI) helps patients to explore and resolve ambivalence about a behavior change, using a brief, client-centered, directive intervention. Practitioners take a nonjudgmental stance and lead patients through the process of exploring their substance use in the light of the patients' personal goals and values. MI has been evaluated extensively and shows moderate efficacy in the treatment of alcohol and drug disorders, as well as in engaging people in other kinds of addiction treatment.

Brief Interventions

Other brief interventions have shown promise in the treatment of substance use disorders. Brief interventions

can have dramatic and long-lasting effects, and increasing the intensity of an intervention does not consistently result in improved effectiveness. Brief interventions are promising because they are inexpensive, allow more people to receive treatment and can be conducted in medical settings where providers have little time to commit to behavioral issues.

Relapse Prevention

Relapse prevention takes into consideration the cognitive and behavioral components within the process of the relapse phenomenon. Two of the most salient features of these interventions are identifying high-risk situations and providing coping skills to manage them more effectively. Relapse prevention is effective in improving clinical outcomes for alcohol use, smoking, cocaine, and poly-substance use.

CRA and Contingency Management

CRA is a treatment, largely based on behavioral therapy, which has been proven to be efficacious among alcohol and drug using individuals. The focus of CRA is to rearrange the contingencies in a substance user's life such that sobriety becomes more rewarding than substance use. CRA patients are often encouraged to examine the antecedents and consequences of substance use, sample sobriety for a prespecified amount of time, improve communication skills, problem-solving, and relapse prevention efforts. In addition, other key components of CRA are job-finding skills and other recreational activities that preclude substance use.

CRA is sometimes used in conjunction with contingency management (CM), another empirically based treatment for substance use disorders. In CM, practitioners provide about 6 months of outpatient therapy in individual counseling sessions, refer alcohol-abusing patients for disulfiram (antabuse) therapy, monitor patients for continuing drug use through the collection of regular urine samples, and reinforce their abstinence by providing contingent vouchers that patients can exchange for retail goods that are consistent with a drug-free life style. CM has been studied extensively in a variety of settings and with numerous substances of abuse.

Pharmacological Treatments

Pharmacotherapy is also available for the treatment of substance use disorders. Disulfiram, or antabuse, has been used in the treatment of alcohol disorders for several decades. A drawback of disulfiram (like many medications) is that it is effective only if taken daily and consistently. Meta-analyses have shown small effects from its use. A medication approved for use more recently is naltrexone, an opiate receptor antagonist that reduces the pleasurable effects of alcohol and, consequently, reduces alcohol cravings. Finally, acamprosate can help people to maintain abstinence after detoxification from alcohol, by normalizing metabolic processes that occur when heavy drinking is discontinued.

Several pharmacotherapies have also been developed to treat opioid dependence. Methadone is an opioid agonist that blocks the pleasurable effects of opiates, such as heroin. Treatment with methadone typically requires visiting a clinic for daily dosing, has been extensively studied, and it is effective and safe. Buprenorphine is the most recently approved medication (2002) for the treatment of opiate addiction. Buprenorphine is a partial opioid agonist that suppresses withdrawal, produces effects similar to other opiates at low doses, and blocks other opiates. Buprenorphine has shown promise in clinical trials. Unlike methadone, buprenorphine does not have to be administered from a specialized clinic; physicians can prescribe buprenorphine directly.

CURRENT STATE OF TREATMENT

While it is difficult to ascertain the extent to which EBTs are utilized by providers in substance abuse treatment settings it appears that some treatments with empirical evidence have been adopted more readily than others. Relapse prevention, cognitive-behavioral

therapy, motivational interviewing, and brief interventions are used with some frequency in treatment settings, whereas CM, the CRA, and behavioral couples therapy are underutilized in treatment settings (for recent reviews of implementation of EBTs, see Further Reading section). Regarding pharmacological treatments, facilities do report prescribing naltrexone whereas buprenorphine is dispensed with less frequency, presumably because it is a newer medication and requires prescribers to obtain a special waiver. Reported use of EBTs in clinics may be inflated due to social desirability biases. In addition, while providers may report use of an approach in their setting, objective evaluation may indicate otherwise.

There are several potential reasons for the slow adoption rates of EBTs among substance use treatment providers. To begin, there is a large literature noting the gap between research dissemination and clinical practice. Thus, many providers may not be well informed of the treatment outcomes literature indicating that some treatments have been found to be more effective than others. The standard route for dissemination of treatment findings occurs via scholarly journals and scientific conferences, both of which are expensive and time-consuming resources of information. While some providers do have knowledge about EBTs, the efficacy supporting these approaches may not be particularly compelling to providers. Treatment outcomes that are regarded as statistically significant may not be regarded as clinically significant or meaningful by providers. Furthermore, clinical trials have received criticism for their strict inclusion criteria, often excluding particularly complicated or severe patients from their studies. Thus, some providers doubt the efficacy of EBTs in front-line clinical settings.

Adoption of EBTs is further complicated by providers' heavy case loads. Many cite time constraints and clinical burdens as barriers to learning about new treatments. Furthermore, EBTs may be in conflict with the providers' or agencies' theoretical orientation, creating an additional barrier for adoption. In addition, high staff turnover at agencies further complicates training issues. Thus, there are a myriad of reasons for slow adoption rates among providers in substance abuse treatment settings.

Nonetheless, providers indicate a willingness to adopt some treatment methods including TSF, MI, relapse prevention, and cognitive-behavioral therapy. Providers are less willing to adopt contingency management or behavioral couples therapy. Hence, providers may be willing to adopt treatment that they are familiar with or that share similarities to their current clinical practice.

Provider attitudes toward pharmacological EBTs are mixed. Recent surveys of providers indicate that less

than half view the use of medications for substance use disorders positively. In addition, many providers report that they are unaware of the efficacy of newer medications such as buprenorphine. Lack of provider support for buprenorphine has been found to be largely related to lack of information about the medication.

Training Issues in EBTs

Recent research has focused on effective ways of training providers in EBTs. Traditionally, training in EBTs has occurred during brief workshops in which providers participate in both didactic and experiential exercises. Despite the relative ease of brief training, it has not been found to be particularly effective in preparing providers to competently utilize new clinical skills. Recent findings support the use of ongoing training enhancements in addition to the workshop. Enhancements that have been found to be effective in increasing training skills include booster training sessions, feedback from recorded sessions with real or standardized patients, and ongoing consultation with experts in the treatment approach. While these training enhancements are costly and time consuming, they may be necessary components for the successful use of EBTs. To reduce barriers to training, research has also begun to investigate the efficacy of long-distance training methods including web-based and video workshops telecast to remote facilities.

Overall, research studies examining the efficacy of training approaches indicate there are a number of provider factors that impact training gains, including provider motivation level and pretraining general clinical skills. In addition, there is strong evidence that clinical skills decay over time, thus training should be viewed as ongoing rather than time-limited task.

There is considerable evidence for directing implementation efforts at the agency or organization level rather than at the individual providers. Research findings indicate that greater agency involvement and support for the adoption of an EBT are associated with greater provider willingness to utilize a new approach. Involving the entire staff in trainings, the provision of ongoing supervision, meetings for problem-solving difficulties related to EBT implementation, and the consideration of how an EBT may need to be adapted for a particular setting are associated with more successful implementation efforts. For more information about training see Chapter 62 in this volume.

Treatment Adaptations

A recent focus on the implementation of EBTs has centered on treatment adaptations for use with specific populations or settings. Adaptations of EBTs are

regarded as a natural process within implementation efforts. Adaptations, while potentially facilitating increased adoption of a particular treatment, also present unique challenges when striving to maintain the integrity of an intervention.

EBT adaptations are particularly relevant when working with minority populations. Applying the adaptations involves a balance between maintaining the integrity of the treatment approach while considering the specific needs and values of diverse ethno-cultural groups. Adaptation efforts usually begin with a treatment approach that has been found to be effective with a population overall. The next step in this process is to garner involvement from the community and with their assistance adapt the EBT and develop a manual. When adapting EBTs for minority populations it is important to consider the impact of factors such as cultural values, religion and spirituality, acculturation, and racism. Often times, adaptation occurs based on knowledge from both qualitative and quantitative data. This allows treatments to be systematically adapted while still having a foundation in the EBT, while allowing enough flexibility to meet the specific needs of a population.

Adoption efforts have begun to focus on the implementation of pieces or processes of EBTs rather than the entire treatment. While research findings on the implementation of pieces of an intervention are still somewhat mixed, advocates for this approach indicate that adoption of specific processes of an EBT may facilitate increased adoption among providers. Adoption of a component of an EBT, such as coping skills or communication skills, may allow providers to implement pieces of an EBT that they feel comfortable with, rather than forgoing their previous treatment approaches entirely in favor of a new treatment. While this approach would result in more individualized treatment, research has not yet substantiated pieces of EBTs in isolation.

CONCLUSIONS AND FUTURE DIRECTIONS

In this chapter, we defined the term Evidence-Based Treatment, described how EBTs are evaluated, and discussed the current state of EBTs in the field of addiction. These treatments, which are deemed evidence based after rigorous analysis, offer great promise to providers dealing with a variety of complicating issues.

When analyzing what makes a treatment evidenced based, it is important to consider the means for assessing evidence. Efficacy and effectiveness studies, pharmacological studies, and meta-analyses provide different information about each treatment. However, factors that impact the validity of these studies, such as

treatment fidelity, sample characteristics, assessment issues, cost-effectiveness, and acceptability, need to be considered when evaluating the evidence.

Even though many EBTs are presently available, unsupported methods continue to be used, while other methods with solid evidence are seldom delivered. We cannot expect that the benefits of EBTs will translate into clinical practice on their own. Current clinical practices have become ingrained over time and although treatment manuals and training aids are widely available, many providers are not aware of them. In addition, some providers are skeptical of treatments they perceive to be developed in laboratories, with no applicability to the real world.

Continued outreach to providers can help address barriers to implementation. Face-to-face interactions with providers can clear up confusions, put misconceptions to rest, and give them a say in the practices they implement. EBTs can also be adapted for use with different populations to increase a treatment's real-world effectiveness. To improve the likelihood of treatment adoption, treatment facilities should be fully engaged in the implementation process and provide ongoing trainings since brief training workshops are insufficient to maintain long-term changes. Researchers should address both institutional and provider concerns in order to facilitate the adoption of EBTs and provide ongoing support to ensure providers can deliver the treatment as directed to make sure clinics are seeing the results needed to maintain adoption.

TSF	12-step facilitation

Glossary

- Assessment reactivity** a process in which, assessments, such as research interviews, have unintended consequences, such as a reduction in substance use by research participants.
- Dissemination** a planned process of providing information on the quality, relevance, and effectiveness of the results of programs and initiatives to key personnel.
- Dodo Bird Effect** a common finding in comparative clinical trials, reviews, and meta-analyses in substance abuse that the treatments perform equally well.
- Effectiveness studies** experimental studies done under less carefully defined conditions reflecting the variation in real-world clinics are known as effectiveness studies. Effectiveness maximizes external validity.
- Efficacy studies** laboratory randomized-controlled trials produce knowledge about the efficacy of a treatment, treatments that work under ideal conditions. Efficacy maximizes internal validity.
- External validity** the main criteria of external validity are the process of generalization, and whether results obtained from a small sample group, often in laboratory surroundings, can be extended to make predictions about the entire population.
- Internal validity** the approximate truth about inferences regarding cause-effect or causal relationships. The key question in internal validity is whether observed changes can be attributed to your program or intervention (i.e. the cause) and not to other possible causes (sometimes described as alternative explanations for the outcome).
- Meta-analysis** a quantitative approach in which individual study findings addressing a common problem are statistically integrated and analyzed to determine the effectiveness of interventions.
- Practitioner** a person who conducts procedures intended to help individuals. Common examples are a counselor, clinician, therapist, or case manager.
- Quasi-experimental design** a research design that contains some of the controls and manipulations of experimental design, but usually lacks random assignment of subjects. A before-after study is an example of a quasi-experimental design.
- Randomized-controlled trial** randomized-controlled trials are studies that randomly assign individuals to an intervention group or to a control group, in order to measure the effects of the intervention.
- Treatment adaptation** the systematic modification of an Evidence-Based Treatment or intervention protocol to consider language, culture, and context in such a way that it is compatible with the client's cultural patterns, meanings, and values.
- Treatment adoption** the use of an Evidence-Based Treatment in a clinical facility.

Treatment fidelity strategies that monitor and enhance the accuracy and consistency of an intervention to ensure it is implemented as planned and that each component is delivered in a comparable manner to all study participants over time.

INTRODUCTION

Harm reduction approaches are strategies that are used to reduce the harmful consequences of addictive behaviors. Harm reduction often includes multiple approaches including pharmacological, psychological, and environmental interventions. Harm reduction approaches typically involve interventions designed to reduce risky behaviors and their consequences. Interest in harm reduction arose partly in response to a body of scientific evidence suggesting that abstinence was not necessarily a realistic goal for people engaging in addictive behaviors, and that many clients preferred moderation goals even after successful completion of abstinence-based treatment programs.

Harm reduction approaches are considered client centered, such that clinical professionals assume a consultant role to work with the client to identify and reach treatment goals collaboratively. Abstinence may or may not be an ultimate treatment goal, but is never a requirement for services and support. In fact,

clients often opt for moderation-oriented goals or may not desire to make reductions at all and instead modify behavior to reduce risk without reduction. Harm reduction approaches are used to flexibly respond to whatever the client's goals for change may be.

HISTORY AND DEVELOPMENT

Harm reduction has a history rooted in pharmacotherapy and in activism. The use of methadone constituted one of the earliest forms of harm reduction interventions. Methadone was prescribed to people addicted to heroin as a safer alternative for those unable or unwilling to abstain immediately. Methadone treatment represented a crack in the wall of staunch belief that abstinence from all substances was the only proper means to improve the lives of people engaging in addictive behaviors. A grassroots harm reduction movement later developed in Europe in an effort to leverage compassionate care for people who engaged in

addictive behaviors, especially those who injected drugs. The harm reduction movement was also driven by concerns about the spread of HIV and other blood borne diseases by those who were sharing needles. Harm reduction developed in the United States as an alternative to the disease model of treatment. Harm reduction approaches in the United States were initially met with great scorn by most treatment professionals who subscribed to the disease model and feared that these approaches were enabling people to continue to engage in a chronic progressive disease to their own peril. The fallout from this dispute was immense and eventually included preeminent researchers in the addictive processes.

Researchers began as early as the 1970s to uncover significant evidence that challenged the prevailing belief that addictive processes were chronic and progressive, as well as the precept that only abstinence oriented treatment can be effective to treat addictive behaviors since clients were considered to be powerless over substances and assumed to immediately lose control with any use. The first area of scientific inquiry that challenged these traditional beliefs was research that found that substance use often is influenced by beliefs as much as the actual consumption of behavior. A classic study by Alan Marlatt and colleagues, using what was referred to as the balanced placebo design, demonstrated that if people believed they had been drinking to intoxication, they would often act intoxicated even when they had been drinking nothing stronger than tonic water and were stone cold sober. The converse was true as well: if people were told they had been served nonalcoholic drinks, they displayed none of the intentional behavioral changes expected by a progressive disease model (e.g. loss of control, increasing consumption, inability to stop, etc.) nor were there any changes in social interactions. Instead, individuals attributed physiological reactions to alcohol consumption to external factors (lack of sleep, room temperature, etc.). The study results challenged prevailing beliefs at the time that addictive processes were primarily biological since alcohol-dependent participants demonstrated behavioral loss of control only when they thought they were consuming alcohol. The study results suggested that loss of control was a function of beliefs about substance use rather than actual substance use itself.

The second area of inquiry to challenge prevailing thinking was longitudinal studies that demonstrated that some people were getting better on their own, without treatment; a process known as natural recovery; and that some people were able to achieve moderate drinking after a period of dependence. This research triggered what became known as the controlled drinking controversy and led to brutal attacks by disease model adherents

against addiction scientists such as Mark and Linda Sobell and Marlatt who published empirical evidence to dispute those beliefs. Although the addiction scientists were unfairly targeted for their early research challenging the abstinence-only model, their findings have continued to be supported and expanded since that time. The body of empirical evidence clearly indicates that harm reduction goals are not only attainable but they are also commonly pursued and reached by clients.

The third area of inquiry that supported the development of harm reduction was research that examined what predicts addiction-related consequences. As one might suspect, researchers have found a positive relationship of frequency/amount of the addictive behavior/substance with frequency of consequences experienced. However, the relationship has been less robust than one would intuitively predict, suggesting that the experience of consequences is not just a function of the addictive behavior alone. Indeed, some research has found that other variables (such as beliefs about addictive behaviors) are independent predictors of consequences, sometimes more potent than consumption. These findings suggest the possibility that harmful consequences may be reduced by intervening on cognitive and behavioral processes other than consumption. As will be explained subsequently, harm reduction approaches provide for ways to do so.

Interestingly, traditional disease model treatment facilities have employed harm reduction approaches (although many would not have referred to it as such) for many years during the detoxification process. For several decades, the use of prescribed controlled substances, usually benzodiazepines, has been to reduce the discomfort of withdrawal symptoms. In effect, this would constitute a harm reduction approach similar to methadone treatment, although arguably some of the benzodiazepines have since been found to be at least as risky as the substances for which the person has sought treatment.

INDIVIDUALIZED HARM REDUCTION STRATEGIES

Recent pharmacological advances have been used successfully to reduce the potential harm from substance abuse. Opiate agonists such as naltrexone, as well as other types of substances (such as acamprosate), have been used to successfully reduce substance-related cravings in many patients. Certain antidepressant drugs such as selective serotonin reuptake inhibitors (SSRIs) have been used similarly to control mood-triggered substance use associated with anxiety and depression. In addition, recently vaccinations have been used with some success to interfere with psychoactive properties

(inhibiting the high) of certain substances of abuse to dissuade further use. Readers interested in pharmacological interventions should refer to the numerous chapters specifically written on this topic within the neuropharmacology section of this volume.

Cognitive-Behavioral Harm Reduction Approaches

Addictive processes are not solely responsive to biological processes: Addictive behaviors are also learned and so reducing harmful consequences of addictive processes will involve learning new beliefs and practices. It will also involve the unlearning of old beliefs and habits. Because of the importance of new learning in behavior change, a number of empirically supported cognitive-behavioral intervention strategies are employed in the use of harm reduction.

Behavioral Control Strategies

A variety of behavioral control strategies are used in harm reduction. One strategy is to simply track and count as a means to manipulate the behavior. An example is challenging the clients to see how many sips are taken to finish a glass of wine or beer, and then finding ways to increase the number of sips over time (in effect slowing consumption). Another example would be to have the clients time (or mentally count) the seconds between puffs on a cigarette and then extend the pauses between puffs over time, which naturally reduced the amount consumed and the time spent engaged in the behavior.

Another behavioral control strategy, referred to as alternating, is a process by which a person naturally reduces the frequency in which he or she engages in the addictive behavior by alternating that behavior with something else. An example of alternating is when a person follows consumption of an alcoholic beverage by a nonalcoholic drink. By alternating the addictive behavior with a compatible nonaddictive behavior, the client limits the amount of time engaging in the addictive behavior and reduces its frequency.

A third behavioral control strategy, referred to as switching, induces a client to switch from a higher risk to a lower risk addictive behavior. One example of this approach is to have the client's switch from a pattern of drinking high alcohol content beverages to lower alcohol content beverages, such as from stout beer to lager, or from multiple shot mixed drinks to something with less alcohol. Another example would be switching from heroin to methadone or marijuana. The idea is to reduce the risk of harm by replacing the high-risk behavior with a lower risk one.

Tapering is also a common behavioral control strategy used in harm reduction. Many clients are challenged to meet weekly goals for reduction in the addictive behavior until a particular targeted goal is reached, in effect tapering engagement in the behavior. An example would be a gambler who budgets \$50 US for a night of gambling that week, then next week is budgeted \$40 US, then the following week \$30 US, until finally reaching a personal harm reduction goal of \$20 US per gambling event. The goal is to gradually reduce the behavior slowly over time to eventually meet the ultimate goal set by the client in therapy.

Another highly effective behavioral control strategy is structuring time with activities incompatible with the addictive behavior including healthy alternatives such as exercising and other recreational pursuits. Sometimes an alternative activity may involve a challenging mental task or other goal-directed activity. The alternative activity should be interesting and challenging to the client and it should be something that makes engagement in addictive behavior difficult or uninteresting in comparison.

Cognitive Modification Strategies

As mentioned previously, beliefs about addictive behaviors potentially predict outcomes; therefore, effective harm reduction approach will include interventions designed to challenge beliefs that contribute to acting in a risky fashion.

One successful approach is to challenge the client's positive expectancies associated with the addictive behavior. Positive expectancies are the beliefs that clients have about the positive effects or outcomes related to the addictive behavior. Common positive expectancies involve beliefs that the addictive behavior will contribute to increased socialization, power, sexuality, and euphoria. Expectations that the addictive behavior are personally enhancing are particularly potent but can be modified with the use of traditional cognitive therapy methods for challenging irrational or dysfunctional beliefs by means of hypothesis testing and data collection. The therapist works with the client to test the assumptions of positive expectancies, and then helps the client to determine ways for collecting data to support or refute the beliefs. In some cases, it may be possible to challenge positive expectancies by testing the realistic probability of the expected positive outcome by examining previous outcomes. Other beliefs, such as cultural myths related to the addictive behavior or thinking errors that place the client in harm's way, can also be challenged through the use of traditional cognitive modification techniques.

Lifestyle Balance Activities

Another class of harm reduction approach is used to restore and maintain lifestyle balance. Lifestyle balance is determined by examining the time spent in various activities by the client and then assessing whether there are significant imbalances in time spent in work-related activities versus recreation, for example, or if the client is not taking enough time for basic self-care. A lifestyle balance assessment focuses on different domains: family life, physical self-care, emotional self-care, spirituality, etc. If too much time is spent in one sector at the expense of another, in a way that is contrary to the personal professional goals of the client and in a way that is causing personal distress, alternative activities are suggested and the client's schedule of activities may be restructured toward more balance.

In addition to examining how time is committed, personal habits may also be examined, such as those related to nutrition and healthy eating, sleep hygiene, routine dental and medical care, and exercise. Adjustments may be recommended to improve client health. Use of over the counter and prescribed medications may need to be examined to see and determine if there are potential harmful interactions with the substances being used. As an example, cold medicines, acetaminophen, ibuprofen, naproxen, birth control medications, and SSRIs all can react adversely to different substances and their concurrent use is not recommended. Vitamin supplements, on the other hand, may be recommended to supplement the diets of clients at risk (such as thiamine with people who are drinking large amounts of alcohol).

In some instances, the client may have other mental health needs that are necessary to be addressed with concurrent psychological or pharmacological care. Harm reduction approaches often involve the use of multiple services to achieve the goals of treatment, so referral for adjunct psychiatric care is common. Harm reduction approaches are highly compatible with multidisciplinary care and team approaches to treatment are commonly used.

ENVIRONMENTAL STRATEGIES

Harm reduction approaches also may employ interventions targeting the environment to reduce the risk of harm to people with addictive behaviors. Environmental harm reduction interventions have generally targeted four broad areas: accessibility, economics, safety, and social support networks.

Harm reduction approaches designed to improve accessibility often involve policy changes to lower the threshold for accessing services. Lowering the threshold

to access may include providing services to people without a condition of abstinence on entry, decreasing the administrative barriers for admission into services, increasing the number of care providers available including nontraditional care, providing transportation to services, and providing multiple services under one roof for ease of access. The philosophy of harm reduction is to make access easy, convenient, and safe for those who need the services.

Harm reduction proponents also have used economic principles in attempts to reduce risks by increasing prices to shape behavior. Researchers have found, for example, that increasing the costs of alcohol and cigarettes can profoundly impact their use, especially among people of limited means. Price increases, reductions of bargain events (such as sales and happy hours), and increased taxes have been used as harm reduction approaches by communities attempting to address heightened public health risks due to drinking and smoking behavior.

Harm reduction approaches designed to improve safety depend upon the nature of the activity. Risky addictive behaviors that are commonly targeted include the use of unclean needles and drinking and driving. Examples of harm reduction approaches targeting those behaviors include use of needle exchanges to reduce the risk of blood borne pathogens such as HIV and hepatitis and free taxi services on campuses or in communities on New Year's Eve to reduce drinking and driving. Marketing campaigns are often employed to inform the public of such programs.

Sometimes marketing campaigns are also used in efforts to shape the behavior of the public. One commonly used method is referred to as social marketing, which advertises social norms in an effort to present data to the public about normative behavior for that particular group. Social norms interventions directed by trained interventionists are empirically supported and can be highly effective. Since overestimations of norms are often associated with increased individual use, challenging and correcting these norm perceptions are generally associated with individual reductions. However, because of the nature of social marketing campaigns, they do not include interventionists who can provide feedback to recipients of the campaign. An example would be a social marketing campaign that shares social norms around marijuana usage in the last month by the students in that school in a poster on campus. The poster is meant to encourage reduction in order to conform to the social norms of the campus. Although advertising norms seems intuitively useful, researchers have not found consistent support that social marketing as an environmental strategy that works broadly or consistently to reduce harm.

Public Policy

Environmental interventions frequently impact public policy, especially if those environmental interventions are enacted at a community, state, or national level. In addition to conducting research that often pushes the boundaries of public policy, many practitioners of harm reduction also choose to intervene on an environmental level by promoting or speaking out against societal laws, policies, and proposals. While it is important to separate research-supported findings from personal opinions, both are vital in educating and influencing policy makers and the public in general. However, when considering controversial topics, this is not necessarily agreed upon perspective even among those from a harm reduction background.

For example, one current controversial topic in the United States is the proposed legalization of illicit drugs. Some harm reduction practitioners argue for legalization of these substances to elevate the behaviors from an illegal and largely underground problem to a visible public health problem that can be addressed without fear of legal jeopardy. Proponents also argue that legalization would improve quality control and generate large amounts of revenue from fees and taxes that could be used to fund prevention and treatment efforts as well as potentially regulate consumer demand. However, not all practitioners of harm reduction agree, having concerns that legalizing drugs would have an impact on perceived norms as well as increased access, both of which were discussed prior as having an adverse effect on use and related consequences. Because harm reduction approaches tend to be highly pragmatic and client centered, the complex intersection of science, practice, and policy tends to impact the work of harm reduction professionals routinely.

Cultural Variables

Culturally relevant harm reduction approaches represent collaborations between harm reduction professionals and the community being served. Because of its strong emphasis on client-centered goals, harm reduction approaches are sensitive to the importance of cultural relevance in helping the clients. In particular, use of the community-based participatory model for collaborations between scientists, practitioners, and the communities they serve is particularly important for achieving the goals of harm reduction therapy. The community-based participatory model suggests that when conducting research and providing services among people who have been historically disempowered within societies, it is critically important to place the needs of client and community at the center of therapy to avoid the potential for disrespect or abuse

to either. Harm reduction professionals serve in a scientific advisory role to the client and community. However, decisions about cultural relevance and the ultimate direction of research and services are made by the client and community. The community-based participatory model is particularly effective when working in cultures where collectivism and interdependence are highly valued.

Culturally relevant harm reduction often includes the use of culturally relevant practices as a key component of the intervention. Culturally relevant practices may include traditional spiritual and healing practices, use of traditional language, inclusion of culturally important ceremonies and events, inclusion of culturally historic content including traditional stories, and use of culturally sensitive interpersonal styles. The harm reduction goals chosen by the client will likely be linked in very specific ways to the culture of the community. It is important for the harm reduction professional to be educated by the community about what may be the culturally relevant norms related to addictive behavior being targeted and its treatment. What may be a culturally appropriate goal for harm reduction in one culture may be entirely inappropriate for another.

EXAMPLES OF AGE-SPECIFIC PSYCHOLOGICAL INTERVENTIONS

Older Adults

Harm reduction has been found to be an effective means for improving lives for adults, especially for those who may not be realistic candidates for abstinence-based treatment. Research has found that many adults who enter treatment do not necessarily cease the addictive behavior after discharge, but many do reduce the frequency and severity of their engagement in the behavior. Many high profile treatment outcome studies (e.g. Project MATCH; Project COMBINE) have found that significant numbers of clients reduce but do not cease the targeted behavior.

Adults often experience slips and relapses during the early stages of recovery as they practice the new behaviors learned in therapy. Relapse is a normative part of the change process; it is not surprising that the client will have lapses or slips on the way of achieving their personal goals for recovery. The principles of relapse prevention have found to be efficacious to help the clients achieve their goals, whether those goals are for cessation or reduction of the addictive behavior. When used with people seeking harm reduction goals, relapse prevention has been more correctly referred to as relapse management, since the goal is to minimize the harm of the relapse rather than prevent engagement in the

addictive behavior. The goal of relapse management is to use traditional relapse prevention therapy techniques to moderate addictive behavior.

One effective use of relapse management for harm reduction is to address apparently irrelevant decisions that clients make. Apparently irrelevant decisions are decisions made that may appear benign to the client because the natural consequences of the decision are not fully appreciated. As an example of an apparently irrelevant decision, a client may decide to go fishing with a former drinking companion and not see the risk involved with such a decision. It may be that the client even takes nonalcoholic drinks to consume on the trip but does not adequately assess the risk of observing his friend drinking, or perhaps has not considered the risk of being offered an alcoholic beverage by the friend. In harm reduction therapy, the focus is on preventing apparently irrelevant decisions from leading the client away from his/her goal for treatment.

Another effective method is the use of mindfulness techniques to help the client improve attention and concentration at that moment. Improving the client's moment-by-moment focus will likely improve the client's ability for self-control in the moment, an important skill to hone in order to achieve moderation goals. Mindfulness also has been found to be effective for reducing depression, a condition that often co-occurs with addictive behaviors.

Gradualism

Some researchers and treatment professionals have advocated for a combination of harm reduction approaches with traditional abstinence-based treatment to provide a menu of options for clients when they seek help. Some have argued that clients who initially opt for harm reduction goals may go on to cease the addictive behavior if given the time to reduce the behavior gradually. The idea that harm reduction may gradually lead to abstinence has been referred to as gradualism, often by those who oppose it on philosophical grounds. Proponents of the disease model actively oppose the inclusion of moderation goals into treatment programs and see gradualism as a threat to client health. On the other hand, those who operate under a biopsychosocial model of addictive behaviors see an advantage in having multiple options for treatment for clients that would appeal to a wide range of posttreatment goals and that consider the multifaceted complexity of addictive behaviors.

Harm Reduction Support Groups

Some clients have found an advantage to participate in a support group as they strive to reach harm

reduction treatment goals. However, clients have not been able to utilize traditional 12-step support groups with any success because of the belief by many 12-step group members that moderation goals are not acceptable for group members. The incompatibility of harm reduction and 12-step recovery goals has led to the clients seeking harm reduction goals to form support groups, which have a philosophy that moderation rather than cessation is an acceptable and attainable goal for therapy. One example of such a group is called Moderation Management, and they offer face-to-face groups as well as online virtual groups.

Adolescents and Young Adults

Harm reduction approaches have been especially appealing to adolescents and young adults who often have not experienced the severe and longstanding consequences that older adults may have experienced over the course of chronic engagement in addictive behaviors. Since adolescents and young adults have not generally experienced widespread aversive consequences, they generally do not see the need for cessation or abstinence and often will not do well in programs that expect abstinence as a precondition for treatment admission or as an expected treatment outcome. In addition, adolescents and young adults do not fit nicely into the diagnostic categories used for adults to determine addiction severity and often do not respond well to older adult-oriented treatment models. As an example, young adults who have experienced problems with drinking have been routinely referred to Alcoholics Anonymous meetings. However, young adults often have very little in common with the experiences of Alcoholics Anonymous members and usually report that those referrals were unhelpful and unnecessary.

The most extensively studied harm reduction approaches for this age group have been conducted and evaluated in college and university campuses. College students present researchers with accessibility to large samples and multiple options for incentives, as well as high rates of alcohol misuse and related consequences. National surveys estimate past year drinking rates over 80% among college students, with two in three students drinking at least once in the past 30 days and one in three students reporting a heavy drinking episode (five or more drinks in one occasion) within the past 2 weeks. This kind of heavy alcohol use is associated with increases in risks ranging from meeting DSM-IV criteria for alcohol abuse and dependence to myriad alcohol-related consequences. The most common aversive consequences for students include regrettable decisions, blacking out, unprotected

sex, and injuries, though many others also experience consequences subsequent to drinking and driving, academic failure, and interpersonal consequences.

Offering college students interventions beyond a just say no message is an important strategy for health and wellness efforts. College students are at a developmental phase described as emerging adulthood, a unique stage between adolescence and adulthood, characterized by increasing responsibility while retaining some of the interdependence of earlier stages. At this phase, students identified as more independent and perceived threats to their autonomy (e.g. through abstinence-only interventions) can be counter-therapeutic and may be inconsistent with perceived campus norms. Furthermore, since many students do not view their alcohol use as a problem, abstinence-only programs and scare tactics may not be personally relevant and appear too extreme to be individually beneficial. Harm reduction approaches, on the other hand, are designed to meet a student where he or she is in terms of substance use.

As discussed above, effective interventions to reduce substance abuse and related harms on college campuses have been extensively studied. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) identified strategies with demonstrated effectiveness in impacting alcohol use and consequences in college students. Each of these strategies, cognitive-behavioral techniques, motivational interviewing, and norms clarification, impact different areas related to decisions about drinking.

Cognitive-behavioral techniques combine accurate information, such as blood alcohol concentration levels and realistic effects of alcohol, with behavioral techniques to assist students in reducing alcohol use. These techniques are designed to provide the students with specific tools strategies to reduce drinking and other substance use, reduce consequences associated with drinking and other substance use, and/or choose or maintain abstinence either short-term or on a permanent basis so that they may choose to implement as appropriate, thereby supporting autonomy. One of the common strategies taught to college students involves use of protective behavioral strategies, or techniques to limit consumption (such as the alternating strategy mentioned earlier in this chapter or adding additional ice to a glass) or minimize related consequences (including not leaving a drink unattended and employing the buddy system). These strategies have been associated with decreases in consumption as well as reduced risk of alcohol-related consequences including unwelcome and unsafe sex.

Motivational interviewing is a clinical intervention that combines a nonjudgmental style while attempting to evoke self-motivated talk about behavior change. The four primary tenets include expressing empathy (understanding the student's perspective and experience),

developing discrepancy (typically between the positives expected from alcohol use and the potential negatives that are actually experienced), rolling with resistance (approaching with a nondefensive style and focusing on what is most useful for the student), and supporting self-efficacy (giving the tools to make change while supporting the autonomy and capability of the individual). Motivational interviewing is particularly important with this group, as prior studies have found that information-only interventions do not necessarily lead to behavior change. Thus, using motivational interviewing to help a student identify personal reasons for change increases the likelihood of decreased consumption and consequences.

Norms clarification attempts to correct misperceptions of descriptive and injunctive norms. In other words, students' overestimations of how much their peers consume as well as how much they believe their peers approve of drinking behaviors are related to increased drinking. Providing normative reeducation through use of assessment and personalized feedback has also been associated with decreases in drinking behaviors and consequences.

In a process to determine the best practices for intervening upon college student drinking risks, the NIAAA identified what is referred to as Tier 1 interventions, or approaches that have favorable outcomes with college students in at least two independent studies. Two harm reduction approaches are provided as specific examples that utilize the above strategies: Alcohol Skills Training Program (ASTP) and Brief Alcohol Screening and Intervention for College Students (BASICS).

ASTP combines cognitive-behavioral skills, norms clarification, and motivational enhancement techniques in a group setting. The intervention includes information about alcohol as a drug, tolerance and withdrawal, alcohol expectancies and actual physical effects at varying levels, information about drug interactions, and tips to reduce harms from drinking including drink refusal skills. One of the key components of the ASTP is discussing the point of diminishing returns, or the point at which one more drink will not increase the desirable effects but will heighten the dysphoric outcomes, by referring to research on the biphasic effects of alcohol. Beyond the point of diminishing returns, positive effects such as relaxation and increased social ease will not improve, but negative effects including nausea, black outs, and poor decision-making become more likely. Students are reminded that alcohol is a depressant; thus the only way to avoid all negative consequences and effects is to not drink at all. However, for those who make the choice to drink, the intervention attempts to reduce the associated harms by maximizing positives and minimizing negatives through reduction of peak consumption.

BASICS, on the other hand, incorporates personalized feedback with motivational interviewing and skills training in brief, one-on-one sessions. Typically, a student will complete assessments so the facilitator (who might be a psychology professional, graduate student, or undergraduate peer) can provide feedback of drinking behaviors, perceived and actual norms, expectancies and consequences, and any number of other potentially relevant data to motivate change (e.g. calories consumed from alcohol, money spent on alcohol, etc.). The graphic feedback presents the opportunity to display drinking patterns and misperceptions in new ways for the student. After feedback is provided, a menu of options for behavior change may be offered, if welcomed and appropriate, including harm reduction strategies described earlier. While the goal is to increase motivation to reduce alcohol consumption and its aversive consequences, the intervention is oriented toward what the student sees as most relevant. If a student is experiencing myriad consequences but dismisses them as irrelevant or unlikely to occur again, the facilitator true to the style of motivational interviewing will roll with this perceived resistance and focus on another aspect that is more salient.

Harm reduction interventions for students are also being implemented via web-based or computer-mediated forms, often using ASTP and BASICS as guides for intervention content. These interventions range from individualized feedback produced from survey questions to interactive atmospheres that teach strategies to avoid alcohol use or misuse. Whether conducted in person or electronically, the goal of these interventions is to reduce the harm associated with drinking. For some students, reducing harm means encouraging and supporting the choice for abstinence. For others, reducing harm means teaching behavioral skills and supporting maintenance of moderate drinking, or it may simply mean increasing awareness of some of the bad and adverse effects of drinking while encouraging contemplation of behavior change sometime in the future.

While the majority of this section has focused on interventions for alcohol use, it is important to note that harm reduction with college students spans a wide range of problematic behaviors including tobacco, marijuana, and other drug use, sex-related behaviors, gambling, and eating disorders. The techniques used for reducing harm subsequent to alcohol consumption also may reduce harm subsequent to other addictive behaviors, enhance personal reasons for change, provide tools to support that change, and educate students on norms and expectancies while respecting the autonomy and individuality of students. In addition, these programs are potentially helpful for use with adolescents and with young adults not attending colleges and universities. However, it is still

somewhat controversial to suggest the use of harm reduction programs with adolescents since addictive behaviors are mostly illegal activities for minors. Some treatment professionals and policy makers see harm reduction programs as condoning illegal activities, whereas harm reduction professionals would argue that reducing risk to adolescents outweighs concerns about legal issues.

SUMMARY AND FUTURE DIRECTIONS

Harm reduction approaches have been found to be helpful for clients who are not willing or able to cease addictive behaviors. The biopsychosocial model of addictive behaviors suggests that effective harm reduction interventions may need to target client physiology, client's cognitions and behavior, or the client's environment. Harm reduction approaches have been empirically supported and have demonstrated efficacy to help people reduce aversive consequences of addictive behaviors as well as reach moderation goals that may eventually lead to cessation (although not necessarily). Harm reduction differs from traditional treatment in that it operates under the assumption that client goals for treatment may vary and may not include cessation of the addictive behaviors. The harm reduction professional defers to the client in establishing the goals for therapy, and serves as an advisor to the client on how to best reach these goals. Harm reduction programs have great appeal to specific demographics of clients, such as to those with cooccurring problems that make behavior change difficult, to youth and young adults who may not see the need for cessation, to older adults who also do not desire cessation, and to groups where moderation may be a culturally relevant value. Researchers continue to test and refine pharmacological and psychological harm reduction methods, and the research they generate contributes to reevaluating and redesigning prevention and treatment methods and to challenge the policies that suggest one size that fits all treatment is appropriate or effective for all clients.

Glossary

Apparently irrelevant decisions decisions made by clients that often place them at risk for relapse. The client is generally oblivious to the risk at the moment of making the decision; therefore the decision seems apparently irrelevant.

Balanced placebo design study a classic psychological study by Marlatt and colleagues (1973) that demonstrated that an intoxicated behavior may be a function of beliefs about drinking behavior rather than the result of actual drinking experiences.

Community-based participatory model a model designed to protect traditionally underserved and vulnerable communities from abuses through a collaborative process where the community and professional work together to design and implement research and clinical services conducted within the community that is culturally relevant and appropriate.

DSM-IV *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, is commonly used by clinical professionals to diagnose mental health issues. The manual is produced by the American Psychiatric Association and revised periodically through a committee process.

Harm reduction interventions designed to reduce the risk of experiencing harmful consequences from addictive behaviors without a requirement of cessation of the addictive behavior.

Natural recovery the ability of some people to change addictive behaviors on their own without the need for therapy or treatment.

Relapse management use of relapse prevention strategies for harm reduction goals.

INTRODUCTION

Drug-free residential programs for substance abuse appeared a decade later than did therapeutic communities (TCs) in psychiatric hospitals pioneered by Maxwell

Jones and others in the United Kingdom. The term *therapeutic community* evolved in these hospital settings, although the two models arose independently. The TC for substance abuse emerged in the 1960s as a self-help alternative to existing conventional treatments.

This chapter is abstracted from a comprehensive account of the therapeutic community theory, model, and method provided elsewhere (De Leon, 2000).

Recovering alcoholic and drug-addicted individuals were its first participant developers. Although its modern antecedents can be traced to Alcoholics Anonymous and Synanon, the TC prototype is ancient, existing in all forms of communal healing and support.

Contemporary TCs for addictions are sophisticated human services institutions. Today, the label *therapeutic community* is generic, describing a variety of short and long-term residential and nonresidential programs that serve a wide spectrum of drug-abusing and alcohol-abusing clients. Although the TC model has been widely adapted for different populations and settings, it is the traditional long-term residential prototype for adult substance abusers that has documented effectiveness for substance-abusing individuals. The last section of this chapter summarizes the adaptation and modifications of the traditional TC model for various populations and settings.

TRADITIONAL TCs

Traditional TCs are similar to each other in structure, staffing pattern, perspective, and treatment regimen although they differ in size (30 to several hundred beds in a facility) and client demography. Staffs are composed of TC-trained clinicians, with and without recovery experiences, and other human service professionals who provide medical, mental health, vocational, educational, family counseling, fiscal, administrative, and legal services. The recommended planned duration of stay of long-term TCs has gradually decreased across the years from 15–24 months to 9–15 months.

THE TC PERSPECTIVE

The TC perspective or theory shapes its program model and its unique approach, community as method. The perspective consists of four interrelated views of the substance use disorder, the individual, the recovery process, and of healthy living.

View of the Disorder

Drug abuse is viewed as a disorder of the whole person, affecting some or all areas of functioning. Cognitive and behavioral problems are evident, as are mood disturbances. Thinking may be unrealistic or disorganized; values are confused, nonexistent, or antisocial. Frequently there are deficits in verbal, reading, writing, and marketable skills. Moral or even spiritual issues, whether expressed in existential or psychological terms, are apparent. Thus, the problem is the individual, not the drug. Addiction is a symptom, not the essence of the disorder.

View of the Person

In TCs, individuals are distinguished along dimensions of psychological dysfunction and social deficits rather than according to drug use patterns. In many TC residents, vocational and educational problems are marked; middle-class, mainstream values are either missing or not sought. Usually these residents emerge from a socially disadvantaged sector. Their TC experience is better termed habilitation, development of a socially productive, and conventional lifestyle for the first time. Among residents from more advantaged backgrounds, the term rehabilitation is more suitable which emphasizes a return to a lifestyle previously lived, known, and perhaps rejected.

Regardless of differences in social background, drug preference or psychological problems most individuals admitted to TCs share clinical characteristics that center around the immaturity or antisocial dimensions (Table 66.1). Whether they are antecedent or consequent to serious involvement with drugs, these characteristics are commonly observed to correlate with chemical dependency. More important, in TCs, a positive change in these characteristics is considered to be essential for stable recovery.

View of Recovery

In the TC perspective, recovery involves a change in lifestyle as well as in social and personal identity. Thus the primary psychological goal of treatment is to change the negative patterns of behavior, thinking, and feeling

TABLE 66.1 Typical Behavioral, Cognitive, and Emotional Characteristics of Substance Abusers in Therapeutic Communities

- Low tolerance for all forms of discomfort and delay of gratification
- Problems with authority
- Inability to manage feelings (particularly hostility, guilt, and anxiety)
- Poor impulse control (particularly sexual or aggressive impulses)
- Poor judgment and reality testing concerning consequences of actions
- Unrealistic self-appraisal regarding discrepancies between personal resources and aspirations
- Prominence of lying, manipulation, and deception as coping behaviors
- Personal and social irresponsibility (e.g. inconsistency or failures in meeting obligations)
- Marked deficits in learning and in marketable and communication skills

that predispose the individual to drug use; the main social goal is to develop the skills, attitudes, and values of a responsible drug-free lifestyle. Stable recovery, however, depends on a successful integration of these social and psychological goals. Behavioral change is unstable without insight, and insight is insufficient without felt experience. Several key assumptions underlie the recovery process in the TC.

Motivation

Recovery depends on pressures to change, positive and negative. Some individuals seek help, driven by stressful external pressures; others are moved by more intrinsic factors. For all, however, remaining in treatment requires continued internal motivation to change. Therefore, elements of the treatment approach are designed to sustain motivation or to enable detection of early signs of premature termination.

Self-Help and Mutual Self-Help

Strictly speaking, treatment is not provided; rather, it is made available to the individual in the TC through its staff and peers and the daily regimen of work, groups, meetings, seminars, and recreation. However, the effectiveness of these elements depends on the individual, who must fully engage in the treatment regimen. In self-help recovery, the individual makes the main contribution to the change process. In mutual self-help, the principal messages of recovery, personal growth, and "right living" are mediated by peers through confrontation and sharing in groups, by example as role models, and as supportive, encouraging friends in daily interactions.

Social Learning

A lifestyle change occurs in a social context. Negative behavioral patterns, attitudes, and roles were not acquired in isolation, nor can they be altered in isolation. This assumption is the basis for the use of a peer community to facilitate recovery. A socially responsible role is learned by acting the role within a community of similar others.

View of Right Living

TCs adhere to certain precepts, values, and a social perspective that guide and reinforce recovery. For example, there are community sanctions to address anti-social behaviors and attitudes: the negative values of the street, jails, or negative peers; and irresponsible or exploitative sexual conduct. Positive values are emphasized as being essential to social learning and personal growth. These values include truth and honesty (in word and deed), a work ethic, self-reliance, earned rewards and achievement, personal accountability, responsible concern (being one's brother's or sister's keeper), social manners, and community involvement.

The precepts of right living are constantly reinforced in various formal and informal ways (e.g. signs, seminars, in groups and community meetings).

THE TC APPROACH: COMMUNITY AS METHOD

The TC approach can be summarized in the phrase "community as method". Theoretical writings offer a definition of "community as method" as *the purposive use of the community to teach individuals to use the community to change themselves*.

The fundamental assumption underlying community as method is that individuals obtain maximum therapeutic and educational impact when they engage in and learn to use all of the diverse elements of the community as the tools for self-change.

Thus, community-as-method means that the community itself provides a context for social learning. Its membership establishes expectations or standards of participation in the community. It continually assesses how individuals are meeting these expectations and responds to them with strategies that promote continued participation. The diverse elements and activities of the community can be organized in terms of the TC program model, specific methods, and the program stages that facilitate the process of change.

THE TC PROGRAM MODEL

The TC program model is its social and psychological environment. Each component of the environment reflects an understanding of the TC perspective and each is used to transmit community teachings, promote affiliation, and self-change. The key components of the program model are summarized in terms of its social organization, work, peer, and staff roles.

TC Structure/Social Organization

The social organization of a TC consists of a relatively small staff complemented by a large base of residents or peers at junior, intermediate, and senior levels. This vertical structure arranges relationships of mutual responsibility to others at various levels in the program.

The daily operation of the community itself is the task of the residents, who work together under staff supervision. The broad range of resident job assignments illustrates the extent of the self-help process. Residents perform all house services (e.g. cooking, cleaning, kitchen service, minor repair); serve as apprentices; run all departments; and conduct house meetings, certain seminars, and peer encounter groups.

The TC is managed by the staff that monitor and evaluate client status, supervise resident groups, assign and supervise resident jobs, and oversee house operations. The staff conduct therapeutic groups (other than peer encounter groups) provide individual counseling, organize social and recreational projects, and confer with significant others. They make all decisions about resident status, discipline, promotion, transfers, discharges, furloughs, and treatment planning.

Work as Education and Therapy

Work and job changes have clinical relevance for substance-abusing patients in TCs, most of whom have not successfully negotiated the social and occupational world of the larger society. Vertical job movements carry the obvious rewards of status and privilege. However, lateral job changes are more frequent and permit exposure to all aspects of the community.

Peers as Role Models

TC participants who demonstrate the expected behaviors and reflect the values and teachings of the community are viewed as role models. Thus, all peers and staff are expected to be role models. TCs require multiple role models in order to maintain the integrity of the community and ensure the spread of positive social learning effects.

Staff as Rational Authorities

Staff facilitate community as method, as role models, counselors, and particularly as rational authorities. In their management and clinical functions, staff as rational authorities provide the reasons for their decisions and explain the meaning of consequences. Staff exercise their authority to teach, guide, and correct rather than to punish or control.

THERAPEUTIC COMMUNITY METHODS

In the TC, all activities, planned and unplanned (e.g. interpersonal and social interactions) facilitate recovery and right living. However, planned activities are viewed as interventions or methods, designed to impact both individuals and the general community in specific ways. They can be organized in accordance with their primary purpose, therapeutic-educational change, community enhancement, and community and clinical management.

Therapeutic-Educative Activities (Groups-Counseling)

Therapeutic-educative activities consist of various group processes and individual counseling. They increase communication and interpersonal skills, bring about examination and confrontation of behavior and attitudes, and offer instruction in alternative modes of behavior.

The main groups include encounters, probes, and tutorials. These differ somewhat in format, objectives, but all have the goal of fostering trust, personal disclosure, intimacy, and peer solidarity to facilitate therapeutic change. The encounter is a peer led group that utilizes supportive confrontation. Its basic objective is to heighten individual awareness of specific attitudes or behavioral patterns that should be modified. Probes are staff-led group sessions, which have as their primary objective emotional change and psychological insight. (Marathons are extended group sessions whose objective is to initiate resolution of life experiences that have impeded individuals' development. The use of marathons has sharply declined commensurate with the decreases in planned duration of residential stay.)

Tutorials are primarily directed toward skills training (e.g. management of the department or the reception desk; training in the use of encounter tools). Additionally, cognitive-behavioral tutorials using manualized curricula are employed for targeted clinical areas such as relapse prevention, criminal thinking, and anger management.

Other groups that convene regularly or, as needed, supplement the main groups. These vary in focus, format, and composition. For example, weekly or biweekly "static" (caseload) groups are convened. These home groups consist of the same cadre or composition of peers who address and mutually monitor ongoing clinical progress. Special theme groups relating to gender, ethnic, age-specific, or health issues may use encounter or tutorial formats. Dormitory, room, or departmental encounter groups may address issues of operating the community. In addition, sensitivity training, psychodrama, and emotionality ("feelings") groups are used to varying extents. Like marathons the frequency of these groups has declined significantly commensurate with shorter planned durations of treatment.

One-to-one counseling balances the needs of the individual with those of the community. Peer exchange is ongoing and is the most consistent form of informal counseling in TCs. Staff counseling sessions may be formal or informal and are usually conducted as needed. The focus of staff counseling is to address issues that may impede progress and to facilitate the patient's adjustment to and constructive use of the peer community.

Community Enhancement Activities (Meetings)

Community enhancement activities include the four main facility-wide meetings: the morning meeting, the seminar, the house meeting that meet daily, and the general meeting (which is called when needed). Though different in format and specific purpose, all meetings have the common objective of strengthening community cohesion.

The purpose of the morning meeting is motivational, to instill a positive attitude in the community at the beginning of the day. This meeting is particularly relevant for residents in TCs most of whom have never adapted to the routine of an ordinary day. Led by resident teams, morning meetings occur daily for 30 min and utilize a plan of songs, dance, music, games skits, and inspirational words to achieve its objective.

The afternoon seminar is viewed as a community meeting since it includes all the residents in the program (subsets of all residents are groups). Residents conduct most seminars, although some are presented by staff members or less frequently by outside speakers. Seminar topics directly or indirectly relate to the TC perspective including themes of personal growth, recovery, and right-living concepts (e.g. self-reliance, maturity, relationships). However, topics may include special knowledge themes (e.g. such as the brain and addiction, preparing for re-entry, family genealogy). The educational format of the seminar focuses on impacting conceptual and communication skills.

House meetings take place nightly after dinner, usually last 30–60 min, and are coordinated by senior residents. The main aim of these meetings is to transact community business (e.g. departmental reports, special announcements, phase changes, introduction of new residents, disciplinary issues, etc.), although they also have a clinical objective. In this forum, social pressure through public acknowledgment of positive or negative behaviors is judiciously applied to facilitate both community and individual change.

General meetings are called when needed to address negative behavior, attitudes, or incidents in the facility. All residents and staff members are assembled at any time and for an indefinite duration. Conducted by staff they are designed to identify problem individuals or conditions or to reaffirm motivation and reinforce positive behavior and attitudes in the community.

Community enhancement occurs in a variety of informal activities. These include rituals and traditions, and celebrations (e.g. birthdays, graduations, phase changes), ceremonies (e.g. those relating to general and cultural holidays), and memorial observances for deceased residents, family members of residents, and staff members.

Community and Clinical Management Elements

Community and clinical management elements maintain the physical and psychological safety of the environment and ensure that resident life is orderly and productive. They protect the community as a whole and strengthen it as a context for social learning. The main elements are staff managed and include privileges, disciplinary sanctions, surveillance, and urine testing.

Privileges

In the TC, privileges are explicit rewards that reinforce the value of achievement. Privileges are accorded with overall clinical progress in the program. Staff members deliver all privileges, which may range from telephone use and letter writing early in treatment to overnight furloughs later in treatment. Successful movement through each stage earns privileges that grant wider personal latitude and increased self-responsibility. Displays of inappropriate behavior or negative attitude can result in loss of privileges, which can be regained through demonstrated improvement. The privilege system in the TC teaches that productive participation or membership in a family or a community is based on an earning process.

Disciplinary Sanctions

TCs have their own specific rules and regulations that guide the behavior of residents and the management of facilities. The explicit purpose of these rules is to ensure the safety and health of the community. However, their implicit aim is to train and teach residents through consequential learning. The code of rules may be organized into three levels of severity or strictness reflecting their importance to the health and safety of the community: Cardinal rules (such as no drug use, violence or threat of violence); major rules (such as stealing or vandalizing); and house rules (such as respect for authority, no displays of street code behaviors). Disciplinary actions may also be delivered for resident's persistent failure in meeting community expectations. Examples are nonparticipation in community activities or repeated displays of negative attitudes toward the program.

Delivered by staff members, the disciplinary sanctions employed relate to the severity of the infraction. For example, these may range from written assignments, job demotions, or loss of privileges to administrative discharge. The sanction is usually a written contract with the resident. These agreements make explicit the behaviors addressed, nature, and duration of the consequences. Although contracts may be perceived as punitive, their basic purpose is to promote a learning experience by compelling residents to, attend to their own conduct, to

reflect on their own motivation, and to consider alternative forms of acting under similar situations.¹

Surveillance

The TC's most comprehensive method for assessing the overall physical and psychological status of the residential community is the house run. Several times a day, staff members and selected senior residents walk through the entire facility, examining its overall condition. House runs provide global snapshot impressions of the facility: its cleanliness, planned routines, and safety procedures. They also illuminate the overall morale and psychological tone of the community in the attitudes and social functioning of individual residents and peer groups.

Most TCs implement unannounced random urine testing or incident-related urine-testing procedures. When urine tests are positive for drugs, the action taken depends on several factors (e.g. the drug used, the resident's time and status in the program, the resident's history of drug and other infractions, and the locus and condition of use). Positive urines initiate a disciplinary action or learning experience that includes exploration of conditions precipitating the infraction.

Peer Confrontation: Verbal Affirmations and Correctives

In the TC, verbal affirmations and correctives are the main ways that peers engage in community management. These verbal interactions illustrate examples of peer confrontation in that they provide face-to-face feedback to members as to whether they are meeting community expectations concerning program participation, recovery, and right living. Correctives aim to raise the individual's awareness of behaviors and attitudes that require changing. Correctives range in severity from mild reminders ("pull ups") to stern conversations ("verbal reprimands"). Affirmations aim to encourage or reinforce positive clinical change or personal growth and provide the crucial balance to verbal correctives and staff disciplinary sanctions.

Peer confrontations are intended to facilitate learning for those delivering as well as receiving them. Observing, affirming, reminding, and correcting others reciprocally reinforce self-learning through practice, rehearsal, or role modeling. Thus, verbal affirmations and correctives are quintessential examples of the principle of mutual self-help (see *Center for Substance Abuse Treatment 2005a*, p. 169).

¹(An evolutionary change in TCs is the abandonment of questionable learning experiences (e.g. shaved heads, stocking caps, wearing signs). These were once rationalized as useful strategies for some clients in addressing the immaturity and social deviancy features of their disorder. Such practices were largely abandoned by the 1980s and are excluded in the practice standards of contemporary TCs. It should be noted that while such practices were unnecessary and appropriately renounced, there is no compelling statistical or clinical evidence that they resulted in harmful outcomes).

THE PROGRAM STAGES AND PHASES

Recovery in the TC is a developmental process, one that occurs in a social learning setting. The developmental process itself can be understood as a passage through stages of learning. The learning that occurs at each stage facilitates change at the next, and each change reflects movement toward the goals of recovery. Three major program stages characterize change in long-term residential TCs: orientation-induction, primary treatment, and re-entry.

Stage 1: Orientation-Induction (0–60 Days)

The main goal of stage 1 is to provide new residents with a formal orientation to the TC. The aim of orientation in the initial phase of residence is for the individual to be assimilated into the community through full participation and involvement in all of its activities. Formal seminars and informal peer instruction focus on dissemination of information and instruction concerning program philosophy, rules, house regulations, and community expectations as to participation in the program meetings and group activities.

Stage 2: Primary Treatment (2–12 Months)

The stage of primary treatment consists of three subphases that roughly correlate with time in the program (2–4, 5–8, and 9–12 months). The daily therapeutic-educational regimen of meetings, groups, job assignments, and peer and staff counseling remains the same throughout the year of primary treatment. However, progress is reflected at the end of each phase in terms of three interrelated dimensions of change: community status (role model), development or maturity, and overall psychological adjustment.

Stage 3: Re-Entry (13–24 Months)

Re-entry is the stage at which the individual must strengthen skills for autonomous decision-making and the capacity for self-management and must rely less on rational authorities or a well-formed peer network. The main objective of the early re-entry phase (13–18 months), during which clients continue to live in the facility, is to prepare for separation from the TC. Particular emphasis is placed on life-skills seminars, which provide training for living outside the community. Plans

are developed for long-term psychological, educational, housing, and vocational objectives. Clients may be attending school or holding full-time jobs, either within or outside the TC.

The objective of the later re-entry phase (18–24 months) is successful separation from the TC. Clients have a “live-out” status; they hold full-time jobs or attend school full time, and they maintain their own households, usually with live-out peers. They may participate in Alcoholics Anonymous or Narcotics Anonymous or attend family or individual therapy sessions. Contact with the TC is gradually reduced to weekly telephone calls and monthly visits with a primary counselor.

Graduation

Completion marks the end of active program involvement. Graduation itself, however, is an annual event conducted in the facility for individuals who have completed the program, usually 1 year after their residence is over. Thus, the TC experience is preparation rather than a cure. Residence in the program facilitates a process of change that must continue throughout life, and what are gained in treatment are tools to guide the individual on a path of continued change. Completion, or graduation, therefore, is not an end but a beginning.

Aftercare

TCs have always acknowledged the client’s efforts to maintain sobriety and a positive lifestyle beyond graduation. Until recently, long-term TCs addressed key clinical and life adjustment issues of aftercare during the re-entry stages of the 2-year program. However, funding pressures have resulted in shorter planned durations of residential treatment and the stages and phases therein. This has underscored the necessity for aftercare resources to address both continuing primary treatment as well as re-entry issues. Thus, many contemporary TCs offer post-residential aftercare treatment and social services within their systems, such as intensive day treatment and step down outpatient ambulatory treatment, or through linkages with outside agencies.

WHO COMES FOR TREATMENT?

TCs accommodate a diversity of drug abusers. Males exceed females (70–30%) but the number of female admissions is increasing. Most community-based TCs are integrated across gender, race, or ethnicity, although the demographic proportions differ according to geographic regions and specific programs. Originally

attracting primary opioid abusers the current TC client populations have histories of multiple drug use, including marijuana, cocaine, crack, opioids, alcohol, and prescription medications.

Despite sociodemographic and drug use differences, psychological profiles of admissions appear relatively uniform, as has been shown in a number of TC studies. For example, the character disorder elements and poor self-concept of delinquent and repeat offenders are present, as are the elements of dysphoria, anxiety, and confused thinking seen in emotionally unstable or psychiatric populations. Therefore, in addition to their substance abuse, clients in TCs have considerable degrees of psychological disability.

Similarly, in diagnostic studies, nearly three-fourths of clients admitted to TCs have had a non-drug-related psychiatric disorder in their lifetime in addition to substance-related problems. The most frequent non-drug-related diagnoses were phobias, generalized anxiety, psychosexual dysfunction, and antisocial personality. Serious Axis 1 diagnoses (e.g. lifetime affective disorders) occur in more than one-third of those studied, although the prevalence of schizophrenic diagnosis is low.

Contact and Referral

Approximately a third of adult admissions to community-based TCs have a legal status, in terms of being paroled, probated, or otherwise court ordered to treatment. However, some programs serve legally referred (mandated) clients exclusively. Voluntary contacts with TCs occur through self-referral, social agencies, treatment providers, and active recruitment by TCs. Although most adult admissions to TCs are voluntary, many of these clients come to treatment programs under various forms of perceived pressures originating from conflicts with family members or significant others, employment difficulties, or anticipated legal consequences.

In contrast with adults, a high majority of juvenile admissions to TCs are legal referrals. Thus, for the younger substance abusers, actual legal pressure is a prominent form of external motivation to enter treatment. Their lower internal motivation to change reflects the shorter time-correlated negative consequences of their substance abuse.

Criteria for Residential TC Treatment

Traditional TCs maintain an open-door policy with respect to admission for residential treatment. This understandably results in a wide range of treatment candidates, not all of who are equally ready for, suited for, or motivated to face the demands of the residential

regimen. Relatively few are excluded, because the TC policy is to accept individuals who are mandated to or elect residential treatment, regardless of the reasons influencing their choice.

The general consideration concerning suitability for the TC is risk – the extent to which clients present a management burden to the staff or pose a threat to the security and health of the treatment community. Thus, specific exclusionary criteria most often include histories of arson, suicide attempts, and serious psychiatric disorders. Psychiatric exclusion is usually based on documented history of psychiatric hospitalizations or evidence of psychotic symptoms on interview (e.g. frank delusions, thought disorder, hallucinations, confused orientation, signs of serious affect disorder). However, psychotropic medication is more widely used in TCs to accommodate increasing numbers of admissions with comorbid conditions.

Clients taking medication for medical conditions can be admitted, as can disabled individuals or persons who require prosthetics, providing these individuals can participate fully in the program. Physical examinations and laboratory workups (blood and urine profiles) are performed after admission. Because of concern about communicable disease in a residential setting, some TCs require tests for conditions such as tuberculosis, and hepatitis to be performed before clients enter the facility or at least within the first weeks of admission.

Policies and practices concerning testing for human immunodeficiency virus (HIV) and management of acquired immune deficiency syndrome (AIDS) and hepatitis C emphasize voluntary testing with counseling, special education seminars on health management and sexual practices, and special support groups for residents who are HIV positive or who have a clinical diagnosis of AIDS or hepatitis C.

RESEARCH: THE EFFECTIVENESS OF THERAPEUTIC COMMUNITIES

Over the past four decades, a considerable scientific knowledge base has developed with follow-up studies on thousands of individuals treated in TCs worldwide. The main findings and conclusions are briefly summarized from multiple sources of outcome research in North America including multi-program field effectiveness studies, single program controlled studies, meta-analytic statistical surveys, and cost-benefit studies.

The most extensive body of research bearing on the effectiveness of Addiction TC programs has amassed from field outcome studies. These all employed similar longitudinal designs that follow admissions to TCs during treatment and 1, 5 years (and in one study up to 12 years) after leaving the index treatment.

TABLE 66.2 Meta Estimates From Field Outcome Research: Multi-Program Surveys and Single Program Studies

Sources

1. Multimodality/multi-program studies

Drug Abuse Reporting Program (DARP): Simpson, D.D. and Sells, S.B. (1982)

Treatment Outcome Prospective Study (TOPS): Hubbard, R. L., Marsden, M. E., Rachal, J.V., Harwood, H.J., Cavanaugh, E.R., and Ginzburg, H.M. (1989)

National Treatment Improvement Effectiveness Survey (NTIES): (1996)

Drug Abuse Treatment Outcome Study (DATOS): Simpson, D.D. and Curry, S. (Eds.): (1997)

2. Single program field outcome case studies (no comparison condition)

Phoenix House (De Leon, Wexler, and Jainchill, 1982; De Leon and Jainchill, 1981–1982)

Eagleville Residential Program (Barr and Antes, 1986)

Gateway House (Holland, 1983)

Estimates

- ▶ Over 5000 admissions to community-based TCs in North America have entered into multimodality and single program studies (1969–2000) and have been followed 1–12-years post-treatment
- ▶ Studies have been conducted by different research teams, across different eras
- ▶ Studies have assessed outcomes on multiple variables using similar methodology (e.g. assessment instruments, longitudinal follow-up designs, and statistical analyses)
- ▶ Results are strikingly similar yielding “lawful” findings with respect to profiles, outcomes, and retention

Main research questions and findings

▶ Who comes for treatment?

All studies show that TC admissions have poor profiles in terms of severity of substance use, social deviance, and psychological symptoms

▶ What are the outcomes?

All studies show significant decreases in measures of drug use, criminality, and psychological symptoms and increases in employment and/or educational involvement. In studies, which utilize a composite index of favorable or successful outcome over 60% of the intent to treat, samples (dropouts and completions combined) show most favorable or favorable outcomes

▶ Is there a relationship between treatment “dosage” and outcomes?

All studies show that reductions in drug use, criminality, and increase in employment are related to time spent in treatment. Those who complete the planned duration of residential TC treatment show the best outcomes; among dropouts, retention is highly correlated with outcomes.

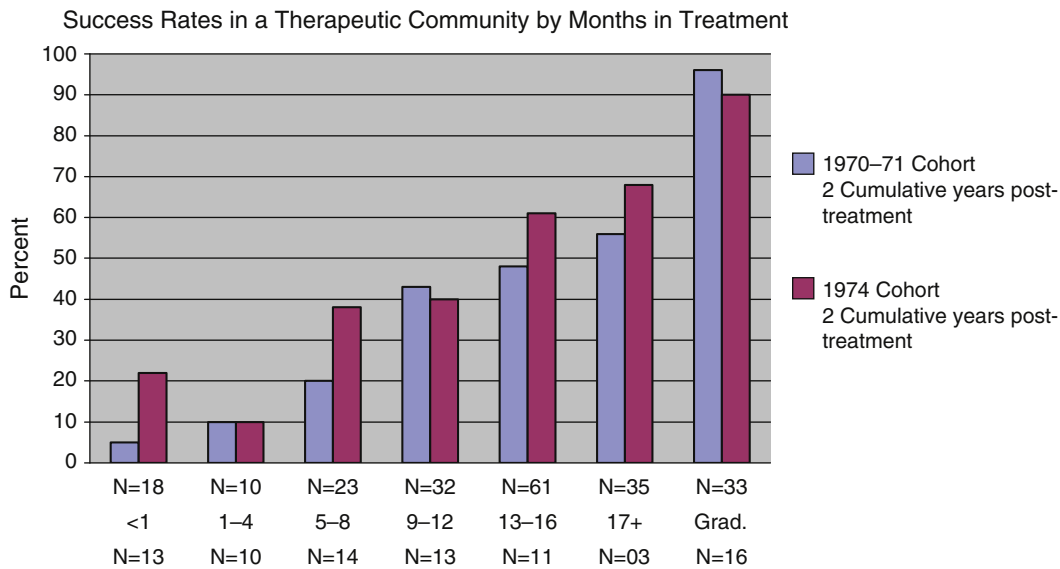

FIGURE 66.1 Success (defined as no drug use and no criminal activity) through all years of follow-up for primary opioid abusers. Adapted from De Leon (1984).

Table 66.2 summarizes the major findings from this research expressed as “Meta-Estimates” – the pooled information from the four major national multimodality, multi-year evaluations. Also included in these estimates is the information from three notable uncontrolled “case studies” of single community-based TC programs.

The striking replications across studies (though not shown, often within percentage points on some variables) leave little doubt as to the reliability of the main conclusion from these studies. Namely, there is a consistent relationship between retention in treatment and positive post-treatment outcomes in TCs (Figure 66.1).

Similar conclusions are obtained with the smaller number of controlled and comparative studies involving TC programs. With few exceptions in the studies with a bona fide non-TC comparison condition, the TCs showed significantly better outcomes than the comparison condition. Finally, the main findings from five published cost-benefit evaluations involving TC programs report a significant and positive cost-benefit outcome for TCs. In comparative studies, the TC shows relatively higher benefits particularly as reductions in costs associated with criminal activity and gains in employment.

Overall, the weight of the research evidence from multiple sources (multi-program field effectiveness studies, single program controlled studies, meta-analytic statistical surveys, and cost-benefit studies) is compelling in supporting the hypothesis that the TC is an effective and cost-effective treatment for certain subgroups of substance abusers particularly those with serious social and psychological problems in addition to their drug abuse.

THE EVOLUTION OF THE TC: MODIFICATIONS AND APPLICATIONS

The traditional TC model described in this chapter is actually the prototype of a variety of TC-oriented programs. Today, the TC modality consists of a wide range of programs serving a diversity of patients who use a variety of drugs and present with complex social and psychological problems in addition to their chemical abuse. Client differences as well as clinical requirements and funding realities have encouraged the development of modified residential TC programs with shorter planned durations of stay (3, 6, and 12 months) as well as TC-oriented day treatment and outpatient ambulatory models. Having become overwhelmed with alcohol and drug abuse problems, correctional facilities, medical and mental hospitals, and community residences, and shelters have implemented TC programs within their settings. Most community-based traditional TCs have expanded their social services or have incorporated new interventions to address the needs of their diverse residents.

These changes and additions include family services; primary health care specifically geared toward HIV-positive patients and individuals with AIDS; aftercare, particularly for special populations such as substance-abusing inmates leaving prison treatment; relapse-prevention training; components of 12-step groups; mental health services, and other evidenced abused practices (e.g. cognitive-behavioral therapy, motivational interviewing). Mostly, these modifications and additions enhance but do not substitute for the basic TC approach, community as method.

Current Applications to Special Populations

An important sign of the evolution of the TC is its application to special populations with substance abuse problems (e.g. adolescents, mentally ill chemical abusers, criminal justice clients, women with children, methadone maintained clients) and special setting (e.g. prisons, shelters, mental hospitals). Research provides impressive evidence for the effectiveness and cost benefits of modified TCs for special populations.

Modifications in practices and in program elements for special populations and settings center on the treatment goals and planned duration of treatment, flexibility of the program structure to accommodate individual differences, and in the intensity of peer interactions. Special services and interventions are integrated into the program as supplemental to the primary TC treatment. An example of the modification of the TC for clients with serious co-occurring psychiatric disorder is outlined in [Table 66.3](#).

THE TC WORLDWIDE

In the past 40 years, the TC for Addictions launched in North America has been adapted worldwide with programs implemented on every continent. These programs reflect cultural and societal differences (e.g. influences of religion, the prominence of the family, the political orientation). To a considerable extent, however, many retain the basic perspective, approach, and elements of the standard TC. A developing research

literature documents the effectiveness and cost benefits for these programs.

TCs worldwide are also undergoing the evolutionary changes described above including modifications for special populations and particularly adapting to fiscal pressures to reduce time in residential treatment. Another notable development is the rapprochement between the addiction TC and the psychiatric TC pioneered by Maxwell Jones that has been prominent in Europe. Both of these TC approaches share many of the common elements of community as method to treat populations with both substance use and personality disorder.

Nevertheless, maintaining uniformity and fidelity of the TC approach in light of these changes remains a challenge. In response to this challenge, the World Federation of Therapeutic Communities (WFTC) that represents regional and individual TC programs worldwide is currently exploring initiatives to develop universal standards for TC practice.

THE TC IN HUMAN SERVICES

The modifications of the traditional model and its adaptation for special populations and settings are redefining the TC modality within mainstream human services and mental health services. Most contemporary TC programs adhere to the perspective and approach described in this chapter. However, the basic peer/social-learning framework has been enlarged to include additional social, psychological, and health services. Staffing compositions have been altered, reflecting the

TABLE 66.3 Modifications of the TC for Co-occurring Disorders

TCs for mentally ill chemical abusers (MICAs)

Clinical issues

The special needs of severely mentally ill chemical abusers center on the themes of the mental illness' symptoms, their fragility to intense social interactions, overall level of social dysfunction, their lower tolerance of structured regimens, their proneness toward social withdrawal, and their need for appropriate utilization of mental health services.

Treatment goals

The basic goals of lifestyle and identity change are viewed as long-term objectives that can be realized dependent upon the functional level of the individual. Realistic goals are the individuals' acceptance of the mutual effects of their substance abuse and mental illness problems, engagement into the change process, learning to use and be effective in the peer community, strengthening daily living skills, commitment to continue drug abuse and mental health treatment beyond the program, and preparation for vocational and educational training. Homelessness is a third major problem for many of these MICA clients. Thus, an additional treatment goal is training clients to seek and secure permanent housing to minimize risk of relapse.

Adaptation and modifications

The clinical issues of the MICA clients shape the key modifications. There is greater focus on individual differences evident in more use of individual psychotherapy, case management, and skills training activities, more flexibility in the daily regimen of activities and in the phase format, a less demanding work structure, use of standard psychotropic medications, moderated intensity of group process, more focus on mental health issues, and greater use of psycho-educational formats. Adaptations in host settings such as hospitals and shelters require intensive cross-training of personnel and accommodation to institutional features.

fact that traditional professionals – correctional, mental health, medical and educational, family, and child care specialists; social workers; and case managers – serve along with experientially trained TC professionals.

Indeed, the cross-fertilization of personnel and methods between traditional TCs and mental health and human services portends the evolution of a new TC: a general treatment model applicable to a broad range of populations for whom affiliation with a self-help community is the foundation for effecting the process of individual change.

INTRODUCTION

Substance abuse and addictive behaviors are a widespread problem in all parts of the world and have a significant impact on physical and mental health. Tobacco and alcohol abuse are historically the most common forms of substance abuse followed by drug abuse. More recently, other forms of addictive behaviors have been added to the list, such as eating, sexual, and gambling disorders as well as Internet addiction.

Due to the magnitude of tobacco and alcohol abuse, there has long been an intensive search for cost-effective interventions to tackle the burden these conditions inflict on society. Although the health care system has an important role in offering advice and support for addictive behaviors, a number of barriers have been identified, such as competing demands, lack of time,

insufficient reimbursement, and lack of training, hampering widespread implementation of addictive interventions to all in need of such support or treatment. Since the Internet has the potential to reach a substantial number of people with instant feedback, it is a potentially interesting means of implementing behavioral change interventions.

Access to the Internet is steadily increasing worldwide. In 2011, it was estimated that over a quarter of the world's population uses the Internet. However, access to the Internet varies considerably between continents (from approximately 10 to 80%) and between countries (from less than 1% to more than 97%).

In Europe, nearly 60% of the population uses the Internet, and in the North America the figure is nearly 80%. Thus, it is not surprising that considerable research has focused on how to use the Internet to offer cost-effective interventions for addictive behaviors.

The Internet already encompasses a vast amount of information on addictive behaviors; for example, a search on Google using the phrase “alcohol abuse” revealed 11.6 million results at the beginning of 2011, “drug abuse” revealed 41.8 million results, and “sexual addiction” 5.5 million results. When looking for Internet treatment for addictive behaviors, Google offers 166 000 results.

Between 75 and 80% of Americans and Europeans routinely use the Internet to find health-related information, but only around 10% are looking for information on substance use. There is a strong trend toward patient control of health information seeking, and already a majority of Americans go to the Internet first before seeking the help of a health care provider.

However, the quality of the content of Internet sites designed for promoting behavior change varies considerably and by itself does not necessarily offer the information needed to promote behavioral change. Thus, owing to the vast amount of information on the Internet, it seems to be a challenge for an individual person to find adequate information and help.

As a consequence of this explosion of health information on the Internet, a substantial amount of research has emerged on how to design and deliver specific interventions for a great variety of health conditions. In general, outcome trials have consistently shown a positive change in health behavior compared with controls. A number of reviews and meta-analyses have been performed in this fairly new research area. Nonetheless, most of the research so far has suffered from a lack of consistency on what constitutes an Internet intervention. The lack of accepted standards makes it difficult to compare different studies. Also, a number of methodological problems in Internet research must be taken into account in future research. One important area to consider is recruitment bias when recruiting participants online and retaining a reasonable number of participants throughout the study period.

Some Internet interventions have considerable human involvement with various forms of online support. This kind of intervention is more expensive and implies a smaller reach since the resources needed are similar to traditional face-to-face treatment. Consideration of external validity is important when designing an Internet intervention because what is easy to perform in a smaller study with extra resources might not be possible on a larger scale.

On the other hand, due to the advantages of the Internet with its 24/7 accessibility, without having to schedule an appointment, and thereby lowering the barriers for seeking treatment for certain vulnerable groups, certain researchers argue that Internet interventions might not have to offer the same level of treatment effect as face-to-face interventions since “some help

might be better than none.” Instead, Internet interventions can be seen as part of a stepped-care model offering a supplement to traditional treatment.

WHAT IS AN INTERNET INTERVENTION APPLICATION?

Internet intervention applications can be defined as various forms of computer software such as (1) public websites with interactive tests offering personalized feedback on response to some questions, (2) provider-controlled websites where a patient obtains a personal user name and interacts with a therapist online, or (3) software applications on stand-alone computers in a professional’s office or in a waiting room. Internet intervention is primarily a self-guided intervention program that is accessible through a website and attempts to create a positive change in a behavior or at least improve awareness and knowledge concerning an unhealthy behavior.

In addition to these computerized solutions, other forms of computerized applications are emerging for additional support, such as short message service (SMS) reminders that could be a daily reminder of a targeted goal (e.g. quit smoking or decrease drinking). The person could also answer these SMSs and, for example, be asked to type the amount of alcohol drunk in the last 24 h and then receive weekly feedback on consumption. Another example of computerized applications where the individual does not interact with a computer is the interactive voice response (IVR) technique. This is an automated phone call in which a person is asked a number of questions and answers by tapping the response into the keyboard of the phone or by talking into the phone and then receives personal feedback based on the answers, with very much the same content as on an interactive website.

Most studies so far have focused on applications reached by a computer with access to the Internet. There is as yet no consensus on a clear terminology when describing what constitutes an Internet-based intervention leading to a lack of clarity and consistency. This is most certainly due to the fast expansion of websites offering help and support, making it impossible for research on scientific evidence to keep up with all the new ways of delivering Internet interventions.

Several terms have been suggested to encompass Internet interventions, such as web-based therapy, e-interventions, e-therapy, cybertherapy, eHealth, and computerized interventions. In an attempt to distinguish between the various forms, it has been suggested that Internet interventions can be organized into four main categories: web-based interventions, online counseling, Internet-operated therapeutic software, and

other online activities. Web-based interventions encompass most Internet interventions developed and implemented so far, but the future might show a different picture with the rapid development of new Internet technologies.

Web-Based Interventions

Web-based intervention in its simplest design could be primarily a self-guided intervention delivered on a computer either as an online website or a preinstalled program on a computer in a health care facility, for example. However, web-based interventions include a great variety of applications from mostly passive educational sites aiming to increase knowledge in order to increase motivation for change to interventions with a more self-guided therapeutic approach partly or mainly with human support delivered over the Internet.

Obviously, program content is vital for the effectiveness of all types of web-based interventions, and not surprisingly there is a considerable variety among Internet interventions with regard to whether the website only offers educational material or specific tools for behavioral change.

The least interactive mode, educational intervention, may still offer some interactivity such as self-assessment or quizzes in which the individual mostly receives a generic automatic response. Research has shown that for some conditions such as risky drinking, this level of intervention might be sufficient for a behavioral change, especially if the information is tailored to the individual user.

In self-guided therapeutic interventions the content is more theory based, often with cognitive behavioral therapy (CBT) as the foremost behavioral change approach. However, the content varies in this kind of intervention and not least in the amount of online activities offered. The intervention might be a single session with brief normative feedback or a multisession intervention where the individual has to create a password and log on at certain intervals. Multisession interventions have the advantage that content can be built up bit by bit in order to enhance the motivation to change behavior. On the other hand, the burden of using the website might be an important barrier to completion of the intervention. In contrast to generic educational interventions, more tailored feedback is commonly offered in self-guided interventions, although the amount varies. Meta-analysis of self-guided therapeutic interventions has shown that this approach is effective for some addictive behaviors.

Human-supported therapeutic Internet intervention adds access to a health professional for support, guidance, and feedback. Most commonly, this is done on an

individual level by e-mails, SMS, or webcam sessions. In previous studies, the amount of time the individual had access to a therapist varied from a few minutes to several hours. A recent meta-analysis reveals that human-supported programs could be more effective than self-guided programs. However, educational and self-guided interventions are often open websites that do not require registration and are always open, whereas human therapist interventions require registration and are not as widely accessible, undermining the possibility for widespread implementation.

Online Counseling and Therapy

In its most basic form, a counselor might have a website with some basic information about a certain addictive behavior offering the user contact by e-mail, instant messaging, or some kind of chat forum. Another example is peer-delivered therapeutic support and advice – for example, various 12-step groups who meet online. The website at <http://www.aabigbook.com> links to online self-help support groups for many forms of addictive behaviors. Although little research has been performed on peer-delivered support and advice, there are a number of obvious reasons why these social networks have become popular. They reduce social desirability, which might lead to increased honesty and thereby self-disclosure of addictive problems. Also, these sites have links to a number of professional lead services both online and face to face.

There are dedicated online counseling websites with virtual clinics that list online therapists. There are also hundreds of independent online therapy or e-clinics and a number of larger e-clinics that are linked to a large number of therapists. These sites mostly offer either written answers to mail questions or a real conversation with a therapist often via a chat room.

Generally, online counseling offers two basic means of communication: individual or group contact. The communication can either be direct online or delayed in time, allowing people to log in when they have time to comment on issues. Although some online websites offer communication via web cameras, written communication has become the most frequently used means of interaction.

Some controversies still exist about this kind of Internet-delivered therapy due to inconsistency in the quality and professional guidelines. Some research has been performed on the effectiveness of this form of Internet-based therapy and has shown that it is possible to accomplish a change in an addictive behavior. However, due to the ever-expanding number of sites offering online therapy for addictive behaviors, it is

difficult to know which sites are of good quality and which are not.

Therapists who want to offer online support must be trained adequately in the challenges of using the Internet. Thus, a face-to-face therapist cannot directly step into cyberspace but needs training in the various means of communicating on the Internet. With the right amount of training, studies have shown that online therapy can establish a close and emphatic alliance between the therapist and client. However, there is a lack of outcome studies, although a few studies have shown online therapy to be effective in addictive behaviors such as smoking cessation.

Internet-Operated Therapeutic Software

Internet-operated therapeutic software refers to more advanced therapeutic software such as gaming programs and virtual environments and to expert systems, including assessments followed by treatment selection and progress monitoring. Among these is the Drinker's Check-up site which contains various decision-making modules that are dynamic in relation to the individual's responses.

Studies have demonstrated the potential effectiveness of Internet-operated therapeutic software for various psychiatric conditions, but not yet for addictive behaviors. However, the cost of developing this kind of application is rather high, and there is a lack of experience among clinicians of the technical possibilities. Nevertheless, the potential for such applications is enormous and in the light of increasingly sophisticated commercial games that have already been developed, technical knowledge and competence are becoming more widespread. This advance might lead to the development of advanced applications for addictive behaviors in the near future.

Other Online Activities

Online support groups have existed for decades. This category of support consists of online activities such as personal blogs and support groups, which can be used as stand-alone functions or added as a supplement to other Internet treatment interventions. Online support groups and networks can be moderated by a facilitator or they can be unmoderated. Social networks and others such as MySpace and Facebook are growing more popular. However, research on such networks is very limited, although anecdotal information is encouraging when it comes to emotional support and information exchange between users. In a review of the effectiveness of virtual communities with regard to interventions for psychiatric and addictive behaviors, most such social

networks were offered as part of a complex intervention, and therefore the effect of the network per se was difficult to determine. Thus, the potential of using various kinds of social networks remains to be explored.

ADVANTAGES OF COMPUTERIZED APPLICATIONS

Computer-assisted interventions have several advantages over conventional face-to-face counseling. The use of computers decreases the effect of social desirability and increases the amount of information disclosed. Thus, a person might prefer to reveal information of a personal and potentially embarrassing nature to a computer rather than a person.

Another advantage is the access to the Internet 24 h a day, which makes Internet interventions convenient and flexible to use and not confined to a specific physical location. The Internet can reach a large number of people, even those living in remote areas with poor access to health care providers. Furthermore, groups of individuals who might not seek traditional help for an addictive condition might be attracted to using the Internet due to the anonymity offered in most cases. Thus, women and young people have been shown to be more prone to seek help on the Internet, as is the case with traditional treatment services.

The content of an Internet intervention is more stable than a face-to-face intervention and will always be as accurate as constructed. An Internet intervention can be personalized and tailored to match an individual in a more systematic and consequent manner than a face-to-face intervention, although a human interface or contact might be more sensitive and flexible depending on the response from an individual.

The cost of Internet intervention is probably far less than an individual face-to-face intervention, although more cost-effectiveness studies are warranted due to the relatively high cost of developing and maintaining more advanced Internet applications.

METHODOLOGICAL CHALLENGES IN EVALUATING INTERNET INTERVENTIONS

Conducting an effectiveness trial of an Internet intervention poses a methodological challenge. So far, most studies have used conventional methods for recruitment, randomization, and outcomes assessment. Also, many evaluations of Internet interventions for addictive behaviors have been performed on a fairly small number of individuals in special settings, such as college and university students.

Before disseminating Internet interventions on a large scale to a broader audience, however, it is important to know the effectiveness among individuals who enter an Internet intervention site when browsing the web rather than referred by a health care staff professional. Unfortunately, entirely online trials most often have a substantial drop-out rate, making it difficult to analyze the effectiveness.

The transition of relatively small-scale Internet intervention studies to a large-scale implementation reaching a larger segment of the population is an important aspect.

CHALLENGES IN THE DEVELOPMENT OF EFFECTIVE INTERNET INTERVENTIONS

Internet interventions face a lot of challenges, such as supplying the right information for a particular individual, at the right time and place, and providing the best way to guide an individual to a behavior change. Thus, Internet interventions need to be flexible, interactive, engaging, and easy to use for all individuals accessing the intervention. So far, most developers of Internet interventions have been fascinated by the technical possibilities of the Internet reaching a large audience rather than by finding the best way to communicate a health behavior intervention. As a consequence, many websites offering more time-demanding interventions have a problem getting visitors to stay for a longer time and to read all the information or take all the steps necessary for a behavior change to take place. Thus, it is a challenge to design Internet interventions that create interest and engage the users.

Researchers have summarized the directions that must be taken in developing effective Internet interventions; they must be designed to encourage as much as interactive communication as possible; they should work on different platforms, such as computers and smart phones, and attract individuals with various needs and backgrounds. Internet interventions should be designed so that individuals become interested and emotionally involved in performing all steps of the intervention. It has been repeatedly suggested that users of Internet interventions should be involved in the design of new interventions in order to develop more effective and widely implemented interventions.

Interactivity

Many websites offer only information on addictive behavior and are not designed to promote interaction and collaboration. Nonetheless, interactivity (i.e. the user is requested to answer a question or choose

between various alternative pathways) probably plays an important role in the effectiveness of an intervention and, in particular, tailored feedback to the individual user. Interactivity has been shown to be related to meaningful participation in both the process and content of communication. Health behavior change has been shown to be largely dependent on social values and networking. Thus, all social Internet-based forums such as blogs might play an important role in the development of effective Internet interventions, although research so far is limited as to the effectiveness of such social networks. In a review of tobacco cessation Internet interventions, only half of more than 100 sites reviewed contained at least one interactive component, although the proportion has been increasing in the last 5 years.

In particular, tailored feedback promotes an interpersonal interaction between the computer and the users that simulates interpersonal communication and thus bridges interpersonal and mass media forms of communication.

Unfortunately, research has shown that many visitors leave the sites before completing them, and so this is a major challenge because many websites are designed to be revisited in order to achieve substantial change. This situation could be remedied by offering follow-up assessments with the provision of a graphic illustration of change over time concerning a certain health behavior or by offering new information each time a person revisits the site. Also, some sites have a certain number of prescheduled CBT sessions that have to be attractive and user friendly in order to inspire the user to revisit or follow the program. Reminders by e-mail have also been shown to increase revisits to websites.

THEORETICAL BACKGROUND, DELIVERY EFFECTIVENESS, AND UNDERLYING COMPONENTS

As in face-to-face interventions, the message in Internet interventions is based on different theoretical backgrounds. One reason why is that most Internet interventions have been transformed from earlier known effective interventions. Most of the Internet interventions are behavioral treatments, including different types of methods, depending on the purpose of the intervention. As the Internet is worldwide, country-specific cultures concerning the goals of the interventions must be taken into consideration when designing Internet interventions. Some cultures do accept, both legally and socially, behaviors that are totally unacceptable in other cultures. Therefore, Internet behavior change models must relate to the local society.

Methods often used in Internet interventions are related to CBT and social learning theory, using

feedback, motivational enhancement, skills training, self-monitoring, and self-regulation as components to regulate the behavior. These methods are commonly used in other non-Internet interventions. To avoid client resistance, motivational interviewing, including components such as avoiding direct confrontation and making judgments, often influences the message of the intervention. However, in the Internet-based interventions developed so far for addictive behaviors, it is difficult to find a specific theoretical model that explains behavior change and improvement.

Different well-established theoretical models must be used when designing an Internet intervention, but new models or components not yet defined by behavioral change science may have to be added. These new models should include factors such as the environment, both physical and mental, as well as the website design itself. In face-to-face interventions, we normally have control over factors important for the intervention, but in Internet-delivered interventions we cannot anticipate those factors. The environment could either provide support or be a barrier for behavior change. If the environment is positive and supports the use of the Internet intervention, as well as the behavior change, it could enhance the delivered message.

Websites targeted to influence people to change behavior involve different factors such as appearance, instructions, behavioral prescriptions, content, message, and degree of participation. Several more important factors could probably be added to the list. So even if we attempt to individualize the message in the website, the look and feel of the application attract people differently and thereby dictate the appeal to the user. In the same way, the instructions on the site attract people differently, so it is not only the message that is important but also knowledge about how the receiver can handle the Internet-delivered intervention from a technical point of view.

The main message in trying to encourage the patient to deal with the unwanted behavior has been described as a behavioral prescription. This instructs the user in how to address the targeted problem and should be designed so that it increases commitment and boosts adherence. Supporting techniques such as automated e-mails or mobile phone messages can enhance willingness to take part in the intervention. The single most important component of an Internet application is the actual content of the intervention. As there is a considerable amount of misinformation on the Internet, it is important that the content provided in the intervention is accurate, clear, and simple. The organization delivering the intervention is also an important factor. If the user considers the organization to be serious and trustworthy, this will enhance willingness to accept the information.

As in face-to-face interventions, the length of the Internet intervention is important. If the intervention is too long, the patient may lack endurance, resulting in early withdrawal and poor outcome. Therefore, the main components in the intervention should be at the beginning of the program. Later in the program, it is possible to add complementary information. Another alternative is to create short Internet interventions.

Depending on what kind of behavior change methods are used, there are different aspects of the power of the relationship between the therapist and the person seeking treatment. In dependence treatment, it is claimed that the alliance between the therapist and the person seeking help could be a component as powerful as the method itself. Evidence on the relationship has been proved, showing that a good relationship is worth a lot for the treatment outcome. However, although a certain treatment method, often manual based, has been proved to be effective in several studies, lack of experience and skills by the therapist can reduce the expected outcome. In Internet interventions, the importance of the alliance between therapists and patients is no longer a component that influences the effectiveness of the method. It has been suggested that there may be some kind of alliance between the user and the organization delivering the message. If the organization actively keeps in contact with the person receiving the intervention, this probably could create some kind of alliance or closer relationship.

As described earlier, Internet interventions are not only about behavior change; they also include the sciences of web design, social marketing, computer programming, and technical support. Therefore, many different disciplines have to cooperate to create effective Internet-based interventions in the behavioral change area.

ALCOHOL INTERVENTIONS

Alcohol Internet interventions typically use a range of components such as alcohol self-assessment with personal feedback relating to a certain norm, general information concerning alcohol and health, various forms of interactive chat forums, and links for further treatment. So far, it is not known which components have the most effect, although few visitors to alcohol websites go beyond the first few pages. Also, just answering questions about alcohol consumption appears to reduce drinking levels, which might indicate that the various forms of feedback have no additional impact at least for risky drinkers. More research is needed in order to find the optimal amount of information and intervention needed to reach risky drinkers.

Many alcohol Internet interventions have been designed for use among college and university students, including various forms of normative feedback. Many of these interventions have been developed as a single-exposure intervention offering a normative feedback that does not require a log on. The effectiveness of such single-exposure interventions among college and university students has been found to be in the same range as a shorter face-to-face counseling session. One example is the website for Thrive, which has been designed for students (<http://www.uq.edu.au/healthservice/selfhelp/thrive-alcohol-self-check-survey>).

Some of the single-session alcohol interventions have been delivered in a student health care setting on stand-alone computers in the waiting room. Also, stand-alone computers with a single-session alcohol intervention with normative feedback have been used in waiting rooms in emergency departments and primary health care waiting rooms.

A number of sites have also been developed for the general population. Most require a log on in order for the user to have repeat visits to fulfill an interactive behavior change program over a number of sessions, typically around six sessions. One example is the Down Your Drink website (<http://www.downyourdrink.org.uk>). A recurring problem with this intervention design is to get the person to revisit the website at certain set intervals, typically every week. In one trial on Down Your Drink, 60% stayed for 1 week and only 6% for the entire 6 weeks of the intervention. Therefore, the website was redesigned so that the individuals could go through the six sessions at any time, making the site more flexible for the individual user; they were able to navigate freely throughout all parts of the intervention. Other trials have shown that only a small proportion of users visit the part of a website that provides additional information besides an initial assessment. However, individuals looking for more help were more likely to be risky drinkers, and those who clicked on the link for more help were more likely to be abusing or dependent on alcohol.

Most individuals who visit alcohol Internet sites have not seen a health care professional before, and thus the web is the first attempt to learn more about alcohol. Drinkers with high alcohol consumption or more severe problems tend to stay longer and read more of the information provided, including where to find additional help. However, several researchers have found that many individuals using alcohol websites consume just as much alcohol as people seeking treatment in health care, but they do not experience the same level of negative consequences. Men and women seem to use alcohol websites in equal numbers, and in contrast to alcohol treatment services in general, where most of the

attendees are men, the Internet seems to especially attract women with alcohol problems.

In general, alcohol Internet interventions have an effect among risky drinkers without alcohol dependence, but due to the great variety of content, it remains to be shown what is needed to accomplish behavior change. However, with the possibility of an Internet intervention reaching a large proportion of the population, it might be fully acceptable to have a lesser behavior change effect than a face-to-face intervention. Also the Internet intervention on alcohol could be seen as the first part of a stepped-care model.

For people with more severe alcohol dependence, there are dedicated websites with a more extensive online design. The Internet can be used to guide the individual to a face-to-face treatment or telephone counseling. A vast number of such sites are seen in North America with hundreds of independent online therapy or e-clinics and a number of larger e-clinics that are linked to a high number of therapists (e.g. <http://www.thecounselors.com> and <http://www.egetgoing.com>). These sites offer either written answers to e-mail questions or a real conversation with a therapist, often via a chat room function. On <http://www.aabigbook.com> there are links to online self-help support groups for many forms of addictive behaviors, but the effectiveness of such support has not been evaluated in a research study.

TOBACCO INTERVENTIONS

The first computer-assisted smoking cessation intervention was limited to computer-generated printed feedback which was mailed to the participants. However, smoking cessation Internet interventions now include more tailored feedback often with some kind of reminder system, typically e-mail, SMS, or applications for the newer smart phones.

A review of Internet smoking cessation interventions found more than 100 websites and concluded that interactive sites are still underrepresented. Less than half the sites were offering at least one interactive feature. Evaluation of sites with interactive components in the form of e-mail, IVR, and SMS reminders shows promising results compared with just general health information. In a comparison of 10 smoking cessation Internet interventions of various lengths and content, there was some evidence that tailored interactive advice might be more effective than static sites. Some interventions are used as an adjunct to therapist-delivered treatment, whereas others are a fully self-guided intervention. The interventions vary considerably in length, ranging from a single session to several sessions, and even as many as 400 contacts were used in one intervention. A core

component in many interventions is CBT, with the addition of chat features or online therapist support in some interventions. This variety of content makes it very difficult to compare the overall effect of Internet-based smoking cessation interventions. This observation also applies to most other Internet interventions for addictive behaviors. When comparing the effectiveness of existing alcohol and smoking interventions, the effect size is small to moderate and somewhat less for tobacco than alcohol. But given the accessibility of the Internet, this might still imply a reasonable reach of the target population. Not surprisingly, studies with treatment-seeking individuals reveal a higher smoking cessation rate than studies recruited from the general population.

Although there are rapid developments in Internet smoking cessation interventions with more sophisticated designs involving interactive components, it is still unclear "what works for whom." Many of the existing stop smoking sites contain a considerable amount of information in contrast to many alcohol sites. It is unclear how much detailed information is needed to help smokers quit. Moreover, smokers might hesitate to use a site with too much information that they regard as irrelevant or difficult to find due to the many options offered. Thus, as well as considering general usability features, it is also important to understand the ways in which individuals use websites when considering changing behavior.

In 2010, there were about 20 controlled trials, including 40 000 participants in various Internet smoking cessation interventions. Due to a great variability in design and outcome, however, there is still inconsistency in the effectiveness and more studies are needed. There is a need for trials focusing on the likely mechanism or components through which these interventions mediate their effects. In another recent review of more than 50 studies, the proportion of effective studies was examined. Overall, the authors found Internet smoking cessation interventions to be effective in particular when they incorporated reminders via e-mail and SMS and provided tailored feedback. Although not all studies have been able to show the effectiveness of Internet interventions, some studies with self-guided smoking interventions have been shown to be effective with a quit rate between 10 and 30% at 1-month follow-up.

Several additional reviews of the literature on Internet smoking cessation interventions have been performed with somewhat varying conclusions. In general, some evidence exists that the intervention needs to be tailored and interactive as opposed to a more static intervention, although not all trials have found this necessary. Adding chat forums or online support has not been shown to be more effective than fully automated interventions. Several studies with online activities

have shown difficulties in getting the participants to use these online tools. In most studies, a very small proportion (around 5%) utilized chat forums and access to an online therapist.

DRUG INTERVENTIONS

Only a few studies have been performed on Internet interventions for drug abuse. Most of these interventions have been used in addition to face-to-face therapy. One study found a positive effect of a computerized CBT delivered in a clinic in conjunction with standard face-to-face treatment. More and more sites are offering self-tests and information about drug abuse and where to find more help. These sites also most often offer either written answers to mail questions or a "real conversation" with a therapist, often via a chat room. So these sites must be classified as online treatment rather than web-based interventions. Because online treatment sites generally suffer from a lack of scientific evaluations and quality control, it is difficult to estimate the results. All the same, they may well serve as an important means of informing users of the Internet about addictive behaviors and where to get more help. Thus, many sites on the Internet offer information about drug abuse but cannot be considered to be a formal intervention. There is a need for more properly designed studies in order to evaluate both the effectiveness of these services and the cost-effectiveness of using the Internet for general information about drug abuse, and the value of various online supports.

OTHER ADDICTIVE BEHAVIORS

Pathological gambling has been shown to be an increasing problem, especially among young people. The Internet has been predicted to be a suitable means of offering interventions based on CBT principles. So far, only one study with 66 participants has been performed for pathological gambling. The intervention consisted of eight modules, four of which had a motivational interviewing focus, and the other four were based on CBT. Each module included exercises that were mailed to the site, and feedback was given within 24 h. The participants were telephoned once each week by a therapist in order to encourage continuous participation, and in total during the 8-week program the time spent with each participant was 240 min. Follow-up at 18 and 36 months revealed a significant decrease in pathological gambling in the intervention group, as well as less anxiety and depression, and increased quality of life. Future studies will reveal whether these results can be replicated, but given

the positive results from other addictive behaviors, this will probably be the case.

Treatment for sexual addiction via Internet interventions has not been described in the literature as a stand-alone intervention. There has been some focus on cybersex and its impact on the addicted person and related consequences. However, the interventions used have not been delivered via the Internet. There are websites where you can take part in other peoples' experiences. Those websites also recommend different kinds of non-Internet treatment.

Anabolic steroids are a growing problem for adults and teenagers. On the Internet, there are many websites that provide information about the drug, but no Internet interventions are offered through those sites. In research, the role of the Internet is described more as a tool than as a place where a person could easily buy illegal drugs.

Eating disorders are also a growing problem in many countries, especially among young women. So far the number of studies on these behaviors is far less than for many other addictive behaviors; nevertheless, some comparisons have been made between face-to-face CBT interventions and Internet interventions of similar design, with promising results. Typically, Internet intervention for an eating disorder is based on CBT with weekly sessions, including reading material, support group activities, and homework assignments. One study showed that participation in discussion groups with other participants increased the adherence to a program, but for certain individuals this might also exacerbate the eating disorder. Having moderators for discussion boards was suggested as one solution; on the other hand, this adds to the cost of an Internet intervention.

Internet addiction is becoming an increasing problem and is under consideration as a diagnosis in the forthcoming *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition (DSM-V) classification. The prevalence in Western countries ranges from 2 to 8%, with a higher prevalence among young people. Interactive features on Internet sites such as online games, chat rooms, and bulletin boards have been suggested to add to the risk for addiction. Treatment for Internet addiction encompasses a great variety of psychotherapeutic approaches and medications, and so far the area is in its early stages. The question of whether Internet addiction could be treated online has not been discussed and may seem contradictory, but some attempts will probably be made to use the Internet for treatment of Internet addiction in the future. One Internet site, which has been running for 15 years (<http://www.netaddiction.com>), provides self-testing for Internet addiction, including cybersex addiction, general information about Internet addiction, and the opportunity to sign on for individual

counseling delivered face-to-face or by telephone. However, the effectiveness has not been formally evaluated.

SUMMARY

Traditional treatment for addictive behavior is increasingly being augmented in various ways by applications found on the Internet, and in certain cases it is more or less being substituted by Internet interventions. Websites concerning addictive behaviors offer a wide range of general information, self-tests with tailored feedback, self-guided interventions, therapist-assisted intervention, and guides as to where to find more help. With the fast increase in the number of websites, it has been difficult to evaluate the quality and effectiveness of all new components added over time. Studies so far have mostly focused on alcohol and tobacco abuse and to a minor extent drug abuse, pathological gambling, eating disorders, and Internet addiction, including cybersex addiction, work addiction, shopping addiction, and addiction to prescription and over-the-counter medication. Given the magnitude of addictive behaviors in society and the effects on the individuals' surroundings, there is a need for cost-effective widespread interventions to address the challenge. The results so far are promising, especially on use of the Internet to gain more information about addictive behaviors and participation in self-guided interventions. Online chat and therapy-guided group counseling have been found to be less favored by participants owing to fears of lack of privacy and security.

Glossary

Interactive websites sites that not only contain information that is the same for all visitors but also offer interaction in various ways producing a cause-effect action; for example, answering questions

and getting personal feedback based on the individual's answers. Another form of interactivity used on websites involves more complex branching logic that responds differently to differing responses from the individual.

Internet intervention primarily a self-guided intervention program accessible through a website that attempts to create positive change in a behavior or at least improve awareness and knowledge about an unhealthy behavior.

Internet-operated therapeutic software refers to more advanced therapeutic software (such as gaming programs and virtual environments) and to expert systems including assessments, followed by treatment selection and progress monitoring.

Online counseling in its most basic form, a website with some basic information about a certain addictive behavior supplied by a counselor and offering the user contact by e-mail, instant messaging, or some kind of chat forum.

INTRODUCTION AND BACKGROUND

The ultimate objective of health services research is to achieve the more effective delivery of health-care services (i.e. to further reduce disease and promote greater well-being). In the area of substance abuse, the objective of health services research has been to increase the capacity of treatment to enable individuals to become drug free and socially productive. Because research advances are seen as being so tightly tied to improving the nation's health, the Congress regularly provides vast sums to support health care studies with such faith in the scientific community that it rarely demands an accounting of sums expended. It seems fair to say that the legislators, like the public they represent, assume the link between knowledge development and improved practice has been well forged and stands

intact. It has become increasingly clear that the link has been imperfectly forged to the extent it has been forged at all. It is noteworthy that recognition of the problem and the call for corrective action as described below has been the work of the federal agencies responsible for the conduct of research and a cadre of the investigators funded. We might first usefully explore the conditions that have existed to permit, if not promote, the gulf between researcher and clinician before examining efforts and issues significant to reducing that gulf.

Research and Clinical Practice March to the Beat of Different Drummers

Research is a slow and deliberative process. The time to the development of new knowledge is measured in years – and even then the answer may not appear

definitive. Thus, the time from the recognition of a clinical problem to its solution is unlikely to satisfy the needs of clinical programming. The clinician has to respond to that same identified problem immediately and lack the luxury of years to mount a satisfactory therapeutic process. In addition to proceeding along very different timelines, researchers and clinicians have a need to be responsive to different audiences. Researchers acquire tenure, promotion, prestige, and an increased capacity to garner federal grants based on their ability to add to the scientific literature. Contribution to the scientific literature does not equate to contribution to change and improvement in clinical practice, but it is all that is required of researchers by their peers, supervisors, and funding agencies. Clinicians' capacities to acquire promotion, prestige, and job satisfaction are based on their abilities to contribute to the health and well-being of their clients and to satisfy the demands of payers. Apart from often being housed in different settings, the trade publications and sources of communications for both research and practice are largely separated by language and focus. Thus, research articles focus on methodology, and the vagaries of statistics to explain study findings, while the clinical literature focuses on the intervention and its proper implementation. Effective knowledge transfer requires at a minimum that the media and language of communication are held in common by contributors and their audience if there is to be translation into knowledge application. Clearly, research and practice have been separated by a gulf that needs to be bridged. Whatever the loss to researcher and clinician in this process – and there is loss to both – the most significant loss ultimately is to the clients in need and the public of which they are a part.

Different Drummers and No Conductor

The problem of multiple musicians is easily solved by anointing someone as conductor such that while solo performances can be encouraged, individuals can also be aided to make music together. It can be argued that the National Institute on Drug Abuse (NIDA) as originally organized had such a capacity. That is, the federal contributions to both research and services were administered through a single organization. While there were unquestioned deficiencies in the process and success of translating research to practice, it is noteworthy that, based on a large part on national studies of treatment effectiveness, and reports of the significance of their findings for clinical activity, stand-alone methadone detoxification was dropped as a separate treatment modality and support was generated for both the Therapeutic Community and methadone maintenance treatments. Indeed, even preceding the formation of NIDA, the awareness

of relevant officials of evidence of the effectiveness of community-based (and multi-modality) programming in New York, Chicago, and Washington, DC, resulted in support for the creation of a national community-based treatment system and ultimately led to the formation of NIDA itself. Whatever the shortcomings in the work of NIDA to promote knowledge application, the difficulties can be seen as having been exacerbated by the separation of research and practice demanded by Congress through the Alcohol, Drug Abuse, and Mental Health Administration Reorganization Act of 1992, housing each function in its own federal agency without developing crosswalks or demands for integrated activities. Even under those circumstances some significant efforts at knowledge application (i.e. of effecting clinical change based on research findings) have gone forward such that various iterations of diversion from Criminal Justice systems have been implemented (e.g. Treatment Alternatives for Safe Communities – TASC; Drug Courts, etc.), long-term (6 months) methadone detoxification was legislated, and HIV outreach programming was initiated in a vast number of communities as well as being written into law.

EFFECTING THE TRANSITION FROM DISSEMINATION TO APPLICATION – THE FEDERAL ROLE

In recent years, there has been the adoption by NIDA and the drug abuse field of implementation science, and the elevation of that area of study from having been of modest interest – when it was of any interest at all – to becoming a significant research concern. Implementation science, as embraced by NIDA, involves the development and testing of strategies designed to foster the transfer of evidence-based treatments into practice. In placing an emphasis on the implementation of evidence-based treatment, the Institute and field acknowledge the distinction between dissemination and application. As defined by the National Institutes of Health (NIH), dissemination involves the distribution of information about empirically supported treatments. Indeed, dissemination of information through journals, books, and monographs is a long-standing staple of the research community and, while it has not been a first priority for NIDA, the sharing of information with the service community has nonetheless been viewed as appropriate to its mission and has occupied a corner of its activities since the Institute's creation (see, e.g. the NIDA Notes initiated as the Services Research Branch (SRB) Notes in the 1970s). Application, with its focus on increasing the rate and likelihood of adopting new treatment practice, has never been seen as an obligation by the research community whose responsibilities have

been limited to knowledge development and dissemination of findings to peers and to the funding agency. Both dissemination and application can be seen as having the potential to improve the quality and effectiveness of existing treatment services. However, as described above, dissemination is most often a peer-to-peer communication and embraces a language, style of reporting, and set of concerns that make it largely inaccessible to service providers. In addition, and in large part, because of the projected audience for disseminated materials, there is as great or greater emphasis on the use of findings to spur additional research as there is to stimulate treatment program change. Knowledge application, on the other hand, is concerned with changing process (or providing support to existing process) and therefore has a typically different audience, and thereby a different means of communication and set of strategies for achieving its objectives.

Given NIDA's historic mission and concern with knowledge development, and with its emphasis on using the research media for sharing information, caution can be raised as to how NIDA plans on making findings with regard to strategies for knowledge application available. It would strain the bounds of irony for NIDA to support the reporting of findings in the area of knowledge application in the research literature alone or even primarily. In that regard either NIDA or another agency with a dedication to knowledge application, and with actors and a structure in place to foster knowledge application, is essential to the task. As will be described below, an agency and structure do exist, but its effective use will require the joint activity of independently functioning federal organizations. To date there is reason for optimism in that the organizations in question – NIDA, and its sister Institutes, and the Substance Abuse and Mental Health Services Administration (SAMHSA)—are working together on several initiatives. These include the NIDA and SAMHSA Blending Initiative to accelerate the translation of research into practice; the SAMHSA/Center for Substance Abuse Treatment (CSAT) Practice Improvement Collaboratives to improve treatment through the adoption of evidence-based practices; and the National Institute on Alcoholism and Alcohol Abuse (NIAAA/SAMHSA/CSAT) Research in Residence Program to encourage the adoption of research-based improvements.

Two critically important initiatives speak to actions by an agency, SAMHSA, to assume responsibility for the application of research findings to clinical practice through an identification of transferable treatment strategies, on the one hand, and the development of a structure and actors to carry out knowledge application, on the other. The National Registry of Evidence-based Programs and Practices (NREPP) provides the basis for selection of treatment components that can be seen as

supported by a body of research. It would be difficult to overstate the importance of having available a dispassionate and respected body of researchers to conduct such peer review. As has been noted earlier, research is an extraordinarily deliberative activity and the results produced by researchers are rarely sufficiently definitive to rule out the investigator's mantra: "Further study is warranted." In truth, further study is always warranted in relation to effectiveness with additional populations and/or in additional settings. However, as has already been described, research is of necessity always late to the show. At some point, some equally deliberative body has to be empowered to say whether a treatment component can be seen as effective even if caveats need to be stated with regard to the population and/or settings and/or providers on which findings are based. NREPP permits a structure to accomplish that and thereby has performed a major role in moving the knowledge application process significantly forward.

The second initiative undertaken by SAMHSA involves the development of a structure and actors for the conduct of knowledge application, namely the regional Addiction Technology Transfer Centers (ATTCs). As has been described, the Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA) Reorganization Act of 1992 effectively put substance abuse and mental health research and substance abuse and mental health services in separate boxes, creating a SAMHSA with its component agencies and dispatched NIDA and its sister institutes to the NIH with a request that people communicate across agency, but without incentive for them to do so or penalty if they did not. This left no organizational presence to unite research and practice with particular regard to taking treatment components capable of being described as evidence-based, introducing those to the service community, and brokering their adoption by that community. While SAMHSA has assumed large responsibility for the selection of research-based initiatives for transfer, it appears appropriate for the organizations that originate and monitor the development and testing of those initiatives to play a role in suggesting and evaluating them. More importantly, in large measure, NREPP provides little more than a list of available strategies. While manuals and other materials may be solicited from those who were involved with the intervention in question, there is need for more than even these printed materials to achieve knowledge application. The ATTCs represent an important presence in that regard, but have received only modest funding even as that funding has come jointly from differing federal agencies (SAMHSA and NIDA) over time and has been accorded little if any responsibility for undertaking the interpersonal activities with treatment programs, which has been found critical to effective knowledge application.

ACHIEVING PROGRAM CHANGE

The adoption of new clinical initiatives by a program can be seen as having two interrelated components. The first involves preparing the organization to accept the need for change and the second involves preparing the organization to adopt and maintain the specific change proposed.

Preparing the Organization to Accept Change

Program staff must be willing to accept a need for change before we can expect any new initiative to be embraced and adopted by the organization. Change is discomfiting and the status quo provides the security of the known and the routine. To move beyond the status quo and embrace a period of unease, members of an organization must come to have a view that (1) change is needed and/or desirable to increase program and/or personal effectiveness; (2) the proposed new initiative will have the effect of increasing program and/or personal effectiveness; and (3) the adoption and implementation of the proposed new initiative are feasible. Thus, clinical administrators and their line staff must be of one accord that current program functioning is ineffective or inadequate in some significant part. This allows for a willingness to explore new clinical initiatives. Next, the new clinical initiative proposed must be seen as capable of meeting the challenge of increasing program and/or personal functioning and promoting greater effectiveness (i.e. must be seen as responsive to the need identified). In that regard, it becomes important to be able to cite a body of research indicating the proven ability of the proposed initiative to promote greater effectiveness with clients, and in settings comparable to those in which the new initiative is being introduced. To embrace it, the staff must be convinced of the greater utility of the new initiative for their organization and themselves. Finally, program staff must view the new initiatives as capable of being adopted by themselves and their program. That is, the new initiative must not be seen as demanding human or material resources that exceed program or individual capacity, and the initiative suggested for adoption must appear capable of being learned and incorporated into daily routine. An individual, or individuals, seen by the organization as having expertise (i.e. credibility) in the area in which change is being advanced, is typically seen as essential to the change process.

It is essential, then, to prepare the organization to accept a need for greater effectiveness in a given area, on the one hand, and to accept the utility of the proposed new clinical intervention for meeting that need, on the other. Nonetheless, preparing the organization for change is an area that has received far less attention

than it merits from both the research and service communities. As suggested above, research has concentrated far more on knowledge development and the identification of effective treatment initiatives than in understanding strategies essential for their acceptance and adoption. At the program level, to the extent new initiatives are introduced, they are often mandated with the expectation of acceptance and adoption, and without use of a process designed to gain staff understanding and support. Without preparation for change, there is the danger that the organization and its staff will be slow and unenthusiastic in adopting new procedures, and lack appreciation for the need to implement new procedures with fidelity to the selected model and/or lack concern for the long-term maintenance of those procedures.

Preparing the Organization to Adopt the New Initiative

With acceptance of a need for change to achieve greater clinical effectiveness, and of the utility of the proposed initiative to accomplish that, the next task becomes one acquisition of skills. Staff must be given the capacity to implement the new initiative with fidelity to the model found effective in other settings. That is, there must be administrative support for the tasks necessary to achieve adoption and implementation, training to permit the acquisition of new skills, and supervision to guarantee the continuing application of those skills with appropriate fidelity. Administrative support translates to making both time and resources available for training and supervision as well as providing visible continuing commitment to the new initiative as significant to program functioning. In contrast to the limited attention and literature devoted to other aspects of the change process, a great amount of attention has been paid to the training needed to achieve acquisition of the skills necessary to implementation with less attention paid to the supervisory strategies that can be seen as essential to implementation with continuing fidelity. In the latter regard, the risk of "drift" from the program model found to be effective has been well documented in earlier work.

Because training to achieve acquisition of skills is of unquestioned importance and has received the greatest attention in the field's literature, a particular attention will be paid to training by us as well. A first step in promoting training has been seen as the development of manuals detailing the step-by-step implementation of the proposed initiative. At the same time, it has become clear that dissemination of manuals alone is not sufficient to promote widespread adoption and implementation. Interpersonal contact has been found

indispensable to training with a particular emphasis on making use of trainers experienced with the initiative who can convey, thereby, an understanding and confidence in its capacity to be incorporated by program staff and to make a difference in program functioning. Training also involves the use of pre-training homework assignments, workbooks, role playing, and skills practice exercises, with an attention to the environment of learning such that the surroundings employed can be seen as being comfortable and nonthreatening. Increasingly, as well, there is a concern with getting away from the traditional single-shot training that ignores concerns about drift with the passage of time from the training event, a drift that is capable of reducing both fidelity and enthusiasm. Thus, there is an interest in incorporating booster sessions as a continuing education strategy as well as troubleshooting, or coaching, as a strategy for dealing with any issues or problems that emerge as trainees make effort to apply what they have learned in the real-world experience of clinical programming. It is noteworthy that both booster sessions and troubleshooting call for a commitment to the training process of greater duration and expense than that which is typically made by organizations. Finally, one has to acknowledge the high rates of counselor turnover common to many treatment settings. This creates a need to have a system in place for developing the skills of new staff for the implementation of the initiative in question (i.e. that create a need to make ongoing training and support available to assure the organization's capacity to sustain the initiative adopted).

Clinical supervision plays an additional and critical role in the change process. Supervision can serve as a primary source of support and monitoring to assure fidelity, and can provide a mechanism for continuous quality improvement as well. A challenge lies in the fact that training and supervision will typically be the responsibilities of different people. Trainers, as noted above, can be seen as most authentic and knowledgeable when drawn from the ranks of those who have themselves seen and employed the proposed initiative. They constitute the outside experts whose credibility rests, in part, on their having had experiences different from those of program staff. Clinical supervisors are part of the ongoing organization staff. It is essential that they be so if they are to provide continuing monitoring and support. This means that for some period of time supervisors will require continuing access to those outside experts to assure that they have the continuing support they will need to play their roles properly in implementing and sustaining change.

Knowing that change can be a painful and/or a difficult process, some have employed incentives, particularly financial inducements, to support the adoption of

new initiatives. Single State Agencies and third party payers have made effort to increase motivation for use of science-based treatments through the availability of purchasing levers such as regulations requiring treatment standardization, contractual requirements to employ empirically supported treatments, and the imposition of performance standards for reimbursement purposes. These material inducements for change still need to be accompanied by the strategies described above in preparing the organization to accept a need for change and developing activities for the adoption of change. Moreover, it is well to remember that while material incentives can have unquestioned utility, we work with people who are in the helping business, and if the proposed change provides promise of benefiting their clientele while making realistic demands on themselves and their organizations, counselors are likely to be ready allies in acquiring those skills that will permit them to perform their helping roles with greater effectiveness. Regardless, the promise of increased competence, and the work that will be demanded to make good on that promise, suggest that one incentive to be uniformly made available is continuing education credit units as those may contribute to licensure or certification.

A further aid efforts to promote the adoption of new initiatives and to training in particular, has been the rise of the Internet putting us within a keystroke of information that can be provided in an appealing medium, often making use of interactive programming that can simulate the action of interpersonal programming. With the advent of computer-based training and online learning, a significant barrier has been removed for those wishing to continue their learning, but finding it difficult to do so due to responsibilities associated with their full-time employment. The Internet is accessible during and beyond the normal work-day, vastly increasing the availability of training opportunities. Online teaching, which can occur 24 h a day with an available Internet connection, offers a low-cost option for training, booster sessions, and an alternative for reaching new hires in the addictions field which is significant in light of the field's high turnover. Moreover, the new technology holds the potential for individualized instruction to help maintain and increase the knowledge and skills. To an increasing degree, new materials will be capable of being disseminated through different online, multi-media formats (e.g. video, webinars, podcasts, simulations, virtual tours, real case studies, demonstrations designed to stimulate and capture attention, etc.) with a capacity to meet the needs of different learning styles (e.g. visual or auditory learners) and schedules. While the Internet is certain to become increasingly important to knowledge application efforts, a single caution needs to be raised regarding that use. To date, interpersonal, as

compared to impersonal, change strategies have been found to be the more effective. Impersonal strategies investigated have made use of print media. It remains to be seen to what extent interactive programming through the Internet can reduce the distance between audience and change agent (i.e. can simulate interpersonal strategies and achieve the adoption and implementation of new treatment).

CONCEPTUALIZING THE CHANGE PROCESS

Clearly, the successful incorporation of any new clinical initiative demands a process of organizational change. If the comfort of the status quo is to be overcome and knowledge application achieved, there will need to be a plan for allowing members of an organization to understand, accept, adopt, manage, and preserve that change. Leaders and managers within the organization play a special role in having a greater capacity than others to support or frustrate change by virtue of their greater control over resources and the administrative machinery of an organization, but everyone whose roles and functioning will be impacted by the change should be, and should feel themselves to be, a part of the process if they are to adopt and sustain change. Conceptual frameworks and models of change have been described in the literature and we offer a brief synthesis and integration of their common elements.

In general, there are only a few brief steps described as characterizing the change process. Across most conceptual models there is a planning phase, an action or implementation phase (carrying out what was planned), and an evaluation phase. In action steps, this translates to (1) introduction of the rationale for change with particular attention to the reasons for believing the intervention under consideration can enable the organization and individual to function more effectively; (2) adoption with specific regard to understanding and accepting the incorporation of the intervention into organizational functioning; (3) implementation with specific regard to making use of and testing the fit of the intervention into clinical practice; (4) sustainability with regard to setting up structures to permit the routine use of the intervention with an attention to fidelity to the model adopted; and (5) assessment of the utility of the intervention for the organization with an implied capacity for modification to the change process based on the results of the evaluation. The major differences between conceptual models typically lie in the number of detailed steps to the action plan or the elaboration of principles explaining the process. In all instances, organizational change is viewed as dynamic and participatory where those expected to implement change are

not passive recipients of information and direction, but are active in assessing, questioning, and understanding the demands to be placed on them and the larger organization, and the benefits and difficulties associated with the adoption of change.

Since the process of change involves an active exchange between change agents and change adopters/implementers, there is an implication that the initiative targeted for adoption may be modified to fit the organization's circumstances. Earlier, we described the phenomenon of "drift" as a negative activity in which there was the risk that, overtime, the initiative as practiced could become increasingly dissimilar to the initiative as adopted. Thereby, the initiative would become different from the model whose research base makes it appear worthy of being adopted by the organization. While drift from the model adopted can be seen as undesirable, there is another kind of modification that can be seen as inevitable even as it demands caution in its use.

Organizations differ in the nature and characteristics of clients served, staff, resources, and the physical structure in which services are offered. Those differences can be significant for the expression of a strategy to be adopted by an organization. An aftercare strategy found effective with a client population having limited responsibility for childcare may need to include elements responsive to the needs of a population with a greater number of dependent children. That same model developed in association with a largely voluntary population may need to be adopted for use by any organization whose clientele make it necessary for staff to work with significant numbers of parole and probation agents, and so on. The key here is that the intervention, in its basic structure and strategy, is found appropriate to the needs of the organization and its clientele, but in terms of selected elements may need to be tweaked to fit the organization's circumstances. Arguably, the process of adaptation is very nearly inevitable, but the adaptation demanded can be so extreme as to make necessary a model so different from its research-based original that it must be regarded as an essentially new, or at least, drastically altered intervention demanding its own evaluation. There are, unfortunately, no hard and fast rules for making the determination of when adaptation has crossed over to innovation, but it is a determination that needs to be made as best as the change agent and organization can. Where the intervention has lost critical association to the research-based model in structure and strategy, it risks failure frustrating clinical staff at the treatment setting, and defeating any opportunity to encourage adoption of the research-based model by others aware of its failed effort.

Just as organizations differ in their similarity to the organizations on which an intervention's effectiveness was established, organizations differ from one another

in readiness to adopt innovation. Organizations differ in receptivity to new information and change based on past experience, individual staff characteristics, leadership, external pressures, and so on. The extent to which some organizations will be early adopters and others will lag behind or reject change altogether is well-known and has been widely reported. While an awareness of these differences is useful to any effort to induce or encourage change in practices in any one organization, it can be of great importance and utility in efforts to encourage changed practices over a large number of organizations. Thus, with the identification of organizations more and less accepting of change, effort can be made to first encourage an adoption of new practice in those organizations most likely to be early adopters for purposes of demonstrating to others that change is possible, need not be painful, and can reap benefits for the individual and the organization. There is also a capacity for change agents to work through issues related to encouraging adoption of the specific intervention with organizations most likely to act cooperatively with them. Significantly as well, change agents have opportunity to build confidence in their own capacities to achieve goals of adoption of new practices by working initially with organizations likely to support success.

A consistent message throughout this discussion is that organizational change processes are complex and involve many factors in terms of the organization's history, staffing, current functioning, and external pressures. Given that complexity, and the state of knowledge regarding organizational change strategies, the capacity to orchestrate change is both art and science. As will be explored below, we have need to expand the science even as we recognize our efforts are likely to continue to involve some degree of art in their elaboration.

DEVELOPING A SCIENCE OF IMPLEMENTATION

Even as we describe efforts to achieve the adoption and implementation of research-based clinical initiatives as an urgent issue, we find ourselves with only a modest knowledge base available to guide those efforts. It is more than a decade since the Institute of Medicine (IOM) alerted the field to the gap between research and practice, and to the need to develop a research base to guide the development of evidence-based approaches for effecting knowledge application. The IOM report stimulated a research focus on organization change (i.e. on the process of gaining the adoption and implementation of new initiatives by a treatment program). Without the findings from such research, we find ourselves in the embarrassing position of seeking the application of research-based clinical initiatives

through the use of untested application efforts. In fact, primarily because of work outside the substance abuse field, the situation is not nearly that bleak as we have the capacity to adapt findings from work undertaken with organizations in related health and service fields even as we have begun testing additional strategies specific to our field and its workforce. It is safe to say we are now, however belatedly, earnestly engaged in developing the science base necessary to the effective diffusion of innovations. As we develop that science base, four issues appear worthy of consideration.

Focus on the Practical

In considering strategies of organization change for study – just as should be the case in selecting research-based treatment initiatives to be transferred – there is a need to be aware of the capacity of each organization to marshal the resources needed to participate in a program of adoption and implementation. If the knowledge application strategy demands resources in terms of computer capability that an organization doesn't have and can't acquire, or includes a training regimen demanding either time or dollars (as for off-site activity) that an organization cannot generate, the organization change strategy will need to be modified or abandoned. Arguably, any knowledge application strategy (i.e. organization change strategy) adapted from other fields, or developed for use with substance abuse programs, should make realistic demands on the resources of its most modestly endowed programs. That is, we should be concerned with developing knowledge application strategies that have the broadest possible potential for use. As we will discuss below, there is one possible exception to this general principle. For now, however, we are sufficiently familiar with the development and testing of clinical innovations having a life span confined to the length of the federal grant under which they have been implemented, to make effort to avoid recapitulating that situation in the study of knowledge application. We cannot afford the testing and development of instantly irrelevant strategies of knowledge application and should not tolerate such activity in clinical research.

In that regard we might add a word specific to the selection of clinical initiatives for adoption and implementation. Researchers, involved with university-supported treatment programs, and/or allying themselves with treatment agencies, to which they bring substantial resources, may find themselves exploring the effectiveness of treatment initiatives with limited capacity for adoption by other, typical, organizations. Any of several factors may put a clinical initiative out of reach of the typical program: a treatment model may make unrealistic demands on a program's physical structure (e.g. specialized individual and group counseling rooms,

facilities specific to the needs of particular populations such as mothers and their children); may conflict with immutable organizational policies and procedures (e.g. hours and days open for business); or may require staff and/or technology to which an organization lacks access. Before an increased interest was developed in securing the adoption and implementation of clinical initiatives, it was of less consequence whether or not an initiative could meet the needs of the typical treatment organization. As knowledge application has become a significant concern, the degree to which a clinical initiative meets a program's resource availability comes to have increased importance. Noticeably absent throughout the knowledge development process is the lack of attention to costs. Price tags have not been attached to the initiatives offered for purchase (i.e. adoption, implementation, and sustainability) by service providers. The clinical initiative that demands inaccessible resources is quite simply irrelevant to the process of knowledge transfer. This begs a question for the agency that funds clinical research: to what extent should it restrict funding to those clinical initiatives that appear to make realistic demands on available resources.

An Eye to the Possible

While we would argue for clear bias in favor of funding those studies of both clinical initiatives and knowledge transfer strategies that make realistic demand on available resources, we acknowledge the need for a modest investment in those initiatives and strategies that demand greater than typical resources. Such targeted investment can be made to satisfy two needs of the field. First, if we are to convince those providing governance to our field of a need for change in policy and/or financing, we will need evidence to support the change. A clinical case in point lies with a growing enthusiasm among some clinicians and clinical investigators for adoption of a recovery model of behavior change such that substance abuse treatment, as currently delivered, is viewed as a part of the process of effecting long-term behavior change rather than as the totality of that process. The recovery model can then be seen as demanding a period of continuing care posttreatment involving long-term monitoring and support. The recovery model would appear to demand a reconfiguration of treatment and the inclusion of services and a time frame well beyond current procedures. It will be essential to marshal evidence of the program effectiveness of service delivery strategies based on the recovery model paradigm if we can expect to see its adoption as treatment policy and the funding that a new and expanded service delivery system would require. Similarly, in terms of knowledge transfer, one can anticipate that continuing breakthroughs in distance learning, as highlighted above, make it essential that we conduct study

allowing us to plan for the use of the electronic media and of electronic equipment that is not now available across all programs, but that almost certainly will become broadly available over the next several years.

Practice to Research

To this point in our discussion and in the field, knowledge application has focused on the transfer of clinical information and strategies from research to clinical practice. That is, we deal with a one-sided discussion such that new information flows in one direction only. Research is employed to influence practice, but practice is given no – or at best limited – opportunity to influence research. However, it is apparent that the more relevant the clinical research undertaken, the greater its likelihood of adoption. Research conducted on clinical issues volunteered by providers as being significant to them would appear to possess obvious clinical relevance.

Policy Change Research

A final area of concern involves an issue even less likely to be addressed than capturing the research concerns of clinicians. Again, knowledge application efforts have targeted treatment organizations, while – as suggested above – policy makers may be the appropriate audience for the translation of research findings into new regulation, and changed levels and targets for financing. As obviously critical as it would seem to be to develop a knowledge base to inform policy change, there is little evidence of enthusiasm for any such effort. In part, work with policy makers is seen as foreign to the task of research and far beyond researchers' area of expertise or comfort. As noted, the research community has only come recently to accept a responsibility for changing practice. Influencing policy is more than another step: it is a leap. Moreover, study to understand strategies for effecting change in policy will require methodology far removed from the clinical trials paradigm of which funding agencies are so enamored. However, if policy change is the intended outcome of some portion of our research it behooves us to understand how to accomplish that objective. That will require knowledge application strategies appropriate to a specialized audience and particular set of issues.

SUMMARY AND CONCLUSIONS

The substance abuse field has, understandably, concentrated its attention on a first task of knowledge development while assuming modest responsibility for sharing that knowledge through means other than the scientific journals. Thus, the emphasis has been on

knowledge dissemination and, in that effort, the written word has taken precedence over all other means of information sharing. More recently, there has developed a concern with knowledge application, that is the adoption and implementation of new practice, and the recognition that knowledge application demands a greater – and different – kind of activity, one that necessitates organizational change. That is, in accommodating new clinical initiatives the organization is, in some measure, transformed. Consequently, the process of bringing about knowledge application (i.e. of achieving the adoption and implementation of new initiative) is an organizational change process. That process has been found best accomplished through interpersonal contacts, making use of an external change agent and involving a staged sequence of events beginning with engaging organization staff in appreciating a need for the new initiative to allow themselves and the organization to function more effectively, and leading ultimately to the development of a strategy for the maintenance of the new initiative after initial adoption and implementation, and for evaluating its utility to the organization. There is, too, need to make knowledge application the subject of study, in terms of strategies with immediate potential, and with an eye to the future and particularly to the strides being taken in the development of strategies of distance learning.

While we find ourselves in the position of playing catch-up in acquiring knowledge application strategies appropriate to our field, there is good reason to believe that continuing progress is possible. Although the congressional action separating research activities from services support at the federal level has, in our judgment, complicated the task of transferring research to practice, the two organizations created – NIDA and SAMHSA – have nonetheless taken steps to increase our capacity to conduct knowledge application. The CSAT within SAMHSA has committed itself to the constant updating and maintenance of a registry of research-based interventions for adoption and implementation by treatment programs (NREPP), and has developed as well a regional organization of ATTCs with specific responsibility for knowledge transfer. While modestly funded, and functionally separated from NREPP, the creation of a regional system of organizations with responsibility for encouraging knowledge application provides the essential mechanism for making available the interpersonal contacts to date found necessary to the effective adoption and implementation of new initiatives. At the same time NIDA has, in the last few years, accepted responsibility for developing and testing strategies of knowledge application specific to drug abuse treatment organizations.

It remains to be seen whether these encouraging developments will be maintained and expanded in

difficult economic times and with pressures to invest scarce resources elsewhere. To date, the primary strategy for knowledge sharing still appears to be one of knowledge dissemination rather than knowledge application and, however laudable the publication of Treatment Improvement Protocols (TIPs), NIDA Notes, and so on, publications provide information not organization change. Ideally, NIDA, NIAAA, and SAMHSA would join forces (as suggested to them in the legislation dividing them) to work together in (1) the selection of research-based initiatives ready for transfer such that the Institutes, with their oversight of substance abuse treatment research, play a role in extending the great strides undertaken through NREPP, (2) the conduct of knowledge application strategies expanding the institutional resource created by SAMHSA such that the ATTCs are empowered to contract with appropriate change agents (depending on the clinical change sought) to employ interpersonal strategies of knowledge application with evaluation of those efforts jointly by SAMHSA and the Institutes, and (3) a program of knowledge application research by the Institutes involving the development and testing of strategies suggested in significant part by the experiences and judgment of SAMHSA and the service providers ultimately responsible for adopting and implementing change.

Glossary

- Adoption** the process of selecting and employing a new and innovative technology for at least a limited period of time.
- ATTC** the Addiction Technology Transfer Center is a network of 14 Regional Centers and National Office designed to develop and strengthen the addictions treatment workforce by increasing the knowledge and skills of addictions professionals, and fostering regional and national alliances among practitioners, researchers, policy makers, funders, and the recovery community.
- Knowledge application** the adoption and implementation of evidence-based practices and associated organizational change.
- Knowledge development** the conduct of studies and generation of findings having potential for increasing the effectiveness of clinical practice.

Knowledge dissemination the distribution of information about empirically supported treatments.

Knowledge implementation the use of strategies to foster the transfer of evidence-based interventions into practice.

NREPP the National Registry of Evidence-based Programs and Practices is a searchable online database that includes substance abuse prevention, and mental health and substance abuse treatments based on research and available for use.

INTRODUCTION

A majority of substance use disorder (SUD) treatment in the United States is delivered in specialty substance abuse treatment settings. There are currently over 13 000 specialty treatment programs in the United States, including community-based programs, opioid treatment programs (OTPs), programs in the Veteran's Administration (VA) system, and treatment facilities located within the corrections system. These programs vary in terms of ownership, funding, treatment modality and services (e.g. outpatient, residential, detoxification, aftercare), and patients served. For example, programs may be owned by private corporations, local or state governments, or the federal government. Treatment programs operate as both for-profit and nonprofit entities and

may receive funding from private insurance, health maintenance organizations (HMOs) and preferred provider organizations (PPOs), government block grants, Medicaid, Medicare, self-payment, and the criminal justice system. Further, programs are located in both hospital and nonhospital-based settings. Substance abuse programs offer treatment for any combination of alcohol use disorders (AUDs), drug abuse and dependence (e.g. opiates, cocaine, methamphetamine), and tobacco dependence. Many programs also treat patients with co-occurring mental health disorders. SUD treatment may also be delivered in general medical settings such as primary care; however, the prevalence of SUD treatment in these settings is unknown.

Substance abuse treatment is typically delivered in individual counseling and/or group counseling sessions.

Available evidence-based treatments for SUDs include behavioral and pharmacologic therapies. Behavioral therapies used in substance abuse treatment include 12-step facilitation therapy, cognitive behavioral therapy, motivational incentives/contingency management, motivational interviewing/motivational enhancement therapy, community reinforcement approach, matrix model, brief strategic family therapy, and dual focus schema therapy. A majority of treatment programs in the United States include a 12-step component that may help explain low rates of medication adoption since 12-step approaches have not traditionally supported the use of medications in SUD treatment.

Medications for the treatment of SUDs are intended for use as an adjunctive treatment to behavioral therapies. In other words, medications are not recommended as stand-alone treatments; rather they are intended for use in conjunction with behavioral therapy. There are currently six medications approved by Food and Drug Administration (FDA) for the treatment of SUDs. These medications can generally be classified into two categories: (1) medications for the treatment of AUDs and (2) medications for the treatment of opiate abuse and dependence. There are four medications FDA approved for the treatment of AUDs: disulfiram, oral naltrexone, acamprosate, and extended-release injectable naltrexone. There are two medications FDA approved solely for the treatment of opiate abuse and dependence: (1) methadone and (2) buprenorphine. Oral naltrexone and injectable naltrexone are also FDA approved for opiate treatment.

This chapter will (1) describe the pharmacologic properties of each medication and provide a brief summary of clinical trial findings, (2) summarize the literature on the use of each medication in SUD treatment and identify key barriers to the use of each medication, and (3) offer overall strategies for improving the use of SUD medications. (Note that Levo-Alpha Acetyl Methadol (LAAM) is not discussed in this article. For a discussion of LAAM see Treatment Improvement Protocol (TIP) 43. In addition, smoking cessation medications are not discussed here.)

PHARMACOLOGIC PROPERTIES AND CLINICAL TRIAL FINDINGS

AUD Pharmacotherapies

Disulfiram (Antabuse®)

Disulfiram was the first medication FDA approved for the treatment of AUDs in 1951. Disulfiram is an alcohol-aversive medication that causes a severe physical reaction when mixed with alcohol. If a patient consumes disulfiram and then ingests alcohol, a

disulfiram–alcohol reaction is produced. The reaction begins 10–30 min after the alcohol is ingested and the adverse effects may include nausea, vomiting, headache, chest pain, weakness, blurred vision, mental confusion, sweating, and difficulty breathing. However, effects vary by individual patient. Disulfiram is available in tablet form and the recommended dosage ranges from 250 to 500 mg day⁻¹.

Findings from clinical trials on the efficacy of disulfiram therapy are mixed. Results emphasize the importance of treatment setting and ongoing supervision of patients. The National Institute on Alcohol Abuse and Alcoholism TIP 49 states that both the level and the quality of supervision received by a patient are important elements in the success of disulfiram therapy and optimum response to the medication requires its use in specialty SUD treatment settings.

Oral Naltrexone (ReVia®)

Oral naltrexone was the second medication FDA approved for the treatment of AUDs in December 1994, nearly 50 years after disulfiram. In contrast to disulfiram, naltrexone is a mu-opioid antagonist medication that blocks the effects of heroin and most other opiates. Naltrexone has been shown to reduce the rewarding effects of alcohol, reduce craving for alcohol, and decrease the likelihood of alcohol relapse. It achieves effectiveness rapidly following the initiation of an oral dose. Naltrexone does not have addictive properties or produce physician dependence, and tolerance does not develop. The oral formulation of naltrexone is taken once daily by patients and is available in 25, 50, or 100 mg tablets.

Naltrexone was found to be effective in clinical trials in the United States but the effect size was small to medium over placebo. Results also indicated problems with patient compliance. A recent Cochrane Review found that naltrexone was associated with reductions in the risk of heavy drinking, number of drinking days, number of heavy drinking days, and amount of alcohol consumed per drinking day.

Acamprosate (Campral®)

Acamprosate was FDA approved for the treatment of AUDs in 2004. Acamprosate's mechanism of action is not clearly understood. However, acamprosate helps modulate and normalize alcohol-related changes in brain activity and reduces symptoms of post-acute (protracted) withdrawal. In contrast to naltrexone, acamprosate is not metabolized by the liver. Acamprosate must be taken three times daily and is available in 333 mg tablets.

While results from European clinical trials of acamprosate support the medication's efficacy, findings from US clinical trials are mixed. European trials found

that acamprosate was associated with reduction in drinking days, increased complete abstinence, and increased time to relapse. However, the Combining Medications and Behavioral Interventions (COMBINE) study showed no evidence of efficacy with or without combined behavioral intervention.

Extended-Release Injectable Naltrexone (Vivitrol®)

Extended-release injectable naltrexone was approved by the FDA for the treatment of AUDs in 2006. Injectable naltrexone is microspheric formulation of naltrexone that is administered via monthly intramuscular gluteal injection. The medication has the same mechanism of action as the oral form of naltrexone. It is an opioid antagonist that binds to the opiate receptors in the brain and blocks the action of opioid medication and opiate neurotransmitters. Injectable naltrexone uses a lower dosage of naltrexone than the oral form, so it does not undergo first-pass metabolism in the liver and does not carry the same risk of hepatotoxicity as the oral form.

Clinical trial results showed efficacy in decreasing drinking days compared to placebo and decreasing the event rate of heavy drinking days compared to placebo. Injectable naltrexone also demonstrated efficacy in prolonging abstinence and reducing the number of drinking days and number of heavy drinking days in patients who were abstinent for as few as 4 days before beginning treatment.

Opiate Pharmacotherapies

Oral Naltrexone (Revia®)

Oral naltrexone was FDA approved for the treatment of opiates in 1984. Again, naltrexone is an opioid antagonist that blocks the effects of heroin and most other opiates. Naltrexone cannot be used in combination with methadone or buprenorphine and is less widely utilized in opiate treatment than methadone or buprenorphine. In contrast to methadone and buprenorphine, oral naltrexone is not a scheduled narcotic and is therefore not highly regulated by the federal government.

Patients addicted to opiates must be fully withdrawn for up to 2 weeks from all opiates before beginning naltrexone treatment. During this withdrawal period, many patients relapse to use of opiates. After beginning naltrexone therapy, the risk of overdose death may increase if the patient relapses. The FDA-approved oral naltrexone for opiate maintenance therapy without requiring proof of efficacy in clinical trials.

Extended-Release Injectable Naltrexone (Vivitrol®)

In October 2010, the FDA approved the injectable formulation of naltrexone for prevention of relapse to opiates. A randomized clinical trial showed a lower rate of relapse to opiates over a period of 6 months for

patients receiving injectable naltrexone compared to placebo.

Methadone (Dolophine®, Methadose®)

Methadone was never FDA approved for the treatment of opiate addiction in the United States; however, it has been used since the 1960s to treat opiate dependence. Methadone is a full mu-opioid agonist that works by suppressing opioid withdrawal for 24 h or more. Methadone suppresses opioid withdrawal, blocks the effects of other opiates, and decreases craving for opioids. Methadone is available in several formulations including diskettes, tablets, oral solution, liquid concentrated powder, and intramuscular injection (for patients that cannot take oral medications). Methadone can be used for detoxification, maintenance, and pain management. Patients taking methadone for maintenance are administered the medication daily.

Methadone is a Schedule II narcotic and is highly regulated by the federal government. The medication's production, distribution, and dispensing are subject to the requirements applied to Schedule II controlled substances by the Drug Enforcement Administration (DEA) to prevent diversion and illicit use. There is currently a three-tier system of federal regulation which includes the FDA, DEA, and most recently the Substance Abuse and Mental Health Services Administration (SAMHSA). In May 2001, the regulation and monitoring of methadone maintenance treatment (MMT) shifted from the FDA to SAMHSAs Center for Substance Abuse Treatment (CSAT). OTPs must be accredited by SAMHSA (42 CRF Part 8) and programs must be recertified every 3 years.

The distribution and use of methadone for opiate treatment is restricted to hospital pharmacies and physicians registered to both the FDA and the DEA who were authorized to dispense the medication in licensed OTPs only. Licenses are obtained through CSAT. In some states, methadone treatment is further restricted by state governments and agencies at the county and municipal level.

Patients receiving methadone must go to a methadone clinic daily to receive their dosage of the medication. After a period of time, some patients may be given take-home privileges. However, this varies based on state and local regulations.

Buprenorphine (Suboxone®, Subutex®)

Buprenorphine was FDA approved for the treatment of opiates in 2002. Before buprenorphine was FDA approved for opiate treatment it was used for pain management. FDA approval of buprenorphine for treatment of opiate dependence was intended to increase access for opiate addiction by allowing physicians in office-based settings to prescribe the medication.

Buprenorphine is a partial opioid agonist compared to methadone and heroin which are full opioid agonists. Buprenorphine has a lower risk of abuse, addiction, and side effects compared to full agonists. Buprenorphine can be used for detoxification, maintenance, and pain management.

There are currently two buprenorphine products FDA approved for the treatment of opioid addiction: Subutex and Suboxone. Subutex is comprised of only buprenorphine and is a partial mu-opioid agonist. Suboxone combines buprenorphine with naloxone and is both a partial mu-opioid agonist and a mu antagonist. The buprenorphine/naloxone combination appears to reduce abuse potential as compared to buprenorphine alone. Naloxone is added to buprenorphine to decrease the likelihood of diversion and abuse. Both Suboxone and Subutex are sublingual tablets that are available in two dosages.

In contrast to methadone, which can be administered only by OTPs, buprenorphine can be administered by waived office-based physicians. In fact, one of the reasons for the FDA approval of buprenorphine was to facilitate greater access to treatment for opiate dependence, especially in areas of the county that do not have OTPs.

Buprenorphine is a controlled substance (Schedule III drug) that is monitored and regulated by the federal government (i.e. DEA and CSAT). Buprenorphine may be prescribed only by a waived physician. To qualify for a waiver, physicians must complete 8 h of training; waivers are granted by CSAT. During the first year, physicians can treat only 30 patients at a time. After the first year, physicians may apply to CSAT to treat up to 100 patients.

Prior to 2003, OTPs were not allowed to dispense buprenorphine. However, in 2003, SAMHSA began allowing OTPs to also get certified to prescribe Subutex and Suboxone for maintenance or detox (not pain management). OTPs providing buprenorphine must conform to 42 CFR 8.12 which requires that OTPs provide medical, counseling, drug abuse testing, and other services to patients admitted to treatment. OTPs must also modify their registration with the DEA to add Schedule III narcotics to their registration certificates.

Clinical trials indicate that buprenorphine is more effective than placebo and equally effective to moderate doses of methadone and LAAM in opiate maintenance therapy. Results also show that buprenorphine is unlikely to be as effective as more optimal-dose methadone and, therefore, may not be the treatment of choice for patients with higher levels of physical dependence. Buprenorphine has been shown to be effective in short-term detox as well and may be used with pregnant women and adolescents.

USE OF SUD MEDICATIONS

Research shows that medications are underutilized in the treatment of SUDs. Data from studies of specialty substance abuse treatment providers and prescription/insurance claims data confirm the low utilization of SUD medications. Despite the availability of four medications for the treatment of AUDs and three medications for the treatment of opiate use disorders, less than 45% of specialty substance abuse treatment programs in the United States prescribe at least one of these medications. Not only are there low rates of adoption of substance abuse medications, but treatment programs have also been very slow to implement medications into routine clinical practice, that is, the diffusion of medications has been slow. Although the extent of use of medications in other health care settings (i.e. settings outside the specialty system) is understudied, data from prescription and health insurance claims reveal low use of medications for SUDs, especially, when compared to the number of prescriptions for medications to treat mental health disorders (e.g. SSRIs).

Use of Medications in Substance Abuse Treatment Settings

There are several sources of data on the use of medications for the treatment of SUDs in SUD treatment settings. A publicly available data source is the National Survey of Substance Abuse Treatment Services (N-SSATS), a self-report mail-based survey conducted by CSAT. This annual survey of substance abuse treatment providers provides a cross-sectional snapshot of substance abuse treatment services delivered by 13 000+ substance abuse treatment programs in the United States. N-SSATS data provide an annual report of the percentage of programs prescribing SUD medications. Table 69.1 shows that the use of buprenorphine (Subutex/Suboxone) increased since FDA approval in 2002 and acamprosate increased since FDA approval in 2004. However, the use of the other SUD medications remains consistently low with no more than 17% of programs reporting use in any given year. Note that N-SSATS data do not distinguish between the oral and injectable form of naltrexone, so it is not possible to determine the percentage of programs prescribing injectable naltrexone from 2006 to 2009. Since N-SSATS data are cross-sectional, it is not possible to examine longitudinal trends in use of medications. (For more information on N-SSATS, see Further Reading.)

In addition to the N-SSATS, there are several research studies that examine use of SUD medications in samples drawn from subsets of the specialty substance abuse treatment system. The samples include programs in the VA, the National Institute on Drug Abuse Clinical

TABLE 69.1 Percentage of Substance Abuse Treatment Programs Using SUD Medications by year

	2002	2003	2004	2005	2006	2007	2008	2009
Disulfiram	17.0	17.0	16.0	16.0	15.9	16.5	16.0	16.2
Naltrexone	13.0	12.0	11.0	12.0	12.8	15.2	15.4	15.8
Acamprosate	*	*	*	8.0	13.3	17.0	18.5	17.2
Methadone	*	*	9.0	10.0	10.1	10.7	8.3	11.3

Subutex	*	*	*	5.0	6.1	7.5	7.8	7.9
Suboxone	*	*	*	8.0	10.1	13.5	14.4	16.5

*Data not reported.

Data from the National Survey of Substance Abuse Treatment Services (N-SSATS)

Trials Network (NIDACTN), outpatient only programs, and regional samples of treatment programs. Data from these studies examine organizational characteristics associated with SUD medication adoption and implementation and clinician (e.g. physicians, substance abuse treatment counselors) attitudes toward the use of medications for the treatment of SUDs. The theoretical framework guiding a majority of this research is Everett Roger's classic diffusion theory. (For more information on diffusion theory, see Further Reading.)

One major source of data on the use of SUD medications in specialty treatment is the National Treatment Center Study (NTCS) conducted by researchers at the University of Georgia's Institute for Behavioral Research. This family of research studies includes nationally representative samples of privately funded treatment programs, publicly funded treatment programs, specialty AUD treatment programs, and treatment programs participating in the NIDACTN.

Disulfiram

Although the medication has been FDA approved since 1951, there are relatively few research studies that examine the adoption of disulfiram in substance abuse treatment programs. A 2005 NTCS study showed that consistent with diffusion theory, programs were more likely to use the medication if they were based in a hospital setting and had a more professionalized staff (i.e. percentage of master's level or higher counselors). Treatment culture (i.e. emphasis on a medical treatment model) was also a significant predictor of disulfiram adoption. Another NTCS study revealed that the use of disulfiram decreased significantly from 1995 to 2004 from 51.6 to 35.7% in a nationally representative sample of privately funded treatment programs. The same study showed that government-owned programs, programs with a physician on staff, and programs

with greater revenues from private insurance were more likely to adopt disulfiram.

A study of counselor attitudes toward the use of disulfiram in publicly funded treatment programs showed that only 28.2% of counselors were unable to rate the effectiveness of disulfiram, indicating that the medication was widely diffused among counselors. Counselors in recovery and counselors with strong 12-step orientations held less favorable attitudes toward disulfiram. Counselors who received disulfiram specific training and worked in programs that currently used the medication also viewed the medication as more effective.

In summary, a number of organizational factors facilitate the use of disulfiram including medical infrastructure, access to prescribing staff, government ownership, and revenues from private insurance. Exposure to disulfiram via medication-specific training and use in the treatment programs were associated with more positive views of the medication by counselors. Barriers to the adoption of disulfiram include treatment culture at both the organizational and the clinician level.

Oral Naltrexone

A majority of research on the use of AUD medications in specialty treatment programs focuses on oral naltrexone. For example, in a study of treatment programs in New England, researchers found that agency mission, program size, counselor educational level, involvement with managed care, and use of selective serotonin reuptake inhibitors (SSRIs) were associated with oral naltrexone adoption. A set of studies using data from the NTCS revealed that program size, accreditation, staff professionalism, access to a prescribing physician, and percentage of patients paying with private insurance were positive predictors of oral naltrexone adoption. Treatment culture (e.g. 12-step orientation) and percentage of referrals from the criminal justice system were negatively associated with use of oral naltrexone.

A pair of studies examining oral naltrexone prescribing patterns in a sample of physicians found that patient insurance coverage, physicians' perceptions of effectiveness, and exposure to information about oral naltrexone were associated with prescribing behavior. Barriers included concerns about patient compliance and the cost of the medication. A study of both physician and nonphysician clinicians (i.e. counselors) found that only 15% of clinicians prescribed or recommended oral naltrexone often. Both sets of clinicians were more likely to prescribe or recommend the medication if they worked in an organization that supported use of the medication. Clinicians cited lack of information about the medication, perceptions of clinical effectiveness,

treatment ideology, and concerns about the cost of the medication as barriers to adoption. Other studies cite lack of knowledge and confidence in the value of adjunctive AUD medications as barriers to use of oral naltrexone.

A 2009 NTCS study of counselor attitudes toward oral naltrexone found that 58.1% of counselors were unable to rate the effectiveness of the medication, indicating a moderate to low level of diffusion. Counselors receiving medication-specific training, counselors working in programs that currently used oral naltrexone, and those holding more favorable attitudes toward SUD medication adoption held more favorable attitudes toward the medication.

Key facilitators of oral naltrexone adoption include staff professionalism, use of SSRIs, program size, accreditation, and patient payer source. Organizational barriers to the adoption of oral naltrexone include ideological barriers (i.e. medications are not consistent with the program's treatment ideology), lack of knowledge about the medication, resource constraints, and lack of access to prescribing staff. Exposure to oral naltrexone via training and use in employer organization are associated with more favorable attitudes among counselors. Studies of clinician attitudes identify patient noncompliance, cost, ideological barriers, lack of information, and perceptions of clinical effectiveness as prominent barriers.

Patient Compliance with Oral Naltrexone and Disulfiram

Several research studies have investigated patient compliance with oral AUD medications since this has been identified as a critical barrier to wider utilization. Specifically, prescription and insurance claim data confirm low rates of patient compliance with the medication. A study in the New England VA using pharmacy data showed that less than 50% of patients received oral naltrexone prescriptions for more than 2 months and approximately 20% of patients received their prescription for 6 months or more. The same was true of disulfiram prescriptions. More specifically, 38.8% of patients received disulfiram for 1 month or less and 36.5% of oral naltrexone users received the medication for 1 month or less. Two additional research studies show low rates of patient compliance with oral naltrexone. First, a study using paid health insurance claims data revealed that less than 20% of patients in this population were supplied oral naltrexone for more than 1 month. Second, a study of oral naltrexone prescription persistence for AUDs (2000–2004) using data from Marketscan commercial claims and encounters database (50 large US employers) revealed that more than 85% of patients failed to fill their prescription for 80% or more of a 6-month treatment period.

Acamprosate

Two organizational-level studies examine the adoption of acamprosate in specialty treatment programs. A 2006 NTCS study used bivariate analyses to identify predictors of early acamprosate adoption (adoption in the first year of FDA approval) and found that early adopters of acamprosate were more likely to be hospital based, accredited, have access to a prescribing physician, have fewer referrals from the criminal justice system, and to use SSRIs. A 2010 NTCS study found that adoption of acamprosate was associated with participation in research, staff professionalism, and access to a prescribing physician.

A 2009 study of counselor attitudes toward acamprosate showed that 76.1% of counselors were unable to rate the effectiveness of the medication, indicating a low rate of diffusion. The study also showed that counselors with a strong 12-step orientation rated the medication as less effective and counselors with positive attitudes toward general SUD medication use rated the medication as more effective. Counselors working in programs that currently used acamprosate viewed the medication as more acceptable for use in AUD treatment.

In summary, facilitators of acamprosate adoption in treatment organizations include medical infrastructure (hospital based), accreditation, staff professionalism, access to a prescribing physician, and use of SSRIs. Exposure to acamprosate via medication-specific training and use in the treatment program were associated with more positive attitudes toward acamprosate among counselors. Key barriers to adoption are treatment culture and referrals from the criminal justice system.

Extended-Release Injectable Naltrexone

A 2010 NTCS study of early adoption of injectable naltrexone for alcohol dependence in privately funded treatment programs revealed that program size, percentage of patients paying with private insurance, and programs using other alcohol pharmacotherapies (i.e. either disulfiram, oral naltrexone, or acamprosate) were more likely to be early adopters of injectable naltrexone. The study also identified barriers to the adoption of injectable naltrexone including the cost of the medication, lack of knowledge, treatment culture, and access to a prescribing physician. Patient compliance was not identified as a barrier to use the medication.

Methadone

Since methadone treatment is restricted to licensed OTPs (currently numbering roughly 1230), this section outlines key barriers associated with methadone treatment, focusing specifically on MMT. A major barrier to the treatment of opiate dependence is related to access. First, the number of patients in need of opiate treatment in the United States exceeds the number of available

slots in methadone clinics. Since the number of methadone clinics and the location of clinics are limited, many persons in need of opiate treatment do not have access to a methadone clinic. For example, some states do not have methadone clinics. Second, opiate abusers have been reluctant to seek treatment in methadone clinics due to the stigma associated with MMT and the inconvenience of required daily visits for dosing. In fact, it is estimated that only 20% of those in need of opiate treatment seek treatment in methadone clinics.

The stigma surrounding opiate abuse and opiate treatment is significant. Historically, opiate abuse has been considered a moral weakness rather than a medication condition or disease. MMT has been viewed as a 'substitute therapy' that replaces one addiction with another addiction. This stigma affects the patients, the treatment programs and their staff members, the general public, the criminal justice system, and the wider medical community. Further, the media has perpetuated negative views of methadone patients and methadone clinics.

Some of the negative consequences of this stigma include isolation of opiate treatment from mainstream medicine, community resistance to OTPs due to patient loitering, drug sales, diversion, and lack of funding for methadone treatment (e.g. Medicaid does not cover methadone treatment in all states). To reduce the potential for diversion, methadone clinics have employed a number of strategies including closely monitored take-home dosing. However, research shows that methadone is more likely to be diverted to opiate-dependent persons who cannot afford methadone treatment rather than recreational use.

In order to improve use of MMT, efforts are needed to address the high levels of stigma surrounding methadone clinics and methadone patients. Strategies for reducing stigma include national educational campaigns to the general public and medical community, increased training and education for substance abuse treatment professionals, and prohibition of loitering and strategies to reduce and prevent diversion on the part of methadone programs.

Research actually demonstrates a number of positive outcomes associated with MMT including a decrease in opioid use and related crime, increase in employment, decrease in transmission of HIV, decrease in needle sharing, improvement in physical and mental health, and decreases in overall mortality from opiate use disorders. However, these positive outcomes are not widely disseminated to the general public or medical community.

Buprenorphine

Several studies examine the early adoption of buprenorphine in substance abuse treatment programs. An NTCS study of early buprenorphine adoption

(2002–2005) found that adoption of buprenorphine increased from 6.4 to 14.1% over a 1-year period. Privately funded programs were significantly more likely to adopt the medication than public sector programs. Multivariate analyses showed that adoption was greater in accredited centers, for-profit facilities, organizations offering detoxification services, and programs using oral naltrexone. A study of VA treatment programs also showed increases in the use of buprenorphine from 2003 to 2005. Another study that examined early adoption of buprenorphine using 2003 N-SSATS found that use of buprenorphine was greater in OTPs, naltrexone-using centers, and programs offering medically supervised withdrawal.

Several studies examine clinician attitudes toward buprenorphine. A 2005 NTCS study examined diffusion of buprenorphine among substance abuse treatment counselors in a national sample of private and publicly funded treatment programs. This study found that a majority (66.5%) of counselors were unable to rate the effectiveness of buprenorphine (i.e. buprenorphine was not widely diffused among treatment counselor). Exposure to buprenorphine via specific training and use in the treatment program were associated with more favorable attitudes toward the medication. Counselors with a stronger 12-step orientation held more negative attitudes toward buprenorphine.

A 2007 study of counselor and client attitudes toward buprenorphine in three different treatment settings (i.e. methadone, outpatient, and residential settings) found that intentions to use buprenorphine were neutral in methadone and outpatient settings and negative in residential settings. Clients were less informed about buprenorphine compared to other opiate medications. Overall, perceptions of buprenorphine were neutral, with the most positive views of the medication being found in outpatient treatment settings.

A more recent study of physician attitudes toward buprenorphine found that willingness to prescribe buprenorphine varied based on the physicians level of experience with the medication (i.e. experienced, novice, nonprescribers). The study indicated that evidence of clinical effectiveness and preferences for alternative treatments for opiate dependence did not influence physician willingness to prescribe buprenorphine. However, training of clinical staff on buprenorphine, access to behavioral health services (counseling, mental health services, supportive services), an effective referral system for alternative drug treatment, adequate time per patient visit, and concerns about chronic pain medications strongly affected their willingness to prescribe buprenorphine. More experienced buprenorphine prescribers rated reimbursement as significantly more important than novice or nonprescribers.

Buprenorphine addresses a number of the limitations of methadone, namely access to treatment, daily attendance requirements, and diversion. However, there are barriers to the use of buprenorphine. Key barriers include lack of information, lack of clinician training in the use of buprenorphine, lack of access to waived physicians in specialty SUD treatment settings, the cost of the medication, clinician and patient attitudes toward buprenorphine, and state-level barriers such as funding and policy (e.g. support from the Single State Authority (SSA)).

Comparing the Use of SUD Medications

While a majority of research focuses on the use of a single SUD medication, three studies compare overall utilization of SUD medications. First, a 2008 study examined availability of SUD medications in private health plans, that is, whether the medications were included on formularies and placement of the medications on co-pay tiers. The study showed differences in access to AUD and opiate medications. In general, AUD medications were most accessible. Approximately 6% of health plans excluded naltrexone and only 1.3% excluded disulfiram products. However, 31% of insurance products excluded buprenorphine from their formulary and more than 80% of insurance products placed buprenorphine on the highest cost-sharing tier.

Second, data from the IMS National Prescription Audit (NPA) Plus ^(TM) database of retail pharmacy transactions were used to evaluate trends in US retail sales and prescriptions of SUD medications. National data showed that the overall prescriptions for AUD medications increased from 2003 to 2007, growing from \$30 million in sales to \$78 million in sales. According to the researchers this growth was largely attributed to the introduction of acamprosate to the market in 2004. Prescription of buprenorphine (i.e. Subutex and Suboxone) increased over the study period as well, growing from \$5 million in sales to \$327 million in sales. While the sales of SUD medications have increased, they are still extremely low when compared to sales of antidepressants, estimated at \$15 billion in 2006.

Third, a 2010 NTCS study compared use of SUD medication in privately funded treatment programs. Programs reported greater use of buprenorphine for detoxification (32.8% of programs) compared to the use of buprenorphine for maintenance (20.9% of programs). Roughly 22% of programs reported using oral naltrexone for the treatment of opiate dependence. Turning to AUD medications, approximately 32% of programs reported using oral naltrexone for AUDs and acamprosate while only 24% reported using disulfiram. The study also examined the percentage of eligible patients receiving each SUD medication. Results

showed that a greater percentage of opiate patients received medications than AUD patients, indicating the opiate medications are more widely utilized than AUD medications.

STRATEGIES FOR IMPROVING USE OF SUD MEDICATIONS

As described throughout this chapter, medications are underutilized for substance abuse treatment. Researchers have identified a variety of barriers to the use of SUD medications including stigma, state policy and funding, public and private insurance coverage and reimbursement, treatment culture, clinician attitudes, and patient-related barriers. To improve the use of SUD medications, these barriers must be addressed. Given this wide range of barriers, improving the use of SUD medications will require a number of strategies. This section outlines potential strategies for improving the use of medications for the treatment of SUDs.

Stigma associated with SUD treatment among the American public and wider medical community must be addressed. While endorsement of the medical view of SUDs (i.e. SUDs are a disease similar to diabetes and hypertension) has increased over the past two decades, many Americans continue to view SUDs as moral weakness. An effective strategy for reducing stigma is more effective educational campaigns and information dissemination about substance abuse treatment and the use of SUD medications to the American public (e.g. through media campaigns sponsored by federal health care agencies). If Americans are more informed about SUD treatment, perhaps there will be more acceptance of the medical view of SUDs, leading to greater support for treating SUDs on par with other medical conditions. To increase knowledge about SUDs in the wider medical community, medical schools should incorporate training about SUDs into the curriculum. As of 2010, there are only a few medical schools that offer specialty training for SUDs and this training is optional.

Improving the use of SUD medications will require major changes in state policy and funding. A majority of SUD treatment is funded by federal block grant funds allocated to states and administered by the Single State Authority (SSA). Medicaid, administered through the state system, also plays a role in the funding of substance abuse treatment services. Therefore, the delivery of substance abuse treatment services, including SUD medications, varies by state. Each SSA, for example, decides whether block grant funds will be allocated for SUD medications and whether the state will actively support the use of SUD medications in substance abuse treatment programs. Further, each state

system decides which SUD treatment services are included in the Medicaid benefit and how much money will be allocated for the selected treatment services.

Policy barriers could be addressed through reallocation of portions of existing state budgets to cover SUD medications and related services. Another strategy is to create more uniform state policy regarding the delivery of substance abuse treatment. Policy could also be altered to include incentives for treatment programs to provide medications for the treatment of SUDs.

Improving the use of SUD medications will also require expanding both public and private insurance coverage and reimbursement for SUD medications. Data show that many states do not include medications in the Medicaid benefit or have limitations on Medicaid benefits for SUD treatment (e.g. low reimbursement rates for SUD medication, no reimbursement for physician time associated with prescribing SUD medications). In fact, a recent study of barriers to SUD medication adoption in public treatment programs revealed that the programs' primary funder would not pay for costs associated with medications, including the medications themselves, physician time, and lab costs associated with medications.

Many private insurance plans also exclude SUD medications from their formulary. For example, a 2008 study showed that 31% of private insurance products excluded buprenorphine from formularies and 55% placed it on the highest cost-sharing tier. Many states also control substance abuse treatment services through contracts with managed care organizations which often limit benefits for SUD treatment services.

These barriers could be addressed through the creation of new billing codes for SUD medication related services, changes in reimbursement for medication related services on the part of Medicaid and private insurers, and reallocating portions of existing substance abuse treatment budgets to cover medications.

The recent parity and health care reform legislation promises to address state policy and funding issues. Specifically, parity legislation, enacted in January 2010, ensures equal coverage for SUDs among private insurers (with 50 or more employees) that choose to cover mental health/substance abuse treatment services. For Americans with such private insurance coverage, access to SUD medications should increase. Health care reform legislation seeks to increase public insurance coverage for SUDs, largely through Medicare and Medicaid. Since health care reform is in the early stages of implementation, it is not yet clear how health care reform will impact the delivery of substance abuse treatment services. However, since Medicaid and Medicare will remain under state control, benefits for SUD medications will continue to vary by state.

Barriers within substance abuse treatment programs must also be addressed, beginning with treatment

culture (i.e. ideological resistance to the use of medications). Many treatment programs in the United States are based on 12-step models that traditionally have not been supportive of the use of SUD medications. The 12-step approach views treating SUDs with medications as substituting one drug for another drug. In fact, research shows that programs with a strong 12-step ideology are less likely to use SUD medications. The development of more effective dissemination strategies to address lack of knowledge and perceptions of ineffectiveness of SUD medications may be a viable strategy to address ideological resistance to the use of medications in treatment programs.

Resistance to the use of SUD medications extends beyond treatment programs to community-based self-help groups (e.g. Alcoholics Anonymous (AA)) that are part of the recovery process for a majority of patients. Many AA groups and other self-help groups will not accept members who use SUD medications as part of their treatment regimen. In response, new self-help groups that are amenable to the use of medications have emerged in various parts of the United States. Efforts to disseminate information about SUD medications should be targeted to self-help and other community service agencies who interact with SUD patients to address this barrier.

Another critical barrier to improving the use of SUD medications in treatment programs is access to physicians. This barrier can be addressed by increasing funding to cover the costs of employing physicians and nurses in treatment programs through federal block grant dollars and other state funds. This would likely require a change in state policy. Research also shows that a large percentage of treatment programs with access to a physician do not prescribe any SUD medications, suggesting that SUD-specific training for physicians and nurses already embedded in the treatment system is necessary. This could be facilitated through increased funding and incentives for physicians and nurses to obtain specialty SUD training from state and federal funding agencies. Since turnover is a major issue in the substance abuse treatment field, the treatment system must also develop mechanisms to attract and keep physicians and nurses with specialty SUD training.

Another strategy to increase access to prescribing staff is to integrate SUD treatment services with primary care and other general medical settings such as emergency rooms and dental clinics. The federal government and related health agencies are strongly promoting this strategy. However, since a minority of primary care physicians do not have specialty substance abuse training, SUD training and other incentives will likely be necessary to facilitate integration. Each of these strategies will require additional funding and incentives for medical staff to obtain specialty SUD training.

Research consistently finds barriers to the use of SUDs among clinicians, including both counselors and physicians. These barriers include lack of information about medications, perceptions of clinical effectiveness, lack of knowledge about how to implement SUD medications within their treatment settings, lack of training, and general treatment ideology. Educational interventions and SUD specialty training for clinicians, as well as greater dissemination efforts (through written and web-based materials), will be necessary to address clinician willingness to prescribe and recommend SUD medications.

Finally, to improve use of medications in SUD treatment, patient-level barriers must be addressed. For example, research shows that patients lack knowledge of SUD medications as a treatment option. Patient willingness to take SUD medications may also be affected by stigma. To increase patient awareness and knowledge of SUD medications, educational interventions and information dissemination should be targeted at SUD patients. Patients ability to pay for SUD medications is also a key barrier. Since many SUD patients have no insurance, public or private, they are not likely to receive SUD medications. Again, increased insurance coverage and reimbursement for SUD treatment would facilitate greater access to medications.

CONCLUSION

Although there are promising medications available for the treatment of SUDs, these medications are not widely used in the US substance abuse treatment programs or in general medical care settings. In fact, less than 45% of specialty treatment programs prescribe any single medication for the treatment of SUDs. Strategies to improve adoption and implementation of SUD medications include changes in state policy and funding, increased access to physicians through partnering with local primary care physicians and other general medical care settings, increased clinician training in the use of SUD medications, increased dissemination of information about SUD medications to patients, and changes in insurance coverage of SUD medications.

Glossary

Acamprosate was FDA approved for the treatment of alcohol dependence in 2004. Acamprosate helps modulate and normalize alcohol-related changes in brain activity and reduces symptoms of post-acute withdrawal from alcohol dependence.

Buprenorphine is a Schedule III narcotic that was FDA approved for the treatment of opiate dependence in 2002. There are two buprenorphine products available for opiate treatment, Subutex and Suboxone. Buprenorphine is a partial mu-opioid agonist in contrast to methadone, which is a full mu-opioid agonist. Buprenorphine has a lower risk of abuse, addiction, and side effects compared to full agonists.

Disulfiram was FDA approved for the treatment of alcohol dependence in 1951. It is an alcohol-aversive medication that causes a severe physical reaction when mixed with alcohol.

Methadone is a Schedule II narcotic that has been used for the treatment of opiate dependence in the United States since the 1960s. Methadone is a full mu-opioid agonist that works by suppressing opioid withdrawal for 24 h or more.

Naltrexone there are two formulations of naltrexone FDA approved for the treatment of substance use disorders. The oral formulation of naltrexone was FDA approved for the treatment of opiate dependence in 1984 and alcohol dependence in 1994. The injectable formulation of naltrexone was FDA approved for alcohol dependence in 2006 and prevention of relapse to opiates in 2010. Naltrexone is a mu-opioid antagonist medication that blocks the effects of heroin and most other opiates. Naltrexone has been shown to reduce the rewarding effects of alcohol, reduce craving for alcohol, and decrease the likelihood of alcohol relapse.

Substance use disorders (SUDs) it refers to abuse or dependence of a substance (e.g. alcohol, heroin, prescription opiates, cocaine, marijuana) as defined by the *Diagnostic and Statistical Manual of Mental Disorder IV (DSM-IV)*.

INTRODUCTION

In many developed countries, policies that prohibit adults from using drugs like cannabis, cocaine, and heroin are criticized as ineffective and counter-productive. Critics of these policies argue that it would be a better policy to decriminalize or legalize the adult use of all currently illicit drugs. In this chapter, we consider these arguments with a primary focus on developed countries because these are the settings where such proposals are most often made and where drug use has been most extensively researched.

If we define a rational social policy as one that uses the most efficient means to pursue a society's goals, then there can be no unique rational drug policy unless there is societal agreement on what the goals of the policy should be. Such policy goals, however, depend upon deeper beliefs about the priority that should be given to competing ethical values such as individual freedom and the protection of human health and well-being. These turn on questions about what role, if any, the state should have in restricting adult behavior that primarily harms the

individual. There are major differences of opinion about these issues in most liberal democracies.

According to libertarians, adults should have the liberty to pursue their own choices so long as they do not harm anyone else. Harms arising from drug use that affect the user are solely the user's concern; harms that a user may cause to third parties (such as, car crashes if users drive while intoxicated) or social nuisances (e.g. being kept awake by noisy drunks) are matters for criminal and tort law, respectively. A rational drug policy for a libertarian would therefore be one that allowed any adult to use the drug if they wished. The only restrictions would be limiting this use to those over the age of adult autonomy (18 or 21) and banning use by adults in situations that put others at risk, for example driving a car while intoxicated.

Legal moralists, by contrast, believe that (at least some types of) drug use is inherently wrong, for example, because drugs are intoxicating or undermine autonomy, and argue that such wrongful behavior should be criminalized. For legal moralists, a rational drug policy would be one that prohibited the use of the drug and imposed

criminal sanctions on those who used it. Any societal costs in enforcing the law are irrelevant from this perspective because legal moralists would argue that laws against drug use, like laws against murder and theft, are morally right, and hence should not be evaluated by considering the costs incurred in enforcing them.

Many people reject both the libertarian and legal moralists' views. They are at least conditionally prepared to accept that the state may have the right to restrict adult choices if there is good evidence that these choices cause serious harm to individuals and society. Anyone who takes this implicitly utilitarian approach would want to know whether prohibiting drug use prevented these harms, and if so whether this outcome was achieved at an acceptable social and economic cost. This approach to policy formulation requires some form of social accounting that examines the costs and benefits of drug use and the enforcement of the prohibition on such use. There are two major problems in undertaking any such accounting: advocates of both liberalization and of a continuation of criminal penalties often have very different views on what these costs and benefits are; and disagree on how these costs and benefits should be weighed against each other.

ILLICIT DRUG USE AND PROBLEMS IN DEVELOPED COUNTRIES

Cannabis is the most commonly used illicit drug in most developed societies, such as Australia, Europe, and North America. The next most commonly used drugs are the so-called party drugs, MDMA and amphetamine-type stimulants (ATS). Cocaine and heroin and other opioids have the lowest rates of use among the illicit drugs.

Illicit drug use can adversely affect the health of those who use the drugs and the health and safety of nonusers. Heroin and other opioids are the illicit drugs that are least likely to be used, but they cause the most harm to users and to public health. They produce opioid dependence that can be difficult to overcome; premature deaths from drug overdoses; and increased rates of accidents, injuries, and suicides. They can also contribute to violence, blood-borne viruses (BBV) infection (HBV, HCV, HIV) leading to AIDS, hepatitis, chronic liver disease, and some cancers.

The ATS can also produce dependence which can be difficult to treat. When these drugs are used regularly in large doses they can cause heart disease and stroke, psychosis, severe depression, and violence. These drugs are often favored by criminal offenders because they fit well with life in the "night-time economy" by increasing wakefulness and energy, improving mood and self-confidence, and facilitating the use of violence.

Cannabis is a drug of dependence but its dependence risk is less than that of opioids and cocaine. In Australia in 2007–2008, cannabis was the principal drug problem in 22% of 154,000 drug treatment episodes and was a drug of concern in 44% of these episodes. It is a popular drug among disaffected young men who are at high risk of criminal careers: poor school performers, sexually precocious, and anti-socially oriented. Heavy cannabis use probably contributes to failures of social role in much the same way as alcohol does: increasing the likelihood of early school leaving; depression; poor mental health, including psychoses; poor employment performance, increased likelihood of welfare dependence, and unstable relationships; and poor life satisfaction in young adulthood.

DRUG CRIMES

Possession and use of most controlled substances is a crime by definition in all developed countries that are signatories to international drug control treaties. In many countries, cannabis use and possession has comprised the majority of drug offenses for several decades. The police do not specifically target cannabis offenses, so the high rate of these arrests reflects a number of factors. Firstly, there are many more users of cannabis than there are of other illicit drugs. Secondly, around half of all persons arrested for any offense are regular cannabis users. This makes cannabis possession an easy charge for police to lay when they lack evidence to support a more serious offense. Very few cannabis users end up serving prison sentences for possession and use, but police and judicial processing of such cases requires a substantial amount of scarce resources.

Property crime and drug dealing to finance use are probably most often engaged in by regular users of opioids and ATS. Heavy cannabis users may also engage in low-level dealing (buying in bulk to reduce their costs and selling the surplus to other users). These patterns are reflected in the prevalence of different types of illicit drug use among arrestees in Australia and other countries. They are also supported by studies showing that enrollment in methadone maintenance treatment (MMT) reduces crime among dependent opioid users and by evidence that property crime in New South Wales declined after the onset of a heroin shortage at the beginning of 2001.

DECRIMINALIZATION OPTIONS

In the remainder of the chapter, we focus on decriminalization policy options for cannabis and heroin. Cannabis is the drug for which decriminalization and

legalization have been most often advocated. This is for several understandable reasons. It is the most widely used illicit drug among young people. Cannabis users are not as involved in drug-related and property crime as are heavy users of opioids, cocaine, and ATS. Cannabis does produce adverse health effects in heavy users (such as dependence) and such use is associated with a variety of adverse health effects. Nonetheless, cannabis does not cause fatal overdose, as the opioids do, and its other adverse health effects are much less severe than those that can arise from the heavy use of stimulant drugs.

Heroin and other opioids present the largest public health and order problem arising from illicit drugs in many but not all developed countries. The decriminalization policies advocated for heroin are not as radical as those advocated for cannabis. They typically involve measures designed to encourage heroin-dependent people to reduce the risks of their drug use and engage with addiction treatment. These include decriminalization of personal possession and use and injecting equipment; decriminalization of opioid and other drug use in medically supervised injecting rooms; the medical prescription of oral opioids such as methadone and buprenorphine for therapeutic purposes; and the medical prescription of injectable heroin to treat refractory heroin-dependent persons.

HOW CAN WE TELL WHAT WORKS?

In evaluating drug policies, we can only randomly assign persons with illicit drug problems to one or more treatments and compare the effects of the different treatment on drug use and crime. Randomization (e.g. by a coin toss) ensures equivalence between the groups in relevant characteristics and thereby makes treatment the most plausible explanation of any differences observed in drug use and crime after treatment. This approach to evaluation can be used to assess the effectiveness of treatments for drug dependence (e.g. methadone and heroin maintenance treatment) and school-based drug prevention. Its use in the criminal justice system has been largely restricted to drug courts.

In the absence of randomized controlled trials, the next best type of evidence comes from quasi-experimental studies that attempt to simulate the characteristics of controlled experiments. These involve conducting statistical analyses of the effects of policy interventions on health or other outcomes over time (e.g. drug-related deaths or arrests); assessing the effects that “natural experiments,” such as the Australian heroin shortage, have on drug use and crime; and comparing the effects of different policies in different states of countries with a Federal system (e.g. Australia and the

United States); and much less certainly, comparing the effects of different policies in different countries.

A major problem in evaluating proposals to legalize currently illicit drugs is the lack of any experience with legal markets for these drugs in the past century. This is because international drug control treaties severely constrain the policy options that can be trialed in all countries that have signed them.

IS PROHIBITION A FAILURE?

A popular argument for decriminalization is that drug prohibition has failed, just as it is asserted alcohol prohibition failed in the United States in 1920–1932. Evidence cited in support includes the fact that during the 1990s cocaine and heroin prices fell while purity increased in the United States, despite steep increases in funding for law enforcement; and rates of illicit drug use rose among young adults in many developed countries during the 1990s, despite increased drug-related arrests in these countries over this period.

What outcomes should we reasonably expect from any drug policy, including prohibition? Some advocates of prohibition do set the implausible goal of a “drug-free society.” Indeed, the UN General Assembly resolved in 1998 to eliminate illicit opiate and cocaine production by 2008. When judged against its own goals, drug prohibition has failed.

But requiring the elimination of all drug use is arguably an unreasonably high standard against which all social policies would be adjudged failures. It is not a standard used to evaluate public health programs where we ask instead: Does the policy improve public health overall? Is this achieved at an acceptable social and economic cost? Are there other ways of achieving the same benefits at a smaller cost?

A similar approach to evaluating drug policy would ask: Does the criminalization of drug use reduce drug use and drug-related harm? If so, is this achieved at an acceptable social cost (in terms of the creation of a black market, violation of the law, police corruption, etc.)? Are there other ways of reducing drug related-harm while minimizing the adverse effects of criminalization?

DECRIMINALIZATION POLICIES FOR CANNABIS

Decriminalization of Possession and Use

Under this policy it remains illegal to produce or supply cannabis, but fines or other noncriminal penalties would be imposed on persons who possessed and/or used quantities of cannabis up to a specified

maximum. Persons possessing larger quantities of cannabis may face criminal charges. The main argument in favor of this policy is that it reduces some societal costs of cannabis prohibition while retaining most of its benefits. For example, since the mid-1980s, three Australian territories have legislated to replace criminal penalties for cannabis use with fines (referred to as expiation). South Australia adopted the Cannabis Expiation Notice (CEN) system in 1987. Under the CEN, possession of up to 100 g of cannabis was punished by a \$50–\$150 fine. If the fine was paid within 60 days, there were no criminal proceedings and no offense was recorded. Failure to pay the fine could lead to criminal proceedings and imprisonment.

Most evaluations of cannabis decriminalization have compared lifetime and past year cannabis use in household surveys in states or countries where criminal penalties have been retained and those in which they have been removed. These studies found that cannabis use increased during the 1990s at the same rate in South Australia and other states. More recently, rates of past year cannabis use decreased at the same rate in states that had decriminalized use as in states that retained criminal penalties. The Australian experience largely replicates analyses of survey data in the United States in the 1970s and 1980s. There is less data on the impact of similar policy experiments in Italy, Portugal, and England in the 1990s and 2000s, although rates of use do not appear to have increased after decriminalization in any of these countries.

These evaluations have a number of limitations. First, the small sample sizes in these surveys can rule out large increases in recent use, but it is more difficult to exclude the possibility that use is heavier or more persistent among existing users. More recent studies using large nationally representative samples and more sophisticated statistical models suggest that criminal penalties may discourage some people from using cannabis but they do not appear to influence the quantity that is used by those who do use.

Second, the differences in penalties imposed between jurisdictions that have nominally decriminalized and those who retained criminal penalties may be small. States that nominally retain criminal penalties rarely impose them and residents of states that have decriminalized cannabis are often unaware of the change in penalties. States also vary in the rigor with which they enforce these laws. Third, jurisdictions with different cannabis policies also differ in other ways that may affect rates of cannabis use.

Overall, even with these caveats, reducing penalties for cannabis use has had minimal impacts on rates of cannabis use. This is probably for two reasons: there is little difference in practice between states that do and do not enforce criminal penalties; and the risk of arrest

for cannabis use is so low (typically only 2% of persons who used cannabis in the past year) that the criminal penalties do little to deter use.

Decriminalization can have the unintended, counterproductive effect of increasing the number of cannabis users who are penalized by the police and appear in court. This happened, for example, after the cannabis infringement notice system was introduced in South Australia. There was more than a doubling in the number of people who were issued CEN notices between 1987/88 and 1993/94. Because only 45% of those charged paid their fines, decriminalization increased the numbers of cannabis users who received criminal sanctions because those who failed to pay fines ended up in court and could be gaoled for nonpayment of fines.

De Facto Legal Cannabis Markets

A legal cannabis market would legally allow the cultivation, production, distribution, wholesale and retail sale, promotion, and advertising of cannabis to adults. There are no legal cannabis markets anywhere in the world because UN treaties preclude them. A number of countries have nonetheless tolerated limited de facto retail cannabis markets.

In the Netherlands, since 1976 a policy of nonenforcement has made it de facto legal to possess and sell up to 30 g of cannabis while the country officially retains a prohibitionist policy against cannabis. Prosecutors and police refrained from enforcing the law when the quantity possessed or sold did not exceed 30 g and when sales occurred in licensed coffee shops. Over the next decade, a series of guidelines regulated the de facto retail cannabis market by preventing coffee shops from advertising, selling hard drugs, cannabis to minors, or more than the legally specified maximum quantity to each customer, or allowing public disturbances. In the 1990s, the Dutch government limited the number and location of coffee shops and in 1995 it reduced the amount of cannabis that could be sold to 5 g.

Policy analysts disagree about whether the coffee shop system affected cannabis use in the Netherlands. MacCoun and Reuter compared survey data on cannabis use in the Netherlands, the United States, Denmark, and Germany. They concluded that while removing criminal penalties for use had little effect on rates of use until 1992, increasing access to cannabis via coffee shops between 1992 and 1996 was followed by increased rates of cannabis use by young people. Their critics argued that trends in cannabis use in the Netherlands, other European countries, and the United States simply mirrored changes in youth culture in all these countries.

Why Not a Legal Cannabis Market?

The major problem with Dutch cannabis policy is the “back door problem,” namely that retail cannabis sales are legal in coffee shops but the supply of cannabis through the coffee shops’ back door remains illegal. The solution, according to critics of prohibition, is the legalization of the cultivation and sale of cannabis. There are a number of major social and political obstacles to doing so in developed countries that have signed the Single Convention on Narcotic Drugs.

First, the international drug control treaties prohibit the legalization of cannabis for nonmedical use. These treaties have strong support in the international community (most especially by the United States). Any country that legalized cannabis would have to renounce these international treaties and bear the strong international and public disapproval that would follow.

Second, a minority of the public support cannabis law reform even in the Netherlands. Support had declined during the early 2000s, probably because of strengthening evidence that cannabis use can harm some users. In many other developed countries, the cannabis policy debate has often been simplified to a choice between two policy options: (1) we should legalize cannabis, or at the very least decriminalize its use, because its use is harmless; or (2) we should continue to prohibit its use because it harms some users. Given this policy framing, evidence that cannabis use harms some users has seemingly strengthened the case for prohibition, as was evidenced by the decision of the UK government in 2009 to reinstate criminal penalties for cannabis use citing evidence that cannabis use caused psychosis.

Medical Marijuana in California

A different route to legalizing cannabis has been adopted in California. In 1996, a citizen-initiated referendum, Proposition 215, was passed by 44 to 56%. This allowed the medical use of marijuana for a set of indications that included not only nausea, weight loss, pain, and muscle spasm (for which there was some evidence of efficacy), but any serious medical condition that a doctor believed could be relieved by using cannabis.

Proposition 215 (and similar referenda later passed in other US states) created a number of problems. First, these State laws conflicted with US Federal law that banned the use and the sale or supply of cannabis for any purpose. Second, securing a legal supply of cannabis was solved in California by Cannabis Buyers’ Clubs that sold cannabis to patients who had a doctor’s prescription and sourced their cannabis from the illicit market. The US Supreme Court ruled in 2001 that persons who sold or supplied cannabis for medical use

were not protected from Federal criminal prosecution by State laws. The Bush administration attempted to enforce Federal laws, but the Obama administration decided not to do so in states that allowed the medical use of cannabis.

There have been no evaluations of Californian marijuana policy, but studies of medical marijuana patients in the San Francisco Bay area in 2001–2007 suggested that compassion clubs largely function as marijuana maintenance programs. Most (77%) of the patients were males with an average age of 32 years; 89% had used cannabis since the age 19; and 90% were daily smokers. The patients’ age and sex suggest that they are unlikely to have had cancer or neurological diseases. Indeed, one study reported that a substantial proportion of these users used cannabis as a substitute for alcohol and other illicit drugs.

In November 2010, a citizen-initiated referendum in California that proposed to legalize marijuana production for sale to any adult over the age of 21 years was narrowly defeated (46–54%). Advocates of the referendum argued that California would save up to \$1 billion from no longer having to enforce cannabis prohibition and that a \$50/oz tax would generate \$1.4 billion in revenue. There was a great deal of uncertainty about these claims because of a lack of detail on the regulatory regimes that would be adopted if production, distribution, and sale of marijuana were made legal, and the lack of any similar policy changes anywhere in the world from which to predict the effects on state revenue, law enforcement costs, marijuana use, and harms related to such use. Proponents of legalization have indicated that they intend to reintroduce the referendum proposal.

DECRIMINALIZATION POLICIES FOR HEROIN USE

Possession of Heroin and Injecting Equipment

Possession of small quantities of illegal drugs that are injected remains a criminal offense in most developed countries, but the possession of injecting equipment has been de facto decriminalized. While it is still technically a criminal offense, many governments distribute clean needles and syringes as a public health measure to prevent HIV and other BBV. The fact that possession remains a criminal offense allows the police discretion in enforcing the law; it may also deter injectors from disposing of used injection equipment in a socially irresponsible way. But politicians have often been unwilling to change these laws to reflect actual practice for fear of being seen to be soft on drugs.

Medically Supervised Injecting Rooms

Supervised injecting facilities (SIFs) are legally sanctioned places, usually located near illicit drug markets, in which injecting drug users can inject drugs under medical supervision. They have primarily been introduced to reduce injecting in public and discarded needles while reducing injecting drug users' exposure to BBV, treating drug overdoses, and engaging drug users in medical, drug treatment, and social welfare services.

Opponents of SIFs argue that they facilitate injecting drug use, attract drug users into the local area, and send the wrong signal about the social acceptability of injecting drug use. Rigorous evaluations of SIFs have not proven easy to do for a number of reasons.

Firstly, randomized controlled trials cannot be done. SIFs are usually established in areas where public injecting is a problem and they aim to attract as many injectors as possible. Injectors cannot therefore be randomly assigned to use an SIF or not.

Secondly, evaluations usually compare risk behavior, drug use, and drug-related harm in samples of injectors who do and do not use SIFs. The interpretation of these studies is complicated by pre-existing differences in risk behavior between injectors who do and do not use SIFs. Critics are unconvinced by reductions in self-reported risk behavior but it has proven difficult to use HIV or hepatitis C infections, fatal and nonfatal drug overdoses as indicators, because the rate of these events can be affected by many other factors.

Thirdly, the conditions under which governments have allowed SIFs make it unlikely that they will have a large impact on the harms caused by injecting drug use. Governments typically impose age limits on SIF clients, exclude intoxicated and pregnant injectors, and restrict the number of facilities (e.g. only one each in Sydney; Australia; and Vancouver, Canada). These restrictions limit the impact that SIFs can have on population-level drug-related harm. When multiple SIFs have been allowed, as in some German cities, overdose deaths appear to have been reduced at a community level.

Research suggests that SIFs can operate safely and to the benefit of the health and well-being of the socially marginalized injecting drug users that use them. They do not increase crime or public nuisance and they reduce the public visibility of injecting drug use, the most probable reason for public tolerance of SIFs in Europe.

Opioid Substitution Treatment

Opioid substitution treatment (OST) involves substituting a long-acting, usually orally administered, opioid for the shorter-acting injected heroin. MMT is the most common form of opioid substitution worldwide. When taken daily in high doses, methadone

blocks the effects of heroin, allowing individuals to take advantage of rehabilitative services. Its effectiveness is supported by randomized controlled trials and observational studies that show it decreases heroin use, criminal activity, and HIV transmission while users remain in treatment.

Buprenorphine is a mixed agonist-antagonist that has similar effects to those of morphine and blocks the euphoric effects of heroin. When given in high doses, its effects can last for up to 3 days enabling dosing every 2–3 days (rather than daily with methadone). It is marginally less effective in retaining patients in treatment than methadone but approximately equivalent in reducing heroin use. Because of its antagonist effects, buprenorphine has a substantially lower risk of overdose and it is easier to withdraw from than methadone.

Heroin maintenance treatment (HMT) maintains dependent heroin users on daily injectable heroin. The safety and effectiveness of HMT in treatment refractory patients have been evaluated in a series of randomized controlled trials in Switzerland, the Netherlands, Spain, Germany, Canada, and the UK. It has been shown to be more effective than MMT in reducing illicit heroin use and crime in these patients. The participants in these trials were more criminally involved than standard MMT patients and they had to have failed at MMT to enter HMT. These were also well-staffed programs that probably provide optimistic estimates of the effectiveness of HMT in routine clinical practice. HMT is much more expensive than MMT because of the need to supervise the more frequent injection of heroin. It is only more cost effective than MMT if its effects on crime are included. This makes HMT harder to sell politically because critics can argue that it rewards the most criminally involved heroin users by giving them their drug of choice. The higher costs of providing HMT mean that it will remain a second-line treatment of modest scale and with limited demand, as indicated by the difficulty in attracting patients into clinical trials. Its impact on public health and drug-related crimes is therefore likely to be modest.

CONCLUSIONS

Options for decriminalizing currently illicit drugs are severely limited by international drug treaties which prohibit legal markets in these drugs for all except medical and research purposes. Public opinion in most developed countries strongly supports this policy.

In most developed countries, marginal changes in penalties for personal possession and use of cannabis have been the most radical policy changes that public opinion has allowed. These changes do not appear to have had any large effects on rates of cannabis use. The Netherlands is one country that has de facto

legalized small-scale retail cannabis sales. The US State of California has liberalized access to cannabis by allowing its use for medical uses very broadly defined.

In the case of heroin, publicly funded needle and syringe programs have de facto decriminalized the possession of needles and syringes in many countries. Many developed countries have expanded access to oral methadone and buprenorphine substitution treatment for opioid-dependent persons. In a small number of countries, injectable heroin maintenance has been offered as a second-line treatment for patients who have failed at other forms of OST. Given the modest scale of use, the impact of HMT on heroin use as a public health and order problem is likely to be modest.

SIF	supervised injecting facilities

Glossary

Amphetamine-type stimulants are drugs that produce effects that are similar to those of amphetamines, namely activating the sympathetic nervous system, increasing wakefulness, lifting mood, and increasing endurance. These include dexamphetamine, methamphetamine, methylphenidate, and MDMA.

Cannabis includes any drug derived from the *Cannabis sativa* plant that contains tetrahydrocannabinol, such as marijuana (flowering leaves and heads) and hashish (resin from the flowering tops of the plant).

Cocaine is a drug with stimulant properties that is derived from the coca plant grown widely throughout South America. It can be used orally or intranasally, smoked, or injected.

Decriminalization is an umbrella term for policies that remove criminal penalties for (1) personal possession and use, (2) drugs used under medical supervision, and (3) drugs manufactured for personal use.

Drug-related crimes include the simple possession and use of illicit drugs and the importation, manufacture, and distribution of these drugs. Drug-related crimes also include property crimes (such as shop-lifting and house-breaking) and drug dealing engaged in to finance personal drug use; and violent crimes committed to resolve disputes between participants in illegal drug markets to fund drug use.

Heroin is an illicit opioid drug derived from the opium poppy. It has limited medical use in a small number of countries and is primarily used illicitly, often by injection.

Illicit drugs are drugs whose use by adults is prohibited for all except medical and scientific purposes under international drug control treaties, such as the UN Single Convention of 1961. They include cannabis; heroin and other opioids; amphetamine-type stimulants (such as methamphetamines); cocaine; “party drugs” (such as MDMA, ketamine, etc.); and benzodiazepines.

Legalization is more often used to describe policies that would make it legal to manufacture, distribute, and sell any of the currently illicit drugs, and thereby allow these drugs to be sold in regulated legal markets like those for tobacco and alcohol.

Legal moralists believe that at least some types of drug use are morally wrong (e.g. because they are intoxicating or undermine autonomy) and argue that morally wrong behavior should be criminalized.

Libertarians adopt a moral and political philosophy which argues that the only permissible reason for restricting adults’ rights to use drugs is if that drug use harms others. They advocate for removing laws that prohibit adults from using drugs because they may harm themselves.

Net widening is an unintended effect of decriminalizing drug use that results in more users being prosecuted and appearing before the courts than occurs when drug use remains illegal.

Opioid substitution treatment involves substituting a long-acting, usually orally administered, opioid as a therapeutic substitute for the shorter-acting, injected heroin. The substitute drug (most often methadone or buprenorphine) is taken in doses that block or reduce the effects of heroin and allow individuals to take advantage of rehabilitative services.

Single Convention on Narcotic Drugs, 1961 is a United Nations treaty that commits states who sign it to criminalizing the use of cannabis, cocaine, and heroin for all but medical or scientific purposes.

Supervised injecting facilities (SIFs) are legally sanctioned places, usually near illicit drug markets, in which drug users can inject drugs under medical supervision. These aim to reduce injecting in public and reduce injecting drug users’ exposure to blood-borne viruses (BBV), treat drug overdoses, and engage drug users in medical, drug treatment, and social welfare services.

Utilitarians support a moral theory that the major aim of public policy and ethics should be to select policies that maximize the good (e.g. the happiness) and minimize the costs of all those affected by them. In its simplest form, the aim is to ensure the greatest happiness for the greatest number.

THE IMPACT OF DRINK DRIVING LAWS

The purpose of this chapter is to provide an overview of the role of alcohol in road traffic crashes and to review the historical and current state of practice for addressing alcohol-impaired driving behavior. The evidence regarding the effectiveness of various approaches to the prevention of alcohol-impaired driving and the management of offenders is critically evaluated. Specifically, this chapter discusses the evidence in relation to the three primary components of traffic law enforcement, legislation, policing, and sanctions, with specific reference to the problem of alcohol-impaired driving. The chapter concludes by providing evidence-based best practice principles for preventing and reducing impaired driving behavior and recommendations for future research.

While a variety of terms are used around the world to describe alcohol-impaired driving, the term “drink driving” is preferred for use throughout this chapter rather than “drunk driving.” This acknowledges that

a driver’s crash risk can be significantly increased even at low levels of impairment.

THE ROLE OF ALCOHOL IN ROAD TRAFFIC CRASHES

Road traffic crashes are a major public health problem and a leading cause of death and injury around the world. According to the World Health Organization (WHO), nearly 1.2 million people die in road traffic crashes each year, with millions more injured or disabled. Most of these deaths and injuries occur in low- and middle-income countries. As well as creating enormous social costs for individuals, families, and communities, traffic crashes represent a significant burden on health services and economies. Indeed, WHO estimates that traffic crashes cost countries approximately 1–2% of their gross national product. As motorization increases, so too do road traffic crashes, particularly in developing countries.

Evaluations indicate that a range of road safety countermeasures have proven successful in reducing road trauma. For example, the use of seatbelts, helmets, and child restraints has saved thousands of lives by reducing the severity of injuries. Moreover, safe road infrastructure, the enforcement of blood alcohol concentration (BAC) limits, and the management of vehicle speeds and improvements in vehicle safety have also been shown to be effective in reducing both the incidence and severity of road traffic injuries.

Alcohol and Crash Risk

Alcohol represents a risk factor in two ways. Firstly, it increases the risk of crash involvement by impairing driver performance. Secondly, alcohol is commonly associated with other high-risk road user behaviors that may also increase crash risk and/or the severity of injury in the event of a crash. Research has consistently shown that the consumption of alcohol, even in small amounts, increases the risk of being involved in a crash for motorists and pedestrians. For example, a survey of studies conducted in low- and middle-income countries found that alcohol was present in the blood between 4 and 69% of injured drivers, 18–90% of injured pedestrians, and 10–28% of injured motorcyclists. In high-income countries throughout the world, as many as half of all fatally injured drivers have been reported to have excess alcohol in their blood (e.g. BAC in excess of the legally prescribed limit).

Alcohol impairment increases the likelihood of a crash given that it causes poor judgment, increased reaction time, lower vigilance, and decreased visual acuity. Alcohol-related impairments in judgment can increase crash risk even at relatively low BAC levels; however, the effects become progressively worse as the BAC increases. Indeed, case-control studies suggest that a driver is twice as likely to be involved in a crash when driving with a BAC of 0.05 g per 100 ml, and that crash risk increases dramatically with a BAC beyond 0.05. For example, it is estimated that the risk of crashing is 25 times higher for a driver with a BAC of 0.150 g per 100 ml, compared to a driver who has not consumed any alcohol.

There are a number of common characteristics of alcohol-related crashes. For example, alcohol-related crashes are more likely to occur during high alcohol consumption times, such as at night, on weekends, or other periods of high leisure activity. Alcohol-related crashes also often involve single vehicle crashes (e.g. driver loses control of vehicle and collides with a fixed roadside object) and/or excessive speeds. Finally, alcohol-related crashes tend to be associated with increased severity of injury, partly as a function of the

impact of alcohol on the human body, which can interfere with recovery, as well as the co-occurrence of other high-risk behaviors, as discussed below.

Alcohol and Other High-Risk Road User Behaviors

In addition to directly increasing the likelihood of crash involvement, alcohol consumption also has a negative impact on other aspects of driver safety (such as seat belt wearing, helmet use, and speed choice), which have the potential to increase the risk and severity of crashes. Furthermore, the consumption of alcohol, due partly to its tendency to reduce inhibition, is sometimes associated with the use of other drugs, which can also impact upon driving performance.

Factors Associated with Drink Driving

While the profile of drink drivers differs somewhat between regions of the world, there are a number of factors that have consistently emerged as being associated with increased involvement in alcohol-related crashes. Specifically, research has found that drink-driving offenders are more likely to be male, younger (e.g. under 30 or 35), single, from low socio-economic backgrounds and have low self-esteem. In addition, drink driving offenders are more likely to have engaged in drink driving in the past, have prior criminal offenses, and also engage in other high risk-driving behaviors including speeding and seat belt offenses. Research has also shown that other high-risk groups, such as unlicensed drivers, are more likely to drink and drive.

TRAFFIC LAW ENFORCEMENT

Given the aforementioned association between alcohol consumption and increased risk of traffic crash involvement and severity of injuries sustained, there is a fundamental need to develop and implement effective countermeasures to reduce and prevent drink driving. Arguably, traffic law enforcement approaches represent the most commonly used countermeasures in many countries. Traffic law enforcement consists of three components:

1. Traffic rules, regulations, and laws;
2. Policing practices; and
3. Penalties and sanctions.

Countries with more specific drink driving laws and accompanying traffic law enforcement have observed a decreasing trend in alcohol-related crashes, and such reductions are commonly attributed

to the effectiveness of interventions at all three levels. Moreover, the effectiveness of such approaches is found to be optimized when preceded and/or complemented by public education and awareness campaigns.

The remainder of this chapter will examine the different types of drink driving laws in use internationally and the functions of these laws from a preventative perspective. In addition, this chapter addresses drink driving laws and enforcement from a deterrence theory perspective, given that this doctrine has guided the development and implementation of drink driving policies and practices in many countries.

Briefly, deterrence theory proposes that the ability for enforcement practices to deter drink driving, or any proscribed behavior for that matter, is a function of the perceived risk of detection, as well as the perceived certainty, severity, and swiftness of punishment. Deterrence is argued to be achieved via two processes. Firstly, through the process of general deterrence, the motoring public is discouraged from offending through practices and policies aimed at increasing the perceived risk of detection and punishment. Secondly, specific deterrence refers to the process whereby actual offenders are deterred from re-offending through experiences of the consequences of detection and punishment.

The classical approach to deterrence theory has more recently been expanded to include the concepts of punishment avoidance (e.g. the absence of punishment in association with offending) and vicarious learning (e.g. experiences of punishment and punishment avoidance among significant others). Indeed, it has been argued that punishment avoidance experiences often do more to reinforce behavior than experiences of punishment do to discourage behavior. This is particularly the case for behaviors like drink driving, where the chances of detection remain relatively low despite improvements in policing practices.

General Prevention/Deterrence of Drink Driving

A number of traffic law enforcement and related public education countermeasures designed to prevent or deter the general driving population from drink driving are in use internationally. Such approaches include

- prescribed alcohol limits;
- per se legislation (also known as the Scandinavian model);
- policing provisions, such as RBT and sobriety checkpoints; and
- public education campaigns.

The prescribed alcohol limit in grams per 100 ml of blood, known as BAC, differs between and within jurisdictions. A number of countries, including Sweden and Norway, have adopted a 0 or 0.02 BAC limit for all drivers, which effectively allows no alcohol to be consumed prior to driving. Conversely, other countries have limits ranging from 0.03 to as high as 0.15. Moreover, in many countries, particular high-risk groups of drivers have lower prescribed alcohol limits. For example, in the various Australian jurisdictions, the prescribed alcohol limit for general drivers is 0.05, but a limit of 0.02 or 0 exists for novice and professional drivers. Many jurisdictions use the BAC reading of the driver, when detected, to impose different levels of sanctions, with more severe penalties applied for high alcohol readings, and/or repeat drink driving offenses.

Evaluations have confirmed the road safety benefits associated with lower proscribed alcohol limits, particularly lowering limits to 0.05 for all drivers and to 0 for young drivers. While there is also recent evidence suggesting that reducing such levels below 0.05 for all drivers can produce further benefits, the extent to which these can be attributed to the BAC limit alone, rather than to other associated enforcement and media activity, is not yet conclusive.

Per se legislation means that a driver can be charged with drink driving on the basis of the alcohol reading alone, and that evidence of impaired driving is not required. This type of legislation has benefits for law enforcement, in that the decision about whether a drink driving offense has occurred is objective, making the detection and punishment process more straightforward.

Traffic policing methods that have been used to effectively modify drink driving behavior include random alcohol screening and targeted enforcement based on intelligence. Random alcohol screening predominately serves a general deterrent function, while targeted enforcement serves to facilitate prosecution of drivers who refuse to stop drinking and driving. To maximize effectiveness, a mix of both randomized and targeted enforcement activities should be utilized, such that enforcement activities are unpredictable.

Some countries, such as Australia, allow for random alcohol screening (e.g. RBT) of any driver at any time. For example, Australian jurisdictions use “booze buses” to stop drivers and conduct roadside and evidentiary alcohol screening tests (see Figs 71.1 and 71.2). Other countries, such as the United States, require “probable cause” before a driver can be screened for alcohol consumption, referred to as selective breath testing.

Based on the available evidence, drink driving enforcement operations are most effective when conducted in a random, highly visible and unavoidable

FIGURE 71.1 Random breath testing operations conducted in Australia at night. *Image courtesy of Queensland Police Service.*

FIGURE 71.2 Random breath testing operations conducted in Australia during the day. *Image courtesy of Queensland Police Service.*

manner, sustained over a period of time and are well-publicized. Indeed, visible and frequent enforcement is critical to deterring the general public from drink driving and not simply catch those who break the laws.

Combining enforcement activities with public education has been found to increase the general deterrent impact of drink driving enforcement programs and serve a number of additional functions. Such campaigns are useful both prior to and following the implementation of drink driving laws and associated enforcement programs. Public education can facilitate awareness about drink driving as a road safety issue, inform the

motoring public regarding increases in enforcement intensity or the severity of sanctions (and in turn increase the perceived likelihood of detection), and highlight the personal risks associated with alcohol-impaired driving. These factors can subsequently facilitate greater community acceptance of enforcement efforts.

Managing Drink Driving Offenders

A variety of legal sanctions are applied to drink drivers throughout the world, in order to control and

reduce their offending behavior. Major differences exist in the way these sanctions are administered, depending on whether the primary objective is to punish, restrain, or reform offenders. Nevertheless, the more common sanctions tend to fall into one of the following categories:

- Monetary fines;
- License actions (e.g. demerit point schemes, license suspension/disqualification, restricted licenses);
- Remedial programs (e.g. assessment, treatment, or rehabilitation);
- Vehicle sanctions (e.g. alcohol ignition interlocks, vehicle impoundment/immobilization); and
- Confinement (e.g. jail, home detention, community service orders).

These sanctions have a number of functions including retribution, incapacitation or constraint, reform (e.g. rehabilitation, specific deterrence), and general deterrence. The first function, retribution, refers to balancing the crime committed by an offender with a commensurate punishment. The retributive effectiveness of drink driving sanctions is often difficult to quantify given that it requires an estimate of the culpability of offenders. In addition, given that many drink driving episodes do not result in a crash (and hence any harm to the community), it has been argued that sanctions should be designed to match the *potential harm, or objective probability, of drink driving.*

A second function of drink driving sanctions relates to their capacity to constrain or incapacitate offenders from committing further offenses, such as license and/or vehicle sanctions. A more extreme form of incapacitation involves confinement in jail or some form of supervised detention. In effect, opportunities for re-offending during the term of the sentence are removed, thus acting as an exposure-control measure.

A third function of criminal sanctions is to reform offenders, in order to reduce the rate of re-offending. Reform can operate through two processes: rehabilitation and specific deterrence. The goal of rehabilitation is to resolve the underlying medical or psychosocial factors contributing to criminal behavior. In the case of drink driving, this may involve treatment for alcohol misuse or dependence. In contrast, the goal of specific deterrence is to deter offenders from re-offending due to the fear of further punishment. In the latter case, it is the threat of punishment that motivates behavior change.

Finally, drink driving sanctions can perform a general deterrent function, such that behavior is influenced through the *threat* of punishment rather than via direct experience. As such, general deterrence effects can influence the behavior of the community in general, not just those who are caught and punished.

Impact of Drink Driving Penalties and Sanctions on Drink Driving Behavior

This section will focus on the impact of specific penalties and sanctions for drink driving on preventing or reducing subsequent impaired driving among drink driving offenders. In addition, attention will be given to whether the penalties have any impact on the general driving population.

License Actions

License actions include a range of restrictions that deprive offenders from the use of their driver's license. In many countries, the primary license actions are suspension and disqualification (or revocation). Although these terms tend to be used interchangeably, suspension generally refers to situations where licenses are reinstated automatically after the period of suspension, while disqualification refers to situations where a driver must reapply at the end of the period to have it reinstated. License actions vary in the degree to which they restrict driving. While license suspension or disqualification typically prohibits offenders from using their license under all circumstances, restricted licenses can also be applied, which permit driving for specific purposes, such as for employment or treatment.

Another major difference relates to whether license actions are administered judicially or administratively. Traditionally, license suspension has been applied through judicial processes in most countries, with suspension contingent upon conviction and subject to criminal standards of proof and plea bargaining. Over the last three decades, however, there has been a substantial growth in the use of administrative license suspension, particularly in North America. This process requires less stringent standards of proof, often involves mandatory license disqualification periods, and operates from the time a drink driver is arrested, thus increasing the swiftness and certainty of the sanction. As this process tends to be less costly, administrative suspension appears to improve the overall cost-effectiveness of license loss. In addition, immediate license suspension is increasingly being utilized as a sanction for high-range offenders; however, some have raised concerns about the loss of deterrence associated with non-attendance at court.

For some time, the evidence has indicated that license suspension is a very effective countermeasure, compared with other sanctions commonly applied to drink drivers. In North America, the most compelling evidence has emerged from the use of administrative license suspension laws. Evaluations have suggested that these laws can act as a general deterrent by contributing to a reduction in the level of alcohol-related crashes in the community. This is illustrated by the fact

that license actions reduce non-alcohol-related offenses and crashes among offenders, as well as alcohol-specific incidents. In other words, license actions are effective exposure-control measures that produce road safety benefits well beyond their impact on drink driving. Although the evidence suggests that these effects can persist well after the end of the suspension period, this may, in part, be due to offenders choosing not to become relicensed.

Australian experience indicates that court imposed license disqualification can also be an effective sanction for drink driving offenders. Research conducted in the 1990s examined the records of over 25 000 disqualified drink drivers and found that crash and offense rates during the disqualification period were about one third of the rates incurred during legal driving. More recent research has suggested that offenses during periods of disqualification are suppressed by up to 15% of the level incurred during periods of legal driving among the same offenders. However, evidence relating to the optimum length of license disqualification is inconclusive suggesting that further research is required to identify the most efficacious approach.

In terms of the retributive effect of license actions, there are concerns regarding the impact on an offender's capacity to earn a living. A British study found that while most disqualified drivers considered the sanction justified, some reported that they had lost their job as a direct consequence of the disqualification. However, research in the United States suggests that only a small minority of suspended drivers experience employment or income losses. Some researchers have compared the impact of administrative license suspension on the employment levels of drink driving offenders with the impact of alcohol-related crashes on the employment of "innocent" people involved in these crashes. They found that while there was no pronounced impact on the jobs or incomes of offenders, a substantial effect was experienced by the seriously injured victims. They argued that this justified the continued use of administrative license loss.

The administration of restricted licenses to offenders who can demonstrate that they and/or their family would experience significant hardship associated with the loss of their license is a common approach adopted in some jurisdictions to overcome such problems. However, such practices have been criticized, such that providing restricted licenses for employment purposes only is argued to be discriminatory and fails to acknowledge the importance of educational and domestic functions. In addition, it has been argued that the widespread use of restricted licenses may undermine both specific deterrence (by failing to break an offender's reliance on driving) and general deterrence (by reducing the perceived certainty of license loss).

Interestingly, an Australian study reported no statistical differences between the recidivism rates of drink driving offenders granted restricted licenses with those receiving full license disqualifications, at least during the term of the sanction. However, it was noted that magistrates are typically selective about granting restricted licenses, tending to favor older drivers with better driving records. Therefore, the results do not necessarily countenance the wider use of restricted licenses, since they may not be as effective with more recalcitrant offenders. Moreover, the authors noted that further research was required to determine whether restricted licenses undermine the general deterrent effect of license loss for drink driving.

From another perspective, the effectiveness of license loss may be undermined if offenders continue to drive during the suspension/disqualification period. In effect, these offenders are not experiencing the full impact of their punishment. In this regard, the level of illegal driving by suspended/disqualified drivers has been reported to be relatively high in most jurisdictions. Surveys in the United Kingdom, United States, and Australia have found self-reported levels of disqualified/suspended driving ranging from 25% to almost 70%, and the self-report nature of these studies suggests that these findings may represent underestimates of the extent of the problem. In addition, there is evidence that disqualified drivers who continue to drive have up to three to four times the crash risk of licensed drivers, confirming that they are a high-risk group.

It is likely that many offenders who choose not to re-obtain a license after the expiry of their disqualification/revocation period continue to drive unlicensed. This practice further undermines the integrity of the licensing system by reducing the impact of other sanctions, which manages the driver's behavior, such as demerit points. Therefore, in terms of incapacitation, while license loss is an effective measure it is far from perfect. Indeed, from a compliance standpoint, license disqualification/suspension is a relatively inefficient measure. The likely outcome of this low compliance is that the full impact of the suspension is compromised and the long-term effectiveness of the system potentially eroded.

In addition to targeting offenders, license actions are also intended to perform a general deterrent function. A number of North American studies have suggested that license suspension can act as a general deterrent by reducing the overall rate of crashes likely to involve alcohol. However, some qualifications need to be placed on these studies. Firstly, they almost exclusively relate to the use of administrative license suspension, and it has been suggested that the success of administrative suspension is linked to the greater certainty and swiftness delivered by this process, compared with judicially imposed license suspension. Secondly, in many cases the

studies evaluated the impact of a package of drink driving countermeasures, often featuring a range of sanctions implemented in conjunction with administrative license suspension, creating difficulties in quantifying the specific effect of license actions. Nonetheless, it is worth noting that community surveys in the United States generally indicate that license suspension is the most well-understood and feared drink driving sanction.

Remedial Programs

Unlike most other drink driving sanctions, remedial programs are not generally designed to be retributive or to incapacitate offenders. Rather, they are intended to reform offenders and thereby reduce the likelihood of further drink driving incidents. Despite this common objective, major differences exist in the focus, content, and delivery of remedial programs. At the broadest level, remedial programs fall into two categories: assessment and rehabilitation.

Assessment programs are generally designed to screen and identify drink driving offenders with a high risk of re-offending. These programs use a variety of biological, medical, and psychosocial criteria and can be used to assess whether an offender is suitable to be relicensed or to direct them to appropriate rehabilitation. However, there has been considerable debate about the validity of certain assessment criteria, particularly the use of an offender's BAC.

Similarly, rehabilitation programs also vary in their content and format, ranging from short educational courses through to therapeutic interventions involving medical treatment, psychotherapy, counseling, or a combination of these modalities. In addition, there is substantial variation in the manner in which remedial programs are delivered, ranging from mandatory programs, whereby relicensing is contingent upon completion through to programs where attendance is voluntary or at the discretion of the court. Remedial programs are most commonly used to complement other sanctions, particularly license actions, and may be reinforced by probation.

Traditionally, there have been difficulties in establishing the effectiveness of drink driving remedial programs. During the 1980s, research tended to suggest that the effectiveness of remedial programs was at worst negligible and best limited to reducing subsequent drink driving offenses rather than crashes. Indeed, researchers concluded that the behavioral impact of education and treatment programs are typically small, inconsistent, and limited to first offenders and/or persons diagnosed as non-problem drinkers.

However, from the early 1990s more optimistic findings began to emerge regarding the impact of assessment and rehabilitation programs on drink driving

recidivism in both the United States and Europe. The evidence suggested that remedial programs added to the effectiveness of license actions in reducing alcohol-specific offenses and crashes, compared to when license sanctions were used in isolation. These results suggest that license actions are primarily an exposure-control measure, while remedial programs are more sensitive to the factors contributing to drink driving recidivism.

Perhaps the most compelling evidence in favor of remedial programs was obtained from a meta-analysis of 215 independent programs. This study confirmed an average reduction of 7–9% in drink driving offenses and alcohol-related crashes. The review suggested that multifaceted programs were most effective, particularly those involving education, psychotherapy, counseling, and follow-up contact or probation. It was noted that treatment effects have traditionally been underestimated due to the strong emphasis placed on educational interventions for dealing with all offenders. These findings are consistent with other evidence that problem drink drivers are not a homogenous group and that many remedial programs had traditionally adopted too narrow a focus. While the meta-analysis confirmed the potential effectiveness of rehabilitation, research since this time has focused on identifying the optimum types of approaches with different offenders and in different contexts.

Vehicle Sanctions: Alcohol Ignition Interlocks

Since the late 1980s, a number of jurisdictions in the United States and Canada have implemented alcohol ignition interlock programs for drink driving offenders, while a number of other countries have also introduced such programs in recent years, including Sweden and Australia. Essentially, interlock devices are connected to vehicle ignitions and prevent the vehicle from being started until a breath test has been passed (e.g. at a preset BAC level). Interlocks are administered either judicially or administratively and are generally a condition of license renewal. While research has suggested that the take-up rate for alcohol ignition interlocks is very low unless mandatory, interlocks have been strongly supported in many jurisdictions throughout the world.

Evaluations have produced promising results, suggesting that interlock programs can produce large reductions in drink driving recidivism over and above more traditional approaches. Indeed, evaluations involving electronic data loggers suggest that the devices are an effective tool to prevent alcohol-impaired drivers from operating their vehicles. However, the literature has indicated that recidivism rates typically revert to levels consistent with control group offenders upon removal of the devices. Far fewer studies have evaluated the effectiveness of interlock devices to produce crash reductions. From the limited available evidence, it

appears that there is some potential for the devices to reduce alcohol-related crash involvement while interlocks are fitted to vehicles.

The finding that the impact of interlock devices on recidivism rates is contingent upon ongoing installation of the devices suggests that interlock programs must be implemented as part of a broader approach to reduce alcohol abuse and dependency problems. That is, the device, used in isolation of other approaches, is unlikely to produce long-term behavioral impacts. However, more sustained impacts on recidivism may be achieved when interlock programs require appropriate levels of monitoring (e.g. data logging) and reporting to properly evaluate an offender's readiness to receive full license reinstatement. In addition, there appears to be a need for authorities and courts to apply criterion-based, rather than time-based, principles regarding the removal of the device. Such criteria could include data obtained from the interlocks and objective behavioral assessments of the relative risk of offenders.

While typically utilized for the purposes of secondary prevention, interlock programs can also serve a primary prevention function through implementation in fleet vehicles (e.g. trucks, taxis, and commercial fleets). Such interventions would be the most effective in industries where there are notable problems associated with impaired driving. There have also been propositions in a number of countries to move toward mandated fitting of interlock devices in all new vehicles. Such suggestions represent a long-term proactive countermeasure to impaired driving; however, they have received opposition from vehicle manufacturers and civil rights groups.

Criticisms of interlock programs have typically focused on the potential inconvenience the devices pose for offenders and their families. To some degree, these concerns have been mitigated by the tendency for jurisdictions to utilize interlocks only with high-range and/or repeat drink driving offenders. While anecdotal evidence suggests many offenders may originally resent the imposition of the devices, high levels of acceptance are later reported largely as a function of the educational and motivational effect the device provides as an extra incentive to refrain from drinking.

Another criticism relates to the tendency for evaluations to involve only motivated offenders involved in volunteer programs, whereby installation of an interlock device is associated with a reduction in license suspension or other penalties. Further research is required to explore the effects of alcohol ignition interlocks on these more motivated offenders compared with court-ordered offenders.

Early literature criticized the efficacy of interlock programs based on the potentiality for the offenders to circumvent or tamper with the device, thereby reducing their incapacitation effect. However, research has

suggested that such practices do not appear to be widespread. In addition, in recent years, ongoing development has made interlock devices increasingly robust to circumvention and tampering. Specifically, many devices can detect breath signatures, require a learned breath delivery technique (e.g. hum-blow), require additional "rolling-retests" after the initial sample, include data logs and are regularly inspected and calibrated. Creating an offense category related to attempted or successful circumvention of the devices may also reduce such actions further.

Finally, it is often not feasible to install an interlock device on every vehicle used by an offender. As such, additional license sanctions should be utilized that clearly identify the interlock provisions for driving on an offender's license, as well as approaches that address alcohol abuse and dependence.

Vehicle Sanctions: Vehicle Impoundment and Forfeiture Programs

Vehicle impoundment programs give police and/or other authorities the power to seize and impound vehicles for specific periods of time for engaging in any number of offenses including high-range or repeat drink driving offenses. The specific period of impoundment typically increases as a function of the severity of offenses or the recidivist nature of offending, with forfeiture generally reserved for only the most persistent offenders. Impoundment programs are typically implemented to complement more traditional license actions.

Evidence has suggested that vehicle impoundment programs can produce substantial reductions in drink driving recidivism, as well as reductions in other traffic offenses, particularly unlicensed driving. Such impacts are largely attributed to the specific deterrent effect associated with hardship experienced by individuals close to the offender. Indeed, the potential impact on innocent third parties (e.g. spouses, children, family members, friends, work colleagues), who may also use the sanctioned vehicle, has been cited as a major criticism of vehicle impoundment and forfeiture. Thus, further research is required to determine whether such sanctions are overly punitive in their effect on non-offenders and identify provisions in legislation to mitigate such effects.

Long-term effects of vehicle impoundment have also been evidenced, albeit to a lesser extent when compared to the period of impoundment, suggesting some level of habituation among offenders to not having their vehicle. However, it is unclear whether the cost and inconvenience of the sanction motivates the offender to avoid being detected again (e.g. specific deterrence) or if access to sanctioned vehicles is restricted/denied in instances where an offense resulted in the impoundment of an employer's or spouse's vehicle (e.g. incapacitation).

While there is evidence of the specific deterrent effects associated with vehicle impoundment and forfeiture, there appears to be limited evidence to suggest such vehicle sanctions have a broader general deterrent impact on either offense rates or traffic crashes.

A question that naturally arises is whether or not progression to vehicle forfeiture has an incremental effect beyond impoundment. While the available evaluative literature is limited, there is evidence to suggest positive impacts of vehicle forfeiture on alcohol-related traffic crashes and offending. However, this research has typically only assessed the short-term impact of such sanctions and further research is required to identify the long-term effectiveness of vehicle forfeiture programs. In addition, future evaluations should aim to disentangle the unique and combined general and specific deterrent effects of vehicle-based sanctions and concurrent interventions and sanctions, such as administrative license suspension.

Other Vehicle Sanctions

A number of other vehicle-based sanctions have been implemented or trialled as a countermeasure to unlicensed driving including license plate tagging, license plate impoundment or confiscation, and electronic licenses. While these measures are designed to reduce unlicensed driving in general, they are of particular relevance to drink driving. Firstly, drivers with a history of unlicensed driving have also often been detected for drink driving. Secondly, these sanctions offer the potential to strengthen the effectiveness of license actions imposed for drink driving offenses and further deter the general public from drinking and driving.

A number of studies have provided evidence of the potential effectiveness associated with license plate tagging and impoundment laws. These findings are likely to be a product of specific deterrence, such that offenders are discouraged from driving due to their higher visibility and the ease in which police can identify them as suspended drivers. However, the evidence is typically less compelling than that regarding vehicle impoundment, arguably a function of the relatively low administration of such sanctions, the general lack of publicity given to such laws, and the concurrence of vehicle impoundment laws.

DRINK DRIVING LAWS IN AUSTRALIA: A CASE STUDY

Australia embarked on a sustained program to reduce alcohol-related crashes from the mid-1970s onward. As a result of increasing community concerns about the impairment effects of alcohol, support was obtained for legislation setting a maximum BAC level

for drivers. Given that traffic laws in Australia are enforced at a provincial level by state police services, operating under the federal system of government, the legal BAC level adopted was not initially uniform across all states. Over time, legal limits were reduced, again in a nonuniform manner. However, since the late 1980s these limits have been uniform, with all states enforcing a BAC of 0.05 for general drivers and 0.02 or 0 for novice and professional drivers.

Following the adoption of legal limits, large-scale police enforcement of these limits was undertaken from the 1980s. This was supported by a range of other interventions including publicity campaigns, community announcements, community activity programs, variations in alcohol licensing laws, and distribution arrangements for alcohol. There was also ongoing monitoring of performance involving blood tests on drivers involved in crashes, with particularly high levels of testing for serious crashes.

Over the last 40 years, the role of alcohol in fatal road traffic crashes in Australia has halved. Moreover, there have been notable shifts in community attitudes toward drink driving, with recent surveys suggesting a strong community view that such behavior is socially irresponsible. The success of Australia's drink driving laws can be attributed to a number of factors including:

- Strong political commitment to prevent drink driving, with legislation targeting drink driving receiving strong support from the highest levels of government and subsequently sending a clear message to society that drink driving and traffic safety are vital national issues;
- Legislation that clearly defines illegal BAC levels associated with operation of a motor vehicle and penalties for drink driving offenses including lower BAC limits for younger drivers as part of graduated driver licensing programs;
- Strong and well-publicized enforcement campaigns involving random and targeted breath testing regimes;
- Public education aimed at modifying attitudes toward drinking and driving and informing the community about enforcement practices;
- Prevention programs in licensed venues;
- Strict and swiftly enforced penalties for those caught breaking the law including immediate mandatory license loss for some offenders and increased penalties for repeat offenders; and
- The use of other sanctions to constrain offenders, such as alcohol ignition interlocks and vehicle impoundment, as well as drink driver rehabilitation programs (see above for more information regarding these sanctions).

In summary, for drink driving laws to be successful, the public must: know *why* driving while impaired by alcohol is both unsafe and antisocial, be *aware* of the laws that govern drink driving, *perceive a high risk* of being caught if they break the law, and know that if caught, the *consequences will be severe*.

CONCLUSIONS

Current State of Knowledge

Alcohol, through its impairment of the behavioral and cognitive functions required to operate a motor vehicle, contributes to a substantial degree of road trauma, including fatalities and injuries, as well as producing significant implications for society at large. In addition, alcohol-impaired driving has been found to be highly correlated with a number of other illegal, high-risk driving behaviors. Traffic law enforcement approaches aimed at reducing and preventing impaired driving involve three components: legislation, policing, and sanctions. The literature has suggested positive effects associated with each of these approaches; however, the degree to which recidivism and alcohol-related traffic crashes is reduced differs depending on the approach in question.

Policy Recommendations

Overall, a multifaceted approach to the problem of drink driving is required. As a starting point, the need for appropriate per se legislation and prescribed alcohol limits is clear. There is also scope to consider reduced limits for high-risk groups. Policing approaches should involve highly visible and sustained programs, involving a mix of stationary and mobile, as well as random and targeted operations. There is general consensus that greater effectiveness of testing procedures is achieved when such operations are conducted in a randomized and widespread, rather than selective, manner.

It is likely that the optimal mix of approaches will differ by context. For example, static approaches operated overtly, and augmented with concentrated and highly intensive activities conducted periodically, will predominantly serve a general deterrent function and be most effective in urban areas with high traffic flows. Conversely, mobile operations tend to serve a specific deterrent function and reduce experiences of punishment avoidance among offenders and are likely to be more effective in rural areas. While targeted operations at peak times and locations are important, random operations at non-peak times and locations also increase the unpredictability of enforcement efforts. In either

instance, adopting intelligence-led approaches improves the overall efficacy of enforcement.

Finally, with regard to sanctions, the objective should be to increase the perceived and actual certainty and swiftness of punishment. While penalties must be appropriately severe, there is evidence to suggest overly punitive sanctions can produce diminished returns or even be counterproductive. Moreover, different types of sanctions should not be conceptualized in isolation of one another, given that they can serve separate and complementary functions, such as behavior modification and addressing factors associated with alcohol abuse and dependency.

Future Research Directions

Ongoing research is required to further develop the evidence-base regarding best practice in the prevention of drink driving behavior and offender management. Future research should continue to evaluate specific aspects of policing approaches with the objective of identifying the optimal mix of stationary, highly visible operations and more targeted, mobile approaches. In addition, the impact of sanctions on recidivism, particularly in the long-term, should be fully explored, with findings utilized to further develop and enhance sanctions. From a legislative perspective, further research is needed to investigate the likely benefits of reducing prescribed alcohol limits for high-risk groups or for the driving community at large. Moreover, research should assess the impact of broader alcohol policies, such as those implemented in licensed venues, on drink driving behavior.

INTRODUCTION

Some products in modern life are associated with risks. The potentially negative effects of drinking alcohol, smoking tobacco, using drugs, gambling, and exposure to violent or otherwise detrimental movies or games are widely acknowledged. Risks may involve people's mental or physical health and/or their social well-being. Risks may be especially valid for specific groups in society. Societies generally aim to protect children and adolescents from risky products.

In this chapter, we will focus on availability as an important predictor of the use of risky products. We distinguish four types of availability: physical, economic,

legal, and social availability. Governmental legislation is an important instrument to reduce these types of availability and, as a consequence, curb people's use of risky products. A crucial factor that affects the effectiveness of such legislation is compliance.

RISKY PRODUCTS: CONSUMPTION AND CONSEQUENCES

Many risky products have in common that the risks involved are not associated with moderate and incidental use, but rather with prolonged and/or excessive use. Three general tendencies, however, are relevant in this

respect. First, habituation and addiction are important risk factors in most risky products. Consumers may get used to the products or even become physically or mentally dependent on them. Second, research has shown that early use of risky products is a strong predictor of problematic use during adulthood. Third, the so-called “gateway theory of drug use” predicts that the use of entry drugs (e.g. alcohol or cigarettes; sometimes marijuana is also included as an entry drug) may eventually result in more severe and illicit drug use (e.g. marijuana, ecstasy, or cocaine).

Below we distinguish between five types of risky products: alcohol, tobacco, illicit drugs, gambling products, and detrimental media. We discuss the products and explain briefly why they must be regarded as problematic.

Alcohol

Alcohol is the number one recreational drug in the world. It is embedded in social events in many countries, and positive health effects of alcohol have been reported when used in moderation. However, there are several risks associated with alcohol consumption. In the short term, alcohol use may lead to risky behaviors, including violence, traffic accidents, or unprotected sex. In the long term, excessive alcohol consumption is known to harm physical health, mental health, and social relations. Often addiction is involved. Alcohol use during pregnancy may cause birth defects. Adolescent alcohol use is associated with an important additional risk: Alcohol use at young ages leads to permanent damage to the brain, which is still developing during adolescence.

Tobacco

Despite governmental attempts to reduce tobacco consumption, tobacco products are still very popular worldwide. It is generally recognized that tobacco products are addictive and have detrimental effects on smokers and their immediate environment (passive smoking). In the short term, smoking may lead to allergic reactions and respiratory problems. In the long term, tobacco use may cause heart problems, lung cancer, emphysema, and strokes. Fifty percent of lifetime smokers will eventually die from their habit, and half of these deaths will occur in middle age. Smoking during pregnancy may cause birth defects.

Illicit Drugs

Apart from alcohol and tobacco, which are legal in most countries, many illicit drugs are available. The main types of drugs are opiates (e.g. heroin), cocaine, cannabis, and amphetamine-type stimulants (e.g. amphetamines, methamphetamine, and ecstasy). Cannabis is the most widely

cultivated, trafficked, and abused illicit drug. Research has confirmed the potentially detrimental health effects of all illicit drugs. The degree to which illicit drugs are addictive appears to vary per substance. An extra complication of illicit drug use is that it is closely connected to illegal and criminal environments.

Gambling

Gambling is practiced as a leisure activity, for instance in casinos, in lotteries, online, or private settings. Depending on the national context, some of the gambling opportunities are legal and others are illegal. Research has shown that gambling can be an addictive activity. The addiction urges gamblers to continue playing, even if they cannot afford it. Obsessive or irresponsible gambling may cause severe financial and social problems. Problem gambling is usually defined by the harm that is caused to the gambler or the gambler’s environment, rather than by the gambler’s behaviors.

Detrimental Media

Media products can also be considered to be risky products, as movies, television programs, and video games often contain potentially harmful elements. The harmfulness of media products is usually defined in relation to the media user’s age. In particular, sexually explicit and violent media contents are considered to have detrimental effects on children and adolescents. Several studies found negative effects of harmful media content attitudes and behaviors in the users. Other studies, however, did not find such effects, or only found small effects. Many governments as well as parents agree that children and adolescents should be protected from detrimental media. There is no proof that detrimental media are addictive, but habituation and cultivation effects have been found.

AVAILABILITY AS A PREDICTOR OF CONSUMPTION

Availability can be seen as an important predictor of the consumption of risky products. Based on epidemiological research in the domain of alcohol, the “availability theory” was introduced. The theory assumes a causal relationship between the availability of alcohol and the alcohol consumption levels in a region, and between the alcohol consumption levels and the prevalence of problem drinking and its consequences.

Consumption patterns are more than just personal choices; they are also co-determined by the environment in which people live. If products are easily available, consumption will generally be higher than when

people's access to the products is limited. This applies not only to formal types of availability (e.g. the price of a product, the opening hours of outlets, the location of outlets, or the attractiveness and diversity of the assortment in a store) but also to informal and social types of availability (e.g. the presence of products in people's social network, or the standards and values of peers concerning the use of the product). Below, we distinguish between four types of availability: (1) physical, (2) economic, (3) legal, and (4) social.

Physical Availability

Research into the physical factors of availability, especially in the fields of alcohol and tobacco, focuses mainly on outlet density and opening hours. Several studies show that outlet density correlates positively with consumption: Higher outlet density corresponds with higher alcohol consumption in a region. Other studies, however, have not found such relations, or have even shown contradictory results. The local or national context might play a relevant role here and should therefore be considered when interpreting results. Research on opening hours led to consistent results: restrictions on opening hours are related to a decrease in consumption, whereas longer opening hours lead to higher consumption levels. Physical availability is closely related to the issue of *licensing*. Governments may decide whether or not risky products can be legally sold in their country and may also decide on the kinds and number of outlets that are entitled to sell them and the conditions for those outlets.

Economic Availability

Research generally shows that the price of risky products is negatively correlated to the consumption of these products. Higher prices lead to lower consumption of risky products and lower prices (e.g. in the case of special promotions) increase consumption. The most used governmental tool to curb the consumption of risky products is by taxes. Not only do prices affect usage behavior, but research has also shown that increasing prices or taxes reduces product-related problems (e.g. drinking and driving) and product-related crime. Research with a broader perspective on health care costs and health consequences also shows that a tax increase is a cost-effective policy.

Legal Availability

In addition to the physical and economic availability, governments or other parties may also focus on the legal availability of risky products. This implies that all outlets have to adhere to certain rules when they sell

risky products to customers. A widespread example of measures to decrease the legal availability of risky products is the use of age restrictions, meant to protect children and adolescents from the harmful effects of risky products. In general, higher legal ages correspond to a decrease in consumption. In the context of alcohol sales, the introduction of higher age restrictions was even found to decrease alcohol-related car crashes and other injuries. In the case of age restrictions, adolescents may look for other ways to obtain the product. Adolescents may use fake IDs, or ask older friends or even strangers to purchase the risky products for them. The latter is called "shoulder-tapping." Another example of measures to decrease the legal availability involves the phenomenon of over-serving: In some countries legislation does not allow the serving of alcohol to apparently intoxicated customers.

Social Availability

The last, and least formal, type of availability is social availability – the norms and values that are prevalent in people's social environment regarding the use of the risky products. It includes parents' styles of upbringing, their own role behaviors, the agreements they make regarding the risky products, as well as peers' behaviors in terms of social pressure, social norms, and role behaviors. With respect to the environment of adolescents, research has shown that underage individuals have easy access to risky products in their homes and that easy access leads to higher consumption rates. In the context of alcohol, adolescents not only have easy access to alcohol at home, but some parents appear to actively supply alcohol to their underage children, or facilitate their children's alcohol use in informal drinking places.

REDUCING AVAILABILITY: LEGISLATION, SELF-REGULATION, AND CO-REGULATION

To control and influence availability (in particular physical, economic, and legal availability), three types of regulations may be used, depending on the role of the parties involved (i.e. government versus industry): legislation, self-regulation, and co-regulation. The last-named can be seen as a combination of the first two.

Legislation

The first type of regulation is governmental legislation. In this case, a law is promulgated or enacted by a legislative or governing body. In addition, there is the responsibility to maintain the law and punish violators. Such legislation is as follows.

Legislation Reducing Physical Availability

Governmental legislation may be aimed at reducing the physical availability of risky products. These policies include limitations on the number of outlets, opening hours, and/or geographical location of outlets. Such regulations are mainly executed by licensing. For some risky products (e.g. alcohol, marijuana), sales within a certain distance from schools are prohibited. Restrictions on physical availability might reach the level that a substance is absent, which means it cannot be obtained legally.

A controversial example of the opposite is the Dutch drug policy, which can be characterized as liberal. Dutch drug policy has received much attention worldwide, and many have judged it to be too liberal and too tolerant. The Netherlands' drug policy distinguishes between "soft" and "hard" drugs, and aims at separating the markets and the social contexts of soft and hard drugs. Law-enforcement efforts are focused on the higher levels of the supply system. Retail trade in cannabis is tolerated in the Netherlands' numerous so-called coffee shops. The aim of this policy is to avoid situations in which consumers of cannabis suffer more damage from criminal proceedings than from use of the drug itself (Engelsman 1989). The use of hard drugs is considered to be the Netherlands' major public health problem. Policy components concerning hard-drug use include easily accessible social assistance programs, methadone supply, other drug treatment facilities, and needle exchange. Officially, cannabis remains a controlled substance in the Netherlands, and both possession and production for personal use are still misdemeanors, punishable by fine. However, in practice the possession of soft and/or other illegal drugs for one's own use is rarely punished. The Dutch alternative is a pragmatic compromise between two extreme options: An intensified war on drugs and legalization. By contrast, most other countries view recreational drug use as detrimental to society and as a practice that must therefore be outlawed. Recently, the Dutch had the effects of their drug policy examined. For all narcotics, with the exception of ecstasy, the prevalence of the use in the general population in the Netherlands is below the European average and lower than in the United States.

Legislation may also focus on the visibility of risky products. There is increasing evidence that exposure to alcohol and tobacco marketing practices is one of the environmental factors that has significant influence on juvenile consumption. Many countries therefore have introduced advertising restrictions on risky products. These restrictions include matters such as place (e.g. not near schools), contents (not aimed at youth), channel (not on youth media), or time (no broadcasting before a certain time).

Legislation Reducing Economic Availability

To reduce economic availability, the sales prices of risky products must be raised. When these risky products are sold legally, taxes are levied on most of them (alcohol, tobacco, drugs, gambling products). Legislation may be aimed at minimum levels of taxing and/or pricing. In many countries, for instance, taxes on tobacco are more than half of the final sales prices. Governmental legislation regarding economic availability may also involve limitations of price discounts and advertising at the retail level. Despite legislation affecting pricing and taxes, risky products may still be available at low prices in various ways. People may smuggle cheaper items across the border. To obtain, for example, cheap alcoholic drinks, beverages are sometimes home-brewed or home-distilled. Such illegal production creates even higher risks for people's health, inasmuch as the products are often of questionable quality.

Legislation Reducing Legal Availability

In many countries, age restrictions on the sale of risky products have been introduced to protect children and adolescents. Worldwide, many different age restrictions and age restriction systems exist, also depending on the specific type of risky product. In many countries, the legal age for buying alcohol is 18 years. In the United States, however, the buyer has to be at least 21; in contrast, in some European countries alcohol can be obtained at the age of 16. Some countries have different starting ages for drinking and purchasing alcohol. For example, in Great Britain, one has to be at least 5 years of age to consume in private (Children under 5 must not be given alcohol unless under medical supervision or in an emergency), 16 years to consume in public with a meal and accompanied by an adult, and 18 otherwise, whereas there is only one legal buying age (18 years). For tobacco, the starting ages for buying and consuming sometimes also differ. In general, most countries use either 16 or 18 years as an age restriction.

For media products, many different age-rating systems exist. Media rating systems (also known as age classification systems, warning label systems, or restrictive ratings) can serve as an effective tool in restricting access and exposure to harmful media. Such systems, which at this time are used in at least 52 countries worldwide, are designed to inform parents about and protect children from violent or otherwise harmful media content. Age pictograms (also known as evaluative ratings) show whether a media product's content is harmful for minors below a given age. Furthermore, in various systems, the actual content is specified with additional warning pictograms (descriptive ratings). Both the age classification labels and the warning labels can be placed on covers, packing materials, posters, and

other advertising materials, and they can be shown at the start of a movie or television program. Just as there are different ages for drinking alcohol or smoking tobacco, worldwide, many countries have their own rating systems with their own pictograms and their own regulations. Especially in the ratings of television programs, many differences can be found, for example, regarding whether classifications are compulsory, the types of television networks involved, when the classification is shown, and restrictions regarding the time of broadcasting. Furthermore, most countries have their own system of coding media products, which may result in very different classifications per country for the same media product.

Self-Regulation

Self-regulation involves the regulation of an industry that is intended to achieve shared goals that are deemed important (Dorbeck-Jung et al. 2010). In the private sector self-regulation has a long tradition. The party's own interest is prominently present but goes beyond just making profit. Self-regulation may prevent governmental regulations from being introduced or contribute to the industry's reputation, which is in line with a growing interest in corporate social responsibility. Self-regulation may increase customer confidence and create customer loyalty. The rise of self-regulation may also be explained by unsuccessful enforcement activities by governmental bodies, and the divide between the traditional hierarchical government and new developments in the "civil society." Self-regulation activities play a significant role in Europe, the United States, Australia, and Canada. Often self-regulation is established as a result of governmental initiatives. Pure self-regulation where the initiative comes solely from the industry itself is rather rare.

Co-Regulation

When the government is explicitly involved in self-regulation activities we speak of co-regulation. This means that the industry and government cooperate, and together they formulate the conditions that apply. For example, legal rules prohibiting the exposure of minors to certain media are said to be extremely difficult to enforce. For this reason most countries entrust the protection of minors from harmful media to a regulatory system that combines private and public regulation at various regulatory levels (including international, regional, and national legislation, self-regulation, funding, and distribution of information). In Europe's regulatory systems, all forms of hybrid regulation can be found (i.e. co-regulation, enforced self-regulation, meta-regulation,

and multilevel regulation). In many European countries, different regulatory systems are used for television, movies, DVDs/videos, and games. The regulations on games are based on harmonized self-regulation at the European level, while the other media (DVDs, movies, and TV programs) are controlled by combining governmental and nongovernmental regulatory activities at the national level. Often these kinds of regulations are controversial because of the multiple interests that are at stake. The industry strives for maximum profits, customers may prefer easy access and affordable prices, while governments and health organizations are concerned about the health risks associated with consumption (Heather and Stockwel 2004).

COMPLIANCE WITH LEGISLATION

Rule compliance – the idea that the regulated parties obey established rules – depends on whether those parties are able and willing to comply. The regulated parties must know and understand the rules. Their willingness to comply depends partly on their attitudes toward the regulations (intrinsic motivation) and on their estimations of the consequences of violations (extrinsic motivation). Research into shop-floor compliance with the age restrictions for media products, for instance, showed that three factors were important predictors of compliance: (1) salespersons' personal acceptance of the media rating system, (2) the perceived legal basis for the age restrictions, and (3) the perceived degree of (external) surveillance.

In regulations that combine public and private regulation, rule compliance depends on several conditions, including sufficient overlap of private interests with public interests; the existence of specific pressures to comply; a small number of actors in a highly organized and homogeneous sector; and a high degree of social responsibility within the sector. Public and private interests may overlap when public and private regulators purport to have similar objectives, when private regulators acknowledge reputational advantages, and when they have an interest in forestalling legislation. Compliance with private regulations depends on the pressures on companies to comply. A relatively small number of actors and a relatively high degree of homogeneity and organizational capacity in a given sector are required for the establishment and maintenance of self-regulation. Social responsibility is indicated by the activities of the trade association and by a strong business community with a generalized concern for taking private regulation seriously. The involvement of organizations in societal issues like responsible sales is also referred to as corporate social responsibility. It can be

a natural result of the ideological beliefs of the organization, but can also – through media – be compelled by the public and actually manifest itself in behavior or actions that seem to be inconsistent with an organization’s core activities. Today, corporate social responsibility is no longer conceived solely as a moral responsibility of an organization for greater social good, but also as a strategic resource to be used to improve performance.

MONITORING AND IMPROVING COMPLIANCE WITH LEGISLATION

After setting the rules, it is important to monitor whether all regulated parties actually comply with them. Worldwide, the results of many studies indicate that compliance with regulations aimed at restricting people’s access to risky products is problematic. In many cases customers are still able to obtain the desired products, despite the regulations. The success rates fluctuate and appear to be related to the specific product concerned and the degree of enforcement involved in the region (e.g. the use of fines or license suspensions). Because compliance is important in reducing the consumption of risk-associated products, and given the fact that compliance levels are generally low, it is important to look for approaches to improve compliance. Four general approaches may be distinguished: (1) governmental instruments, (2) industrial instruments, (3) societal instruments, and (4) research.

Governmental Instruments on Legislation and Co-Regulation

Low compliance rates indicate that incentives to continue sales seem to outweigh the incentives to comply. Two types of instruments may complement each other. First, it is important to raise awareness of the importance of the regulations and make all parties involved aware of their (legal and/or contractual) status. This strategy is aimed at reducing ambiguities and convincing people. Second, it is important to connect possible violations of the regulations to negative consequences. The parties involved must be aware of substantial and effective surveillance activities of their compliance and must recognize that the sanctions for violations are severe (either high fines or suspension). Several compliance studies show that more severe interventions, such as increased enforcement levels and police interventions, cause higher compliance rates. Various kinds of enforcement are fruitful ways of reducing sales of risky products, especially if they not only include warnings and penalties in the case of violations, but also focus on the actual and perceived chance

of being caught. Recent discussions on enforcement strategies include the possibility of punishing not only the seller of products but also the buyer.

Industrial Instruments on Self-Regulation and Co-Regulation

In the case of self-regulation and co-regulation, compliance performance has to be assessed by the own industry. In cases of noncompliance, the industry has to impose sanctions on its own members. As a result, compliance and control activities within the own industry are hard to execute. The industry may choose to focus on informing and educating its members, for example, by campaign materials or training programs for personnel. However, several studies show that an exclusive focus on information will not suffice to ensure compliance with rules.

Societal Instruments

Other parties in society may play its role in increasing compliance. When a vendor violates certain rules, many regulatory systems offer customers the opportunity to file a complaint. Complaint boards may then impose fines when the obligations laid down in the statutes are violated. If it is possible for members of the general public to complain, it is crucial that this possibility be made public and that the complaint procedure be easy and transparent.

Research

Research may also contribute to compliance by making policymakers, industry representatives, vendors, and/or the general public aware of problems with compliance. Due to issues of social desirability and the problem of making correct judgments about people’s own behavior in ambiguous situations, survey research is not a valid research option. For instance, despite the fact that compliance levels with age restrictions to sell alcohol are consistently very low in the Netherlands (10–20%), more than 90% of the store managers reported in surveys that no single violation of age restrictions would happen in their stores.

Instead, mystery shopping (also called decoy operations) has proved to be a far more valid way of investigating actual compliance levels. Selling points are then visited by trained research assistants, who pretend to be “regular” customers, but who act according to a script. Immediately after the visit, a detailed form is completed about the mystery shopper’s experiences. Mystery shopping is frequently used to investigate the service quality of stores and the quality of medical care. In more and

more countries and regions, this type of undercover research has also been used to investigate retailers' compliance with age restrictions or other kinds of legislation.

Legal and Ethical Considerations

Conducting mystery visits at outlets that are not aware of the fact that they are being investigated raises some legal and ethical issues. For example, in most countries, stores that sell age-restricted products to underage purchasers commit an offense and are therefore liable to penalty. Also, regarding the stores involved, an important issue is whether it is justifiable to include them in a study without their prior consent. Four important criteria may be found in the literature to judge the appropriateness of undercover research approaches (Gosselt et al. 2007): (1) societal relevance of the research topic, (2) inadequacy of the more conventional research methods, (3) public nature of the events observed, and (4) avoidance of negative consequences for the research participants. In principle, all four criteria can be met. First, age restrictions are designed and implemented for specific reasons, namely, the protection of specific (mostly underage) consumers. It is generally deemed important to protect children and adolescents from the dangers of risky products, and noncompliance with the regulations is the most important potential leak in the system. Second, the inadequacy of more conventional research methods like surveys has been demonstrated in earlier research. Third, the interactions between customers and store personnel are normally not private: Other people may enter the store whenever they want and are able to observe the transaction. Fourth, negative consequences for stores and vendors can be avoided if (1) the mystery shoppers behave like normal customers and do not demand too much time of the store personnel and (2) the anonymity of all stores and vendors in the study is safeguarded. Regarding the minors who may participate in studies like these, two ethical considerations are relevant. First, to avoid unwanted effects on the mystery shoppers' attitudes and behaviors regarding the risky product at hand, it is important to select just those adolescents who have prior experience in buying and consuming the product at hand, to ask their parents for informed consent, and to debrief them personally about the dangers of the product. Second, to prevent adolescents from being confronted with awkward situations, vendor aggression, or police interrogations during the mystery visits, the minor must be given an official letter explaining the research purpose of the buying attempt, and research assistants are required to stand by to intervene.

Research Findings

Recently, compliance checks on legislation have been executed in many countries. Despite the large number of

studies, specific predictors of compliance on legislation are not clear. Literature on compliance states that compliance levels depend on knowledge of the regulation, the cost-benefit ratio, the degree of acceptance of the regulations, the loyalty and obedience of the regulated parties, informal monitoring, informal report probability, monitoring probability, detection probability, selectivity of the inspector, chance of sanctions, and severity of sanctions. Initiatives in the Netherlands issued by the industry and local projects (mainly on alcohol) only achieved a (temporary) increase in compliance of 0–20%. The highest level on compliance in the Netherlands appears to be 50%, but in other countries compliance sometimes reaches about 100%. A crucial factor in the system is that age verification still depends on individual cashiers on the shop floor.

A rather drastic but very promising intervention designed to increase compliance can be remote age verification. Recently, a remote age verification system was developed, aimed specifically at age-restricted products. When customers want to purchase risky products, a live video connection is made with a remote control center, and the cashier can only finish the payment after receiving an authorization from trained judges at the remote center. A compliance study (Van Hoof et al. 2010) found that the compliance rate differed considerably between the remote age verification and the traditional purchase situations. Results showed that the adoption of a remote age verification system led to a drastic improvement in shop floor compliance with age restrictions. The effects may be attributed to three mechanisms. First, the remote age verification system has a priming effect, as is underlined by an increased number of ID requests. Cashiers have many different tasks, such as scanning products, counting money, and interacting with customers, so that age verification becomes an extra activity for them. The remote verification system automatically signals when age verification is required, and the remote age verification employees only have one task. Second, remote age verification employees may be expected to have more expertise and practice in judging the age of adolescents and reading and interpreting IDs (e.g. determining someone's age using a date of birth). Third, remote age verification removes the social pressure from the decision of whether to sell. It may be difficult for cashiers to refuse to sell cigarettes to customers, especially when they are close in age.

CONCLUSIONS

The availability of risky products is a strong predictor of the consumption of these products. To decrease consumption, it seems important to decrease physical, economic, legal, and social availability. To control and

influence availability, three types of regulations may be used, depending on the role of the parties involved: legislation, self-regulation, and co-regulation. After setting the rules, it is important to monitor whether all parties actually comply with the rules. Rule compliance depends on whether those parties are able and willing to comply. The regulated parties must know and understand the rules. Their willingness to comply partly depends on their attitudes toward the regulations (intrinsic motivation) and on their estimations of the consequences of violations (extrinsic motivation). Results of many studies indicate that compliance with regulations aimed at restricting people's access to risky products is problematic. In this chapter, we discussed four approaches that can be used to improve compliance with regulations: (1) governmental instruments, (2) industrial instruments, (3) societal instruments, and (4) research. Interventions all boil down to a combination of enforcement strategies and communication. Communication will only be effective if sellers wholeheartedly endorse the necessity to comply. Enforcement checks will only be effective when store managers are aware of them and are periodically informed about their results and consequences. On the level of stores or store chains, managers inform and train employees, supply aid in facilitating age verification, or create special counters for risky products. Technological innovations include the introduction of cashier systems that beep whenever risky products are scanned. On the national

level, public information campaigns inform people about the requirement to show identification when buying risky products. The effects of these interventions, however, are limited.

WHAT IS THIS CHAPTER ABOUT?

This chapter is about commercial communications (marketing) and the use of alcohol and tobacco, and how commercial communications should best be regulated. Commercial communications play a key role in shaping alcohol and tobacco-related knowledge, opinions, attitudes, and behaviors among individuals and within communities. Media communications include brand-specific advertising and promotion, news coverage, depictions of drinking and smoking and alcohol and tobacco products in entertainment media, public relations, corporate sponsorship, corporate advertising, political advertising for ballot initiatives and referenda, and media campaigns for alcohol and tobacco control (see Fig. 73.1).

Commercial communications on alcohol and tobacco are big business. For example, the total annual advertising expenditure in the United Kingdom across all sectors in 2007 – from car insurance to soft drinks – was just below £9bn, of which some £200m was spent on alcoholic drinks advertising on television, the radio, in the press, outdoors, and in cinemas. In comparison, the expenditure on carbonated soft drinks and hot

drinks was some £100m and £40m respectively, and on all food products (excluding sweeteners, jams and spreads, confectionary and beverages), some £400m. Television was the key medium for alcoholic drinks advertising, accounting for 49% of expenditure compared with 43% of total UK advertising spent on television, the radio, in the press, outdoors, and in cinemas. There were some 440 000 alcoholic drinks advertising spots on television in 2007. Including other marketing activities such as sponsorship, competitions, special promotions, and online and mobile phone advertising increased the UK alcohol industry's £200m annual spend to £800m for marketing communications as a whole. Alcoholic drink companies were the second largest source of sport sponsorship funding behind the financial services sector.

Cigarettes are one of the most heavily marketed products in the United States. Between 1940 and 2005, US cigarette manufacturers spent about \$250 billion (in 2006 dollars) on cigarette advertising and promotion. In 2005, the industry spent \$13.5 billion (in 2006 dollars) on cigarette advertising and promotion (\$37 million per day on average). Currently, most of the cigarette industry's marketing budget is allocated to promotional

activities, especially for price discounts. Price discounts accounted for 75% of total marketing expenditures in 2005 (\$10.1 billion in 2006 dollars). Less than 1% of cigarette marketing expenditures are now used for advertising in traditional print media. Tobacco advertising is dominated by three themes: providing satisfaction (taste, freshness, mildness, etc.), relieving anxieties about the dangers of smoking, and creating associations between smoking and desirable outcomes (independence, social success, sexual attraction, thinness, etc.).

ADDICTIONS AND BRAIN FUNCTION

The pharmacological effects of addictive drugs on behavioral decision-making show that they have a predictable unfair advantage over other products, as also seems to be the case with other consumer products, such as high energy foods, food with high fat and sugar

content. All addictive drugs disrupt calculations made by the brain's reward circuitry. To determine the value of naturally rewarding substances, the brain conducts an in-depth calculation of the impact of consumption of the substance on the consumer within the current and historical environment. Addictive drugs short-circuit this assessment by pharmacologically augmenting a signal thus indicating the difference between the predicted value of the reward and the observed reward, such that the circuit mistakenly overestimates the value of consuming the drug, regardless of whether the consumer was helped or hurt as a result of drug use. This leads the consumer to favor working harder to obtain it, even if it provides no objective or subjective benefit to the user. Thus, addictive drugs, such as alcohol, include a chemical that directly distorts the brains' decisions about how much work to devote to consume them, ensuring that people will pay more to get the drug than it is worth. Adolescents aged 14–17

years with alcohol use disorders showed substantially greater brain activation to alcoholic beverage pictures than control youths, predominantly in brain areas linked to reward, desire, and positive affect. The degree of brain response and the desire to drink increased linearly with the number of drinks consumed per month. This evidence shows that addictive drugs (as well as some high energy dense foods) have an unfair competitive advantage over other consumer products and thus should be regulated accordingly.

ADVERTISING AND EXPECTANCIES

Advertising is one of the many factors that have the potential to encourage young people to drink and smoke. The expectancies (the action or fact of expecting, in this context expecting the use of alcohol or tobacco) of young people who have not started to drink or smoke are influenced by normative assumptions about teenage drinking and smoking as well as through observation of drinking and smoking by parents, peers, and models in the mass media. Research has linked exposure to portrayals of alcohol and cigarette use in the mass media with the development of positive expectancies by children and adolescents. Young people with more positive affective responses to advertising hold more favorable drinking and smoking expectancies, perceive greater social approval for drinking and smoking, believe drinking and smoking are more common among peers and adults, and intend to drink and smoke as adults. Fourteen-year-olds who are more exposed to advertisements in magazines, at sporting and music events, and on television are more aware of them than those with less exposure, as are teenagers who watch more television, pay attention to advertisements and know adults who drink and smoke. Among 10–17-year-olds, the perceived likeability of advertisements is a function of the positive affective responses evoked by the specific elements featured in the advertisements. The liking of specific elements featured in advertisements, such as humor, animation, and popular music, significantly contribute to the overall likeability of these advertisements and subsequently to the effectiveness of advertising indicated by intent to purchase the product and brand promoted by the advertisements.

Theoretical models of the impact of advertising on young people go beyond a simple view that advertising primarily works by changing consumer attitudes to a product or by increasing brand salience before changes in behavioral patterns occur. Studies in neuroscience, psychology, and marketing conclude that adolescents may be especially attracted to risky branded products that, in their view, provide immediate gratification,

thrills, and/or social status. According to the Message Interpretation Process model, individuals progressively internalize messages using a combination of logically and emotionally dominated processing strategies. The model, supported by decision-making theory, social cognitive theory, and dual-process theories of persuasion, proposes that certain responses to messages interrelate in ways that progressively lead to behavioral decisions. If a portrayal corresponds closely to personally relevant reference groups, for example, children will be more likely to wish to emulate the portrayal. If children admire a mediated reference group such as models in an advertisement, they will tend to expect that imitating the models' behaviors will bring positive results.

Although such studies find positive relations between expectancies and drug use, expectancy studies, by themselves, do not establish whether advertising actually influences young people's behavior. Further, there is increasing evidence that such prebehavior cognitions, for example, expectancies and attitudes, are related to consumption in a more complex way. For example, for adolescent smoking, it has been shown that, over time, behavior can predict attitudes more strongly than attitudes can predict behavior.

CROSS-SECTIONAL STUDIES

Because they cannot show whether exposure preceded drinking or smoking uptake, cross-sectional studies, which take a snapshot of exposure to advertising (awareness and/or appreciation) and levels of drinking and smoking, leave open the possibility that any correlation is as likely to reflect drinking and smoking encouraging young people to take an interest in advertising as vice versa. Paying attention to advertising presupposes that the viewer is getting some benefit or reward from it – most fundamentally that they are doing the right thing by consuming the product advertised – and advertisers deliberately design their work to provide such rewards. Thus, cross-sectional data can shed a useful light on the role advertising plays in young people's drinking and smoking; and such studies have consistently reported correlations between increased exposure and greater likelihood of current drinking and smoking.

EXPERIMENTAL STUDIES

Some of the most powerful evidence for the impact of advertising has come from experimental studies and the use of alcohol. An experimental study has found that the portrayal of alcohol on television influences actual

drinking behavior. In a naturalistic setting (a bar laboratory), 40 young adult male pairs (80 participants) watched a film clip with two commercial breaks for 1 h and were allowed to drink nonalcoholic and alcoholic beverages. The films *American Pie 2* (2001) and *40 Days and 40 Nights* (2002) were selected because they were comparable concerning genre and Motion Picture Association of America rating. In *American Pie 2*, characters drank alcohol 18 times and alcoholic beverages were portrayed an additional 23 times. In *40 Days and 40 Nights*, characters consumed alcohol three times and alcoholic beverages were portrayed an additional 15 times. After 14 and 33 min the clips were interrupted by a commercial break for 3.5 min, containing either exclusively neutral advertisements (e.g. promoting a car or a video camera) or neutral advertisements combined with alcohol advertisements. Each of the combined breaks contained two alcohol commercials. The participants were randomly assigned to one of four conditions varying on type of film (many versus few alcohol portrayals) and commercials (alcohol commercials present or not). The results indicated that, independently, participants assigned to the conditions with substantial alcohol exposure in either the film or commercials consumed more alcohol than other participants, controlling for the participant's weekly alcohol consumption. Those in the condition with higher alcohol portrayal in the film and commercials drank on average three glasses within a period of 1 h, compared to one and a half glasses drunk by those in the condition with little or no alcohol portrayal. Thus as little as 1 h of exposure doubled the student's alcohol consumption in real time.

In another experiment, 184 young adults were invited to watch a movie (*Watchmen*) in a real service cinema where people can order drinks and snacks during the movie. On one Wednesday, four alcohol commercials and six nonalcohol commercials were shown and on the other Wednesday, six nonalcohol commercials were shown. For the young adults who normally drank more than seven drinks a week, those who were exposed to the alcohol commercials drank over twice as much alcohol during the 2.5 h movie than those who were not exposed to the alcohol commercials. For the lighter drinkers (those who normally had seven or less drinks a week), the exposure to the movie commercials did not change the amount they drunk whilst watching the movie.

LONGITUDINAL STUDIES

Strong and consistent evidence from longitudinal studies indicate that exposure to cigarette advertising

influences nonsmoking adolescents to initiate smoking and to move toward regular smoking.

Similar findings have been shown for alcohol, but, since they are more recent, the results are discussed in more detail. At least 13 longitudinal studies have been identified from at least two systematic reviews that have investigated the impact of marketing communications on young people beginning to drink and continuing to do so. The 13 studies, which followed up a total of over 38 000 young people, were drawn from the United States (9 studies), Belgium (1 study), Germany (1 study), and New Zealand (1 study). Three studies reported on the impact of overall alcohol advertising, one study on brand recall and receptivity, three studies on television advertisements, two studies on media exposure, three studies on alcohol use in films, one study on radio exposure, two studies on magazine exposure, two studies on beer concession stands, two studies on in-store displays, three studies on ownership of alcohol-branded merchandise (ABM), and one study on outdoor advertisements.

Twelve of the thirteen studies concluded that exposure did have an impact on subsequent alcohol use, including starting to drink and heavier drinking among existing drinkers, with a dose-response relationship in all studies that reported such exposure and analysis. There were variations in the strength of association and the degree to which potential confounders were controlled for. The 13th study, which tested the impact of outdoor advertising placed near schools, failed to detect an impact on actual alcohol use but found an impact on intention to use.

There was no consistent evidence that the size of the impact varied across the countries. When controlling for exposure to all forms of advertising, the size of the impact appeared greater for television and media exposure, including exposure to alcohol use in films, and for ownership of ABM than for exposure to radio, magazines, beer concession stands, and in-store displays. The impact applied to overall advertising (3/3 studies), and, when controlling for exposure to other types of marketing, brand recall and receptivity (1/1 study), TV advertisements (2/3 studies), TV and video exposure (3/3 studies), alcohol use in motion pictures (3/3 studies), beer concession stands (1/2 studies), and ABM (3/3 studies), but not for radio (1/1 study), magazines (2/2 studies), or in-store displays (2/2 studies).

One of the few studies that allowed an estimate of the absolute size of impact was one of 11-12-year-olds. At 1-year follow-up, 17% had reported drinking beer during the past year. Twenty per cent of those in the highest quartile of advertising exposure (including exposure to television advertisements, magazine reading, radio listening, beer concessions, in-store beer displays, and ownership of beer promotional items),

had used beer during the previous year, compared with 13% in the lowest quartile, a 50% increase.

Seven of the eight studies that measured the impact of exposure on initiation of drinking included an interval or continuous level exposure measure, and all seven studies found a dose-response relationship. One study on multiple measurement points at 8-month intervals found that movie alcohol exposure at baseline predicted alcohol use at 8 months, while movie alcohol exposure between baseline and 8 months did not predict alcohol use at 8 months, but did predict alcohol problems at 16 months, and movie alcohol exposure between 8 and 16 months predicted alcohol use at 16 months. At all times, alcohol use predicted alcohol problems and there were significant indirect and independent effects of movie exposure at baseline, 8 and 16 months on alcohol problems at 24 months. In the same study, when investigating the influence of ownership of ABM, this ownership at baseline had a significant direct impact on initiation of binge drinking at 8 months, but not initiation of binge drinking between 8 and 16 months, whereas new ownership of ABM at 8 months had a significant direct impact on initiation of binge drinking at 16 months.

ECONOMETRIC STUDIES

Although potentially very important, econometric studies, which look for correlations between the amount of alcohol and tobacco advertising and the amount of smoking and drinking taking place in a particular jurisdiction, run into a number of methodological difficulties. First, measures of the amount of advertising, which typically use expenditure on advertising, vary in accuracy and inclusiveness. Second, analysis depends on the construction of a complex model that ascribes values for all the different variables – including price, drinking and smoking restrictions, and disposable income – as well as any advertising that might be implicated. Third, variations in the amount of advertising tend to be minor (few comprehensive bans have been introduced). So researchers are looking for potentially small changes in drinking and smoking patterns. Fourth, measures of the overall amount of advertising do not necessarily give an accurate picture of exposure by young people.

Not surprisingly, only modest effects have been found in some studies, while others have found no effects. For example, looking at alcohol advertising expenditure data across states in the United States, it has been found that, when controlling for alcohol price, income, and a number of sociodemographic variables, advertising expenditure had a modest and independent effect on adolescent monthly alcohol use and binge

drinking. It could be estimated that a 28% reduction in alcohol advertising would reduce adolescent monthly alcohol use from 25% to between 24 and 21%, and binge drinking from 12% to between 11 and 8%. In a meta-analysis of 132 studies which provided 322 estimated advertising elasticities, a positive impact of advertising was found on consumption which, in a meta-regression procedure controlling for alcohol price and income, was significantly larger for spirits than for beer. On the other hand, controlling for price, income, and minimum legal drinking age across US states, another study found total alcohol consumption rose after bans on price advertising, but fell after bans on billboard advertising.

The studies of tobacco advertising bans in various countries show that comprehensive bans reduce tobacco consumption. Noncomprehensive restrictions generally induce an increase in expenditures for advertising in “nonbanned” media and for other marketing activities, which offset the effect of the partial ban so that any net change in consumption is minimal or undetectable.

SELF-REGULATION

In some jurisdictions, marketing relies on self-regulation by economic operators including advertising, the media, and producers. To be effective, however, self-regulation needs a clear legislative framework. Furthermore, a self-regulatory system needs sufficient incentive to be effective. There is no reason to believe that the industry will participate for selfless reasons just to improve public health. A threat of government adjudication can be a strong incentive. In general, a self-regulatory system works best when pressure from government and civil society and lawsuits are the greatest and least well where there is little advocacy. Also, regulations should cover the entire range of marketing activities to which young people are exposed in order to avoid advertisers simply using the new media to avoid the regulations. Interpretations by the general public, and especially by vulnerable groups such as young people, should be included in evaluation of the advertisements, since evidence from a number of studies shows that these voluntary systems do not prevent the kind of marketing that has an impact on younger people. Self-regulation can only be effective as long as there is provision for third-party review of complaints concerning breaches. Otherwise, the interested persons who create and agree to abide by a code are the same ones who monitor its application. Sanctions and the threat of sanctions are needed to ensure compliance. An independent body or a government agency should be responsible for monitoring alcohol-marketing practices and should carry it out systematically and routinely.

There are many studies that show that self-regulation does not work. An independent review for the UK government in 2008 of the voluntary social responsibility standards in the production and sale of alcoholic drinks identified many areas of poor practice frequently used in clubs and bars for young people including people who appear to be under 18 years frequently being admitted to age-restricted venues in which they cannot purchase alcohol legally, the promotion of alcohol through low price offers, inducements by DJs to consume greater quantities, and glamorization through links with sexual imagery, encouragement to drink more and faster through shots and shooters being “downed in one,” sales to blatantly intoxicated people, several health and safety issues inside bars and clubs – for example, overcrowding, broken glass, and spilled alcohol, poor dispersal practices, and several instances of antisocial behavior and low level crime (fights and assaults, urinating and vomiting in public places, criminal damage). The review concluded that the trading climate led to a commercial imperative that overrides adherence to self-regulation standards. The standards were considered as having negligible impact in either reducing bad practice or promoting good practice on the ground; they lacked focus and they were a confusing mix of provisions, and there was no evidence to suggest any direct causal link between the impact of self-regulation standards and a reduction in alcohol-related harm.

Another example comes from the United States, where, historically, the alcohol and tobacco industries have been the biggest users of outdoor advertising. However, the 1999 Master Settlement Agreement (MSA) outlawed tobacco billboards and transit furniture (e.g. bus, bench) advertisements, and the Outdoor Advertising Association of America pledged to voluntarily eliminate advertisements for alcohol and tobacco within 500 feet of schools, playgrounds, and churches. However, observational studies in pre-Katrina southern Louisiana and in Los Angeles County during the years 2004–2005 found that more than one in four tobacco advertisements in Louisiana failed to comply with the MSA. In Los Angeles, 37% of alcohol advertisements and 25% of tobacco advertisements were located within 500 feet of a school, playground, or church; in Louisiana, roughly one in five advertisements promoting alcohol or tobacco fell within this distance.

An analysis from the Center on Alcohol Marketing and Youth found that exposure to alcohol advertising on US television increased 71% between 2001 and 2009. Driving this increase was the rise of distilled spirits advertising on cable television. Youth exposure to all distilled spirits TV advertising was 30 times greater in 2009 than in 2001. By 2009, the majority of youth exposure to advertising for all alcoholic beverages on cable

was occurring during programming that youth ages 12–20 years were more likely to be watching than adults 21 and above. Under pressure from the Federal Trade Commission to reduce youth exposure to alcohol marketing, in 2003 trade associations representing beer and distilled spirits companies joined wine marketers in committing to advertise only when the underage audience composition is less than 30%. This threshold has been ineffective in reducing youth exposure on television, either in absolute or in relative terms. Using as the comparison to 2004 (the first full calendar year after beer and distilled spirits adopted the 30% threshold), data show that by 2009 youth exposure to alcohol advertising on television had grown by a greater percentage than that of young adults ages 21–34 or adults ages 21 and above. Moreover, industry compliance with the 30% threshold remained uneven. In 2009, 7.5% of all alcohol product advertisement placements (23 718 ads) and 9% of all alcohol product ad placements on cable (16 283 ads) were on programming with underage audiences greater than 30%.

Although in magazines, alcohol companies have almost universally met the self-regulatory standard they set in 2003 for maximum youth audience composition of media in which they would place their advertising, these standards precluded advertising in only nine of the 160 magazines used by alcohol companies between 2001 and 2008. Compliance with the 30% standard left 25 magazines with youth audience compositions above 15%. Advertisements placed in these 25 magazines accounted for 78% of youth exposure to alcohol advertising in magazines in 2008. Sixteen, mostly major, alcohol brands (5% of the 325 alcohol brands advertising in magazines in 2008) generated more than half of the youth exposure in these 25 magazines. Thus, while total youth exposure to alcohol advertising in magazines has declined, overexposure is still common, and overexposing ad placements account for the majority of youth exposure to alcohol advertising.

An overview of what internal tobacco company documents have to say about tobacco advertising in the UK highlights three things. First, it confirms the key conclusions that tobacco advertising can increase consumption as well as brand share, where young people are a key potential target who are particularly susceptible to psychosocial appeals, that sponsorship works in exactly the same way as advertising (only with greater subtlety), and that advertising is only a small fragment of marketing. The internal documents show that, despite public pronouncements to the contrary, the industry has clearly been working on the assumption that all these findings are correct. Furthermore, it is exploiting the opportunities that result: Market growth is a goal, brand images secure the young, the subliminal qualities of sponsorship are welcomed, and the pack (a marketing

tool often overlooked by regulators) is exploited to the full. Secondly, and perhaps more worrying than these specific practices is the overall picture that emerges of an industry that is doing everything it can to encourage smoking. The commercial imperative is all, and the enthusiasm and competitive drive to meet its demands are palpable. Ethical doubts are not acknowledged, and health consequences barely get a mention.

Thus, a range of experiences demonstrates the unworkability of self-regulation. The only solution is statutory regulation, with the overt aim of removing all tobacco and alcohol marketing. This regulation has to be powerful, comprehensive, and flexible: Powerful to ensure that, in a profitable market, transgression does not pay; comprehensive to ensure that all facets of marketing are controlled, and flexible to ensure that innovations are identified and stopped.

INTRODUCTION

Alcohol is the psychoactive drug of choice in most contemporary societies, and its consumption is responsible for substantially greater harm overall than are all the normally illegal substances such as cannabis, heroin, cocaine, and ecstasy. A group of drug experts in the United Kingdom recently published a report in the prestigious medical journal, *The Lancet*, which ranked the potential hazards from different psychoactive substances against different health and social harm criteria. They concluded that alcohol ranked first as the most harmful, followed by heroin and crack cocaine at some distance.

The consumption of alcohol in most modern societies is so commonplace and the act of pleasurable and apparently harm-free drinking is so familiar that scientific

evidence of harm is often greeted with disbelief both by the public and their elected decision makers. Nonetheless, a substantial body of evidence has accumulated around the world demonstrating the relative effectiveness of different policies designed to reduce consumption and related harms. This chapter provides an overview as well as a discussion of the difficulties in communicating the scientific evidence about alcohol-related dangers and the potential effectiveness of alternative policy responses.

By the way of a small local illustration, a report was released in British Columbia, Canada, in 2009, which linked increasing alcohol consumption and deaths in the province to a dramatic increase in the number of liquor outlets between 2001 and 2008. The report outlined several evidence-based policy responses to reverse this trend involving pricing alcoholic drinks to reflect

their alcohol content, linking prices to inflation and increasing minimum prices. The local media caricatured these policies as a “price hike”; talk radio stations received angry calls pouring scorn on the idea that raising prices would influence the behavior of “alcoholics”; and newspapers published editorials sympathetic to the manufacturers of locally produced high-alcohol content “craft” beers. Members of the government of British Columbia (BC) were skeptical about the need for and effectiveness of such policies, especially when they were given personal briefings offering such objections as the following: “no one else seems to be saying this is a problem; surely alcohol does not cause cancer; people can make their own alcohol and there are always ways to get round increased prices.” In the end, however, the BC government did arrive at some improved public health policies on alcohol, including scrapping a planned reduction in the price of alcohol. This decision may have been influenced by the report, and also the public debate generated – but the overall response still fell well short of an optimal and comprehensive set of evidence-based policies.

The field of alcohol policy can sometimes be characterized as a dialogue of the deaf between well-meaning scientists and educators on the one hand and a mass of skeptical consumers and their elected representatives on the other. Decision makers in democratic societies rarely act on issues like alcohol policy purely in the interest of public health and safety unless they believe a majority of the voting public will be in support. This is despite the fact that the global evidence for the enormous burden of serious alcohol-related harm has never been stronger. Studies sponsored by the World Health Organization have estimated that annually, 2.26 million deaths can be attributed to alcohol. The evidence for what constitutes effective alcohol policy that would reduce this harm has also never been more clearly demonstrated and communicated. However, before political leaders are willing to listen to this evidence, they perhaps need to hear it from their voters rather than earnest scientists. The size of this challenge is well illustrated by studies of public opinion that find significant *and negative* relationships between public support for alcohol policies and regional per-capita alcohol consumption. In other words, the “wetter” a culture is, the more resistant it is to the introduction of effective policies to reduce consumption and its consequent harm. Similarly, studies of drinking behavior and public opinion have found that heavier drinkers tend to be more opposed to effective strategies such as raising the price of alcohol and reducing the hours of sale for liquor. By contrast, almost everyone is in favor of educational approaches, though evidence for the effectiveness of these approaches in isolation is usually extremely limited.

Public discourse about alcohol policy interventions is not for the fainthearted and requires strong counterarguments to dispel popular myths that seem to impede good policy. This chapter discusses drinking patterns and related harms in a way that directly addresses some of these widely held misconceptions. It then describes scientific evidence supporting a range of policies capable of substantially reducing the health, social, and economic costs associated with alcohol misuse. This description is accompanied by a discussion of some common sources of skepticism that have emerged when such policies are discussed publicly.

THE BURDEN OF ALCOHOL-RELATED HARM TO SOCIETY AND THE PREVENTION PARADOX

A common perception of alcohol-related problems is that they are essentially restricted to (1) drinking and driving, (2) liver disease, and (3) a small number of people who become “alcoholic.” The scientific evidence, on the other hand, is that in most countries these three particular issues collectively account for less than a third of all alcohol-related harm. In fact, alcohol-related harm is distributed broadly across the whole drinking population and includes nondrinkers who are often affected by the drinking behavior of other people. Alcohol-related road trauma tends to be the leading cause of “acute” alcohol-related harm, but there are many other effects associated not only with injury (intentional and unintentional) but also some acute illnesses such as poisoning, overdose, and pancreatitis. Alcoholic liver disease is among the most common causes of death and hospitalization attributable to alcohol, but collectively there is more serious harm from cancer, gastrointestinal, and cardiovascular illnesses (all of which are at least partially attributable to alcohol consumption). In 2007, the International Agency for Research on Cancer classified the ethanol contained in alcoholic beverages as a carcinogen, with the evidence strongest in relation to cancers of the mouth, throat, esophagus, liver, bowel, and female breast. Total numbers of deaths in developing countries attributable to alcohol vary depending on the precise methodology used in studies, but they are in excess of those limited to alcohol-related road trauma and liver disease. The World Health Organization methodology for estimating the global burden of disease from alcohol includes in excess 60 separate diagnostic categories of injury or illness at least partly caused by alcohol.

From the perspective of public policy, a grave concern is that the risk of these potentially fatal conditions appears to have no threshold effect, with the risk mostly increasing from an average of one drink per day,

increasing in some cases exponentially as consumption increases. At low levels of consumption (up to roughly two drinks per day for women and three for men), these concerns can be alleviated somewhat by evidence of protection against one of the most common causes of premature death: coronary heart disease. However, the extent of these benefits is probably quite limited for a number of reasons: A pattern of occasional heavy drinking eliminates the health benefits from otherwise "moderate" consumption; the superior health status of moderate drinkers compared with that of abstainers is likely due mostly to a range of other differences in risk behavior such as less obesity, better nutrition, and more exercise. In addition, there are other unresolved methodological problems with many of the studies suggesting health benefits from moderate consumption.

Even if one takes the optimistic view that at low levels of alcohol consumption the health benefits in relation to coronary heart disease compensate for the increased risk of many other serious illnesses, there is worrying evidence that most alcohol consumption in contemporary developed countries falls outside such low levels of consumption. Analyses of national drinking surveys from different countries indicate that the top 10% of drinkers by volume consume at least 50% of all the alcohol – and these are all underestimates due to serious underreporting biases in self-report surveys. Furthermore, when examining the amount consumed per day or per week, as much as 73% of all alcohol consumed in Canada and 64% of alcohol consumed in Australia fall outside of the low-risk drinking levels defined within these countries.

In relation to a number of health and social problems, a "Prevention Paradox" has been identified whereby most alcohol-related problems identified through national survey data are reported by people who, *on average*, are classified as moderate drinkers. It follows that to prevent these problems measures are required, which impact broadly on the drinking of many people and not just a small number of "problem drinkers" or "alcoholics." Subsequent analyses of national survey data have shown that many of these numerous and apparently moderate drinkers can be classified as occasional "binge drinkers" (usually defined as anyone drinking five or more drinks per day), a pattern of drinking that is common in many contemporary societies.

In summary, the threat to public health and safety posed by the widespread use of alcohol is not limited to road trauma, liver disease, and alcohol dependence but is broadly distributed throughout the population, among both drinkers and the people who are affected by the drinking of others. Because of the widely held popular perception to the contrary, it maybe an important first step to embark on a program of community

education regarding the harms associated with alcohol so that efforts to introduce effective public policies will be better received. For this reason, there have been increasing calls for a reorientation of public education and persuasion strategies regarding alcohol away from a goal of changing behavior toward one of preparing the ground for the more effective public health and safety measures.

EDUCATION AND PERSUASION STRATEGIES

Public debates about what can be done to reduce problems of alcohol frequently canvas the proposition that in a free and democratic society there should be no heavy-handed restrictions on access to alcohol; instead, the thinking is that people should be simply educated on the risks and be encouraged to regulate their own behavior. While this viewpoint is appealing from many perspectives, a series of comprehensive reviews of the international research literature have come to the conclusion that the great majority of public education campaigns have had no discernible effect on drinking behavior. A small number of well-designed studies have demonstrated modest progress toward reduced drinking and risk from others who drink in some school-based programs. There have also been some potential benefits from community education programs that support other regulatory and policy measures, for example, drink driving and liquor law enforcement. However, overall it would appear that public education and persuasion in isolation can have only very limited impacts on hazardous drinking patterns and related harms. In addition, efforts to *increase* alcohol consumption through advertising, sponsorship, and other forms of promotion appear to be effective and in many societies, by comparison with public health campaigns, are ubiquitous. This does not mean that education about alcohol and health should cease, but rather that its objectives need to be reconsidered.

The case of alcohol warning labels is an interesting case in point. There is only limited evidence of behavior change triggered by the introduction of warning labels. Most of the relevant research on warning labels has been conducted in the United States where a series of hard-to-read black-and-white labels were introduced in 1988 advising of the risks from alcohol for pregnant mothers and drivers, as well as the potential for dependence and some serious diseases. There was some evidence that after their introduction in the United States the labels increased conversations about the health risks of alcohol and were associated with a slightly reduced likelihood of drinking and driving. The research also

showed quite clearly that warning labels have the unique virtue of reaching those who arguably are most in need of understanding the messages: heavier drinkers. Also, compared with other public policies on alcohol, such as increasing prices for reducing hours of sale of liquor stores, introducing warning labels has been consistently found to be highly popular in surveys of public opinion in North America and elsewhere. In the United States, they actually became more popular after their introduction. In discussions of whether to introduce warning labels on alcohol containers in countries such as the United Kingdom, Canada, and Australia – and quite possibly many European countries as well – the failure of the US warning labels to convincingly change behavior has been used as an argument against their introduction elsewhere. This was certainly the case when the Canadian Standing Committee on Health considered a Private Members Bill to introduce alcohol warning labels in 2005, a committee whose final deliberations were witnessed by this author. It is hard to imagine another substance or product with proven carcinogenic and/or addictive properties for which potential population-wide behavior changes have to be proven before health warnings are required by lawmakers.

Among the many risks posed by alcohol consumption, cancer is perhaps the least well known, and there is a strong argument that the public has a right to be informed of this risk. A comprehensive public education strategy might usefully include the introduction of a series of highly visible, readable, and colorful health messages on all alcohol containers. Given the evidence that warning labels are read most and remembered best by people who drink most, this could be one effective way to communicate the health and safety risks of alcohol consumption within the context of national low-risk drinking guidelines – that is, advice on “how much is too much.” One focus of such a campaign might be to raise awareness of health risks from drinking for the more prevalent forms of cancer – breast cancer and cancer of the esophagus.

A growing body of research also strongly supports the idea that exposure to alcohol promotions during adolescence increases the likelihood of both drinking and drinking heavily as young adults. Analyses of the wide array of media to which adolescents are exposed to in contemporary societies indicate whether through print media, social networking sites, sponsored sporting events, television, or radio, young people are exposed to a higher level than ever before to messages that variously normalize, glamorize, and promote alcohol use. There is also a small literature examining the effects of restricting alcohol promotions, which in the main suggests that restrictions on advertising result in reductions in alcohol consumption. In other words, another place to start with educational and persuasion strategies

is to develop policies that effectively reduce the exposure of young people in the general population to messages promoting the use of alcohol.

PRICING AND TAXATION APPROACHES

In stark contrast to the status of educational strategies, evidence for the effectiveness of increasing and/or maintaining alcohol prices is the strongest of any single intervention that has been evaluated. This has been the conclusion of multiple comprehensive reviews and has recently been confirmed by a series of meta-analyses as well as focused studies of natural experiments in public policy. Dr Alex Wagenaar, a renowned epidemiologist at the University of Florida, identified high-quality studies from many countries across the globe employing data collected across a period of more than 200 years and generating more than 1000 estimates of the relationship between alcohol prices on the one hand and the levels of consumption on the other. The conclusion was that a 10% increase in price led to an average 4.4% reduction in consumption across the entire drinking population. For studies of problem drinkers, there was a slightly smaller but still significant effect size of 2.8% reported. However, it is important to note that very different types of studies focus on individual level drinkers, which typically produce lower estimates of effect sizes than do aggregate studies. It is likely that problem drinkers are just as responsive to price changes as light or moderate drinkers. In fact, some studies suggest they are more responsive. Wagenaar and colleagues also conducted meta-analyses to estimate the relationship between alcohol price changes and changes in the levels of different types of alcohol-related mortality reporting that doubling the US alcohol excise tax would reduce alcohol-related mortality by an average of 35%, traffic deaths by 11%, sexually transmitted diseases by 6%, violence by 2%, and crime by 1.4%. Many country- or jurisdiction-specific studies evaluating the impact of sudden changes in the price or taxation of alcohol show clear reverse effects on alcohol-related harm.

Significant and substantial impacts on rates of death caused by alcohol were also demonstrated for Alaska immediately following two large increases in tax rates over the past 20 years. Similarly, when a special tax was introduced in the Northern Territory of Australia of five cents per drink in the early 1990s, significant and substantial reductions in alcohol consumption, alcohol-caused deaths, road trauma, alcohol-related hospitalization, and economic costs were demonstrated. When the policy was reversed, these gains were lost when a comparison was made with regions in neighboring states with similar population profiles.

Again, in stark contrast to education and persuasion strategies, pricing and tax increases are consistently found to be highly unpopular approaches. There is also evidence that many people simply do not believe that raising the price would impact levels of drinking by people who are harming themselves from their alcohol consumption.

Another difficulty with the proposal that we simply “increase the price of alcoholic drinks” is that in any market there are typically many thousand varieties of alcoholic beverages with different prices and strengths that allow people to choose cheaper alcohol when prices increase. In response to these perceived difficulties in selling the idea of price increases to the public and political leaders, recommendations for effective alcohol price policies have started to become more specific to both better target hazardous drinking and, hopefully, be less rejected in popular opinion. Examples of more targeted alcohol pricing policies include the following:

Inflation Proofing Alcohol Prices

In many countries, alcohol taxes are not linked to the cost of living and so in real terms they have become cheaper, thus placing downward pressure on alcohol prices and increasing the risk of more consumption and related harm. One response from governments has been to use the mechanism of a sales tax that automatically adds a fixed percentage to the retail price of alcoholic beverages and so is automatically linked to inflation. Unfortunately, this strategy also favors cheaper products with low production costs that can deliver high-alcohol content at a very low price. In the United States, there are jurisdictions that have not increased beer taxes in more than 50 years. In Canada, the consent of Parliament is required to raise alcohol excise, and this has been done only twice in 25 years. By contrast, in Australia alcohol excise taxes on beer and spirits are raised every three months with the cost of living so that their real values are maintained. Thailand has developed an interesting twin method of taxing alcoholic beverages both on their alcohol content (i.e. the more alcohol in a product the higher the tax) and on their final retail price (i.e. a sales tax). Their policy has the virtue of selecting that form of taxation that results in a higher price so that prices are automatically indexed to inflation without encouraging a market for cheap high-strength products.

Enforcing Minimum Prices per Standard Drink

Econometric models have suggested that raising minimum prices in the United Kingdom would significantly reduce alcohol-caused deaths and health care costs. Canadian jurisdiction in common with some

Scandinavian countries and a few US states retain government alcohol monopolies on the distribution of alcohol, including the power to set and enforce minimum retail prices. Typically, these prices are set independently of alcoholic strength and are not linked to the cost of living, which guarantees that at least a small number of very cheap high-strength products remain – for example, 8% malt beer, 23% fortified wine, and 75% rum. US research has estimated that the top 10% of heaviest drinkers on average spend less than a dollar per standard drink compared with nearly 5 dollars per drink for the bottom 50% of lightest drinkers. Canadian research has confirmed that raising minimum prices is not only an effective way of targeting heavy drinkers: It is also a highly effective means of reducing overall consumption. Nonetheless, defining a minimum price for a standard unit of ethanol and regularly raising this price in line with inflation would be an even more effective public health strategy.

Linking Price to Both Alcohol Content and Percentage Strength

It is ethanol that causes harm from alcohol, whether this be through dose–response toxic effects on the body over the long term or through levels of intoxication in the short term. Typically, drink prices bear little relationship to the level of alcohol content and hence to potential harm. Health authorities and academics are increasingly calling for ethanol-based pricing within each main category of alcoholic beverage. This is not to be confused with a simple strategy of requiring higher rates of taxation for spirits as opposed to wine and beer. There are many hundred, even thousands of varieties of beverage strengths in each of these broad beverage categories, so that a crude differentiation based on beverage type would be insufficient. Instead, such a policy would mean that lower-strength beers would always be cheaper than beers with higher alcohol content and similarly for wines and spirits. It would be possible to have one unified set of taxation rates based entirely on ethanol content. This approach could replace the complex tangle of literally hundreds of different rates of tax that are often applied to alcoholic drinks in many countries, for example, depending on how they are made, where they are manufactured, and where they are bought. This would not mean that a standard drink of beer would cost exactly the same as a standard drink of wine or spirits, but that the rate of taxation would be tiered according to both the volume of ethanol and the percentage alcohol content of the beverage; that is, 500 ml of 8% beer would cost more than 1 l of 4% beer, even though both contain exactly the same ethanol. Australia has long implemented a policy of encouraging consumption of beers with lower alcohol content

through lower rates of taxation, which created a vibrant market for lower-strength products and effected an overall reduction in the amount of ethanol consumed in the form of beer. This kind of reform could still be beneficial even if introduced in a “revenue-neutral” manner – that is, without necessarily increasing the overall amount of taxes raised from alcoholic drinks (though that would be more effective still).

Introducing Harm-Reduction Levies on Alcohol

There is some evidence that the unpopularity of hiking the price of alcohol to reduce problems can be offset if the rationale provided involves raising revenue to pay for treatment and prevention programs. Such earmarked or “hypothecated” taxes have been introduced in a number of countries variously for alcohol, tobacco, and gambling. As mentioned previously, there is both general and specific evidence that such special taxes reduce harm while generating extra revenues. Not only do increased alcohol taxes result in increases in the price of alcohol, and hence lower consumption and rates of harm, but they also would almost invariably result in increased revenues for government – because reductions in consumption are almost invariably less than the tax increases. Many effective forms of prevention and treatment strategies could be funded from such increased revenue – for example, increased roadside breath testing, violence prevention programs, brief early intervention programs delivered by health professionals, and a more substantial infrastructure of detoxification and rehabilitation programs for people suffering from alcohol dependence.

However well presented and evidence based the above set of strategies maybe, anyone proposing them in the public domain will be subjected to a strong backlash from consumers and commercial vested interest groups. Having said that, this author has observed more favorable public and media comment on the idea of pricing drinks according to their alcohol content without necessarily raising overall revenue and also on the idea of a “harm-reduction levy” to fund much-needed treatment programs.

The two most common counterarguments to such proposals are that (1) they do not impact on the people who drink the most who would drink regardless of price, and (2) their families will consequently suffer and the individuals may turn to more dangerous forms of nonbeverage alcohol. The first argument has already been refuted in this chapter, while the second argument needs further consideration. It would be fairly unique for an increase in price to have absolutely no effect on the consumption of a product, however “addicted” a consumer might be. It is also not clear what strategies alcohol-dependent individuals actually use when they cannot afford to purchase alcohol. Do they wait until

payday or the next welfare check before they go drinking? Do they work harder through legitimate means to raise extra money? Or do they resort to crime and neglect of family members? In a small-scale qualitative study of homeless problem drinkers in Victoria, British Columbia, hardly anyone resorted to drinking nonbeverage alcohol when they last experienced this circumstance, while almost all participants reported instead waiting for the next welfare check and/or “working harder” to earn money by collecting recyclable products left on the street. It maybe that this apparently deep-seated fear of how vulnerable problem drinkers would be affected by price alcohol rises is not based on reality. In addition, certain strategies can be adopted to compensate for the possibility of unintended consequences, such as increased consumption of nonbeverage alcohol: “wet shelters.” Some housing options for people who continue to use alcohol and other drugs have evidence of effectiveness, including programs that actually provide free alcohol to residents. One published evaluation of the latter reported that individuals on the program in fact reduced their alcohol consumption as well as their visits to emergency rooms and problems with the police. Such programs are only offered in a well-structured institutional setting for people who have repeatedly failed with traditional abstinence-based treatments and who would otherwise be putting their lives at immediate risk by drinking nonbeverage alcohol.

Pricing and taxation strategies need to be the first priority of any comprehensive response to alcohol-related problems. Any society that allows unfettered access to very cheap alcohol would make it harder for all other prevention and treatment strategies to be effective. It is important to be aware of counterarguments to the valid case for maintaining drink prices with the cost of living, adjusting them according to alcohol content, ensuring minimum prices are not too low, and taking advantage of the opportunity to raise revenue for those most affected by alcohol-related harm. It is also important to continue to conduct research that carefully examines the validity of the many prevalent arguments against pricing policies.

REDUCING THE AVAILABILITY OF ALCOHOL

Limits on the Number of Liquor Outlets

A substantial body of evidence links the “density” of different kinds of liquor outlets with rates of both alcohol consumption and alcohol-related harm. In addition, there is evidence for changes in the density of liquor outlets (whether measured in terms of number per head of population or per square mile), resulting

in corresponding changes in consumption and harm. For example, increased density of liquor stores has been shown to predict later increases in consumption and to increase per capita consumption as well as rates of alcohol-related mortality at the local area level; changes in the density of liquor stores over time have been related directly and significantly to crime rates.

Limits on the Hours of Sale of Liquor Outlets

There is strong evidence that large changes (e.g. adding or subtracting a whole day) in the trading hours of bars and liquor stores can influence the rates of consumption and harm. At first sight, the wider literature on the effects of adding or subtracting an hour or two to the trading times of bars suggests the following: (1) most studies have evaluated the effects of increasing trading hours reflecting deregulatory trends in the last half of the twentieth century; (2) results are conflicting, with many finding no effect. However, a more careful analysis of the better-designed studies finds that the great majority support the hypothesis that increased hours result in increased problems, including violence and road-safety issues. One study also reported increased blood alcohol levels associated with later trading hours, which provides a plausible causal mechanism for the increases observed in problems. More recently, well-designed studies have also begun to emerge that have demonstrated reductions in violent incidents following reduced trading hours.

Restricting the Legal Age of Purchase

There is strong historical evidence that increases and decreases in the legal drinking age such as that happened in the United States over the past three decades have significantly predicted corresponding decreases and increases, respectively, in road trauma involving young people. There is also a small literature regarding the effectiveness of various enforcement strategies designed to limit access to underage drinkers to alcohol purchases. Both the legal age of purchase and the extent to which this is enforced would limit access to underage drinkers and potentially reduce harm to this specific group who are at very high risk for a range of alcohol-related problems.

Responding to Counterarguments

It can be challenging to debate whether or not to implement such controls in the public domain. Because by their very nature these restrictions can be seen as restrictions on the freedom and liberty of individual citizens, it is important to stress that these issues must be resolved through democratic means with public debate

informed by scientific evidence. Interestingly, there is good evidence of strong public support for strategies that limit the trading hours of bars and restaurants, with levels of support as high as 70% not being unusual. However, this finding has not stopped trends in many countries toward more liberal opening hours over the past few decades. Those who doubt the effect of an hour or two of extra trading after midnight might be persuaded if they consider that at these times on-premise outlets, especially on weekends and holidays, are at their busiest and also when people are intoxicated they are more likely to spend freely. A common counterargument often mounted is that restricting hours would force people to hurry their consumption and they will leave more intoxicated. The empirical evidence suggests otherwise, however: Patrons from premises with longer trading hours picked up by random breath-testing patrols have been found to have significantly higher blood alcohol levels. It is also often argued that bar closing hours should be “staggered” to avoid having drunken patrons all competing for space on the pavement, the roads, and public transit at the same time. Alcohol industry advocates often use this claim as a basis for arguing for all-night or at least much longer trading. The evidence from a number of countries is that all-night trading might lead to a more orderly progression of violent and dramatic incidents associated with alcohol, which might be more readily dealt with by emergency personnel. However, when all the incidents are added up at the end of the night, there are many more when the bars stay open all night. It is also possible to “stagger” closing hours without creating an overall increase in hours. Being allowed to stay open later could be used as a privilege and rather than a right so that, for example, only premises with low rates of violent incidents could be permitted to stay open later.

Public debate regarding restrictions on the sheer number of liquor outlets can also trigger disbelief. Some of this skepticism maybe assuaged with discussions of how: (1) physical convenience in terms of distance to the nearest store and (2) the ability of entrepreneurs to adapt their products to local niche markets can maximize sales and how (3) the proximity of many liquor outlets can lead to greater competition, thereby driving down prices and increasing managers' preparedness to serve underage and intoxicated customers. Ultimately, however, it is never easy to persuade communities where the majority of people consume alcohol at least occasionally that access to this popular drug should be made more difficult.

Other Effective Alcohol Policy Strategies

One of the difficulties associated with each of the more effective population-wide strategies that involve reducing physical and or economic availability is that

they are perceived as inconveniencing or even punishing the great majority of moderate drinkers. While it is possible to argue that those who drink the most are most inconvenienced and light or moderate drinkers are hardly inconvenienced at all, strategies that are seen to directly target harms or high-risk drinkers are generally better received. Some of these strategies show strong evidence of effectiveness as well. In particular, there has been an increase in knowledge worldwide on how best to deter drink-driving and hence reduce alcohol-related deaths. Deterrence theory requires that penalties need to be immediate and certain, though not necessarily severe to achieve maximum effectiveness. A combination of a low legal blood alcohol limit for driving and highly visible and frequent random breath testing would make the most effective contribution to reducing the road toll. Brief interventions for early-stage problem drinkers delivered by health practitioners show very strong evidence of effectiveness. These interventions involve screening all patients attending primary or secondary health care facilities for a range of health-related risk behaviors and then providing brief advice and follow-up to those identified as having early-stage problems. While only a minority of early-stage problem drinkers tend to reduce their consumption when receiving these interventions, it has been estimated that if this approach was employed routinely in a majority of health care facilities, then there would be substantial impacts on the levels of problem drinking and related harm.

There are also a number of strategies with a strong rationale, low implementation costs, but only limited evidence of effectiveness. Some of these strategies can be described as being "harm reducing" in that they modify the environment to reduce risk to the drinker without necessarily requiring reduced alcohol consumption. One example is the thiamine fortification of alcoholic beverages or as an ingredient in food consumed even by heavy drinkers. Thiamine deficiency caused by prolonged and heavy alcohol can generate a serious form of brain damage known as Wernicke-Korsakoff Syndrome. In the late 1980s, the Australian government required that all bread-making flour be fortified with thiamine, a policy that resulted in a measurable decline of this serious condition. Another example involves requiring the use of plastic or shatterproof glassware at events or venues where there is a high risk of alcohol-related violence. There is evidence that many barroom brawls result in injuries caused by using broken glasses or bottles.

REGULATING THE LICENSED DRINKING ENVIRONMENT

In addition to pricing policies and restrictions on the location and hours of operation of licensed premises,

there are a number of policing and environmental strategies that can be effective in reducing problems such as violence and public nuisance issues in bars and clubs.

Some highly predictable aspects of late-night drinking environments are associated with increased risk of problems. In most countries, a relatively small number of bars and clubs contribute to the bulk of incidents of violence and public disturbance – for example, as few as 10% may contribute to more than 60% of disturbances. This means there is a special role for police and licensing authorities being involved in identifying and targeting higher risk venues. Studies of the late-night drinking environment have identified risk factors that are easy to identify and modify – for example, permitting overcrowding, selling discounted alcohol, badly arranged physical spaces in which there is much jostling and bumping between patrons, lax "anything goes" management, and aggressive security staff who escalate rather than defuse potentially violent situations.

The overall regulatory environment in which licensed premises operate is critical to mitigating and reducing some of these risk factors. The density of bars and nightclubs in a particular area will influence the amount of crowding and competition for space on the one hand and degree of competition on the other. Pricing policies will determine how easy it is for patrons to overconsume. The extent to which licensing authorities check whether effective responsible management policies are in place is also key. In many jurisdictions, data on violent incidents and violations of liquor laws are not shared in any effective way between police and licensing authorities so that high-risk premises continue to operate while perhaps only suffering occasional fines. Regular audits of drinking venues in terms of risk for alcohol-related harm have been shown to be an effective way for police to monitor and control problems with the late-night drinking environment. Some studies also support an active community policing role visiting late-night drinking establishments in a way that supports and encourages the management to operate responsibly. In some instances, this has taken the form of a local "accord" between civic authorities, police, and licensees that lays out an agreed code of conduct. Evidence suggests that this approach is effective only if there is some significant deterrence against breaches of the code – that is, owners, management, and staff realize that noncompliance could have serious consequences.

Some studies have used "pseudo-patrons" or "mystery shoppers" to check whether bars permit obviously drunk patrons or whether potentially underage patrons are served. The recommended practice with these approaches is to first deliver warnings that these audits will be happening, then to give a warning for first offenses followed by graded fines, and, ultimately, license suspensions or termination. In general, the research on licensed

drinking environments and violence prevention suggests that effective regulation and enforcement of liquor laws are critical for community-based policing approaches to be effective.

CONCLUSIONS

Public education campaigns in isolation are inadequate and are often wrongly targeted. However, an alternative form of public education aimed toward (1) prompting informed debate on the extent of harms caused by alcohol and on optimal policy responses, and (2) restricting alcohol promotions maybe warranted. Such a campaign might usefully be built on a foundation of nationally accepted low-risk drinking guidelines endorsed by a broad range of public health and medical agencies and promoted through multiple media, including the Internet and messages on alcohol containers. Targeted strategies that are easy to understand as being focused on hazardous drinking and directly reducing harms are most readily supported in public discourse, and some of these have a degree of effectiveness. However, the most effective strategies for managing and improving public health and safety outcomes from alcohol consumption involve imposing restrictions on the economic and physical availability of alcohol to all potential consumers. These are much harder to sell and explain, but the evidence for their widespread benefit is growing. It is suggested that effective national alcohol policies need to start with ensuring that the voting public is fully aware of a causal relationship between particular drinking patterns and a range of serious health and social problems. In addition, pricing and taxation of alcoholic beverages need to be established so that access to very cheap alcohol is minimized. One of the most cost-effective strategies of all (and because it is revenue positive) involves enforcing minimum prices per standard drink which are regularly updated with the cost of living, with prices otherwise geared toward encouraging consumption of drinks with lower alcohol content. Once such fundamental strategies are in place, it maybe easier to implement a raft of other evidence-based strategies, including measures to reduce drink-driving, public violence, problem drinking, cognitive impairment, and alcohol dependence.

INTRODUCTION

Harm reduction is a social and health-related movement that emerged during the twentieth century in response to the risks associated with the burgeoning nonmedical injection of drugs. Today, harm reduction interventions like needle and syringe program (NSP) and opioid substitution treatment (OST) are the international gold standards in human immunodeficiency virus (HIV) prevention among people who inject illicit drugs. In 2010, Harm Reduction International, a nongovernmental organization and global leader in harm reduction and drug policy reform, reported that there were almost 16 million people who inject illicit drugs in 158 countries around the world, with China, the US and Russia having the largest injecting populations. Ninety-three countries and territories explicitly support a harm reduction approach and this number is growing

annually. Nevertheless, only 8% of all people who inject illicit drugs currently have access to an NSP and an OST. High-income regions like Western Europe and North America have the majority of harm reduction services. The adoption of harm reduction policies in many low- and middle-income countries remains slow and patchy despite escalating injecting-related HIV epidemics. There is an urgent need to expand harm reduction services globally given the conclusive evidence of their effectiveness in preventing HIV transmission among people who inject illicit drugs.

Harm reduction is a contentious model of risk management. Controversy arises because a harm reduction sensibility is the antithesis of the punitive ethos of global prohibition, which has been the policy response to illicit drug use for the past century. In contrast to prohibition, harm reduction views an individual's illicit drug use as a health issue that benefits from education

and medical intervention rather than a criminal behavior deserving punishment. Whereas prohibition seeks to criminalize, demonize, and marginalize people who use illicit drugs, harm reduction values the dignity and human rights of illicit drug users and views them as integral parts of communities with partners, friends, and other loved ones who may also be adversely affected by drug-related harm. Underpinning its substantial achievements in HIV prevention is a professed nonideological and amoral stance on illicit drug use, which is augmented by pragmatic evidence-based risk-reduction interventions. Although there are divisions within the movement itself, harm reduction in the early twenty-first century continues to build momentum.

HARM REDUCTION DEFINITION AND OVERVIEW

Harm reduction refers to policies, programs, and practices that aim to decrease the adverse social, health, and economic harms associated with the use of illicit drugs. Harm reduction aims to assist people who feel unable to, or do not want to, cease illicit drug use. Instead of preventing illicit drug use, the emphasis is on reducing its potential harms through the application of individual and community-focused interventions.

Cessation of drug use is supported by harm reduction programs if abstinence is the goal of an individual. However, a focus on drug abstinence per se is not harm reduction. Harm reduction policies, programs, and practices ideally are outcomes of collaboration between people who use illicit drugs, health professionals, community service providers, and policy-makers. Their central aim is to make illicit drug use less risky. Proponents of harm reduction accept that drug use is a part of life and that ways to minimize the potential negative consequences of illicit drug use should be based on scientific evidence. Harm reductionists evaluate current and proposed social, public health, and legal policies related to illicit drugs in terms of their capacity for producing, exacerbating, or ameliorating harm. For example, harm reductionists do not advocate for the decriminalization or legalization of illicit drugs, unless decriminalization or legalization is proved effective in reducing harm to individual illicit drug users and the community. In theory, the principal measure of successful harm reduction is improvement in the health, well-being, and quality of life of people who continue to use illicit drugs. In reality, however, political, economic, and social dynamics have limited harm reduction's core business to mainly HIV prevention among people who inject illicit drugs.

From Human Rights to HIV Prevention

Over the past 30 years, harm reduction has evolved from a peer-based human rights movement to a medical model, which has fixed its focus firmly on efforts to contain and reduce HIV transmission among people who inject illicit drugs. Indeed, the HIV epidemic was the catalyst for the development of the modern harm reduction movement and HIV prevention remains the international priority of harm reduction, as it has immense social, health, and economic benefits for individuals and communities in undeveloped, transitioning, and developed societies. Commentators including harm reduction activists have criticized this successful medical model of harm reduction for being overly preoccupied with the use of medical interventions to prevent HIV infection. They argue that harm reduction must broaden its scope beyond HIV prevention to engage with the myriad risks associated with illicit drug use, while continuing the excellent work in HIV. Critics of the medical model of harm reduction view social and economic issues like poverty and the stigmatization of people who use illicit drugs as neglected areas that generate the majority of the world's drug-related harms. The past decade has seen a renewed interest in harm reduction activism. Human rights groups have called upon the United Nations (UN) to remove the limitations imposed on the expansion of harm reduction programs because of international adherence to the 1961 Single Convention of the global illicit drug control regime. Indeed, some UN bodies like the Commission on Narcotic Drugs as recently as 2010 refused to include the term harm reduction in its Political Declaration on Drugs. On the other hand, the UN Member States of the Economic and Social Council in 2009 included the term in a resolution on the work of UNAIDS. In 2011, most UN bodies supported a harm reduction approach to HIV prevention; however, the ongoing controversy in international drug policy forums highlights an ongoing need for activism. One example of this occurring is The Vienna Declaration of 2010. This is a seminal statement drafted and supported by leading international experts and activists in public health, public policy, and medicine, and which seeks to improve community health and safety by incorporating scientific evidence into illicit drug policies. This declaration calls upon all UN bodies to support a global harm reduction approach.

A HISTORY OF HARM REDUCTION

The origin of harm reduction principles is found in the nineteenth century tenets of preventive medicine. The foundations of the modern harm reduction

movement were laid with the emergence of the disease model of addiction during the early twentieth century. By the late nineteenth century in Europe, the injection of opiates had become increasingly common within some social circles. In response to evidence of increasing addiction among the population of the UK and the poor treatment of people dependent on drugs by some medical practitioners, the Rolleston Committee was formed to investigate possible strategies to limit the health impacts of drug use. At this time in the UK, drug addiction was understood to be a middle-class phenomenon that did not attract criminal sanctions. Accordingly, the Rolleston Committee of 1924 made credible the idea of minimizing health risks to individuals who were dependent on opiates through the medical supply of morphine and heroin. The Committee's recommendations are the first evidence of a modern harm reduction sensibility emerging within medicine.

From the time of the Rolleston Committee until the 1960s, there was little practical or theoretical development in harm reduction. Global prohibition had become entrenched as the response to illicit drug use well before the 1961 UN Single Convention, which drew together all previous drug prohibition conventions under one umbrella. Prohibition is a system devised by the US and implemented by the UN and comprises a series of international agreements, which are underpinned by the political and economic interests of the US. Today, three UN Conventions limit proscribed drugs to scientific and medical purposes. International adherence to this regulatory system has been impressive, albeit driven by nations' fears of political and economic consequences via US pressure through the UN. This system of global illicit drug control remains remarkably resilient and even today is largely invisible to the world outside of academics, policy-makers, and harm reductionists.

Following an escalation of experimental, recreational, and dependent illicit drug use during the 1960s, some Dutch health professionals, social and political activists, and policy makers began to oppose and openly criticize prohibitive policies. Instead, they advocated for pragmatic strategies to address the problems they saw arising from significantly increased levels of illicit drug use. By the 1970s, the Dutch Parliament began to promote the "balance-of-harms" approach, which encouraged the police and the courts to assess whether prosecution for minor drug offenses would be in the best interests of individuals and society, or whether prosecution itself might lead to more harm for people than their drug use. This was an enlightened idea for the time because it positioned prohibitive drug laws as potentially harmful and ineffective at managing the burgeoning rate of illicit drug use in society. Prohibition had criminalized the production, manufacture, export, and import of an ever-expanding list of drug classes, and

demonized people who possessed and/or used them. On the other hand, a balance-of-harms approach privileged the health and well-being of individuals over the supposed deterrent effect of criminalization.

Harm reduction continued to develop in the Netherlands and by the early 1980s networks of injecting drug users in the city of Rotterdam had formed junkiebonden. These were drug users' advocacy groups that lobbied government officials to observe the human rights of illicit drug users. Members of junkiebonden also began distributing sterile injecting equipment in an attempt to ameliorate the impact of a hepatitis B epidemic among people who inject. Similar advocacy and harm reduction activities began shortly after in UK cities like Liverpool in response to the newly identified HIV epidemic. Within a few short years, the risk-reduction strategies implemented by these peer-based social and political movements were informing the development of government-funded harm reduction interventions, like programs for distributing sterile needles and syringes. By the late 1980s for example, the Australian and Canadian Governments had implemented NSP and increased funding for OST to curb HIV transmission rates. The evidence has subsequently shown that harm reduction strategies based on these medical interventions do successfully reduce morbidity and mortality through a reduction of HIV transmission.

HARM REDUCTION TODAY: PRIMARY SERVICES

The following section provides an overview of harm reduction interventions that employ medical and public health strategies to minimize the risk of blood-borne viral (BBV) infections like HIV and hepatitis C among people who inject illicit drugs.

Needle and Syringe (Exchange) Program

The reuse of equipment for injecting illicit drugs is the main risk practice for transmission of HIV among people who inject. In regions like the Netherlands, Spain, the UK and Australia, government-funded NSPs have successfully limited the transmission of HIV among people who inject. Sterile needles, syringes, and ancillary injecting equipment can be accessed at no cost from primary NSPs, which are often shop-front services designed exclusively for the provision of injecting equipment, safer injecting information, and in some cases BBV testing, counseling, and referral to OST. In some countries, injecting equipment is also available through secondary outlets like hospitals and community-health centers. Pharmacies often sell sterile

injecting equipment or provide new equipment at no cost if used equipment is returned. Vending machines are another source of purchasable injecting equipment and these are often located on the grounds of hospitals and community-health centers. In 2010, 82 countries and territories had programs to deliver needles and syringes. A large volume of data has been collected over the past 25 years to demonstrate the cost-effectiveness of an NSP. For example, an analysis of 103 cities from around the world show that in cities that ever had an NSP, there has been an average annual decrease in HIV prevalence of 18.6%. In cities that have not had an NSP, there has been an average annual increase in HIV prevalence of 8.1%. The cost-benefit of an NSP is substantial. In Australia between 2000 and 2009, the NSP is estimated to have prevented more than 32 000 HIV infections with savings to healthcare estimated at \$AUD1.28 billion.

The reuse of equipment for the injection of illicit drugs is the main driver of HIV and viral hepatitis epidemics in regions like Eastern Europe and South-East Asia. Yet, the provision of sterile injecting equipment is either nonexistent or inconsistent across developing, transitioning, and developed nations. In countries that adopted an NSP early in the HIV epidemic, current rates of infection among people who inject are extremely low. For example, Australia has around 1% prevalence of HIV infection in the injecting population. However, in many low-middle-income countries in Europe, Asia, the Middle East, and Latin America, injecting drug use accounts for the highest proportion of HIV infection in the general population, with rates often above 20% and higher than 80% among people who inject in some regions. HIV infection rates are high in some countries or regions because an NSP is nonexistent, or is slow to be implemented, or the demand for equipment cannot be met. The cost of providing HIV antiretroviral treatment to one person is many times greater than the cost of providing them with sterile needles and syringes to prevent HIV infection.

A common criticism leveled at harm reduction is that services like NSP send a wrong message about illicit drug use; that they implicitly condone and materially facilitate illicit drug use. Yet, among the myriad studies of the effectiveness, safety, and cost-effectiveness of NSP, there is no evidence to support such a contention. Key measurable factors such as age of initiation to injecting, the frequency of injecting, and the duration of injecting have not changed since the introduction of NSP and other harm reduction services. When harm reduction programs are introduced, the evidence strongly indicates that they either prevent a HIV epidemic from occurring, or they stabilize or reduce the rate of HIV infection among the injecting population.

Substitution Treatments

Another primary harm reduction strategy is the medical provision of substitution treatments to people who are dependent on illicit drugs. There are a variety of drugs used in substitution programs to reduce craving and withdrawal symptoms and block the euphoric effects of illicit opiates and opioids. Methadone, a semisynthetic opiate, is currently the most widely prescribed OST. Methadone is usually administered from special clinics in the form of syrup that is ingested once daily by registered attendees. Similarly, the drug buprenorphine, usually taken in tablet form, effectively reduces cravings and withdrawals in people dependent on opioids. Compared to methadone, which is addictive, buprenorphine is less likely to lead to dependency, is harder to inject, is less likely to cause overdose, and has less of a euphoric effect. In 2010, 70 countries and territories around the world had OST programs for people dependent on opioids.

Treatment with semisynthetic opiates like methadone and buprenorphine can significantly improve drug-dependent people's quality of life. Treatment increases health and psychosocial stability, which leads to increased employment opportunities and social integration. It also reduces the risk of infection with HIV and hepatitis C because OST drugs replace the need for multiple daily injections of illicit drugs. People usually only require one oral dose of methadone or buprenorphine per day to prevent the onset of withdrawal symptoms. The provision of OST is strongly associated with a reduction in HIV prevalence among people who inject. Also, drug overdose deaths are reduced when people have good access to OST. Opioid substitution drugs are regulated, noncontaminated substances that cost significantly less than, for example, heroin bought off the street.

In some countries like Switzerland, the Netherlands, the UK and Spain, evaluations of heroin prescription for opioid dependence have shown good outcomes. In the UK, heroin has been prescribed to a relatively small number of people for over 40 years, and evaluations show that this pharmacological intervention is cost-effective. Regulated heroin is extended to people when OST drugs do not stabilize their health to a point where they can function satisfactorily.

Finally, the recreational and dependent use of illicit amphetamine and methamphetamine (e.g. ecstasy) has increased substantially over the past two decades. While there are long-standing substitution treatments for opioid dependence, and alternatives are emerging, there is no well-evidenced substitution treatment for dependence on amphetamine-type substances. A number of substitution drugs have been used for this purpose, but research on their efficacy is very limited. The lack

of a well-evidenced substitution treatment limits the options available to those experiencing dependence on amphetamine-type substances.

Drug Consumption Rooms

A drug consumption room (DCR) – sometimes referred to as a medically supervised injecting center – is a supervised clinical environment where people can inject illicit drugs without the fear of police prosecution or harassment and disapproval by noninjectors. They are usually located in inner-urban areas known for their high rates of dependent injectors, and they are staffed by medical practitioners and allied health professionals who can immediately respond to injecting-related emergencies such as overdose. In 2010, there were 92 DCRs operating in 60 cities, mostly in Western European countries like the Netherlands, Switzerland, Spain, and Germany, and also in Canada and Australia. DCRs reduce the health and public-order problems associated with the street-based injection of illicit drugs. These facilities do not provide illicit drugs; however, people can attend a DCR to inject drugs procured elsewhere. While the interior designs vary, DCRs are often clinical in appearance and comprise an admission area, tiled and stainless steel booths for injecting, and a space for clients to recuperate prior to leaving the premises.

Like all harm reduction services, DCRs are politically contentious despite overwhelming evidence for their effectiveness. DCRs prevent overdose deaths and injecting-related injury, and they educate people about the risks associated with injecting. Evidence shows that these facilities reduce the number of risky street-based injecting episodes and improve the safety of local neighborhoods by removing activities associated with injecting away from the surrounding streets. DCRs reduce ambulance callouts and they provide an opportunity to engage some of societies' most marginalized people with harm reduction information, health services, and counseling. Evaluations reveal that clients of DCRs are more likely to seek referrals for OST, and they are more likely to access general health services than people who inject and do not attend DCRs.

Illicit Drug User Organizations

Government and nongovernment-funded illicit drug user organizations provide a range of health information-related services for people who use illicit drugs. These organizations are usually staffed by people who use illicit drugs, or former users, for the purpose of providing peer-education to prevent BBV transmission,

overdose, and other illicit drug-related health problems. As previously noted, peer-based initiatives are the foundation of the modern harm reduction movement. Peers are perceived as trustworthy and having specific expertise and contextual knowledge of the practice of injecting and living as a person who uses illicit drugs. In Canada, Australia, the Netherlands, and the UK, illicit drug user organizations have played a pivotal role in encouraging people to change their injecting practice by teaching safer methods of injecting. The work of professionalized peer-based illicit drug user organizations and the willingness of people to change their injecting behavior continue to be at the core of the successful response in HIV prevention around the world. These organizations also publish health promotion materials and magazines that provide the latest harm reduction information. Peer-workers in these organizations report that harm reduction is more effective when programs, strategies, and interventions are developed in cooperation with affected populations.

Finally, there are a variety of independent (i.e. nongovernment)-funded organizations, which aim to effect change in global illicit drug policy by ensuring that the voice and expertise of people who use illicit drugs inform the development of drug policy and harm reduction strategies. For example, The Vancouver Declaration 2009 is a statement by an international network of activists reclaiming the right to self-representation and self-empowerment through collective action. The Declaration outlines activists' aim to replace global prohibition with policy informed by a harm reduction sensibility, which respects the human rights and dignity of people who use illicit drugs.

Information, Education, and Communication

The provision of information and education is a tenet of HIV prevention, which is endorsed by the World Health Organization. Despite this endorsement, the role of information, education, and communication (IEC) within the medical harm reduction model and its acceptance in political and popular spheres are tenuous. The evidence base for IEC is limited, with little specificity regarding what messages or communication strategies and in what settings (e.g. school, point of purchase of consumption, online) work for which parts of the target group (e.g. novice or experienced users, people using drugs with sexual partners or social networks). Also, providing information on safer drug use poses challenges for conservative groups, like political parties and media outlets, which can effectively silence or dilute crucial aspects of harm reduction IEC and other programs. IEC is more effective, including effects beyond raising knowledge, awareness, and understanding,

when it is employed with other harm reduction services within a supportive social environment.

Interventions for Non-Injecting Drug Use – Pill Testing

Illicit drug supply is subject to unknowable processes in manufacture and distribution that sometimes have fatal consequences for users of illicit drugs. To better inform consumers of what precisely is in a pill marketed as ecstasy (and related drugs), pill-testing programs have been devised where an analysis of the content of pills is offered at the site of consumption (e.g. raves, festivals, or nightclubs), or via the Internet. The goal of pill-testing programs is to prevent people from ingesting pills contaminated with harmful substances. Other programs use pill testing in combination with information provision, sometimes as a draw-card. Implementation of pill testing is not widespread and there are significant limitations to the tests that exist. Pill test results usually inform consumers of the presence of a limited range of toxic substances, without indicating exactly what other ingredients the pill contains. Further, there is lack of adequate research to demonstrate the effectiveness of pill testing as a harm reduction strategy. The legal status of pill testing is uncertain in most countries and the strategy is typically absent or not integrated within drug policies.

Harm Reduction Programs that Address Broader Social and Economic Harms

The literature that has emerged since the late 1990s on the social determinants of health highlights the largely disproportionate burden of harm related to alcohol, tobacco, and illicit drugs experienced by people within lower socioeconomic bands. Since then, a related literature and response to social exclusion has been developed, which recognizes the multiple and interrelated ways in which disadvantage can compound and be expressed within individuals' lives including poorer educational, employment, and income indicators, poorer health and mental health outcomes, and intergenerational patterns of disadvantage and poor outcome. Responses to social exclusion include promoting whole-of-government or joined-up approaches in which social inclusion measures are used as performance indicators for all government portfolios. Harm reduction has had little formal connection to these more sophisticated and integrated initiatives in social policy. This may be because of the focus of medical harm reduction on HIV prevention at the expense of broader social and economic harms experienced by individuals and communities.

A SOCIOLOGICAL ANALYSIS OF MEDICAL HARM REDUCTION

The medicalization of harm reduction is a product of the times; medical harm reduction is a movement in step with globalization, a phenomenon that has led to significant developments in the functioning of capitalism. The emergence of the medical harm reduction movement is part of an overall shift away from addressing social problems through the coercive power of the state (i.e. via law enforcement and military) toward the role of individuals' governance of self and others. Neoliberal values of individualism and self-regulation are salient in the language and interventions of medical harm reduction. Today, harm reduction is a regime of (self) governance, which is predicated upon a scientific calculation of risk based on epidemiological analysis. Epidemiological evidence informs statistical models of risk practice and risk communities with an aim of developing harm reduction interventions that encourage and normalize self-regulation. An example of this is the "injecting drug use community," a geographically and demographically unbounded collective that share a statistically determined susceptibility at a population level to poor health outcomes like HIV infection. The medical harm reduction movement has become critically important for public health through teaching "community" self-management risk-reduction interventions, like using sterile equipment for every injection.

Within a neoliberal framework, the onus is on illicit drug-using individuals to negotiate risk, much of which is generated by the state via prohibitive drug laws and the operations of police. People from lower socioeconomic circumstances are disproportionately affected by drug-related harm relative to those from the middle classes. This is partly due to having less access to healthier but more expensive options and poorer uptake and compliance with modes of self-regulation. Medical harm reduction ignores the constraints against "choosing" healthy practices and lifestyles that many people experience. Individualism and the ideology of personal responsibility can undermine the social effort to improve health for example via community-based capacity building programs that use the arts, sporting, cultural, education, and similar programs to build resilience and "protect" people and communities from anomie, alienation, boredom, and dislocation, which often lead to problematic drug use. An overemphasis on personal responsibility also increases the likelihood of emerging health-related stigma. Individuals or groups of people whose lifestyle practices are deemed to be a personal or community health risk, like people with HIV or viral hepatitis, are held responsible for their own health problems and often viewed as a drain on resources and a threat to others.

Medical harm reduction is also criticized for lacking a coherent theoretical framework, which among other problems makes it difficult to accurately define. Commentators claim that to become a unified paradigm, harm reduction must: (1) maintain its successful programs in injecting-related HIV prevention and (2) foreground human rights to challenge entrenched power, double standards around drug use, and abuses against all people who use any illicit drug. This will be challenging as the value of harm reduction has long been measured by its capacity to prevent transmission of HIV infection, and social and political analyses highlight how the cost-benefit analysis of HIV prevention for governments and wider societies underpins harm reduction's growing international acceptance. By focusing attention on interventions that halt the spread of HIV, harm reduction programs are acceptable enough to politicians, religious leaders, and members of the wider community. On the other hand, advocating for illicit drug users' human rights and drug law reform leaves harm reduction politically vulnerable to opposition from powerful conservative groups and a public that has been socialized to see illicit drug users as criminal deviants.

A reluctance to engage with broader social issues has led some commentators to characterize medical harm reduction as a conservative movement that is dominated by health professionals, academics, and bureaucrats. For the most part, medical harm reductionists are comfortable attending to a set of health risks for people who inject that are largely created by the systems under which we all live and work. In this way, the medical model of harm reduction enables states to continue harming illicit drug users without taking responsibility for state inaction on prohibition, poverty, stigma, and social marginalization. The voice of illicit drug users is silenced by biomedical imperatives regarding population health. Indeed, the success of HIV prevention strategies has reduced the incentive to address more socially and politically difficult dynamics like economic marginalization and punitive illicit drug policies, which continue to damage large numbers of people who use illicit drugs.

The transition in harm reduction over the past 30 years from an activist movement to a medical model has prompted renewed interest in advocacy in the new millennium. Prior to the HIV epidemic, harm reduction was imbued with a strong communitarian ethos. It was a movement that represented the interests of people who used any illicit drugs, not just those who injected opioids at risk of HIV infection. Harm reduction had an expansive agenda to advocate for drug law reform, to protect the dignity and human rights of people who use illicit drugs, to tackle poverty, and to work toward finding long-term solutions to the world's illicit drug problems. Against this background, the medical model of harm

reduction represents a compromise; a band-aid solution that very effectively addresses the immediate risks associated with injecting drug use but has nothing to offer in the way of effecting significant improvements beyond the prevention of physical disorders, as important as that is. People involved in harm reduction advocacy today demand wider social and political change and believe that medical harm reduction must become engaged with ethics in order to optimize health-related outcomes. A reinvigoration of political activism within harm reduction is drawing attention to the impacts of poverty and marginalization on health-related decision-making, and it is encouraging to note that protection of illicit drug users' human rights has begun to emerge in the discourse of medical harm reduction. Harm Reduction International recently highlighted issues such as the systemic torture of people who were forced to attend drug detention centers in countries like China and Cambodia. This is seen as a welcome development, but a small step on a long path ahead.

ILLCIT DRUG USE REDUCTION

This section moves from a discussion of policy, which aims to reduce drug-related harm to a discussion of policy and approaches, which aim to reduce illicit drug use. Beginning in the twentieth century and continuing today, a global prohibition of specific classes of drugs criminalized users of classified substances in an effort to deter their use. The era of global prohibition peaked following the introduction of the "War on Drugs" by the US President Richard Nixon in 1970. Nonetheless, like alcohol prohibition of the 1920s, the prohibition of illicit drugs has been an abject failure in the US and elsewhere. After decades of failed attempts of reducing supply, of criminalizing specific drug classes, and demonizing and targeting the people who use them, prohibition did not result in a reduction of illicit drug use. Conversely, in most illicit drug markets around the world each year, drugs become more accessible, cheaper, and generally of a higher quality.

Below is a review of health-related policies and methods employed to reduce the use of illicit drugs. These approaches are used by people who wish to stop their own illicit drug use, or who provide services to people who want to stop using illicit drugs.

Naltrexone

Naltrexone is a drug used to treat the physical dependence on opioids. It first gained media attention when it was touted as a means of rapid detoxification leading to a "cure" for opioid dependence. However, throughout

the intervening years its usefulness in long-term management of opioid dependence has been questioned because it carries considerable risk for dependent people. Naltrexone decreases tolerance to heroin, thereby increasing the risk of overdose if an individual returns to heroin use after being treated with naltrexone. In addition, it is significantly more expensive to prescribe than other substitution drugs. Naltrexone does not produce physical dependence or euphoric effects, but works by blocking the action of opioid receptors. This means that people taking naltrexone cannot experience the pleasurable high of opiate intoxication. On the other hand, the prescription of naltrexone requires confirmed abstinence from opioids for 7–10 days prior to starting treatment with naltrexone. This period of abstinence can be a significant barrier to those living with opioid dependence. The current state of evidence indicates that people show better outcomes with substitution treatments.

Other Methods of Reducing Illicit Drug Use

A range of other options to address drug dependence exists. For example, professional counseling (e.g. motivational interviewing), peer-to-peer support (see section on Narcotics Anonymous below), detoxification (i.e. medicated or not), and residential rehabilitation (i.e. highly structured programs requiring 6- or 12-month stay within a therapeutic community setting). These treatments are generally considered as a package or provided simultaneously for optimal effect. For example, detoxification is not considered an endpoint of treatment, and those who undertake only detoxification without supporting or ongoing treatment are likely to return to prior drug use levels. The goals of individuals entering treatment may vary. Some people may seek abstinence as a goal of treatment, while others may be seeking assistance in lowering the frequency or level of drug use. Relapse to former patterns of illicit drug use after a period of lower drug use or abstinence places individuals at a higher risk of fatal overdose, particularly in the context of relapsing to opiate use.

There are also a number of methods, sites, and structures in which these services may be provided or facilitated. These include court diversion programs (rather than imposition of a period of incarceration) or online counseling and support services as developed, for example, for people concerned about their level of cannabis use. As with any therapeutic intervention, the motivation and goals of the client underpin the success of the treatment program. However, in all models of treatment, relapse is a common occurrence. Given the chronic, relapsing course of drug dependence, multiple treatment episodes are better understood as parts of a cyclical process of recovery and remission rather than

as failed efforts. While clinicians, researchers, and government policy-makers have long recognized the value in conceiving treatment in terms of episodes, episodes of treatment have received little attention in the literature of research/evaluation treatment outcomes.

Throughout the world, global prohibition has inculcated a widespread belief that people who use illicit drugs are inherently disordered. In some regions, there is evidence that the philosophy of drug treatment has been misused by governments to control and punish people who use illicit drugs. For example, forced treatment in China has been likened to labor camp conditions. Other mechanisms employed to control or punish people who use illicit drugs, such as violence, being placed under arrest, being placed on a drug-user registry, capital punishment, and summary execution, are violations of human rights agreements that serve to drive people away from opportunities for drug treatment.

Peer-to-Peer Support and Other Self-Management Strategies

Narcotics Anonymous (NA) is a not-for-profit, nonsectarian, peer-to-peer support network. NA operates on a disease model of addiction and is premised on the goal of achieving and maintaining abstinence using the 12-step framework. Originally developed in the US, NA groups operate in most countries. Meetings of members are informal, no membership list is held, and anonymity is a key to ensuring that members can participate without fear of legal or social consequences.

The self-management and recovery training (SMART) program is similarly a voluntary self-help group that is focused on assisting people to recover from addictive behaviors. The SMART program is based on cognitive behavioral therapy and advocates for the appropriate use of medications. It is not based on a disease model of addiction and trained, professional staff coordinate the meetings.

Most people who are dependent on drugs will have tried a number of strategies, such as those mentioned above, to manage, reduce, or stop illicit drug use. Other approaches, which are commonly used by individuals to reduce illicit drug use, include removing oneself from networks of people who use drugs (i.e. a “geographical” or a “health-trip”), going “cold turkey” (i.e. nonmedicated withdrawal), or self-medication using benzodiazepines, alcohol and/or cannabis. Many people will have tried these strategies without any professional or peer support. Finally, “maturing-out” of drug use has also been described. In this case, individuals become abstinent when they tire of the undesirable aspects of an illicit drug-using lifestyle and simultaneously aspire to attain the “rewards” from leading a conventional life.

Glossary

- Blood-borne virus** a virus that can be transmitted via blood-to-blood contact e.g. HIV, hepatitis C.
- Epidemiology** the study of patterns of disease within communities; used to inform public health policy including harm reduction strategies and interventions.
- Initiation to injecting** the circumstances surrounding the first time an individual self-injects or is first injected by another person in a nonmedical setting.
- Injecting equipment** includes needles and syringes, tourniquets, spoons, water vials, swabs, winged-infusion sets, and any other equipment used to inject a drug.
- Medicalization** a process whereby human behavior, conditions, and problems become defined as medical issues to be treated by medical professionals.
- Medical harm reduction** harm reduction programs, strategies, and interventions based on medical and public health technologies, like epidemiological surveillance, and needles and syringes and substitution drugs, to reduce the risk of transmission of blood-borne viruses, especially HIV, among people who inject illicit drugs.

Neoliberalism a set of market-driven economic policies underpinned by a social and moral philosophy that privileges individualism and self-regulation, and moves responsibility for risk from governments and corporations onto individuals.

Rave a type of dance party associated with the use of amphetamine and methamphetamine.

Social determinants of health the social and economic conditions into which people are born, raised, and aged, and the relationship of these variables with health outcomes.

Stigmatization characterizing individuals, social groups, health conditions, and practices as highly undesirable and a threat to society.

INTRODUCTION

The World Health Organization (WHO) estimates that there are approximately 6 million tobacco-related deaths per year at present and that this will rise to 10 million in the next 20 years. Currently, these deaths are equally distributed between the developed and the developing world, but in future, the deaths will be predominantly in the developing world because smoking is decreasing in the developed world. The mortality in the past century from smoking has been in the order of 100 million people, but it is expected that this century it could go up to 1 billion deaths; this is because of the rapid spread of cigarette smoking to highly populated countries such as China and India and other eastern countries. While smoking is declining markedly in the West and in so-called developed countries, it is continuing to increase in these highly populated countries. Since it is known that some 50% of people who smoke die because of it

and on average lose 10–15 years of life, the appalling loss of life is likely to increase enormously in countries with very high prevalence of smoking, such as China. In addition to the loss of life, there is the reality that disease from smoking such as chronic heart disease, heart failure, chronic bronchitis, and other chronic noncommunicable diseases often manifest some 10–20 years before death, and therefore in addition to premature death, there is the prospect of many years of ill health, with consequent loss of quality of life and employment possibilities, and heavy usage of resources, particularly in health care.

TOBACCO INDUSTRY

The tobacco industry is active worldwide and is a highly profitable transnational industry. This industry is well aware that its product is addictive and causes death and disability on a massive scale. Rather than

FIGURE 76.1 Tobacco use is a risk factor for six of the eight leading causes of death in the world. WHO 2008b. *Global Tobacco Epidemic 2008, The MPOWER Package*. Switzerland.

alleviating the problems caused by tobacco products, the tobacco industry undermines policies aimed at reducing tobacco smoking and its associated harms. Nicotine makes cigarettes addictive, and smoking cigarettes causes cancer, heart disease, chronic respiratory disease, and a myriad of other illnesses. Therefore, it seems incumbent on the tobacco industry to do more to alleviate this very serious health problem. However, at present, efforts by the industry to produce safer cigarettes appear inadequate and leave their product in its present harmful, deadly state while continuing to maximize profits.

Some countries have implemented measures to limit the supply of tobacco products. These mainly consist of efforts to reduce access by children and to regulate the distribution of the product in the society. Marketing bans, advertising bans, sponsorship bans, and efforts aimed at reducing access to this lethal product are met by the tobacco industry with opposition. The industry tends to respond not with adoption of these bans but with adaptations such that effects of these interventions on the industry are minimized. While current effort to control the supply of tobacco is weak, it seems unlikely that the society will continue to tolerate the tobacco industry profiteering from a product that kills half its consumers (Fig. 76.1).

In the United States, litigation has been used to try to make the industry pay for the damage caused by its products, and although there have been successful cases imposing heavy fines – amounting to US \$216 billion – this does not seem to have alleviated the problem.

FRAMEWORK CONVENTION ON TOBACCO CONTROL

The WHO's Framework Convention on Tobacco Control (FCTC) is an evidence-based international treaty and the first legal instrument designed to reduce tobacco-related morbidity and mortality worldwide. As the most widely accepted treaty in United Nation's history with at present 172 parties to date having signed up to its principles, the FCTC has provisions and sets international standards and guidelines for tobacco control (TC), which those who ratify have a legal obligation to meet. It consists of 11 parts and contains 38 articles, which have a wide-ranging remit aimed at mainly controlling demand for tobacco products and, to a lesser extent, some measures to regulate supply.

Price and TC

It is a firmly held tenet of TC that tobacco taxation is the most effective TC intervention available. Governments can reduce the demand for cigarettes and tobacco through taxation, with its effect related to the price elasticity of demand. Price elasticity of demand for tobacco is the proportional change in consumption of tobacco relative to a change in its price. Since tobacco is addictive, demand for tobacco in response to a price increase is relatively inelastic, meaning that the proportional change in consumption is less than the change in price. Various econometric estimates of the price elasticity for tobacco products have been made in many countries

under many different circumstances; however, robust estimates suggest that for a 1% rise in price, there is on average 0.3–0.5% reduction in consumption. Young people and those in lower socioeconomic groups of the population tend to be more responsive to price increases.

Tobacco taxation helps prevent young people from starting to smoke, encourages smokers to quit, and reduces consumption among those who continue to smoke. The tax structure to achieve this varies and is to some degree regulated, especially in the European Union (EU), which sets limits on what proportion of the retail price of tobacco products should be taxed. For instance, the minimum total tax as a percentage of the retail price is set at 57%, with a minimum rate of €64/1000 cigarettes. This does not preclude Member State governments from having higher taxes but sets the lower limit of tax. The tax structure may consist of *specific taxes*, which are expressed in monetary terms per unit of tobacco (e.g. 1000 cigarettes or per 1000 kg of tobacco) and *ad valorem taxes*, which are a percentage of prices. There are also *value-added taxes*, and these vary from country to country. The tobacco industry usually responds by trying to lower the price by various interventions depending on the tax structure being used by the government. Determining the optimal structure and rates of taxation is very complex and depends on a number of factors. Whatever structure is used, it seems that for every price rise, there will be a reduction in smoking and an increase in revenue. However, there are several concerns about using price as an instrument of TC. First, it can be considered regressive, which means that poorer people pay a greater proportion of their income than the wealthy. Second, increased taxation may have a deleterious effect on illicit trade, smuggling, and counterfeit manufacture of cigarettes. All of these problems are real but surmountable, where there is a will in government to achieve the desired result of better public health. The tobacco industry invariably tries to deter governments from raising the price and will vary their tactics. Often they will argue that government revenue will decrease, smuggling will increase, and public health benefits will be negligible in comparison. Governments seem to be susceptible to these arguments despite counterarguments, which show that despite the realities of these occurrences when the only intervention is a price rise, then revenue increases and consumption falls. There is a theoretical point where so many people will stop smoking that revenue will also fall, but this has not been achieved in any country to date.

The approach to illicit trade varies. TC advocates insist that it is a matter of law and order. Several studies show that while there is a relationship between price and smuggling, it is small and that most illicit trade

and smuggling are related to other factors, including availability of cheap cigarettes, a distribution network and criminal involvement, corruption at many levels, poor enforcement, and lack of political and legal will. This is evidenced by the generally low level of fines imposed. However, these arguments do not seem to hold sway at all times. In the EU, the free movement of goods and the huge differential in the price of cigarettes between countries provide incentives for tax avoidance. Tax avoidance involves the legal purchase of cigarettes in a lower price country for consumption in a higher price country. The price of a package of 20 cigarettes in the most popular price category ranges from €2.50 in some northern European countries to €8.50 in Ireland. As such, there are great incentives for consumption of non-domestic duty-paid cigarettes in high-priced countries especially with the greatly increased cheap air travel between member nations.

The regressivity of tax is a worry, and if taxation is to be used as a principle instrument of TC, then its effects on the poorest in society need to be addressed. While the hope is that more people will stop smoking as a result of this effective intervention, there are many smokers who are not able to reduce their cigarette consumption unaided and wealth redistribution may be needed so that they are not impoverished further by tax rises. The TC approach to this is to increase and improve the treatment of tobacco dependence and improve the access to these services available to the population and in particular to people who are most disadvantaged. It is well known that the smoking rates are higher among lower socioeconomic groups and also that other interventions have less effect among this group, particularly the impact of public health messages. Therefore, targeted services for smoking cessation treatment and targeted media campaigns should be provided to this segment of the population. Revenue earned through tobacco taxation could be directed toward these activities, or other attempts to improve the economic situation of this segment of the population such as better access to transportation, childcare, and social welfare benefits, so that increased tax would not be a further cause of inequality.

As previously stated, young people are particularly responsive to price increases, which discourage them from starting to smoke and encourage them to stop. Also, young people are likely to have less disposable income and may be less addicted and therefore may be more susceptible to price at this stage. Another consideration in using taxation for TC is the range of compensatory behaviors that smokers engage in to minimize the impact of a tax increase. In response to a price increase, smokers may switch to other lower-taxed smoking materials or cheaper cigarettes where these are available. Some countries have a wide price range

for different “qualities of cigarette” but high prices create a greater incentive to seek out illicit or smuggled cigarettes. As mentioned earlier, smuggling and illicit trade need to be tackled in their own right, and if there is any worry about increased price having a further increase on this, then some of the resources becoming available from the higher tax could be used to combat this crime. Intuitively, a measured price rise on already expensive cigarette is unlikely to have a significant influence on smuggling.

The use of tax as a TC measure is unevenly distributed throughout the world, with high-income countries more inclined to avail of this intervention (Fig. 76.2).

Non-Price-Based Articles in the FCTC

In addition to price and tax measures of TC, the FCTC supports non-price measures, such as smokefree legislation, treatment of tobacco dependence, tobacco product regulation health warnings, advertising, promotion and sponsorship, and youth access to tobacco.

Smokefree

The harm caused by exposure to environmental tobacco smoke, passive smoking, or, as it is better known, secondhand smoke (SHS) is also serious. It causes many of the same diseases as direct smoking. These include carcinoma of the lung, heart attacks, strokes, exacerbations of asthma, sudden infant death syndrome, birth abnormalities, and a variety of irritant symptoms, such as watering of the eyes, sneezing, scratchiness of the throat, and hoarseness. It has taken a long time and very painstaking research to establish

SHS as a cause of these diseases because it is difficult to separate the effects of SHS in active smokers. Nevertheless, there are now more than 30 reliable studies showing these effects.

SHS exposure has become an increasingly contentious issue in the society. Smokers and their allies in the tobacco industry state that smoking is legal and therefore they should be allowed do it where they like. On the other hand, the TC community and environmentalists claim that people have the right to breathe clean air, and since the diseases caused by SHS are well known and very serious, smoking should be prohibited in public. The smokefree movement began in North America, with early leaders such as California, Massachusetts, and New York introducing smokefree laws, and spread to jurisdictions within Canada, Australia, and New Zealand. However, Ireland was the first country to introduce comprehensive national legislation extending to workplaces and including bars, discos, clubs, casinos, and restaurants. Since then, the movement has accelerated, with many European countries introducing comprehensive smokefree laws that do not allow any smoking areas indoors including Norway, Scotland, and then the rest of the United Kingdom, France, Slovenia, Turkey, Greece, and Spain. Although others such as Italy and Sweden technically allow some indoor-smoking areas, in practice, the regulations are so strict that effectively they are equivalent to comprehensive laws. Many of these countries had earlier implemented partial bans and restrictions in certain areas, with varying success, but it is now agreed that a comprehensive law is the most likely to be successful if implemented and monitored correctly. The benefits from comprehensive smokefree laws are

Source: WHO GTCR, 2009

FIGURE 76.2 Simple average price of the most sold brand, excise tax per pack, and total tax share by Income Group, 2008. WHO 2010. WHO Technical Manual on Tobacco Tax administration. In: WHO (ed.). Malta.

immediate. After the introduction of a properly implemented comprehensive smokefree law, dramatic reductions in exposure can be shown in particle measurements, such as PM 2.5, which acts as a surrogate for cigarette smoke, in ambient nicotine, and in cotinine in biological samples such as saliva, urine, or hair.

The health benefits of smokefree laws are dramatic and in many cases occur very early. For instance, most studies show that irritant symptoms of SHS exposure are dramatically improved immediately after a smokefree law is implemented. There is also significant improvement in pulmonary function as measured by spirometry and in measurements of other parameters, such as oxygen diffusion into the blood through the lung. However, the most significant health benefit is the immediate reduction in admissions to hospital of patients suffering from myocardial infarction. This effect varies, but most studies show effects in the order of a 10% drop in admissions within the first year. Most of the studies are open to criticism, but the direction and to a lesser degree the magnitude of the effect favor a very positive outcome for smokefree. Clearly, the possible benefits as regards cancer are of a much slower time course. The lag time between exposure and disease in malignancy related to smoking can be very long and is often in the order of 20–30 years. Therefore, it is unlikely that big changes in the incidence of these diseases will be seen in the short term and will require very careful and complex study (Fig. 76.3).

With the known risks of exposure to SHS and the benefits of protecting people from such exposure, it is

surprising that despite this and the undoubted popularity of such legislation, all countries have not adopted smokefree legislation. Arguments concerning civil liberties and infringement of rights do not seem to hold credence when the dangers are so obvious and clear-cut. An analogy is often drawn between SHS and asbestos dust exposure. Both substances have a known and definite risk of causing cancer; however, the former is only regulated in some instances, while the latter is forbidden for use by workers and as a building material. This difference in approach is difficult to understand but may partially be explained by the fact that malignant mesothelioma, although a remote risk, is almost exclusively caused by asbestos exposure, while smoking is a much greater cause of lung cancer than SHS. Whatever the explanation, it is hard to understand why many would still argue that exposure to SHS, which is known to be so harmful, should be allowed because smoking is legal when a workable alternative strategy of smokefree legislation has been shown to be effective where it has been introduced.

Another potential benefit of smokefree legislation is its potential to influence attitudes toward smoking. Legally allowing smoking in the presence of nonsmokers weakens the acceptance of the fact that SHS is harmful or may even reduce the confidence in the fact that smoking is so harmful. People may be reluctant to accept the pervasive risk of SHS exposure if they are legally exposed to it in their daily lives. Comprehensive bans on smoking send a clear message that SHS exposure is dangerous and that people should be protected from exposure. In addition to the aforementioned health benefits of smokefree laws, strong laws are likely to contribute to the process of denormalizing smoking – the gradual shift in social norms away from the social acceptability of smoking. If smokefree legislation does in fact make smoking less acceptable in the society, then these laws could reduce smoking by encouraging smokers to stop smoking and preventing children from starting to smoke. Recent prevalence studies in the Western world have shown a reduction in smoking among children in countries with smokefree laws. However, many other types of intervention are occurring simultaneously, so attributing this reduction to smokefree alone is not proven, although it should at least be helpful in this regard. The FCTC has laid down protocols for implementing smokefree laws; the application of these protocols should facilitate the spread of smokefree environments in all FCTC countries.

Treatment of Tobacco Dependence

Approximately half of all smokers die as a result of their smoking and on average lose 10–15 years of life; however, regular smokers who quit at the age of 60, 50,

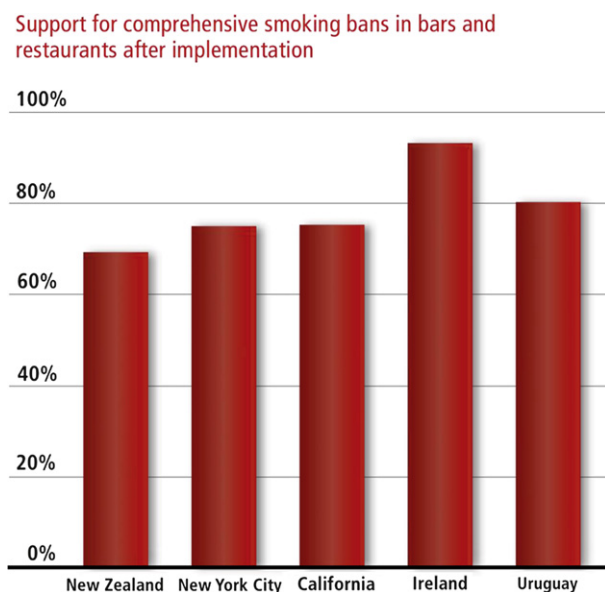

FIGURE 76.3 Smokefree areas are popular. WHO 2008a. *A Policy package to reverse The Tobacco Epidemic*. In: WHO (ed.). Switzerland.

40, or 30 can gain 3, 6, 9, or almost 10 years of life expectancy in comparison with those who continue to smoke. However, smoking is an addiction and people find it very difficult to stop. Nevertheless, most people who stop smoking do so unaided. This shows that it is possible to stop if smokers are fully motivated and make the effort. It is imperative, therefore, that smokers are encouraged and enabled to quit by the use of all available evidence-based, cost-effective methods. Interventions that increase motivation such as mass media campaigns and advice from doctors and other health care professionals have important and proven roles in this regard.

The main reason that people continue to smoke is nicotine addiction; the release of the reward-linked neurotransmitter dopamine is thought to be important in maintaining this addiction and seems to be accompanied by a reduction in cortical control mechanisms. The localization of this release in the brain is reasonably well understood, and the related activity in the nucleus accumbens and amygdala has been mapped in various studies including the use of functional magnetic resonance imaging. The cortical localization of control, including areas such as the dorsolateral prefrontal cortex, anterior cingulate cortex, and insula, is known, but the relationship between bottom-up/top-down neural responses to smoking needs further investigation. However, efforts to block the site of addiction have been only partially successful (Fig. 76.4).

The most successful approaches to cessation seem to be cognitive therapy and pharmacotherapy, either alone

or together. The success rates achieved seem to be similar but variable and in the order of 10–20%; in some clinics, success rates as high as 50% have been achieved. The degree of addiction varies and scores such as the Fagerstrom Scale have been designed to estimate the level of addiction. These scales consist of questions to establish how soon people smoke first thing in the morning after waking, when they smoke, and the total number of cigarettes they smoke per day. While these scales offer a measure of the degree of addiction, they are not always closely allied with success in stopping. In general, the higher the level of addiction, the more difficult it is to stop.

The scientifically proven, cost-effective pharmacological agents at present available for treatment of nicotine addiction include nicotine replacement therapy, bupropion, and varenicline. All of these pharmaceutical agents seem to greatly increase the chance of successful quitting, at least doubling the success rate, and when combined with counseling can yield higher success rates. Access to and appropriate use of these scientifically proven treatments are important health initiatives encouraged by a recent protocol for Article 14 of the FCTC. Nevertheless, it is obvious that better therapeutic agents are urgently needed, and an increase in research in this field is to be encouraged.

Despite the availability of successful treatments, few smokers seem to access such services for many reasons. In many countries, services are not available, and where they are available, they can be difficult to access. The

FIGURE 76.4 Effects of nicotine on the brain. Tomkins, D.M., Sellers, E.M., 2001. *Addiction and the brain: the role of neurotransmitters in the cause and treatment of drug dependence*. CMAJ 164 (6), 817–821.

reasons for this are complex. Although nicotine dependence is a WHO-recognized disease with its own International Classification of Diseases code, it is not regarded as a disease by many of those who have the condition or indeed by some in the medical profession who might be expected to offer treatment for this disease. Furthermore, there is often limited awareness of available services, as they are not always well advertised. The reasons health care workers do not offer such treatment are equally varied. Treatment of tobacco dependence is often not a significant feature of health care training for doctors, nurses, pharmacists, psychologists, or any other health care professional. As such, lack of knowledge may be a barrier to providing cessation treatment. Responsibility for providing these services is not always clearly assigned; the health profession providing these services varies within and between countries and seems to be a function of the individual health professional's interest. Current services are generally poorly developed, poorly accessed, and limited in their success. It is obvious that a standardized approach to the treatment of tobacco dependence is badly needed. The recent protocol for Article 14 of the FCTC is an appropriate step in this direction. Guidelines are urgently needed. With the implementation of FCTC protocols and subsequent guidelines, it is hoped that matters will improve in the future and this underutilized intervention for TC will achieve reductions in smoking prevalence and related mortality. The importance of the treatment of tobacco dependence is crucial to the reduction in smoking-related mortality over the next 25–50 years and so should become a priority in preventive health care.

Tobacco Product Regulation and Labeling

The FCTC has tobacco product content regulations that set standards for contents and emissions and require parties to have guidelines for testing and measuring contents and emissions. Product regulation can be expensive and difficult to undertake and should be managed through regional or international mechanisms, rather than consuming scarce TC resources at the country level. This approach has some merits in achieving a safer cigarette, but the costs involved should be borne by the tobacco industry. It is recognized that tobacco and smoking have disastrous health consequences and various analyses have shown the agents that are likely to be responsible. Also, it is clear that the tobacco industry changes constituents on an ongoing basis, and it is, therefore, important that there is a mechanism in place to get information on the contents and emissions of tobacco products. This should be a simple, legislative matter. On grounds of commercial confidentiality, the industry often refuses to disclose additives that

can have an effect on addictiveness and attractiveness of cigarettes for defined identified targets such as children or women or specific ethnic origin groups. Therefore, the requirement that the industry reveal the contents of its products is important and should be legislated. The United States, which is not as yet a party to the FCTC, enacted The Family Smoking Prevention and Tobacco Control Act in 2009 and is expected to address these issues in the frame of the Act.

The importance of tobacco product regulations and labeling has been studied and is clearly of great importance in initiating or perpetuating the use of these products. Since the overall aim of the treaty is to reduce or eliminate the use of tobacco, it is important that the packaging and labeling of tobacco products are controlled and enforced. Consequently, misleading and erroneous impressions created by labeling such as *low tar*, *light*, *ultra light*, or *mild* have been restricted and increasingly outlawed, and laws to make this possible are recognized by the international community as important. Tobacco product packaging provides an important vehicle for the industry to attract consumers and thereby encourage initiation and usage; likewise, the package could instead be used to dissuade children from starting to smoke and make it less attractive for adult tobacco users. With this in mind, the treaty urges the use of rotating health messages and pictorial warnings, taking up at least 50% of the main display area of the package and no less than 30% of the other main surface. A further development that has occurred since the FCTC was introduced is that many TC professionals now advocate for plain packaging. This would further deprive the tobacco industry of space on the packs to advertise their products and perhaps mislead the public. These plain packages could continue to have health messages and graphic images of smoking-related diseases without the concomitant damage done by allowing the industry to market its products on the packages. This would also make it logical to ban the advertising of tobacco products at the point of sale, as has already been done in Iceland, Ireland, and a number of other countries. In most countries, however, at present where there are strong advertising bans, point of sale has often been exempted. This exemption is clearly not in the interest of TC. The extension of the ban on point of sale advertising is desirable and will probably proceed, especially when other possibilities of advertising have been eliminated (Fig. 76.5).

Tobacco Advertising Promotion and Sponsorship

There has been much debate about the appropriateness of banning tobacco advertising, promotion, and sponsorship. The contra-arguments are usually based

FIGURE 76.5 WHO graphic image/pictorial warning. Adapted from 2011. *European library of graphic pictorial warnings* [Online]. Available: <http://www.tobaccolabels.ca/gallery/european/eu200~3> [Accessed 01.05.2012 2012].

on the fact that tobacco is a legal product and it is legitimate to advertise goods that are legal. Therefore, the advertising of this legal product should be allowed in fairness to the tobacco manufacturers. However, it could be argued that enticing people to buy goods that they may or may not need, on promises that may or may not be true, is probably wrong in itself. Furthermore, tobacco is not a normal good and the normal rules should not apply. Normal goods do not cause medical disease, death, and disability in nearly half of their users when used exactly as intended. Thus, the society can decide that it is an undesirable product and its advertising and promotion should be regulated. Most countries now accept that advertising, promotion, and sponsorship by tobacco companies are wrong and are now required by the FCTC to introduce laws to make these activities illegal within 5 years of signing up to the treaty. It can be assumed that tobacco advertising, promotion, and sponsorship will soon become illegal worldwide as it is now in many countries.

The industry will continue to innovate and find new ways to attract consumers. Therefore, attention should be paid to the industry reports on both its advertising and marketing strategies and budget. TC experts are conscious of the diverse efforts made by the industry to circumvent legislation in this area and should continue to study the marketing tactics and techniques. Such monitoring of the industry is embedded as a requirement in the treaty. In general, advertising bans have been very successful, with restriction on advertising and promotions sponsored on radio, television, print media, and other media such as the Internet. The potential threat to successful implementation of such laws that is posed by social media and advances

in new media such as Near Field Communications is considerable.

The importance of education and communication as well as training and public awareness about the harms of tobacco use is well understood by the TC community. Parties to the FCTC are bound to bring in legislative and other measures to ensure access to educational and public awareness programs about the health effects and the addictiveness of tobacco consumption and the dangers of exposure to tobacco smoke. The methods of doing this and usefulness of it are well known. Nevertheless, it is clear that the message quite often does not get out to the target audience. There seems to be more success in spreading the message about the harmful effects of tobacco but a lot less about the benefits of discontinuing tobacco use in terms of health, economic well-being, and protection of the planet and the promotion of a better quality of life. It is only with access to good and sustained information that awareness can be increased and attitudes changed. Any such information campaigns should include commentary on the tobacco industry and its activities.

The target for such education needs to be focused. There needs to be special training for health care workers, educators, and decision-makers so that they are aware of the most cost-effective and beneficial methods of communication and education. In this way, it is likely that they would be able to communicate the message more effectively and health care workers would be able to deliver more appropriate treatments.

MEASURES TO REGULATE THE SUPPLY OF TOBACCO PRODUCTS

Illicit Trade

The FCTC is at its strongest in advocating measures to reduce demand. In its preamble, it attests to the fact that it concentrates on demand rather than supply-side measures, unlike other efforts targeted at addictive products. While demand-side measures are perhaps more important, it would appear that in strengthening demand-side reductions, the treaty may have diminished the supply-side efforts, by comparison with approaches to other addictions. Failing to strengthen and enforce supply control could prove to be a mistake in terms of TC. Within the treaty, the main efforts to regulate supply are targeted at reduction of illicit trade in tobacco products. This is important as smuggling, illicit manufacturing, and counterfeiting are likely to make available cheap and potentially even more harmful cigarettes. Furthermore, illicit trade complicates the monitoring of tobacco use and the collection of revenues, thereby increasing the burden of associated health

costs. From the society's point of view, this is an important law and order issue but may not be the strongest method of supply control. There needs to be national and international collaboration in this effort and further development of tracking and tracing methods, which will make control better and easier. In this regard, attention to packaging of tobacco products is also necessary. The tobacco industry is arguing that plain packaging, for instance, would make smuggling and illicit trade easier. If appropriate tracking and tracing methods are implemented, which can be just as readily applied to plain packaging, the industry argument need not be a reality. There is no doubt that the control of smuggling and illicit trade is very difficult; it will only be successful if there is international cooperation and further development of methods of control.

Youth Access Restrictions

Another supply reduction measure is the control of sales of tobacco to and by minors. This measure has its basis in the fact that children may not be fully competent to make decisions about the use of tobacco. While there is some truth in this, especially for the very young, it is less obvious in late teenage years when many young people do start. The logic is that restriction of sale to everyone would be justified if a method could be found. It is therefore surprising from a TC's point of view to see that nowhere in the present approach to TC is it envisaged that there will be no access to tobacco in the long term. Most TC specialists are of the opinion that the total banning of tobacco and tobacco products at present would not be feasible and would not lead to better control. However, this does not seem to be a logical reason for the absence of a long-term goal to see the elimination of all use of tobacco products. The support for ban of sales to minors seems entirely justified, but it may be somewhat illogical not to aim to extend this ban to all age groups when this becomes feasible.

Support for Alternative Livelihoods

Also within the supply-side control is the concept of support for alternative economic activities for tobacco growers. It is conceded that this is a difficult problem. Many growers are maintained just above the poverty line by involvement in this industry, with great insecurity and the dangerous health effects that managing this crop entails. This concern also leads to a concept of environmental protection and need for the protection of tobacco growers' health and well-being independent of smoking. It is likely that this aspect of tobacco production will have increasing prominence in the future as it becomes more fully understood as how harmful to the

environment this product is both in its growing and on the health of its growers and in its use in the society when it is processed by a profit-orientated transnational industry.

Litigation

In some countries and in particular in the United States, the use of litigation to enforce liability for the death and destruction caused by tobacco and the liability for this that the industry has because of its knowledge of the harmful effects and its hiding and lying about such effects over a long period made litigation a powerful weapon of TC in that country. Litigation has not been pursued to the same extent in any other country or continent. It is difficult to understand fully why, but in some countries, it seems that such litigation would have difficulties in being successfully prosecuted. There have been some successful cases but they are few, and the legal structures are such that individuals challenging a powerful and rich industry such as the tobacco industry often do not have the resource to get their legitimate claims satisfied. On that basis, it is obvious that joint actions at national and international levels are a more logical approach and would pit the industry against states and communities such as the EU with better access to the necessary resource to mount appropriate legal challenges. If such litigation were undertaken by states, it would certainly help toward TC, particularly if successful but even if not, the gathering of information to show the damage and to show the activities of the industry would certainly be beneficial.

FUNDING

The FCTC provides a model and roadmap on the way to the elimination of tobacco smoking as a norm in the society. However, its aims cannot be attained without planning, effort, and appropriate resourcing. The disparity between resources allocated to other scourges such as tuberculosis, malaria, and HIV/AIDS is striking, considering their relative contribution to the global burden of disease (Fig. 76.6). There is no suggestion that these resources are not needed for those other diseases, but TC is seriously underfunded by comparison and needs much more attention. The paucity of resources is all the more surprising, considering that tobacco taxation amounts to \$162 billion and that only a tiny fraction of this is made available for TC. This needs to be changed if TC is to be successful.

Modeling of interventions individually and as part of a comprehensive strategy suggests that stronger policies would have powerful effects on smoking and related mortality. However, these models have not considered

FIGURE 76.6 Investment in tobacco control compared to other diseases. September 2009.

the possibility of eliminating tobacco use in the short to medium term. While the WHO treaty is a great step forward, it does not go far enough to prevent the continued spread of the smoking epidemic and its calamitous health effects. The treaty acknowledges its limitations in articles calling for continued research, surveillance, and information exchange, so that the treaty itself can evolve and be strengthened by TC research developments. Despite the considerable challenge to health posed by tobacco, at present, TC research is not prioritized and poorly funded, with only a tiny fraction of the revenue from tobacco taxes made available in most countries. The FCTC encourages the provision of an organization, training, and support systems to enable TC research to be performed and translated into activities, which are implemented and evaluated. It greatly encourages cooperation in this regard, both nationally and internationally. A health problem of such high importance should by these means achieve a level of priority commensurate with the seriousness of the problem it addresses. At present, however, although the tools to control tobacco use are known, less than 5% of the world's population benefits from effective use of these tools. It is clear that unless there is a strong and successful research into the best methods to introduce effective control of tobacco, the ravages of the tobacco epidemic will continue.

		Summary	765

THE ASSOCIATION BETWEEN DRUG USE AND HIV RISK

People who use drugs are at elevated risk of HIV infection compared to people who do not. This elevated risk is largely related to injecting drug use (IDU); there is also, however, significant risk associated with drug use via other routes of administration. Typically research, policy development, and programmatic responses to drug use in relation to HIV focus primarily on IDU. This discussion will similarly focus on IDU, but ‘noninjecting drug use’ will also be considered.

Internationally there is a lack of strong data on the prevalence of IDU and of HIV among injecting drug users (IDUs). As a result, there is limited understanding of the exact scale of the potential burden on health posed by the risk of HIV transmission through IDU. It is clear, however, that IDU occurs across the globe, and that the nature and extent of IDU can differ both between and within countries. Further, by the end of the 2000s, IDU had emerged as the primary mode of HIV transmission in many countries within Asia and Eastern Europe.

A range of substances are injected, the most common include opioids, both naturally occurring opiates, such

as heroin, and pharmaceutical opioids; amphetamine-type stimulants, most commonly methamphetamine and amphetamine; cocaine, including 'crack' cocaine; and various other depressants such as benzodiazepines. Different drug types are more commonly used and injected in different geographic regions and between countries. 'Poly-drug use' among IDUs is also common.

Just as there is considerable heterogeneity across countries and settings in which IDU occurs, there also exists significant diversity within IDU populations with respect to demography, social economic status, vulnerability, and need. There is also very often overlap between IDU populations and other groups identified as being at increased risk of HIV, including in particular men who have sex with men and people who engage in sex work.

HIV Transmission Through IDU

HIV can pass from an infected to a noninfected person during the process of drug injection via the use of a piece of injecting equipment that has been contaminated with blood containing HIV. Typically, this is a needle or syringe that has been used previously by an HIV-infected person, but it is also possible, though less likely, to occur via the use of other pieces of contaminated injecting paraphernalia such as spoons or other vessels used to prepare drugs for injection; water for mixing drugs into an aqueous solution; cotton wool or other material used as a filter when drawing up the drug solution into a syringe; or a shared tourniquet.

Reuse or shared use of injecting equipment may occur when sterile equipment is unavailable or when people are unaware of the potential risks of doing so.

Risk of transmission from injecting using a contaminated syringe is estimated to be many times greater than sexual exposure for a female in penile-vaginal intercourse where her male partner is HIV seropositive. Exposure through receptive anal intercourse may confer similar infection risk to the use of a contaminated syringe.

If sharing of injecting equipment occurs, people who inject most frequently are potentially most at risk through repeated exposure. A person who is dependent on a drug will typically inject more frequently than a nondependent person. When there are more people within a network of drug users who are HIV positive, there is a greater likelihood that a used syringe may be contaminated with HIV.

Sexual Transmission of HIV among People Who Use Drugs

Drug use is associated with increased HIV risk through sexual transmission, independent of the risk

associated with injecting as a route of administration. The proportion of incident HIV infections among IDUs attributable to sexual transmission is uncertain, but may be considerable. The sexual transmission of HIV between IDUs and people who do not inject drugs is a significant pathway for the spread of HIV from a concentrated epidemic among this at-risk group to the wider population, the sexual partners of IDUs acting as a 'bridging population.'

Elevated risk of sexual transmission is associated with the use of a variety of substances, including both illicit drugs and alcohol (*see* Alcohol, Sexual Risk Taking, and Sexually Transmitted Infections). The level of risk differs between drug types and is related to drug effects such as disinhibition and enhancement of sexual arousal or pleasure. The association between high-risk sex behaviors and drug use is strongest for cocaine and amphetamine-type stimulant use. Risk behaviors observed among stimulant users include having multiple sexual partners, high rates of unprotected sex, and engagement in sex work.

While drug use, and stimulant use in particular, is strongly associated with elevated sexual risk, whether or not drug use can be said to cause this elevated risk is not clear. People who choose to take drugs may, in general, be more inclined to engage in risk-taking behaviors; having a tendency toward risk taking is itself a risk factor for drug use (*see* Impulsivity, Disinhibition, and Risk Taking in Addiction). Some people may also choose to use a drug in order to become sexually disinhibited or to increase sexual arousal. As such it may be more useful to regard drug use as a marker for high-risk sexual behaviors, rather than drug use necessarily causing sexual risk behaviors.

Sexual transmission of HIV has biologically increased in the presence of many sexually transmitted infections (STIs) such as syphilis and herpes simplex virus. The prevalence of STIs is commonly high in drug-using populations and increases HIV risk in this group.

Other Factors That Can Shape HIV Risk Associated with Drug Use

As outlined above, the primary mechanisms of HIV transmission associated with drug use are the use of contaminated injecting equipment and sexual transmission. While these mechanisms are present across drug-using populations, the risk of acquiring HIV differs in different locations and contexts and between IDUs. Numerous so-called 'structural' factors that are external to the individual have been identified or proposed as having the potential to increase or reduce HIV risk. Structural factors may impact an individual's capacity to avoid HIV risk, the likelihood of being exposed to HIV, or the accessibility or effectiveness of various

interventions that aim to address HIV and drug use. These influential factors overlap and interact, impacting in multiple ways drug users and the broader communities in which they live, and in doing so shape HIV risk.

Drug Availability

Drug availability is influenced by numerous factors including conditions of drug production and distribution, market forces, and law enforcement efforts to limit the availability of drugs. Proximity to locations where drugs are produced and drug trafficking routes impact drug availability, drug use, and the development of drug markets.

Greater drug availability and increased drug use result in more injecting episodes and potential HIV exposure as a consequence. Conversely, however, if drugs become more scarce or more expensive, injecting may increase as this may be considered a more efficient and economical means of deriving enhanced level of effect from a smaller amount of the drug as would be experienced through other routes of administration that result in lower bioavailability. Some forms of a drug may be more easily, or more commonly, injected than others; different forms of a drug may be available in different locations and may influence the prevalence of use by injection and hence HIV exposure.

Social Networks

Drug use commonly occurs in a social context and drug users are socially connected to one another. Social networks that exist between drug users and their peers can exert influence over drug-using behaviors as well the spread of HIV and other contagions.

Because it is through these network connections that HIV is spread between drug users via the sharing of contaminated injecting equipment, the structure and dynamics of these networks, and an individual's proximity within the network to the epicenter of HIV, will determine the likelihood of being exposed to the virus. Population mobility, proximity to trade routes, and migration also contribute to the mixing of networks and populations.

The behavioral norms that exist and evolve within peer groups can perpetuate or modify risky behaviors such as syringe sharing, and patterns of drug use; as people join networks they may be introduced to different behaviors.

Physical Environment

PUBLIC SPACE

When using drugs in public spaces, where there is the chance of being apprehended, riskier drug-using may occur: People may inject more hurriedly to avoid detection and may be more likely to share injecting equipment; used injecting equipment may also be discarded and pose a risk to other community members.

CLOSED SETTINGS

Commonly, a significant proportion of people incarcerated in prisons are drug users. Many of those imprisoned have been incarcerated for reasons related to their drug use, having broken criminal laws relating to drug use, possession or trade, or for undertaking activities that may be illegal such as theft or sex work (which is illegal in some jurisdictions) to fund drug use.

Despite the presence of security measures, drug use commonly occurs within prisons and other closed settings and takes place covertly, generally with limited access to sterile injecting equipment. Because drugs are typically difficult to acquire, drug users may be more inclined to inject drugs in an effort to maximize the effect of smaller amounts of a drug; people may even initiate IDU while in prison. In these environments, sharing of needles and syringes is common with scarce, often improvised, injecting equipment reused many times and shared among large numbers of people.

Similarly, consensual and nonconsensual sex commonly occurs within prisons and HIV risk is elevated if condoms are unavailable. Risk of blood-borne virus transmission through improvised tattooing and other body modification practices also exists in prison environments.

Socioeconomic Factors

Poorer socioeconomic status (poverty, homelessness, low level of education) is associated with elevated HIV risk, increased vulnerability, and poorer health outcomes more generally. Socioeconomic inequalities may vary spatially (i.e. in different geographic locations), across ethnic and language groups, and may be determined by economic activity, access to welfare and social services, and employment and educational opportunities. Each of these factors can have a bearing on drug use, the likelihood of risky injecting and sexual behavior, as well as access to drug treatment and HIV prevention, treatment, and care services.

Stability of accommodation is also important in terms of HIV risk. People who are homeless typically have worse health than those with stable accommodation and have poorer access to healthcare services including treatment for drug dependence and HIV. Homeless IDUs are also more likely to inject in public environments (see above).

Unstable economic conditions can also encourage the growth of informal economies including the development of the drug trade, which in turn influences levels of drug use and associated HIV risk.

Access to Health and Welfare Services

Drug users typically have low rates of utilization of mainstream healthcare services, contributing to poorer health status, with medical conditions going untreated

or presenting in a later stage of disease progression. People who use drugs may be reluctant to access health services for fear of discrimination because of their drug use; they may prioritize other matters such as obtaining and using drugs, shelter, and food over attending to healthcare needs; or they may have difficulty accessing a service due to its location or hours of operation. Some drug users who may have more chaotic lifestyles or those with other mental health or behavioral issues may have difficulty successfully engaging with service providers, particularly those that are not equipped or experienced in dealing with people who use drugs. Specialized drug user services may also be unattractive to people who use drugs if they fear arrest or harassment from police targeting the clients of these services. Further, in some locations mainstream HIV programs may have restrictions excluding drug users from accessing services.

POLICIES AND INTERVENTIONS ADDRESSING HIV AND DRUG USE

There is a clear imperative to reduce HIV risk and prevent HIV transmission associated with drug use. To do so effectively, multiple interventions and policies are required to address the different mechanisms of transmission and influential structural factors that shape this risk.

Responses to drug use and HIV differ between countries, with national strategies having differing focus on health-based approaches to address drug use and related harms (including HIV), or law enforcement approaches aimed at reducing drug use. In those countries where IDU is acknowledged to occur, national HIV strategies typically include specific programs to address it.

Interventions intended to reduce HIV risk associated with drug use aim to interrupt the mechanisms of transmission, address factors that shape HIV risk, or reduce drug use itself. Ultimately, these interventions seek to prevent the individuals from becoming infected with HIV.

'Harm reduction' is a term frequently used to describe approaches that focus principally on preventing and reducing harms associated with drug use, including HIV, rather than seeking exclusively to prevent drug use itself (*see* Harm Reduction Approaches). Harm reduction approaches have been incorporated into national HIV strategies in many countries. The World Health Organization (WHO), the United Nations Joint Programme on HIV/AIDS, and the United Nations Office on Drugs and Crime (UNODC) have endorsed a core set of harm reduction interventions to address IDU and HIV, these are needle and syringe programs (NSPs); opioid substitution therapy (OST) and other drug-dependence treatment; HIV testing and counseling;

antiretroviral therapy (ART); prevention and treatment of STIs; condom programs for IDUs and their sexual partners; targeted information, education, and communication for IDUs and their sexual partners; vaccination, diagnosis, and treatment of viral hepatitis; prevention, diagnosis, and treatment of tuberculosis.

Determining the effectiveness of interventions in reducing HIV incidence among IDUs presents methodological challenges. Recruitment and retention of IDUs in intervention research can be difficult. For most interventions, existing evidence is largely comprised of observational data from ecological, cross-sectional, case-control, and cohort studies. Measuring changes in HIV incidence attributable to an intervention or policy strategy is difficult and much of the existing evidence on HIV risk among drug users is based on observations in changes in self-reported risk behavior attributable to exposure to an intervention.

Reducing Drug Use to Reduce HIV Risk

A range of interventions and policies seek to reduce HIV risk and other harms by both reducing the prevalence of drug use within a population (*see* International Policies to Reduce Illicit Drug-Related Harm and Illicit Drug Use) and reducing the frequency of drug use at the level of the individual. It is intended that achieving reductions in drug use will result in reducing the number of injecting episodes where HIV exposure might occur, as well as reducing the risk of sexual transmission of HIV associated with drug use. Further, management of drug dependence improves treatment adherence and outcomes for co-occurring conditions including HIV, other infections, and mental health disorders; these enhanced treatment outcomes can also contribute to reducing HIV risk.

Treatment of Drug Dependence to Reduce HIV Risk

Treatment for drug dependence is discussed in detail elsewhere in this book (*see* section on Treatment). Treatment that achieves abstinence or a reduction in the frequency of drug use and injection episodes reduces HIV risk. Improvement in general health and social functioning brought about by treatment for drug dependence can also contribute to a reduction in HIV risk.

Drug dependence is typically chronic and recurrent in nature. Following, and often during, treatment people may resume drug use. In addition, for many people abstinence may not be the goal of treatment and they may continue to engage in some level of drug use. Treatment for drug dependence, therefore, may not eliminate HIV risk entirely, and in order to prevent HIV transmission it is important that other HIV prevention strategies are also available to people receiving treatment for drug dependence; for example, by ensuring ready access to sterile injecting equipment for people undergoing or

having completed treatment, and providing follow-up aftercare.

OPIOID SUBSTITUTION THERAPY

Methadone (an opioid agonist) and buprenorphine (partial opioid agonist) are both listed as essential medicines by the WHO, as substitution therapy, for the treatment of opioid dependence. Other opioid preparations are also, but less commonly, used as substitution therapy. Prescribed heroin has been used as substitution therapy in a number of countries and appears to be effective in reducing drug use including among people for whom other forms of OST have proven unsuccessful. (See also Methadone Maintenance, Buprenorphine for Opioid Dependence).

OST is well established in many countries but absent, or not widely available, in some where opioid injection and dependence are common; legislation restricts the use of OST to treat opioid dependence in many of these countries.

The evidence of the effectiveness of OST in treating opioid dependence and in preventing HIV transmission is strong: OST has been shown to reduce drug use and drug injecting; to reduce unsafe, risky injecting behaviors (i.e. sharing of used injecting equipment); and to improve health and social functioning. OST also improves adherence to HIV treatment among opioid-dependent people. Improved treatment outcomes, including reductions in HIV risk, are observed with higher doses, longer duration of treatment, and adjunctive psychosocial support and counseling. Findings from economic modeling suggest that OST is a cost-effective means of reducing HIV incidence and thereby avoiding the much greater costs of treatment for HIV.

OPIOID ANTAGONISTS

The opioid antagonist naltrexone, in oral or implantable preparations, is available in some countries for the treatment of opioid dependence (see Antagonists for the Treatment of Opioid Dependence). Poor patient retention in treatment and the risk of overdose for those who resume drug use posttreatment are significant limitations to the effectiveness of naltrexone. In contrast to agonist pharmacotherapy for opioid dependence, there is insufficient evidence to suggest that naltrexone might be effective in reducing HIV risk and preventing HIV transmission.

PHARMACOTHERAPY FOR STIMULANT DEPENDENCE

Various stimulant drugs, including oral amphetamines, have been investigated to determine if they might be suitable as maintenance therapy for stimulant dependence in the same manner that methadone and buprenorphine are used in the treatment of opioid

dependence. Other drugs, such as the alerting agent modafinil, have also been trialed for the treatment of cocaine and amphetamine dependence. (see Pharmacotherapy of Cocaine Dependence, Medication Development for Amphetamine Dependence. Medications for Cocaine Dependence).

While findings from some trials have suggested that increases in treatment retention, reductions in stimulant use and injection, and improvements in health and social functioning might be gained from these proposed medications, evidence has not been strong enough to support the clinical introduction of pharmacotherapies for stimulant dependence, and hence their role in reducing HIV currently remains limited.

MEDICALLY SUPERVISED DETOXIFICATION

Detoxification is frequently an important first step to drug treatment for many drug-dependent people. Providing support and medication to manage the symptoms of drug withdrawal increase the likelihood that a drug-dependent patient will complete detoxification. While an important part of a comprehensive approach to drug dependence, detoxification is not effective as a standalone treatment in bringing about long-term behavioral change and reductions in drug use; accordingly, reductions in HIV risk have not been observed.

PSYCHOSOCIAL INTERVENTIONS FOR THE TREATMENT OF DRUG DEPENDENCE

Various evidence-based, nonpharmacological, psychosocial interventions are available for the treatment of drug dependence and hence also have a role in reducing associated HIV risk. These include therapeutic communities (see Therapeutic Communities[®]), cognitive behavioral therapy, (see Cognitive Behavioral Therapies) and other psychotherapeutic approaches, delivered in either outpatient or residential settings, in groups, couples, or one-on-one (see Individual and Group Counseling for Substance Use Disorders). Psychosocial approaches delivered in concert with pharmacotherapies can improve treatment outcome compared to these treatment modalities delivered alone.

Psychosocial interventions are particularly important in the management of stimulant dependence where pharmacotherapies are currently not available; with evidence suggesting that cognitive behavioral therapy and contingency management approaches may be of most benefit in reducing stimulant use.

Residential rehabilitation programs are commonly abstinence focused; successful models have been developed, however, incorporating OST as well as providing HIV prevention measures such as the provision of sterile injecting equipment.

Legislation and Punishment to Deter Drug Use

Laws regarding drug use and possession differ between countries, but share the aim of deterring the people from using drugs, other than for authorized medical and scientific purposes. With the exception of a small number of countries, possession or use of any drugs that are listed as controlled substances are considered either criminal or civil offenses. The severity of penalties imposed is generally determined in consideration of the type and amount of the drug involved and may range from incarceration or even physical punishment to lesser administrative penalties such as a fine.

The effectiveness of these approaches in reducing drug use is contested, as is their cost-effectiveness in comparison to other drug use reduction strategies (*see* Drug Decriminalization and Legalization).

While such legislation is not always considered explicitly as part of a country's HIV strategy in response to drug use, in many countries the resources allocated to address drug use via these law enforcement approaches greatly exceed that for other interventions that aim to reduce drug use, including evidence-based approaches such as the drug-dependence treatment modalities discussed in the preceding sections. Punishment for drug use in these countries represents the predominant policy approach to reducing drug use and consequent harms including HIV transmission.

Legislation that criminalizes drug use has a number of important consequences in relation to HIV risk. Imposing custodial sentences as punishment for drug use or possession contributes to a greater number of people incarcerated who may be drug dependent or IDUs; drug use and elevated HIV risk in prisons are significant (*see* above).

Compulsory Detention Aiming to Achieve Abstinence from Drug Use

Drug detention centers operate in a number of countries with the aim of preventing ongoing drug use by removing drug users from the community and compelling them to participate in activities that are intended to promote abstinence from drug use. In many of these countries, compulsory detention represents the predominant drug demand reduction strategy, both in terms of resource allocation and numbers of drug users participating in these programs.

These compulsory detention centers differ from prisons in a number of ways, notably that they operate outside of the judicial system, and lack a process by which an appeal against detention can be made. Typically medical assessment of drug dependence is not made, programs within these centers are not medically supervised, and detoxification is not medically assisted. Programs may involve participation in forced labor, military style drills, or in

some cases punishment. Release from detention is arbitrarily or administratively determined and is not related to demonstrated treatment outcomes.

Rates of relapse to drug use following detention are high, and reentry into these centers is common. There is no evidence that compulsory detention is effective in producing sustained reductions in HIV risk.

Interventions to Reduce Risky Sex and Injecting Behavior

In order to prevent the use of contaminated injecting equipment and to increase condom use by people who use drugs, it is necessary for sterile injecting equipment and condoms to be accessible and for people to have both the knowledge and motivation to practice safer sex and safer injecting.

Access to Sterile Injecting Equipment

Programs for the distribution of sterile needles and syringes have been introduced in the majority of countries around the world where IDU is known to occur; the scale to which these programs have been implemented, however, varies substantially between countries. These NSPs are intended to increase IDUs' access to clean injecting equipment and to decrease the number of used needles and syringes in circulation, thereby reducing the number of injections for which contaminated equipment is used.

Various service delivery models for NSPs have been developed: Some require that used needles and syringes be returned in exchange for new equipment, while others place no such restrictions on the provision of clean needles and syringes, but still encourage the return and safe disposal of used equipment. Distribution may take place from a range of delivery points including from fixed locations, at facilities where other health or welfare services are provided, from vending machines, from mobile distribution services, or through outreach programs, including through peer to peer distribution among IDUs. The presence of multiple distribution options increases the accessibility of injecting equipment.

In many countries, needles and syringes are available for purchase, without prescription, commonly from pharmacies or similar outlets. These are also important access points to sterile injecting equipment, particularly in the absence of NSPs or in circumstances where an IDU prefers not to access an NSP.

NSPs have been studied in multiple settings, in both high- and low-income countries. There is strong evidence that these programs reduce the frequency of injecting with used equipment. Correlations between NSP provision and decreasing HIV prevalence and incidence have been observed in multiple ecological, cross-sectional, and prospective cohort studies. Empirical

evidence that NSPs might increase or encourage injecting has not been produced.

Evidence from observational studies, and supported by mathematical modeling, suggests that the impact of NSPs is proportional to the number of needles and syringes distributed within IDU networks, and accordingly the proportion of IDUs receiving sufficient needles and syringes to enable them not to reuse equipment that has been previously used by another injector.

In some countries where IDU is reported to occur, legislation prohibits the distribution or possession of injecting equipment, thereby preventing the operation of NSPs. As discussed in further detail above, in some countries where NSPs have been introduced other barriers limiting access to NSPs exist including, for example, police activity targeting people who utilize NSPs.

In addition to (or in some cases instead of) providing new, sterile needles and syringes, HIV prevention services may promote the cleaning of used injecting equipment by distributing bleach along with information on how to disinfect injecting equipment. If done correctly, disinfecting used injecting equipment can substantially reduce the risk of reusing injecting equipment and can contribute to reduction in HIV transmission. However, the effectiveness of such strategies is limited by how well the equipment is cleaned; it may be difficult for IDUs to thoroughly clean equipment as required.

Access to Condoms

Consistent condom use has been shown to make a significant impact in reducing HIV transmission in the general population, and condoms are available for purchase in most countries. Because of the elevated HIV risk through sexual exposure among drug users, 'low-threshold' condom distribution programs targeting these groups are often established in an effort to increase condom access and use amongst this group. Programs that provide services to drug users such as drug treatment programs and NSPs are thus common sites for condom distribution.

Behavioral Interventions and Education to Reduce Unsafe Sex and Injecting Behavior

It is important for people who use drugs to have an understanding of how HIV is transmitted as well as other risks associated with drug use and how these can be avoided or minimized.

Risk reduction information conveyed through brief education interventions has been shown to reduce the frequency of unsafe injecting and unprotected sex. Repeated exposure to these interventions over time may be required to maintain positive behavior change.

These interventions appear to be most effective when delivered by drug users. So-called 'peer-led'

interventions involve drug users receiving training to be peer-educators to disseminate risk reduction information, promoting safer injecting and sexual behaviors, through their social networks. Such methods are particularly valuable in being able to reach people at risk who may not otherwise access HIV prevention services. Peer-led interventions make use of the influence behavioral norms and practices have within drug user networks to modify HIV risk.

Discouraging Initiation into IDU

Initiation to IDU is commonly a peer-driven or socially influenced process. Typically, the first time a person injects, he or she will receive assistance from a more experienced injecting drug user to do so. In recognition of this, some interventions that seek to prevent initiation to injecting focus on encouraging existing IDUs to not initiate others.

Drug dependence is also recognized as a risk factor for initiation to IDU among noninjectors. Drug dependence treatment for noninjectors is also therefore important for reducing HIV risk by reducing the risk of initiating IDU.

It has been proposed that drug users may be less likely to move to IDU if the means of consumption by other routes of administration providing similar immediate onset of action and bioavailability are available. Accordingly, some HIV prevention programs distribute equipment for smoking of drugs such as heroin or methamphetamine.

Addressing structural factors that influence the development of drug dependence and initiation to IDU may also contribute to reducing HIV risk (see below).

Interventions to Reduce the Likelihood of HIV Transmission

Antiretroviral Therapy as HIV Prevention

ART for the treatment of HIV reduces viral load in blood and semen. This reduction in viral load has been demonstrated to reduce the risk of sexual transmission of HIV between serodiscordant partners. It has been proposed that a similar reduction in the risk of transmission may occur in the context of exposure to HIV through shared injecting equipment. ART may therefore have a role in the prevention of HIV transmission among IDUs.

Typically, IDUs have poorer access to ART than non-IDUs. This may be due to guidelines that restrict ART to people who are not active drug users, or in some circumstances may be because clinicians are reluctant to provide drug users with ART out of concern that adherence to treatment will be poor. Treatment of IDUs has been shown, however, to achieve positive treatment outcomes, equivalent to that of nondrug users.

Adherence and treatment outcomes among drug users can be improved by the management of co-occurring drug dependence.

Post-exposure prophylaxis (PEP) involving a short course of ART (usually 4 weeks duration) is administered immediately following known or suspected exposure to HIV to prevent infection. While there may be some role for PEP in preventing HIV infection among IDUs, access is generally limited.

Prevention and Treatment of STIs

Given the high prevalence of STIs among drug-using populations, and the potential for STIs to biologically increase sexual transmission of HIV, the prevention and treatment of STIs has important implications for reducing HIV risk among drug users.

Strategies to increase STI screening and treatment access for people who use drugs include integrated models of care where drug treatment, HIV prevention, or other services that provide care for drug users also offer sexual health services, or where there are solid referral pathways to other services able to provide this care.

Prevention of STIs among drug users through the promotion of safe-sex practices and by increasing the accessibility to condoms is also important (see above).

Addressing Structural Factors

Structural factors that shape HIV risk are influenced, or in some cases defined, by policy and legislation. How changes in various policy or legislative conditions might affect changes in HIV risk and incidence is largely untested. A number of policy approaches and interventions have been identified, however, as having some impact on different structural factors and from this in modifying HIV risk. These approaches may act to increase an individual's capacity to reduce HIV risk or the utilization or effectiveness of various HIV prevention strategies.

Legislation and Law Enforcement Supporting HIV Prevention Approaches

Legislation that allows for, and supports, the distribution of injecting equipment is necessary for the operation of NSPs. If legal restrictions are imposed limiting the availability and accessibility of injecting equipment, the prevalence of sharing of used injecting equipment is elevated. If possession of injecting equipment is illegal, or may be used as evidence of drug use and grounds for arrest or police intervention, IDUs may be reluctant to carry clean injecting equipment, and thus are more likely to share used equipment.

As pharmaceutical opioids are controlled substances, legislation is required in most jurisdictions to allow for

the provision of OST; in some countries OST remains prohibited due to such legislative restrictions.

Legislation and policing practices that respect and protect the human rights of drug users contribute importantly to minimizing HIV risk.

Police surveillance of sites where drug treatment and HIV prevention services are provided, or the targeting of drug users using these programs, acts to discourage drug users from accessing services, thereby increasing HIV risk. In some settings, police may also target service providers themselves and thus disrupt the provision of these services. Policies to ensure that police activity does not negatively impact upon service provision or utilization can have a significant impact on HIV risk and prevention.

People may be reluctant to access drug treatment services if the names of those receiving treatment for drug dependence are added to registers that are shared with law enforcement agencies, or if doing so can result in undesirable consequences such as removal of child custody or denial of employment.

Reducing HIV Risk in Closed Settings

Both sexual- and injecting-related HIV risk behaviors occur in prison and other closed settings environments. HIV prevention interventions such as condom provision, NSPs, and evidence-based treatment for drug dependence, including OST, have been introduced in prisons in some countries and demonstrated as being effective in reducing the prevalence of HIV risk behaviors; they have not been shown to increase or encourage sex or drug use.

Supervised Injecting Facilities

Supervised injecting facilities (SIFs) have been established in a number of countries. These are sites where drug users are provided with clean equipment and may consume pre-obtained drugs in a hygienic environment under the supervision of professional staff who, in some centers, are medically trained. SIFs facilitate safer injecting episodes, provide an alternative to public injecting, and enable staff to intervene if drug overdose occurs. These are 'low threshold' services in terms of access and as such can function as a useful entry point to other health and welfare services including drug-dependence treatment and HIV prevention, treatment, and care services. While those SIFs currently in operation are able to reach only a small proportion of the total IDU population, evidence suggests that these services are able to attract those with greatest HIV risk.

Socioeconomic Status

Low socioeconomic status is associated with drug use and HIV risk. Policy approaches to address

socioeconomic inequality and disadvantage are complex and well beyond the scope of this discussion. It is important to note, however, that initiatives and policy approaches that improve access to education, employment, stable accommodation, and other factors may also have the potential to consequently reduce HIV risk associated with lower socioeconomic status.

Drug User Involvement in the Response to HIV Risk Associated with Drug Use

The role drug users themselves have in delivering peer-based interventions to effectively reduce HIV risk is described above. In addition to participation in service provision, drug users, particularly through organized drug user groups, have made important contributions to the development and planning of programs addressing drug use and HIV risk. The principle of meaningful involvement of people who use drugs (often articulated as ‘nothing about us without us’) recognizes the critical role drug users have in improving understanding of HIV risk and the needs of drug users, and in formulating, delivering, and evaluating HIV prevention programs. This principle is supported by international organizations involved in the response to HIV/AIDS and drug use.

SUMMARY

Drug use is associated with significant HIV risk, related to both IDU and sexual transmission of the virus. To reduce HIV risk, strategies are required that address the mechanisms of transmission and influential structural determinants. These strategies can be enhanced by the involvement of drug users themselves in the planning, delivery, and evaluation of HIV prevention programs.

Reducing the prevalence of drug use in a population and reducing the frequency of drug use at the level of the individual reduces HIV risk. Treatment for drug dependence resulting in abstinence or reduction in levels of drug use has been shown to reduce the frequency of HIV risk behaviors. In the treatment of opioid dependence, OST has been demonstrated to prevent incident HIV infections; similar reductions have not been observed for opioid antagonists in the treatment of opioid dependence. Psychosocial interventions for drug dependence can also contribute to reducing HIV risk, and are particularly important in the management of stimulant dependence where pharmacotherapies are currently unavailable for use clinically. Incarceration of drug users in detention centers for the purpose of reducing drug use has not been shown to produce sustained reductions in HIV risk.

Reducing the use of contaminated injecting equipment is critical to reduce HIV transmission among IDUs who are unable or unwilling to abstain from drug use. Distributing sterile injecting equipment through NSPs has been demonstrated to decrease the prevalence of injecting with used equipment, but has not been shown to increase the prevalence of IDU.

Similarly, condom distribution programs targeting drug users and their sexual partners have been developed to increase the availability of condoms and reduce sexual risk. Prevention and treatment of STIs among IDUs also has a role in reducing the risk of HIV transmission among sexually active drug users for whom the prevalence of STIs is commonly elevated.

To encourage safe injecting and sex risk behavior, it is important that drug users have an understanding of HIV risk and how this can be avoided or minimized; this information may be most effectively conveyed by trained peer-educators.

ART for people living with HIV reduces infectivity, thereby decreasing risk of HIV transmission. Provision of ART for both past and active drug users is able to achieve positive treatment outcomes and good levels of adherence that can be enhanced by the concomitant management of drug dependence and other significant co-occurring conditions.

Legislation and law enforcement practices can contribute to reductions in HIV risk through supporting the provision of evidence-based HIV prevention strategies. The existence of legislation prohibiting OST or the distribution of sterile injecting equipment is a critical barrier to effectively addressing HIV in settings where IDU is present.

Addressing various other structural factors that can shape HIV risk among drug users, such as the accessibility of health and welfare services or socioeconomic status and conditions, has also been proposed as having the potential to reduce HIV risk.

The most substantial reductions in HIV risk are observed where these multiple, evidence-based interventions and policy approaches are implemented in combination, both in the community as well as in prisons and other closed settings.

List of Abbreviations

AIDS	acquired immunodeficiency syndrome
ART	antiretroviral therapy
HIV	human immunodeficiency virus
IDU	injecting drug use
IDUs	injecting drug users
NSP	needle and syringe program
OST	opioid substitution therapy
PEP	post-exposure prophylaxis
SIF	supervised injecting facility
STI	sexually transmitted infection

Alcohol misuse or abuse prevention efforts are often synonymous with harm reduction approaches and are best characterized as efforts aimed at reducing the occurrence of serious harm associated with alcohol use, without necessarily requiring abstinence. Prevention efforts include implementing controls on the physical availability of alcohol, creating safer drinking environments, and using social marketing techniques to decrease alcohol misuse. The goal is to reduce the total alcohol consumption of a population as a means for reducing related problems. One of the most significant tools for limiting alcohol-related problems is the ability to control both the physical and economic availabilities of alcohol. Public health advocacy is vital to prevention strategies just as implementation of strategies is dependent on public awareness of the issues. The military provides a unique setting for examining alcohol misuse prevention contexts, strategies, and policies.

THE ALCOHOL MISUSE PROBLEM IN THE MILITARY

Overview

Excessive alcohol use and alcohol-related problems are well known in the military services. Over the years, heavy drinking has been widely accepted and to some extent has become a part of military culture. In earlier times, alcohol was thought to be necessary for subsistence and morale; it was provided as a daily ration to sailors and soldiers. Within the US military population, which is predominantly male, heavy drinking and being able to hold one's liquor have served as indicators of suitability for the demanding masculine military role. Indeed, a common stereotype has been to characterize hard-fighting soldiers as hard-drinking soldiers. In the United States, the availability of alcoholic beverages was seen by military authorities as good for the war

effort. Following the end of Prohibition, brewers were required to allocate 15% of total annual production of beer for use by the armed forces, and local draft boards were authorized to grant deferments to brewery workers who were highly skilled and considered irreplaceable. On one occasion, the Teamsters Union was ordered to end a strike against Minneapolis breweries to help ensure continued beer manufacturing during World War II. Alcohol's ease of availability has no doubt contributed to excessive drinking among many military personnel. Although the modern military has made some progress in changing perceptions and practices regarding alcohol use, heavy alcohol consumption still remains a concern. There is still evidence of norms, traditions, and cultural factors that encourage heavy drinking. For example, in today's US military, over one-third of heavy drinkers report that consuming alcohol is "part of being in the military."

Currently, the US Department of Defense (DoD) strongly discourages alcohol abuse within the armed forces because of its negative effects on the health and well-being of military personnel, its detrimental effects on military readiness, and the need to maintain high standards of performance and discipline. Considerable research indicates that personnel who drink heavily – defined as five or more drinks per typical drinking occasion at least once per week – are likely to experience a variety of physical, social, and psychological problems. Those who consume five or more drinks at one time on a regular basis are more likely than those who drink at lighter levels to experience serious health consequences and injuries, to have poorer academic performance, to have social/family problems, to engage in unplanned or unsafe sex, and to be at higher risk for assault and aggressive behavior.

DoD Health-Related Behaviors Surveys: Alcohol Findings

To help monitor the extent of substance use, including alcohol use and abuse, and to define the need for increased prevention efforts, DoD initiated a series of comprehensive worldwide surveys of health-related behaviors (HRB) among active duty military personnel in the Army, Navy, Marine Corps, and Air Force (HRB surveys). Ten of these surveys have been conducted from 1980 to 2008, of which nine (all but the first) were by Robert Bray and his colleagues at RTI International. These surveys, which provide the most definitive information on alcohol use in the military, have all been carried out using similar methods. RTI researchers, working with DoD, first randomly selected a sample of approximately 60 military installations to represent the armed forces throughout the world and then randomly

selected men and women of all ranks at those installations to represent active duty personnel. Civilian research teams administered printed questionnaires anonymously to servicemembers in classroom settings on military bases or aboard ships. Personnel who were unable to attend the group sessions (e.g. those who were on leave, sick, or temporarily away from the base) were mailed the questionnaires and asked to complete and return them. These procedures yielded between 12 000 and 28 000 completed questionnaires for each survey.

It is important to realize that the military population has a considerably different demographic makeup than the general population of the United States. The armed forces comprise personnel who are predominantly male (85%), relatively young (47% aged 18–25 years), white non-Hispanic (64%), married (54%), and reasonably well educated (45% have some college education, 22% have a college degree or higher). Nearly 83% of personnel are enlisted members ranging from junior to more senior ranks, and the remaining 17% are officers spanning junior to senior ranks. This compares with the civilian population aged 18–64 years, which is about 51% male, and 15% aged 18–25 years.

Figure 78.1 presents HRB survey data showing trends from 1980 to 2008 of the percentages of active duty military personnel who were abstainers or infrequent/light drinkers and those who were heavy drinkers during the 30 days prior to each survey. As shown, there has been a substantial increase from 1980 (26%) to 2008 (38%) in servicemembers who were abstainers (drank once a year or less) or infrequent/light alcohol users (drank from one to four drinks per typical drinking occasion, one to three times per month). Heavy alcohol users (five or more drinks on the same occasion at least once a week) decreased between 1980 and 1988, showed some fluctuations between 1988 and 1998, and increased significantly from 1998 (15%) to 2008 (20%). Of interest, the heavy drinking rate in 2008 (20%) was not significantly different from the rate in 1980 (21%) when the survey series began. These findings indicate that over the years, the military has shown increases in those who are abstaining or drinking alcohol at light levels but that there has not been much change in the proportion of heavy drinkers.

Binge drinking is another term that has been used widely in recent years to indicate excessive alcohol use that is likely to lead to problems. For the military, binge drinking is defined as consuming five or more drinks on a single occasion at least once in the past 30 days. The definitions of binge and heavy drinking are related; heavy drinkers are also binge drinkers, but binge drinkers are not necessarily heavy drinkers. Data from the HRB surveys indicate that the rate of binge drinking

FIGURE 78.1 Alcohol use trends, DoD services, past 30 days, 1980–2008.

increased among active duty military personnel from 35% in 1998 to 47% in 2008.

Figure 78.2 shows the relationship between drinking levels and serious consequences among military personnel in the different military branches. Serious consequences were defined as one or more alcohol-related problems in the past 12 months and included such things as being passed over for promotion because of drinking, loss of 1 week or more from duty because of drinking-related illness, or arrest for driving under the influence (DUI) of alcohol. As shown, rates of serious consequences are higher among binge drinkers than among regular drinkers but are highest among heavy drinkers, more than double the rates of binge drinkers.

Because military binge drinkers and heavy drinkers are likely to experience negative outcomes from their drinking and because these binge and heavy rates have remained steady or increased over the years, the military needs effective alcohol abuse prevention programs.

Comparisons of Military and Civilian Heavy Drinking

To understand alcohol misuse prevention efforts in the military, it is useful to know how heavy drinking in the military compares to heavy drinking among civilians. To answer this question, Bray and colleagues compared military data from the HRB survey with civilian data from the National Survey on Drug Use and Health after equating the data for age and geographic location and adjusting the civilian data to resemble the demographic distribution of the military. Comparisons were made for four age groups: those aged 18–25, 26–35, 36–45, and 46–64 years. The analysis showed that military personnel had significantly higher rates of heavy drinking than civilians among persons aged 18–25 years (26 versus 16%) and 26–35 years (18 versus 11%), no significant difference in rates for those aged 36–45 years (10 versus 8%), and lower rates among those aged 46–64 years (4 versus 9%).

FIGURE 78.2 Serious consequences from alcohol use by Drinking Category and Service, 2008.

These findings indicate that heavy drinking patterns in the military do not mirror similar use among civilians. The higher rates of heavy drinking in the military among those aged 18–35 years suggest that certain aspects of military life may foster heavy drinking or that those military policies and programs directed toward reducing heavy drinking have not been as effective in the military as similar efforts among civilians.

Factors Influencing Alcohol Use in the Military

When addressing alcohol misuse prevention, it is important to consider a number of complex factors that may contribute to alcohol misuse and subsequent alcohol-related problems in the military. These include individual, social/cultural, and environmental factors. Individual factors include demographic and psychological components. Individual factors such as age and gender are possible risk factors for alcohol use: young adults and males are more likely to engage in alcohol misuse than their older or female counterparts. Psychological components include individuals' beliefs, attitudes, intentions, and values, some of which lead to higher risk for heavy alcohol use. In addition, some civilians who are heavy alcohol users may choose to join the military due to the perception that heavy alcohol use is accepted and thus bring their alcohol habits with them.

Social/cultural factors include family; friends; norms and perceptions about traditions and acceptable practices; and perceptions of acceptance, support, and tolerance for use. Peer pressure to fit in with friends (normative influence) or expectations about drinking after work may lead servicemembers to engage in the heavy drinking habits of their buddies. Customs and traditions about drinking rituals and celebrations, as well as high alcohol consumption in the countries where servicemembers are stationed, may also encourage excessive alcohol use.

Environmental factors include easy access to alcohol, advertising that encourages use, and lack of enforcement of policies to control use. With the exception of basic training, during which alcohol use is banned, alcohol is readily available to servicemembers and use is encouraged via advertising (e.g. alcohol advertisements in military news publications such as *Army Times* and *Navy Times*). These factors may contradict and interfere with some policies and programmatic efforts to reduce alcohol use in the military. Similarly, the finding that rates of heavy drinking among young adults in the military are higher than those in the civilian population indicates some level of acceptance, tolerance, and/or lack of enforcement of policies among some services, installations, or commanders.

PREVENTION AND POLICY APPROACH

Military Prevention Emphasis

The armed forces approach to alcohol misuse prevention combines education, training, slogans and campaigns, and intervention programs. DoD directives provide an overarching framework and objectives, and the military branches implement alcohol abuse prevention policies and programs aimed at the needs of their servicemembers. Training and education classes provide members with basic information on alcohol and alcohol abuse and emphasize early detection and early intervention as critical in the prevention of alcohol abuse. On-base driving privileges are revoked if military members are convicted of driving while intoxicated (DWI) either on base or off base. Many commands offer safety stand-downs and red ribbon campaigns prior to holidays and the vacation season, reminding members of the dangers of drinking and driving. National Drunk and Drugged Driving Awareness Week is another opportunity that commands use to make members aware that "drinking and driving do not mix."

Commands encourage their personnel to use designated drivers for situations where alcohol will be available, and most bases provide server training for employees of on-base clubs and restaurants that serve alcohol. Designated drivers often receive free nonalcoholic beverages from various clubs and restaurants. It is common for bases to set up driving mazes at gates and other checkpoints to detect intoxicated drivers, especially on weekends. Alcohol deglamorization campaigns stress the importance of food and nonalcoholic beverages at command-sponsored social events. In addition, the armed forces emphasize personal responsibility and caring for your buddy. Supervisory personnel are expected to lead by example and be role models for junior personnel, both on and off duty.

Alcohol control policies and minimum age requirements are also part of the military's prevention efforts. However, alcohol control policies are inconsistent across service branches. In earlier times, anyone on active duty could consume alcohol on military installations, regardless of the legal drinking age off base. However, in the mid-1980s, advocacy groups, such as Mothers Against Drunk Driving (MADD), lobbied Congress to change this. Federal law now requires military installation commanders to adopt the same drinking age as the state in which the military base is located. There is one exception to this rule. If the base is located within 50 miles of Canada or Mexico, or of a state with a lower drinking age, the installation commander may adopt the lower drinking age for military personnel on base. Even with these restrictions, commanders of DoD installations may waive age requirements if they determine that the

exemption is justified by special circumstances such as the conclusion of arduous military duty or the anniversary of the establishment of a military service or organization. However, the event must be held on a military installation and the commander must ensure that appropriate controls are in place to prevent endangering servicemembers or the surrounding community.

Development and Implementation of DoD Alcohol Policy

Serious substance abuse prevention efforts in the military began as a result of drug and alcohol abuse problems that became increasingly visible during the late 1960s and early 1970s. In response to the recognition of widespread reports of drug and alcohol abuse of military servicemembers, particularly during the Vietnam War, DoD convened a task force in 1967 to investigate drug and alcohol abuse in the military. In 1972, it implemented an alcohol abuse policy based on task force recommendations. The overall policy emphasized the prevention of alcohol abuse through education and law enforcement procedures focusing on detection and early intervention, with the goal of rehabilitating users with problems and returning them to service. This policy was issued as a DoD directive titled "Alcohol Abuse by Personnel of the Department of Defense."

In 1980, the directive on alcohol abuse was combined with a directive on drug abuse under a single comprehensive directive titled "Drug and Alcohol Abuse by DoD Personnel," which shifted the focus away from the rehabilitation of problem users to a broader emphasis on detection, treatment, rehabilitation, and prevention. This consolidated policy has been updated periodically (1985, 1997, 1999) but has remained largely unchanged since its 1980 origination. Alcohol abuse is defined under this directive as "the use of alcohol to an extent that it has an adverse effect on the user's health or behavior, family, community, or the DoD, or leads to unacceptable behavior as evidenced by one or more acts of alcohol-related misconduct." This policy defines prevention programs as "training, education, and public information activities designed to influence participants to avoid alcohol abuse."

Under these policy guidelines, specific tasks to be accomplished include the deterrence and identification of alcohol abuse and dependence that exist on installations and facilities under DoD control; periodic assessment of the extent of alcohol abuse in the armed services; the provision of education and training on DoD policies for alcohol abuse and/or dependency and on effective measures to alleviate problems associated with alcohol abuse and/or dependency; counseling and providing treatment and/or rehabilitation for

military personnel who abuse alcohol; and prohibition of DoD personnel from possessing, selling, or using alcohol other than in accordance with laws, regulations, and DoD directives.

DoD policies and programs typically encompass both alcohol and other drugs. Army alcohol misuse prevention falls under the umbrella of the Army Substance Abuse Program, which provides comprehensive alcohol and drug abuse prevention and control policies, procedures, and responsibilities for soldiers. Alcohol and other drug abuse prevention are conceived broadly as all measures taken to deter and reduce the abuse or misuse of alcohol and other drugs to the lowest possible level. The Navy Alcohol and Drug Abuse Prevention Program serves both Navy and Marine Corps personnel in providing support to individual and command alcohol abuse and drug use prevention efforts. Its mission is to support readiness by fighting alcohol abuse and drug use. The Air Force calls its program Alcohol and Drug Abuse Prevention and Treatment (ADAPT). The objectives of ADAPT are to promote readiness and health and wellness through the prevention and treatment of substance abuse; to minimize the negative consequences of substance abuse to the individual, family, and organization; to provide comprehensive education and treatment to individuals who experience problems attributed to substance abuse; and to return identified substance abusers to unrestricted duty status or to assist them in their transition to civilian life, as appropriate.

Pricing Discrepancies

While the DoD directive "Drug and Alcohol Abuse by DoD Personnel" seeks to prevent and eliminate alcohol abuse, it does not formally address approaches to responsible alcohol use within the military community. Another DoD directive titled "Armed Services Exchange Policy," issued in 2005, is related to the promotion of responsible alcohol use through regulation of the sale and pricing of alcohol in DoD facilities. These include military exchanges or convenience stores, commonly referred to as Class 6 stores or Shoppettes, which are located on the vast majority of US military installations worldwide. This policy stipulates that alcohol prices in DoD facilities may be discounted up to 10% less than the best local shelf price in states under Alcohol Beverage Control (ABC) regulation and in overseas facilities and up to 5% in states not under ABC regulation. Unfortunately, this policy may send a mixed message to servicemembers that the military is supportive of alcohol use because the government is making it available to them at somewhat discounted prices. Discounted alcohol prices on military facilities may encourage

increased rates of alcohol use, possibly evolving into abuse, if policies and programs do not define and teach tenets of responsible use.

MILITARY ALCOHOL MISUSE PREVENTION PROGRAMS

As part of their efforts to encourage alcohol abuse prevention, DoD and the armed services have developed or adopted several programs ranging from media campaigns to interventions. Their goal is to increase awareness about problems that can result from excessive drinking and to encourage persons to engage in responsible alcohol use. Six such programs are described below.

“That Guy” Campaign

“That Guy” is a DoD-funded, multifaceted campaign to increase awareness of the problems associated with binge drinking and to reduce excessive drinking behaviors. The campaign encourages young enlisted personnel to reject binge drinking because it detracts from the things they care about: family, friends, dating, sex, money, and reputation. The campaign uses a combination of humor, realistic imagery, and drinking facts to raise awareness of the impact of drinking too much during a social event or outing, and to deliver a serious message: “Don’t Be That Guy!” (i.e. anyone who, because of excessive drinking, behaves in a manner that others do not want to emulate or be around). The campaign leverages its Web site as the key communication tool in its counter-marketing efforts to provide prevention education to servicemembers worldwide. The “That Guy” campaign also includes the distribution of its key message through the display of posters and flyers in various locations on military installations and other community-based media, including billboards, newspapers, and television and radio ads.

The Right Spirit

The Navy’s Right Spirit campaign emphasizes promoting healthy lifestyles for all Navy members, with the primary focus of prevention education. With additional focus on deglamorization of alcohol use, alternatives to drinking, and clear and enforceable policy guidance, the campaign stresses responsibility at all levels: command, leadership, shipmate, and individual. The Right Spirit campaign calls for removing alcohol from traditional ceremonies, providing alternatives to drinking, recognizing the effects of alcohol use, and promoting personal responsibility concerning

alcohol use. The Right Spirit Web site provides information about available education and training materials, publications, and links to other relevant Web sites. The Navy credits the Right Spirit campaign with a sizable reduction in alcohol-related incidents and a decline in arrests for DUI.

Personal Responsibility and Values: Education and Training

The Navy’s Personal Responsibility and Values: Education and Training (PREVENT) Program is designed primarily for young adult sailors aged 18–26 years. The program addresses four main areas, including alcohol misuse prevention and related substance abuse and mental health concerns. The 3-day, 24-hour preventive education course is designed to clarify individual values and to increase behaviors that enhance personal wellness and are consistent with established Navy organizational standards for military bearing and character. The program applies a stages-of-change approach to motivate young recruits to modify their behaviors toward a more healthy lifestyle. PREVENT is offered on a regular basis at Navy installations worldwide. Approximately 26 000 Navy men and women complete PREVENT education courses annually.

101 Days of Summer Campaign

The Marine Corps’ 101 Days of Summer campaign encompasses both alcohol and illicit drug abuse prevention efforts, utilizing programs that share the mission of promoting responsible use of alcohol and eliminating illegal drug use. Aimed at prevention through education, the program includes a variety of activities between Memorial Day and Labor Day, an especially risky period for alcohol- and drug-related incidents. Through a variety of unit competitions, giveaways, entertainment, and educational opportunities, the campaign seeks to raise awareness of substance abuse; promotes responsible alcohol use; educates servicemembers regarding the dangers and consequences of illicit drug use; and offers fun, healthy activities as viable alternatives.

0-0-1-3 Campaign

In 2004, the commander of Francis E. Warren Air Force Base located near Cheyenne, Wyoming, recognized that heavy alcohol use was creating problems and developed a campaign called 0-0-1-3 to address this issue. At the time, a base-wide survey found that the average airman thought “unsafe” drinking began with eight drinks or more. Many seasoned servicemembers appeared to

have false perceptions on what constituted normal drinking, so it was decided to specifically define “responsible, periodic drinking” as a way to help set realistic expectations. The slogan 0-0-1-3 was an easy way for airmen to remember an approach to safe drinking: (0) zero drinks if you are under 21, (0) zero DUIs, (1) if of age, no more than one drink per hour, and (3) no more than three drinks per night. The campaign is based on research by the National Institute on Alcohol Abuse and Alcoholism and the National Academy of Sciences that underlines the importance of setting a clear standard. Although research found that people might not immediately follow the standard, they would at least start counting their drinks and comparing their habits to the standard. Francis E. Warren Air Force Base reported that the program was successful in reducing alcohol incidents, underage drinking, and drunk driving. Because of the success of 0-0-1-3 at this base, the Air Force subsequently implemented the program at all Air Force bases.

Program for Alcohol Training, Research, and Online Learning

Program for Alcohol Training, Research, and Online Learning (PATROL) is a Web-based alcohol program for military personnel adapted from two interventions that were originally designed for and tested on civilian populations. The first intervention, called Alcohol Savvy, is a universal prevention program aimed at adults in the workplace. It is a fully narrated, multimedia primary prevention program that incorporates rich video and audio elements as well as interactive components. Alcohol Savvy’s primary goal is to encourage moderate drinking and to prevent escalation of alcohol use among mainstream populations. The second intervention, called the Drinker’s Check-Up, is based on the principles of motivational interviewing and focuses on assessment of alcohol use, personalized feedback of alcohol use relative to peers, and exercises to encourage individuals to change their drinking behavior. The primary goal of Drinker’s Check-Up is to reduce alcohol use among high-risk drinkers. PATROL integrated Alcohol Savvy and Drinker’s Check-Up with the goal of providing low-risk drinkers with a primary prevention program (Alcohol Savvy) and high-risk drinkers with an alcohol reduction program (Drinker’s Check-Up). Both programs were substantially modified for the military, including the use of military graphics and language and military-specific norms regarding alcohol use.

The interventions were evaluated in a scientific study using approximately 3000 active duty military personnel at eight military installations (two each from the Army, Navy, Marine Corps, and Air Force). Participants

completed an initial baseline survey and were assigned to one of three study conditions – (1) Alcohol Savvy, (2) Drinker’s Check-Up, or (3) control – where they completed the intervention materials. Follow-up surveys were completed 1 and 6 months following baseline. Findings showed that at the 1-month follow-up, participants who completed the Drinker’s Check-Up had significant reductions on several indicators of alcohol use compared to persons in the control condition. These 1-month reductions were maintained at the 6-month follow-up. Unfortunately, there were no statistically significant changes in alcohol use for participants who completed the Alcohol Savvy intervention. This study is important because it provided a scientific evaluation of two possible interventions and provided evidence that Web-based programs (Drinker’s Check-Up in particular) can significantly decrease alcohol use in the military. The PATROL program has been made available to all the military services.

APPROACHES TO ENCOURAGE RESPONSIBLE DRINKING

To be effective, efforts to prevent alcohol misuse need to address the individual, social/cultural, and environmental factors noted earlier that may encourage irresponsible drinking. This section describes the efforts of DoD and the military branches to address these factors.

Individual Factors

A key effort in military campaigns to promote safer drinking among servicemembers gives large emphasis to individual factors, especially encouraging members to take personal responsibility for their own behavior and ensuring that behavior is in keeping with military and personal values. Each service calls special attention to this facet of the prevention and education cycle, citing personal responsibility as the most important factor in decisions regarding safe alcohol use. It should be noted that, in addition to targeting individual behavior, these campaigns recognize and endorse the collaborative efforts of individuals, fellow servicemembers, military leadership, and military organizational structure and values to form a comprehensive framework for responsible alcohol use and prevention of problem use. Nonetheless, the cornerstone of prevention is individual responsibility.

Service-level programs promote responsible drinking behaviors, which logically include discouraging drinking to intoxication. DoD’s “That Guy” campaign graphically depicts a variety of the pitfalls of excessive drinking to the point of vomiting or blacking out,

behaviors that are depicted as not only embarrassing but also directly counter to military values. In addition, zero tolerance for any drinking behaviors by servicemembers under the age of 21 bolsters the services' policies and campaigns for responsible, safer drinking within the military. Military installations located in close proximity to areas with lower drinking ages, such as overseas locations and locations along the US–Mexico border, may be at higher risk for problem drinking by servicemembers between the ages of 18 and 21; however, these installations often take precautionary measures to deter such behavior. Although penalties for alcohol-related problems (such as DWI) can be more severe for military members than for civilians (including reduction of rank and pay), these penalties are harsher still for underage members. The services also recognize that punitive actions alone are likely to fail. Therefore, service-level prevention and education programs seek to provide information to servicemembers in a way that allows them to obtain and evaluate necessary information prior to being confronted with difficult choices on their 21st birthday. In this way, the services not only discourage any drinking prior to age 21 but also equip members with the tools they will need to make good choices when they become of drinking age.

Social/Cultural Factors

The US military services have taken several steps in their alcohol misuse prevention efforts to incorporate social and cultural factors into their programs and campaigns, focusing particularly on the use of normative and peer influences. The "That Guy" campaign makes use of humor and entertainment to engage the young audience. It focuses on social disapproval and short-term negative consequences and pushes a peer-to-peer approach as opposed to top-down influence through the chain of command. The Right Spirit campaign attempts to change social norms and cultural traditions and practices as a mechanism for changing alcohol use behavior. Specifically, the program attempts to develop norms of responsible use and a culture that does not rely on alcohol abuse to define success. PREVENT and the 101 Days of Summer campaign also make use of peer pressure and influence to modify behavior. Similarly, the 0-0-1-3 campaign encourages healthy, controlled alcohol use behavior and nonuse for those who are underage. The 0-0-1-3 campaign established safe normative behaviors that move DoD forward in addressing the health threats of alcohol. PATROL also uses normative influences to change expectations about acceptable levels of drinking. This is done by helping servicemembers realize that their peers are likely to be

drinking less than they formerly believed and using this discrepancy as motivation to reduce their use.

In recent years, the military has placed an emphasis on deglamorizing alcohol use among servicemembers. The general approach has been to help change norms and perceptions about alcohol use by ensuring that nonalcoholic beverages are available at functions where alcohol is served and to make clear that alcohol use before or during work hours is unacceptable. Commanders are urged to emphasize that alcohol consumption should not be the main focus of any unit event. As noted above, deglamorization is a key element of the Right Spirit campaign. Data from the HRB surveys indicate that the practice of having alcohol alternatives is generally being implemented, but deglamorization is not yet having its full intended effect. In the 2008 HRB survey, over 60% of servicemembers agreed that nonalcoholic beverages are always available at parties. However, about 15% also indicated that personnel are encouraged to drink at parties and social events. A survey of Air Force officers attending Air Command and Staff College found that although the environment was supportive of alcohol deglamorization, students' attention was often focused on alcohol and emphasis was placed on bringing alcohol to social activities.

Environmental Factors

A number of approaches are available to address environmental factors, including licensing provisions, policy development, education, publicity campaigns, and working with the local community. The military's focus on safer drinking environments to prevent alcohol-related problems includes limiting access to establishments that are known to have violations, for serving underage patrons, being a location for the purchase of illegal drugs, having a large number of alcohol-related arrests, or some other violation. Lists of "off-limits" establishments are circulated to military members, and routine inspections of bars are conducted to ensure servicemembers' compliance.

Policy decisions are often made that are specific to installations. For example, US forces in Okinawa have been banned from patronizing off-base establishments that sell alcohol after midnight in response to a series of alcohol-related incidents and accidents. Servicemembers at installations located near the Mexican border are often drawn to the bars in Mexico by inexpensive alcohol and a minimum drinking age of 18. In response, commanders at Camp Pendleton, located in southern California 65 miles from Mexico, adopted a policy that required Marines to receive written permission to cross the border. After the policy was implemented, the

number of underage Marines returning across the Mexican border was reduced by 78% and the number returning with blood alcohol content of 0.08% (the legal limit for intoxication) or higher was reduced by 84%.

Two areas with somewhat inconsistent policy applications are the minimum drinking age and alcohol pricing. On most installations, the minimum drinking age is 21. However, the Marine Corps recently instituted a new policy to allow the consumption of alcohol by persons aged 18 years or older at unit-sponsored functions if the unit function is held on a US base. The new policy defines these circumstances as infrequent, non-routine military occasions when an entire unit, as a group, marks a uniquely military occasion at a military installation. Although the policy opens the door for Marine commanders to lower the drinking age temporarily on any service's birthday, as well as the day their unit was formed, commanders must ensure the safety of military servicemembers and the surrounding community. In addition, the minimum drinking age on a DoD installation located outside the United States is 18 years or older if specified by international treaties and agreements and based on the local situation as determined by the installation commander.

With respect to alcohol pricing, there is a wealth of data to support the idea that raising alcohol prices reduces use and alcohol-related problems. Unfortunately, the military has not used higher prices as an environmental mechanism to address alcohol misuse. Although the lower prices for alcohol products are set by military regulations and targeted to be within 5–10% of the lowest prices in the civilian community, it is not unusual to find that the prices on beverages can range from 9 to 27% less than prices in state-operated alcohol stores.

Thus, although the military is making efforts to address environmental contributors to the increasing rates of alcohol problems among its members, there is inconsistency in minimum age requirements and pricing policies that may encourage patterns of excessive alcohol use.

SUMMARY AND FUTURE DIRECTIONS

The military has a long tradition and culture of excessive alcohol use, which often creates problems for individual servicemembers and for the military as a whole. To address this issue, DoD and individual armed services have developed alcohol policies and alcohol misuse prevention programs that emphasize on education, training, slogans and campaigns, and interventions. These prevention programs target key individual, social/cultural, and environmental factors related to the highest risk of misuse.

There is evidence that the policies and prevention efforts of the military are having some positive effects in reducing some alcohol misuse, but additional efforts and continued vigilance are needed. The fact that the rates of heavy and binge alcohol use have been rising in recent years suggests that some of the policies and prevention programs are not reaching a key target group. Approximately 20% of personnel are heavy drinkers, the group most likely to experience negative outcomes. The fact that the programs are not fully effective should not be surprising. The military poses a challenging and complex environment in which to implement and monitor programs. There are several reasons for this. One is the relatively high rate of turnover in the military. Leaders must regularly and consistently review and emphasize the principles of safe drinking and resources available to personnel. Another may be a somewhat uneven emphasis and implementation of the programs by commanders and other leaders who bring their own personalities and potential biases to their jobs. Because military leaders face many demands, some of them are likely to give greater emphasis to the issues of alcohol misuse prevention and others are likely to give lesser emphasis. Finally, personnel undergo regular transfers to different installations, sometimes to unfamiliar overseas locations that may have cultures that encourage high alcohol consumption.

Looking to the future, military alcohol misuse prevention efforts would benefit from two important actions. The first action is to give greater emphasis to more uniform implementation of existing prevention programs and policies across installations both within the United States and abroad. This relatively simple step should yield high dividends if all commands were to give alcohol misuse prevention high priority at their installation. The second is to invest in research to ensure that there is scientific evidence underlying the effectiveness of the current programs and that they are changing behaviors as expected. Although the military has adopted or developed a variety of alcohol misuse prevention programs, there has been little attempt to evaluate these programs with rigorous scientific studies to understand if they are having their desired effects. Having a solid evidence base for prevention programs will ensure the most effective use of resources to contain alcohol misuse in the military.

INTRODUCTION

Substance use by youth and young adults¹ is a significant public health problem due to its high prevalence and negative consequences. In 2000, the use of alcohol and illicit drugs was estimated to contribute to 10% of the total global burden of disease for people aged 15–29 years, particularly in economically developed countries, where approximately 23% of the global burden is attributable to alcohol (18%) and illicit drugs (5%). Results of the most recent 2010 Monitoring the Future survey given to 8th, 10th, and 12th grade students in the United States indicated that 27% of

students used an illicit drug in the past year and 16% reported illicit drug use in the past month. In terms of alcohol use, 26.8% reported consuming alcohol and 14.6% had gotten drunk in the past month. Moreover, recent national studies of US college student alcohol use in the past month indicate 70% of students have consumed alcohol and over 40% engaged in binge drinking, defined as five or more drinks in a row for males and four or more drinks for females.

It is well established that adolescents and young adults who use alcohol and other drugs (AOD) are at risk for a range of physical, psychological, social, and legal consequences, and heavy drinking is a leading

¹In this chapter, youth (i.e. adolescents) and young adults are defined as being 12–17 and 18–22 years of age, respectively. These age ranges have been defined in previous developmental research. The majority of instruments discussed in this chapter have been standardized across these age groups.

cause of morbidity and mortality in young people. In order to better identify individuals who are at risk for or are currently exhibiting AOD problems, the development and implementation of standardized screening and assessment tools have been at the forefront of prevention efforts. It is essential that screening, assessment, and treatment strategies for AOD for younger populations be specifically designed to the needs of adolescents and young adults, rather than simply modifying protocols established in adult populations. Given the developmental differences between adolescents and adults, using screening instruments that are developmentally appropriate is essential to appropriately identify potential AOD issues with this younger population. This chapter addresses strategies and tools that have been widely used for AOD screening and assessment in adolescents and young adults in nonmedical settings.² The specific goal of this chapter is to provide readers with a greater understanding of the following topics related to screening and assessment of AOD in adolescents and young adults: (1) developmental considerations in substance use patterns; (2) defining and differentiating the goals of screening and assessment; (3) commonly used screening and assessment tools and rationale for their use; and (4) clinical implications and future research directions.

DEVELOPMENTAL CONSIDERATIONS

Applicability of Diagnostic Criteria

The current diagnostic criteria for substance abuse and dependence in the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR)* specify the presence of substance use-related problems (1 symptom for abuse, 3 symptoms for dependence) within the previous 12 months. It is noteworthy that the diagnostic classification of substance use disorders was validated using adult samples, and it is questionable whether the current criteria are adequate when applied to adolescents. Adolescents exhibit different patterns of substance use than adults, have unique developmental and social issues, and show a higher prevalence of substance use and co-occurring disorders. Short-term use of substances such as alcohol and tobacco typically occur in a social context, which makes identifying those individuals at risk for developing long-term consequences challenging. Results of studies evaluating substance use patterns in adolescents suggest that adolescents are more likely to use alcohol in conjunction with other

drugs (e.g. marijuana) rather than just using alcohol, and that adolescent substance use is typically more sporadic and involves experimenting with a number of different substances as opposed to heavy use of one substance. Due to their developmental stage, it is less likely that adolescents will report impairment in romantic or occupational functioning. Furthermore, dependence symptoms may look different in adolescents, with studies demonstrating that adolescents have a lower likelihood of experiencing physiological dependence (e.g. withdrawal, tolerance, medical complications) than adults. Alternatively, alcohol-dependent adolescents do report blackouts, cravings, risky sexual behavior, reduced activity level, and affective symptoms. Many researchers are investigating whether the criteria for substance use disorders accurately reflect the unique features of adolescents and if not, what modifications to adult criteria are needed.

Although adolescents are more likely than adults to meet diagnostic criteria for substance use disorders within a shorter time period after initial use, researchers note that this finding may reflect a limitation of the diagnostic criteria to adequately capture developmental patterns of substance use in adolescents. Studies also suggest a low occurrence of withdrawal symptoms and related medical problems in youth, as these problems typically occur after prolonged use of alcohol or drugs. Studies have shown that another symptom of substance dependence, tolerance, has low specificity in terms of poorly distinguishing adolescents with varying levels of substance use problems. Additionally, due to the one-symptom diagnostic threshold for substance abuse, there is a large amount of heterogeneity across adolescents who may endorse one of the four symptoms indicative of substance use-related problems. Perhaps most relevant to the topic of screening and assessment, many adolescents may not meet criteria for abuse and only endorse two symptoms of dependence. Thus, while these individuals may not receive a formal diagnosis for a substance use disorder, further assessment and follow-up treatment may still be needed.

Normative versus Clinical Patterns of Substance Use

Substance use is related to adolescent developmental transitions and goals. Adolescence in general is characterized by experimentation with a variety of behaviors and lifestyle choices as one develops their identity. This process typically involves separating from parents, connecting more with peers and gaining acceptance

²Given the impact of cultural factors on substance use, we acknowledge that we do not address language issues related to the instruments discussed in this chapter. Screening and assessment tools have not been validated specifically within minority populations, and any use of them with these individuals should be interpreted cautiously.

from them, and developing one's sense of autonomy, independence, and maturity. While some form of substance use in adolescence is considered normative, there is substantial heterogeneity in patterns of clinical and functional impairment in relation to substance use. Alcohol, tobacco, and marijuana are the most frequently used substances among adolescents, with other drugs being rarer but still problematic. During early adolescence, substance use typically occurs in a social context and involves substances that are easily available (e.g. alcohol, tobacco, inhalants). Many adolescents discontinue use after a short period of experimentation; however, other adolescents develop patterns of regular use, and some may progress to other substances such as marijuana, hallucinogens, and other illicit drugs. It appears that there are various steps or stages of adolescent substance use, progressing from experimentation to more problematic levels of use and disorder, where initial social motivations for substance use become more psychologically or pharmacologically driven.

No single factor predicts adolescent alcohol and substance use problems; rather, multiple factors influence risk at different levels (individual, interpersonal, contextual). Furthermore, there are numerous subtypes and trajectories of adolescent substance use disorders. Adolescent alcohol and drug use often co-occur with each other and other adolescent problem behaviors (e.g. delinquency and sexual risk behavior), and these relationships can be dynamic and complex. For example, illicit drug use is both a risk factor and a consequence of sexual risk behavior; early initiation of substance use is associated with later sexual risk behavior, and early sexual risk behavior predicts later drug use. Frequently, adolescent substance use disorders are also co-morbid with other disorders, including both internalizing (depression, anxiety) and externalizing (ADHD, conduct disorder) disorders. The heterogeneity and diversity of patterns, trajectories, consequences, and co-occurring disorders and risk behaviors support the need for psychometrically sound brief screening and comprehensive assessment tools.

SCREENING AND ASSESSMENT: DEFINITIONS AND GOALS

Screening

The first step to identifying the presence of a substance use problem is an initial screening, a process that involves asking questions carefully designed to determine whether a more thorough assessment for a particular problem or disorder is warranted. A screening instrument is used as an indicator, not as a diagnosis, and

evaluates the possible presence of a particular problem. This is typically assessed by a "yes" or "no" response to a brief set of specific questions. Screening can be differentiated from assessment in that the purpose of screening is to identify people at risk for or actually experiencing harm associated with their substance use. The purpose of assessment is to gather details about specific patterns of use and consequences to inform intervention. Although screening does not serve as a diagnostic tool, results may indicate that an individual demonstrates behaviors or possesses attributes shared by people who are at risk for substance abuse or dependence. Screening can serve as a brief and effective method for identifying at-risk populations and an effective use of limited resources. Adolescents and young adults who are not at risk for substance use problems are identified with little time and effort, and those who are at risk can have resources directed to their needs.

Assessment

Results of an initial screening for substance use problems indicate whether a more comprehensive biopsychosocial assessment is needed to gather more detailed information about an individual's substance use patterns and to determine whether treatment is indicated. The specific goals of the assessment are to (1) evaluate whether a substance use disorder exists based on formal diagnostic criteria, and if so, to determine its severity, (2) permit the evaluator to learn more about the nature, correlates, and consequences of the individual's substance use behavior, (3) ensure that additional related problems not noted in the screening process are identified, including medical and psychological status, social functioning, family relations, academic performance, and delinquent behavior, (4) examine the extent to which the adolescent's family can be involved, (5) identify specific strengths of the adolescent (e.g. coping skills) that can be used in developing an appropriate treatment plan, and (6) make specific recommendations for interventions or referral to treatment services.

Selection of Screening and Assessment Tools

A number of factors influence the use of a particular screening or assessment instrument, including the severity of the problem being assessed, the ability of the measure to identify the problem within the population of interest, and ease of administration (e.g. length and format of the measure). Selection of screening and assessment instruments for use with adolescents and young adults should be guided by several factors including (1) reliability and validity of the tool, (2) appropriateness to the target population, (3) type of

setting in which the instrument was developed, and (4) the intended purpose of the instrument. Important features of screening and assessment instruments include high test-retest reliability, evidence of convergent validity (i.e. the instrument is strongly correlated with other instruments that measure similar constructs), and ability to predict relevant outcomes, such as school performance, performance in treatment, and substance use relapse. Another consideration when selecting a screening or assessment tool is the availability of normative data for representative samples based on age, gender, race/ethnicity, and setting (e.g. school, clinic).

The use of a validated and brief screening tool is important to ensure accurate results while making the administration and scoring procedures user-friendly. Self-report is the most widely used source of information for screening and assessment, as this method yields valid and reliable data when confidentiality is assured and there are no consequences for responding honestly. Most self-report questionnaires are available in paper-and-pencil format, and an increasing number of screening tools are becoming available for completion via a computerized, web-based questionnaire. Online screening strategies are becoming more favorable, particularly in college student populations, due to ease of administration and scoring. While research supports the validity and reliability of online screening of substance use, in-person comprehensive assessments that may incorporate multiple methodologies (e.g. diagnostic interview, urinalysis) are appropriate for addressing a wider range of biopsychosocial variables.

Assessment strategies generally consist of a combination of self-report scales and interviews. While self-administered questionnaires are convenient, it may be necessary for the assessor to supervise and assist the adolescent, depending on their reading and comprehension skills. Comprehensive assessment interviews can be structured or semistructured based on the decision rules and the degree of clinical judgment required and allowed when determining symptoms and diagnoses. Most structured interviews can be administered by a well-trained layperson, although some standardized instruments and interview protocols are available that require little or no special training to administer. Important considerations that should be addressed in the context of screening and assessment with youth are how the results will be used and potential limits to confidentiality of results. Depending on the setting (e.g. school, court), screening and assessment results with young people may have academic, legal, and clinical consequences. Any limits to confidentiality should be addressed based on whether counselors, parents, or teachers are privy to screening and assessment results. Whenever possible, obtaining information

from other sources (e.g. parents, teachers) about adolescents' substance use provides valuable supplemental data. When used appropriately, screening and assessment can identify the nature and severity of substance use to distinguish between problem and dependent substance users, while also determining the level of treatment indicated.

SCREENING AND ASSESSMENT TOOLS FOR ALCOHOL AND OTHER DRUGS

The following sections provide an overview of commonly used instruments available for screening and assessment of AODs among adolescents and young adults. Our selection was guided by a combination of psychometric rigor and user-friendliness, but should not be considered exhaustive in its coverage. A list of suggested readings and resources is provided at the end of this chapter. The features we were most interested in include strong psychometric properties, simple scoring, efficient length and administration time, and availability of user training. Other types of AOD screening and assessment tools, including measures of problem recognition, motives and expectancies of use, and readiness for change are also mentioned in the context of future research directions and clinical implications.

Alcohol

College Aged Students (Ages 18–22)

In response to the identified risk of heavy drinking and related consequences, increased attention has focused on implementation of routine screening procedures for alcohol use on college campuses. Effective brief interventions are available for college student populations, and an important component of these interventions is an effective screening program that serves as a first step in identifying students who are abusing alcohol and may need follow-up intervention. Results from a study published in 2004 that assessed alcohol screening policies across US college campuses indicated that among 249 four-year institutions, 32.5% of health centers routinely screened for alcohol use-related problems, and 11.7% used a standardized alcohol screening instrument. To expand upon these findings, a more recent study that assessed the use of alcohol screening tools across four-year US colleges found 148 of 333 colleges (44%) reported using at least one formal alcohol screening tool. Results indicated that the four most commonly used screening tools reported by campus health service directors were the following: CAGE (54%), Alcohol Use Disorders Identification Test (AUDIT) (33%), Substance Abuse Subtle Screening

Inventory (SASSI) (28%), and Michigan Alcohol Screening Test (MAST) (16%).

The AUDIT is a 10-item instrument that assesses how often in the past year individuals have engaged in a number of behaviors indicative of unhealthy alcohol use. The AUDIT was developed by the World Health Organization to identify persons in primary care settings whose alcohol consumption has become harmful or hazardous to their health. The appropriate cutoff score to use for screening college students has been disputed. One study using *DSM-III* criteria for alcohol abuse and dependence has shown adequate sensitivity at a score of 11 (84%), whereas another study using *DSM-IV* criteria found that a cutoff score of 6 led to a similar degree of sensitivity (80%). A more recent study, using high-risk drinking as the criterion, suggested a cutoff score of 8 results in levels of sensitivity (82%) and specificity (78%) comparable to the earlier studies. Use of this cutoff score, however, may be more appropriate for universal screening efforts within this population, given the greater prevalence of high risk, heavy episodic alcohol consumption relative to clinically diagnosable alcohol use disorders.

The CAGE is a brief four-item measure that takes approximately 1 min to complete with “yes” or “no” response options. A score of two or more (at least two “yes” responses) have been used to indicate a positive screen for clinically significant alcohol-related problems. Specific items of the CAGE ask individuals if they have ever thought they should *Cut-down* on their drinking, found that others have *Annoyed* them for criticizing their drinking, felt *Guilty* about their drinking, or ever needed a drink to relieve a hangover (i.e. *Eye-opener*). While the CAGE has been used with college student populations, it has been criticized for lacking adequate sensitivity to detect the spectrum of drinking problems experienced by people in this age group. Alternatively, the CUGE questionnaire is a revised version of the CAGE in which three of the four items were retained, and only the second item (CAGE item: “Have people ever annoyed you by criticizing your drinking?”) has been replaced by “Have you ever been under the influence of alcohol in a situation where it increased your chances of getting hurt?” Results of comparative evaluation studies with college samples indicates the CUGE has more favorable psychometric properties than the CAGE, and researchers have identified the CUGE as a recommended alcohol screening tool for college students.

Another alcohol screen used with adolescents and young adults, the MAST, is a widely used instrument with versions ranging from 9 to 25 items. The longest version takes less than 10 min to complete. One study using a convenience sample of college students found that a cutoff score of 7 on the full 25-item version of the MAST resulted in perfect sensitivity (100%) and

reasonable specificity (87%) when compared with a score of 14 or greater on the Alcohol Dependence Scale (ADS), the criterion used to indicate the presence of alcohol dependence. A limitation of the MAST when used with adolescents and young adults is the scale’s focus on more advanced and/or stable problems with alcohol (e.g. dependence) that are less prevalent in younger people.

Two instruments, the Young Adult Alcohol Problem Screening Test (YAAPST) and Brief Young Adult Alcohol Consequences Questionnaire (B-YAACQ), are used to screen for alcohol-related consequences. The YAAPST consists of 27 items evaluating the occurrence of drinking-related problems across different domains (e.g. academic, legal, social). The YAAPST takes less than 10 min to complete and has demonstrated good reliability and validity, with reasonable sensitivity and specificity when using a cutoff score of 4. The B-YAACQ is a 24-item measure that was created using a confirmatory factor analysis of a variety of alcohol consequences measures. Dichotomous items (yes/no) are summed for a total number of alcohol-related consequences experienced in the past month. In studies with college students, the B-YAACQ has demonstrated high internal consistency and good validity using a cutoff score of 5 to indicate risky drinking.

Another instrument designed to screen for alcohol-related problems in college students is the College Alcohol Problems Scale-Revised (CAPS-r). The CAPS-r is an 8-item self-report scale (the original CAPS had 10 items) that also estimates the relative frequency with which clients experience drinking-related personal and social problems. Advantages of using the CAPS-r compared to the YAAPST are its shorter administration time (2–3 min), and its ability to be scored immediately. The CAPS-r is available in pencil-and-paper self-administered and interview formats. In a general college student population, the CAPS-r has demonstrated good reliability and concurrent validity, as the total score correlated significantly with other measures of alcohol consumption and with the YAAPST.

Questions about alcohol consumption also can be used as a screening tool for alcohol problems. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) produced four sets of questions ranging from three to six items that provide an increasingly detailed picture of a person’s drinking pattern. The three-item version takes less than 5 min to complete and includes questions on the frequency of drinking occasions over the past 12 months, the typical amount consumed, and the number of binge-drinking episodes. Although these questions have not yet been used specifically for screening, people who endorse one or more of the behaviors assessed by these questions (i.e. binge drinking and frequent alcohol use) have been shown

to be at high risk for experiencing alcohol-related problems and therefore would be appropriate candidates to receive further assessment and brief intervention.

Adolescents Aged 12–17

In addition to alcohol screening tools that have been developed within college samples, there are a number of screening instruments that focus exclusively on alcohol use among adolescent populations. The Adolescent Alcohol Involvement Scale (AAIS) is a 14-item self-report questionnaire that assesses alcohol consumption in addition to related behavioral and perceptual aspects of drinking. An overall score from 0 to 79 provides information on the severity of alcohol abuse ranging from minimal use to symptoms of abuse and/or dependence. Norms are available for 13- to 19-year-olds in both clinical and nonclinical samples, and studies have found scores on the AAIS are significantly related to substance use diagnosis and ratings from other sources, including comprehensive clinical assessments and parent reports of their teen's alcohol use. Estimates of internal consistency have been more favorable in nonclinical samples of adolescents and young adults compared to clinical samples.

The Adolescent Drinking Index (ADI) is a 24-item instrument that examines adolescent problem drinking by measuring psychological, physical, and social drinking-related problems, as well as loss of control. Written at a 5th grade reading level, the ADI takes approximately 5 min to administer and 10 min to score, and it yields a total score as well as two subscale scores that have been used for research purposes (self-medicating drinking and rebellious drinking). Research has shown that the ADI yields very good reliability and has demonstrated good validity in measuring and classifying the severity of adolescent drinking problems.

The CRAFFT is a brief screening test for alcohol and other drugs that was specifically designed at a developmentally appropriate reading level for teenagers. The CRAFFT is verbally administered, simple to score (each yes answer = 1 point), and the scale name is a mnemonic of the first letters of key words in the test's six questions: *C*: Have you ever ridden in a *car* driven by someone (including yourself) who was "high" or using alcohol or drugs (AOD)? *R*: Do you use AOD to *relax*, change your mood, feel better about yourself, or fit in? *A*: Do you ever use AOD while you are by yourself, *alone*? *F*: Has any *friend*, *family member*, or other person ever thought you had a problem with AOD? *F*: Do you ever *forget* (or regret) things you did while using? *T*: Have you ever gotten into *trouble* while using AOD, or done something you would not normally do (break the law, rules, or curfew; engage in risky behavior to you or others)? Based on a study in a large hospital-based adolescent clinic, including pediatric settings, scores

from the CRAFFT were found to be highly predictive of the presence of a substance abuse or dependence diagnosis (as defined by an existing and valid measure of DSM-IV-defined SUD, the Adolescent Diagnostic Interview). When evaluated in a general pediatric setting, a cutoff score of ≥ 2 correctly classified in 86% of cases whether the youth did or did not have a current substance abuse or dependence disorder.

The 23-item Rutgers Alcohol Problem Index (RAPI) measures consequences of alcohol use pertaining to family life, social relations, psychological functioning, delinquency, physical problems, and academic functioning. Two versions of the RAPI currently are in use – the original 23-item version and a briefer 18-item version— both of which can be completed in less than 10 min. The RAPI has shown good internal consistency and test-retest reliability using 1-, 6-, and 12-month time frames, and it has been correlated significantly with a composite of drinking frequency, typical quantity, and frequency of intoxication. Another measure, the Adolescent Obsessive–Compulsive Drinking Scale (A–OCDS), was developed to identify problem drinking and is a 14-item instrument containing one scale that measures obsessive thoughts about drinking and a second scale that measures compulsive drinking behaviors. The A–OCDS has demonstrated favorable reliability, and scores have been used to differentiate adolescent problem drinkers from less severe groups of adolescent drinkers.

Alcohol and Other Drugs

Given the tendency for adolescents to use alcohol in conjunction with other drugs, a number of screening tools include questions about alcohol and other drug use, including the Drug and Alcohol Problem (DAP) Quick Screen, the Personal Experience Screening Questionnaire (PESQ), and the Substance Abuse Subtle Screening Inventory for Adolescents (SASSI–A). The 30-item DAP was tested in a pediatric practice setting, in which the authors report that about 15% of the respondents endorsed six or more items, considered by the authors to be a cutoff score for "problem" drug use.

The 40-item PESQ consists of a problem severity scale and sections that assess drug use history, select psychosocial problems, and response distortion tendencies ("faking good" and "faking bad"). Norms for nonclinical, juvenile offender, and drug-abusing populations are available, and the PESQ is estimated to have an accuracy rate of 87% in predicting need for further drug abuse assessment. The 81-item adolescent version of its adult companion tool, the SASSI–A yields scores for several scales, including face valid alcohol, face valid other drug, obvious attributes, subtle attributes, and

defensiveness. Validity data indicate that the SASSI-A cutoff score for “chemical dependency” corresponds highly with intake diagnoses of substance use disorders.

Drugs Other Than Alcohol

In order to independently screen for drugs other than alcohol, researchers have modified previously used alcohol screening tools or adult versions of drug screening tools, in addition to creating drug-specific screening instruments for adolescents and young adults. The Adolescent Drug Involvement Scale (ADIS) is a modified version of the AAIS. Psychometric studies on this 13-item questionnaire reveal favorable internal consistency for the drug abuse severity scale. Validity evidence indicates that the ADIS is strongly positively correlated with drug use frequency and with independent ratings by clinical staff.

The CAGE-AID (Adapted to Include Drugs) is a modified version of the CAGE that was designed as a screen for drugs other than alcohol. Like the CAGE, the CAGE-AID focuses on lifetime use; although individuals who are drug dependent may screen positive, individuals who are at risk may not. Limitations of the CAGE-AID are similar to the CAGE in that it does not distinguish between active and inactive problems and has not been validated for identifying hazardous or harmful use. The Drug Abuse Screening Test for Adolescents (DAST-A) was adapted from the adult version (Drug Abuse Screening Test, DAST). The 27-item DAST-A reveals favorable reliability data and is highly predictive of a *DSM-IV* substance use disorder when tested among adolescent psychiatric inpatients. The Assessment of Substance Misuse in Adolescence (ASMA) is an 8-item questionnaire that has been tested in a large nonclinical sample of general students. It has a very favorable internal consistency, and the total score was significantly related to several indices of drug and alcohol use.

The Cannabis Use Problems Identification Test (CUPIT) is a brief cannabis-screening instrument that is reliable, valid, and acceptable for use across diverse community settings and consumers of all ages. The 16-item CUPIT measures risky use (items 1 and 2), dependence/using behavior (3–10), and health and social problems (11–16), and scores can range from 0 (no use at all) to 82 (daily/more than daily use, severely problematic). Research suggests that it reliably classifies both currently diagnosable and potentially problematic cannabis use among respondents.

The Adolescent Cannabis Problems Questionnaire (CPQ-A) was adapted from the adult version of the CPQ. The original 58-item CPQ-A comprises 30 “core” items, with 28 additional items grouped into four topic areas relevant to young people: parental issues, personal

relationship issues, school performance, and employment issues. The CPQ-A is intended to supplement *DSM-IV* diagnostic and other data in the exploration of cannabis-related problems among young people. In addition to providing assessment data and, potentially, an instrument with which to measure change (e.g. pre- and post-treatment), the CPQ-A may be useful as a clinical tool in highlighting potential problem areas and encouraging problem recognition and self-assessment. The Cannabis Problems Questionnaire for Adolescents, Short Form (CPQ-A-S) is a shorter 12-item version that was developed in 2010. Psychometrics of the shorter scale were evaluated through factor analysis, and logistic regression was used to demonstrate scale validity. This is the first short scale of cannabis problems derived for adolescents, and it should prove a useful tool for clinical and research purposes.

The Cannabis Use Disorders Identification Test (CUDIT) is a 10-item, self-report screening instrument that is a modification of the AUDIT. It was recently developed, and its ability to accurately assess cannabis abuse or dependence was tested on a sample of alcohol-dependent outpatients who reported some use of cannabis in the past 6 months. The maximum score possible is 40 with a cutoff of 8 demonstrating a positive predictive value of 81% and a sensitivity of 73%. In 2009, the CUDIT was revised (CUDIT-R) to be shorter (down from 10 items to 8–4 items from the original CIDT and 4 new items). The CUDIT-R has improved psychometric properties over the original scale and appears well suited to the task of screening for problematic cannabis use and has potential as a brief outcome measure.

Comprehensive Assessments and Diagnostic Interviews

Comprehensive assessments of substance use are more time consuming and require greater training to administer and score, but yield more in-depth diagnostic data, while also evaluating other domains of functioning. The Adolescent Diagnostic Interview (ADI) is a 213-question structured interview based on *DSM-IV* criteria for substance use disorders. In addition to substance use, it evaluates psychosocial stressors, school and interpersonal functioning, and cognitive impairment. It can be used to identify the need for treatment and treatment planning. The ADI can be administered in 50 min and scored in 20 min by a counselor or trained interviewer.

The Global Appraisal of Individual Needs (GAIN) is a semistructured interview that measures recent and lifetime functioning in several areas, including substance use, legal and school functioning, and psychiatric symptoms. Favorable internal consistency, test-retest reliability, and construct validity data are associated with

the GAIN, including evidence that GAIN scores are significantly correlated with independent ratings of drug involvement problem severity and that youths referred to drug treatment score higher on these core sections than youths not referred for treatment. The comprehensiveness and multidimensionality of the GAIN require a relatively long administration time and a lengthy and detailed training. The GAIN-Short Screen (G-SS) is a shorter 20-item version of the GAIN that also evaluates total severity and domain-specific substance use problems; it may be a more optimal screening tool given that it requires less administration time and scoring.

Adapted from the Addiction Severity Index (ASI) that was developed for use with adults, the Teen Addiction Severity Index (T-ASI) is a semistructured interview that consists of seven content areas: chemical use, school status, employment-support status, family relationships, legal status, peer-social relationships, and psychiatric status. Adolescent and interviewer severity ratings are elicited on a 5-point scale for each content area. Psychometric data indicate favorable interrater agreement and association of the various scales to existing valid measures of similar constructs. A computerized, Internet- and telephone-based, modified version entitled T-ASI-II and its psychometrics has been piloted on a large number of adolescents and will be available for clinical use.

Another multiscale questionnaire is the Personal Experience Inventory (PEI), which consists of several scales that measure drug use problem severity, psychosocial risk, and response distortion tendencies. Supplemental problem screens measure eating disorders, suicide potential, physical/sexual abuse, and parental history of drug abuse. The computerized report includes narratives and standardized scores for each scale as well as other clinical information. Norms for drug-clinic and nonclinical controls are provided. Psychometric data include internal consistency and test-retest reliability data and a range of convergent, discriminant, and criterion validity (e.g. scores compared with existing validated measures, independent clinician ratings, and archival data).

The 139-item Problem Oriented Screening Instrument for Teenagers (POSIT) is part of the Adolescent Assessment and Referral System developed by the National Institute on Drug Abuse (NIDA). It screens for 10 functional adolescent problem areas: substance use, physical health, mental health, family relations, peer relationships, educational status, vocational status, social skills, leisure and recreation, and aggressive behavior/delinquency. Cutoff scores for determining need for further assessment have been rationally established, and evidence of convergent and discriminant validity for the POSIT has been reported by several investigators.

Another instrument is the 159-item Drug Use Screening Inventory (revised) (DUSI-R), which includes items addressing AOD use problem severity and related problems. It produces scores on 10 subscales as well as one lie scale. Domain scores were related to *DSM-III-R* substance use disorder criteria in a sample of adolescent substance abusers, and published reports have indicated evidence of scale sensitivity. In addition, the Adolescent Self-Assessment Profile (ASAP) is a 225-item self-report instrument comprised of subscales that represent risk-resiliency factors established in the literature, including family, mental health, school adjustment, peer influence, deviancy, and drug use symptoms. Another in-depth assessment of drug use is the Chemical Dependency Assessment Profile (CDAS), consisting of 232 items assessing 11 dimensions of drugs use (e.g. quantity and frequency, expectations of use).

Lastly, there are a number of structured and semi-structured diagnostic interviews that are specifically used to assess *DSM-IV* criteria for substance abuse and dependence. The Structured Clinical Interview for the DSM (SCID) is a semistructured interview used to assess diagnostic criteria of a full range of psychological disorders. While the entire interview takes approximately 2 h to complete, the Substance Abuse Module can be completed in 30–60 min, and should be administered by a trained clinical evaluator or mental health professional. The Diagnostic Interview Schedule for Children (DISC) is a highly structured diagnostic interview designed to be administered by lay interviewers to assess most of the commonly occurring mental disorders of children and adolescents included in the DSM diagnostic system. The DISC is probably the most extensively tested of all the child and adolescent diagnostic interviews, and its performance has been evaluated using both clinical and community samples. Another interview that assesses DSM criteria for substance use disorders, in addition to specific patterns of use and consequences, is the Customary Drinking and Drug Use Record (CDDR). Evidence from psychometric studies suggests good reliability and validity of the CDDR.

CLINICAL IMPLICATIONS AND FUTURE DIRECTIONS

Implications for Prevention and Intervention Efforts

While the primary goal of AOD screening and assessment is to identify individuals who may be at risk for substance use problems, results inform prevention and treatment efforts with regard to the type and intensity of intervention that may be warranted for a given

population. Universal prevention and screening strategies are designed for the general population, regardless of whether individuals have engaged in substance use or appear to be at greater risk of substance use problems. Selective or targeted prevention addresses subsets of the population that are identified to be at increased risk for substance abuse, based on variables such as family history of substance use, academic or behavioral problems, and other risk factors. Indicated prevention is designed to identify individuals who are demonstrating early signs of substance abuse and other problem behaviors associated with substance abuse and to offer services to help prevent further substance use problems. For each of these levels of prevention, screening and assessment procedures inform the use of an appropriate referral or brief intervention to prevent the development of more severe substance use problems.

There are several effective prevention and intervention programs for adolescent alcohol and substance use that operate on a variety of levels. On the individual level, many programs target adolescent knowledge and skills related to alcohol and substance use prevention such as increasing adolescents' awareness of social influences on substance use and enhancing self-regulation, problem solving and decision making, assertiveness and resistance skills, and coping skills to manage stress and anxiety. On the family level, many programs target family functioning and parenting skills, including communication, monitoring, and limit-setting. On the community and societal level, several programs target social norms through mass media or restricting access to substances through public policy initiatives. The most effective programs are guided by psychosocial theory, target empirically supported risk and protective factors at a variety of levels (e.g. individual, family, social), and are developmentally appropriate.

Recent developments of brief alcohol and marijuana interventions demonstrate how screening and assessment results can be utilized in providing individuals with feedback about their alcohol or drug use. For example, protocols such as Brief Alcohol Screening and Intervention for College Students (BASICS) and the Teen Marijuana Check-Up provide feedback based on screening and assessment results, pertaining to use patterns and consequences, expectancies and motives for use, perceived substance use norms, and readiness to change. Results of treatment evaluation studies indicate reductions in alcohol and marijuana use over time following exposure to these brief interventions.

Conclusions and Future Directions

In response to the continued problems associated with adolescent and young adult substance use, significant progress has been made in developing more

effective screening and assessment methodologies. Advances in knowledge about scale norms based on age, race/ethnicity, and gender are critical for standardizing the use of screening and assessment tools with diverse populations. Studies are needed that include adolescent and young adult samples from clinical and nonclinical samples (school, community) in order to adequately address the spectrum of treatment needs across groups and settings. Studies addressing the reliability and validity of screening and assessment tools across minority populations are extremely important given the changing demographic makeup of the United States.

In light of anticipated changes to the diagnostic criteria for substance use disorders within the *DSM-V*, further refinement of screening and assessment tools will likely be needed. More research is necessary to better understand factors that contribute to variability in the effectiveness of tools to identify substance use problems in young people, as well as factors that impact the actual use of valid and reliable instruments. It would be helpful to learn why schools, clinicians, and researchers decide to use one screening or assessment tool over another; these factors may include cost, convenience, and psychometric rigor of available instruments. However, many of the instruments reviewed in this chapter are free, widely available, and user-friendly, and have demonstrated good psychometric properties. Barriers to successful implementation may include little awareness about existing instruments, lack of clinical expertise, and limited access to adequate treatment services to address substance use problems. It would be useful to further explore these and other potential barriers to employing effective screening and assessment procedures with a standardized tool as the use of standardized tools is critical to accurately identifying problematic substance use and informing selective/targeted and indicated prevention and brief intervention programs.

Glossary

Binge drinking according to the National Institute on Alcohol Abuse and Alcoholism, a pattern of drinking that brings a person's blood alcohol concentration (BAC) to 0.08 g percent or above. This typically happens when men consume five or more drinks and when women consume four or more drinks in approximately 2 h.

Internal consistency an estimate of reliability (often assessed using Cronbach's Alpha) based on the grouping questions in a questionnaire that measure the same concept. Items that are highly correlated with each other are said to have a higher internal consistency

Reliability the consistency of a measure or the degree to which an instrument measures the same way each time it is used under the same testing conditions. A measure is considered to have good test-retest reliability if a person's score is similar when the test is administered on more than one occasion, assuming there is no change in the underlying construct being measured.

Sensitivity measures the proportion of actual positives that are correctly identified as such (e.g. the percentage of people with a substance use disorder who are correctly identified as having the condition).

Specificity measures the proportion of negatives that are correctly identified (e.g. the percentage of people without a substance use disorder who are correctly identified as not having the condition).

Validity the extent to which an instrument measures the construct (e.g. alcohol-related consequences) it is designed to measure or assess.

ALCOHOL, YOUNG PEOPLE, AND THE ROLE OF HEALTH CARE

Adolescence is broadly defined as the developmental stage that occurs between the age of 10 and upward to 25, with the upper range often referenced separately as young adulthood. Culturally derived, the concept of adolescence was first recognized in the beginning of the twentieth century. G. Stanley Hall wrote a hallmark

two-volume book describing the nature of teens and characteristics/needs of this stage of life. As the structure of society has changed (e.g. rise in industrialization, child labor laws), this developmental stage has shifted the role of teenagers and young adults. Adolescence is marked by changes across physical, social, emotional, and especially behavioral domains as youths transition from childhood to adulthood. During this phase of intense identity formation, adolescents are

making more independent decisions and experimenting with new behaviors and experiences. It is during this time when young people will begin to develop patterns of behavior and ways of relating that will shape the quality of health and well-being throughout their lifespan. The pivotal nature of this time frame potentiates the need for quality health care services to be widely available for adolescents. Health care services have historically not been designed to address the unique needs of adolescent populations, resulting in a missed opportunity to positively influence health behaviors, promote good mental health, and impact disease prevention.

The health care community has, more recently, turned focus to adapting services to the needs of adolescents and young adults. This shift is grounded in the understanding that, indeed, the dramatic biological, social, and psychological transition of adolescence impacts adult function. Therefore, intervening at this point in development is critical for impacting health behaviors, and furthermore addressing intervention across context (e.g. family, community, economics, provider training, policy) is essential. While models of health services for adolescents have been generated and implemented, in reviewing the 21 Critical Health Objectives for ages 10–24, the lack of progress made in the health status of adolescents since 2000 has been noted by the Centers for Disease Control. In their 2009 Adolescent Health Services: Missing Opportunities report, the World Health Organization identified five key characteristics to guide responsive adolescent health services. Namely that (1) the services are broadly accessible, (2) policies are culturally and socially acceptable, (3) they appropriately fulfill the needs of all young people, (4) services reflect evidence-based standards of care and appropriate professional guidelines, and (5) services availability be equitable. Evidence-based screening and brief intervention (SBI) for problem alcohol use has been identified as a needed standard of care for adolescents during this highly transitional period.

MISSED OPPORTUNITIES FOR SBIs: ADOLESCENTS AND HEALTH CARE

Drinking and Alcohol Use Disorder Rates

With regard to impacting alcohol-related behaviors, health care providers have primary points of contact with adolescents and young adults in the context of acute care settings and hospitalization for alcohol-related accidents/incidents. In the US, alcohol consumption is the highest for individuals in their late teens and 20s, hence alcohol-related injuries are high in this subgroup as well. The 2010 National Survey on

Drug Use and Health (NSDUH) indicated that 3% of 12–13-year-olds reported drinking alcohol in the past month, 12% of 14–15-year-olds, 25% of 16–17-year-olds, 49% of 18–20-year-olds, and 70% of 21–25-year-olds. Rates of binge drinking, assessed as five or more drinks in one occasion in the past month, were 1% among 12–13-year-olds, 7% among 14–15-year-olds, 15% among 16–17-year-olds, 33% among ages 18–20, and peaked among those aged 21–25 at 46%. The rate of current alcohol use among youths aged 12–17 was 14% and binge and heavy alcohol use rates in this age group were 8% and 2%, respectively. Heavy alcohol use is defined as drinking five or more drinks on the same occasion on 5 or more days in the past 30 days. Overall, the rate of binge drinking was 41% for young adults aged 18–25. In addition, heavy alcohol use was reported by 14% of persons aged 18–25. With alcohol consumption rates being the highest in this age group, the survey reported that after people pass young adulthood (18–25 in this sample) rates of current alcohol use, binge use and heavy alcohol use steadily decline.

Based on analyses of 2002 NSDUH data by researchers at the George Washington University Medical Center, it was estimated that among the 35 million young people between the ages of 12 and 20 in America, almost 3.5 million of them met criteria for an alcohol use disorder. Rates vary by adolescent age group, with 3% of those ages 12–15, 12% of those ages 16–17, and 17% of those ages 18–20 meeting criteria for an alcohol use disorder. Up to 85% of those aged 12–20 with an alcohol use disorder have not received treatment. This is troubling, especially when considering the increased risk these individuals experience and to which they expose others. Specifically, these individuals are nine times more likely to drink and drive, nine times more apt to have serious problems with other drugs, six times more likely to be arrested, twice as likely to smoke, 1.5 times as likely to have a C+ average or lower in school, are likely to miss twice as much school, and are 1.5 times more likely to visit an emergency department (ED).

Death and Disability Related to Alcohol

According to the Centers for Disease Control (CDC) National Center for Chronic Disease Prevention and Health Promotion and Control, 72% of death and disability among those ages 10–24 can be attributed to one of four following causes: motor vehicle accidents (MVA)/crashes (30%), other unintentional injuries (15%), homicide (15%), and suicide (12%), indicating that MVAs are the leading cause of death for US teens. In 2009, MVAs claimed the lives of approximately 3000 adolescents aged 15–19 with many more surviving these

incidents with and without injury. In the prior year (2008), more than 350 000 adolescents were seen and treated in EDs for MVA-related injuries. Medical care and productivity losses due to injury and death among adolescents ages 15–19 are estimated at \$14 billion annually.

Notably these outcomes are highly associated with adolescent choices and behaviors, the majority of which are suitable if not ideal targets for prevention/intervention. For example, the 2009 national Youth Risk Behavioral Survey, found that in the past 30 days, 28% of 9th through 12th grade students rode with a driver who had been drinking alcohol, 10% endorsed driving when drinking, and 10% endorsed never or rarely wearing a seat belt when riding in a car. For 2010, the NSDUH found that past year driving under the influence for ages 16–17 was 6%, 18–20 was 15%, and 21–25 was 23% (the highest of any age group across the lifespan). In 2009, 35% of fatal automobile crashes among ages 18–24 involved a driver with a blood alcohol concentration (BAC) of 0.08 or higher. This was true for 19% of fatal automobile crashes among ages 16–20. Further, a great number of falls, violence-related injuries, and family abuse, which require medical treatment, involve someone who is drinking excessively. While limited because the data were collected between 1990 and 1992, National Comorbidity Study results analyzed by researchers at George Washington University Medical Center indicated that those with serious alcohol problems who were between the ages of 15 and 20 were 5 times more likely to attempt suicide, 4.5 times more likely to get into a serious fight, 3.5 times more likely to carry a weapon, 3 times more likely to be hospitalized for psychiatric reasons, 3 times more likely to meet criteria for conduct disorder, 1.5 times more likely to get into an accident, injure, or poison themselves, and almost twice as likely to have multiple sexual partners.

Health Care Utilization Rates

Outpatient Care Visits

Approximately 60% of office visits for health care by Americans are to primary care providers (versus specialty and emergency care). In 2008, 15–24-year-olds made 74 million visits for outpatient medical treatment (13% of visits were injury-related). Of these visits, 41% were for a new problem, 20% were for a chronic problem (routine or flare up), and 33% were for preventative care. Ninety-five percent of preventative care visits in 2008 made by 15–24-year-olds were provided by primary care providers. Over 80% of visits in this age group were made by White adolescents, and 13% were by Black adolescents. Analyses of 10 years of

data (1994–2003) from the annual National Ambulatory Medical Care Survey and the National Hospital Ambulatory Medical Care Survey (NHAMCS) yielded key data on the frequency and type of health care visits by adolescents (described here as ages 11–21 years) with examination of visits by differing age groups, sex, and rudimentary ethnic breakdown (i.e. White, Black, Other). Adolescents' visits accounted for 9% of all outpatient visits in the US, with an yearly average of 80 million outpatient visits from 1994–2003. Approximately 70 million (88%) of visits were to office-based settings and nearly 10 million (12%) to hospital-based settings annually. Overall outpatient visits by adolescents increased from 69 million in 1994 to 92 million in 2003 (33%). Across age groups, differences in the type of visit differed by both ethnic category and sex. Adolescents seen in outpatient hospital settings (as opposed to clinic settings) were more likely to be Black (24%), female (62%), and to have Medicaid coverage (35%) than those seen in office settings. Overall 9% of visits represented preventative care, with a somewhat higher proportion for preventative visits for early adolescents (aged 11–14 years) than for late (aged 18–21 years). Analysis of the same data sources from 1993–2000 found that in 2000 adolescents aged 13–18 years averaged 1.9 visits an year with those aged 19–24 averaging even fewer.

ED Visits

Almost one-third of all patients seen in the ED, and up to 50% of patients arriving with severe trauma, test positive for alcohol use. The 2008 NHAMCS estimates that there were 124 million ED visits across America: 11 million of these were visits by those ages 5–14, and 20 million were by those ages 15–24. Among the 20 million ED visits by those ages 15–24, 40% were injury-related, almost 60% were made by females, and approximately 70% were by White and 25% Black patients. Youth with alcohol problems reported use of hospital emergency services nearly 50% more often than their peers. They report an average of 0.75 ED visits annually compared to adolescents with no serious alcohol problem rates of 0.56 times annually.

SUMMARY OF GUIDELINES AND RECOMMENDATIONS

Guidelines and recommendations for intervention with adolescents and young adults vary somewhat, however, all guidelines stress the importance of intervention and are consistent in spirit.

- As interventions vary by length and number of sessions, the US Preventative Services Task Force

(USTPF) has classified the range of interventions that are available as follows:

1. Very brief interventions – one session, up to 5 min in length.
 2. Brief interventions – one session, up to 15 min long
 3. Brief multi-contact interventions – one initial session, up to 15 min long, plus follow-up contact(s).
- In 2002, the National Center for Education in Maternal Child Health recommended screening for all adolescents at every primary care visit.
 - In 2011, the American Academy of Pediatrics (AAP) released a policy recommending annual screening for alcohol and substance abuse in primary care encounters.
 - In 1997, the American Medical Association produced guidelines for adolescent preventive services which recommended screening all adolescents at least annually at primary care visit and counseling to avoid the use of alcohol or other substances while using motorized vehicles, or where impaired judgment may lead to injury.
 - As of 2004, the USTPF recommends Screening, Brief Intervention, and Referral to Treatment (SBIRT) for adults based on available empirical data. However, the USTPF does not recommend for or against SBIRT for adolescents in primary care settings, as they found a lack of sufficient data to make such recommendations.
 - The Substance Abuse and Mental Health Services Administration (SAMHSA) recommends that health care professionals provide universal screening and brief intervention, and/or referral for treatment for substance use.
 - In 2006, the World Health Organization (WHO) supports SBIRT health care interventions to address alcohol and substance use, and mental health in adolescents and young adults ages 10–24.

SBI AND SBIRTS FOR ADOLESCENTS IN HEALTH CARE SETTINGS

Despite the enormous opportunities for identification and prevention of risky drinking and alcohol use disorders in adolescents and young adults, it is estimated that very few receive such an intervention when visiting either their primary care providers or when receiving emergency treatment for an alcohol-related injury. While efforts targeting substance-related issues in these contexts have increased, screening and brief intervention for alcohol use disorders is, for the most part, not happening in an organized and efficient manner in health care settings. Below we discuss opportunities

and roadblocks to incorporate these services in varied medical settings.

Most heavy episodic and alcohol use disorder prevention efforts, to date, have focused on primary or community-level prevention (such as school-based alcohol and drug education efforts) and clinical or tertiary prevention (e.g. Alcoholics Anonymous, inpatient detox services). Research supports clinical or tertiary treatments for alcohol use disorders (e.g. motivational interviewing, discussed below), but it is probable that these clinical interventions have only a minimal effect on overall population rates of alcohol use disorders. In part, this is likely due to their limited availability. Secondary or indicated prevention for alcohol (e.g. intervention for those showing symptoms of a behavior or disorder identified for prevention) is beginning to show promise for greater reach in health care settings. For long-term effective secondary prevention of risky drinking and alcohol use disorders on a population level, early intervention would require accurate methods for identifying those at risk, efficacious interventions suitable for delivery on a large scale, and acceptable and efficient models for population-based intervention delivery.

In 2011, the AAP, Committee on Substance Abuse, published a policy report directing routine medical care in primary care settings to facilitate the comanagement of adolescents with addictions by primary care providers and mental health/addictions specialists. Dividing substance use into stages on a spectrum of substance use and impact (i.e. Abstinence, Experimentation, Limited use, Problematic use, Abuse, Addiction) the spectrum is to be applied to characterize risk and severity based on a qualitative assessment of adolescents' use and level of negative impact. The guidelines further offer stage-based goals (e.g. prevent or delay initial of substance use, enhance motivation to make behavioral changes) of intervention and provide step-by-step instruction for assessment, referral, and intervention. In addition, the report of guidelines provides recommended criteria for the selection of a substance abuse treatment program for adolescents requiring intervention beyond screening and brief intervention, as well as addressing billing and payment issues for pediatricians, often a roadblock for intervention in primary care settings. The report provides theoretical and empirical bases for recommendations and is clearly compiled and written for use by the medical health professional.

SBIs are typically one-session interventions to target and change problematic alcohol-related behaviors. As stand-alone interventions, their effectiveness is not reliant on further engagement in treatment. Although demonstrated to be effective, the lack of focus on further intervention in SBIs may miss an opportunity to

maximize the patient-provider contact. Hence, SBI interventions may be less effective for those who need more intensive intervention to assist in their attempts to reduce problematic alcohol use and for those with more contextual barriers to reduced alcohol use or lack of skills to reduce drinking. SAMHSA developed an intervention framework, which includes an additional component for referral, the SBIRT. The SBIRT protocol was developed to be applicable in a range of medical environments including emergency rooms, primary health clinics, or other health care venues. As with SBIs, patients automatically undergo a brief screening to assess alcohol (and drug) use. Those identified as being at risk for developing a serious substance-related problem receive a brief motivational intervention. In the SBIRT protocol, however, patients who could benefit from more extensive treatment receive further referral to specialty care.

Clark and colleagues reviewed data on 459 599 mostly adult patients screened at a variety of medical settings (including individuals in six states where SBIRTs are in use). Of those screened, approximately 23% either had alcohol/drug problems or were determined to be at high risk to develop them. Of those, approximately 16% received a brief intervention, 3% received a form of brief substance use treatment, and a further 4% received referral to specialized care. Patients endorsing items suggestive of heavy drinking during the initial brief screen subsequently reported 39% lower rates of heavy alcohol use at 6-month follow-up. Those receiving either brief intervention or referral to specialty treatments reported fewer arrests, more stable housing, improved employment status, fewer emotional problems, and improved general health.

SBIRTs have demonstrated cost-effectiveness as well. The Washington State Department of Social and Health Services, Research and Analysis Division, determined that after at least a brief intervention (or more), Medicaid costs were reduced by \$185–\$192 per member per month. The majority of the cost reductions were determined to be associated with a reduction in subsequent inpatient hospitalizations from ED admissions. The report indicated that the potential reductions in Medicaid costs could be as high as 2.8 million a year for working-age disabled clients who receive a intervention or referral, should the program continue once federal funding ended.

One challenge to the implementation and utilization of SBIRT protocols in the US is facilitating reimbursement for these services. In January 2007, the US Centers for Medicare and Medicaid Services began reimbursement for alcohol and drug SBIRT. Reimbursement codes for brief interventions are available through commercial insurance CPT codes, Medicare G codes, and Medicaid HCPCS codes; however, some codes may vary from state-to-state and not all providers may be aware of

billing codes that allow reimbursement for SBIRT. To address this limitation, SAMHSA is working with the Centers for Medicare and Medicaid Services to educate medical professionals/practitioners about SBIRT coverage and Medicare billing rules related to alcohol intervention services.

SCREENING METHODS

Screening, more universally, is a process of identifying members of a population who meet specific criteria for the targeting of prevention and intervention services. While symptoms are assessed, typically a formal diagnosis is not made, rather, screening procedures in health care guide subsequent decision-making. Screening of adolescents for alcohol-related disorders assesses alcohol use and related problematic behaviors to determine an associated level of risk for alcohol-related problems. Other than obtaining BAC to measure current intoxication, there are currently no feasible lab-based medical screening tools that could be used regularly in primary care settings for accurate assessment of risky drinking and alcohol use disorders. Therefore, most related information is gathered in an unstructured manner that may or may not illicit information useful for accurate screening. In the absence of standardized text, providers may inadvertently ask leading such as “You have not been drinking have you?” or questions of a too general nature such as “What has your drinking been like?” To yield more comprehensive and accurate results, health care providers should use standardized questions or questionnaires, such as the Alcohol Use Disorders Identification Test (AUDIT), to assess drinking. The validity of brief screening tests, such as the AUDIT, Problem Oriented Screening Instrument for Teenagers substance use/abuse scale (POSIT), CAGE (which stands for Cut down, Annoyed, Guilty, Eye-Opener), and CRAFFT (which stands for Car, Relax, Alone, Forget, Friends, Trouble) have been assessed with adolescents. The AUDIT, POSIT, and CRAFFT have acceptable sensitivity (the percentage of individuals who are correctly identified as having the condition) for identifying alcohol problems or disorders in adolescents, but the CAGE is not recommended for use in this age group. The AUDIT and POSIT are written assessments and thus can be taken without the clinician present (e.g. in the waiting room prior to meeting with the provider). The CRAFFT is a screen for alcohol and other drug use administered orally by the provider.

The most well-validated screening instrument for adults, the AUDIT, was developed by the WHO in order to assess the continuum of unhealthy drinking behaviors and identify those who might benefit from brief interventions. The AUDIT is commonly used in health care settings

including annual administrations to patients in VA hospitals. The measure is comprised of three items assessing amount/frequency of consumption, three items assessing alcohol dependency, and four items assessing problems caused by alcohol use (alcohol-related consequences). Scores can range from 0 to 40. In US primary care research, “4 or more” is considered a good indicator of risky drinking. In adolescent populations, sensitivity ranges from 54 to 87% and specificity (the percentage of healthy people who are correctly identified as not having the condition) from 65 to 97%. The AUDIT-C (which includes the first three items of the AUDIT) has been validated to assess alcohol use disorders among adolescents. The more brief AUDIT-C includes the following questions: (1) How often do you have a drink containing alcohol?, (2) How many drinks do you have on a typical day when you are drinking?, and (3) How often do you have five (different than the full Audit which is six or more) or more drinks on one occasion?

The National Institute on Alcohol Abuse and Alcoholism (NIAAA) recommends a two-item screener for use with children and adolescents. Specific wording depends on age category, but the first question asks about any alcohol use by the patient (not only use defined as binge drinking) and the second asks about alcohol use by the patient’s friends. This second question is important because it provides the practitioner with valuable information about what the patient might consider normal drinking based on their social group. Adolescents who drink often think that they drink less than their peers, but typically individuals are comparing themselves to a nontypical drinker or group of drinkers.

The CRAFFT is a six-item screen used for alcohol and other drug use for adolescents, with the acronym representing the content of the six items. These are, “Have you ever ridden in a Car driven by someone (including yourself) who was high or had been using alcohol or drugs? (Car) Do you ever use alcohol or drugs to Relax, feel better about yourself, or fit in? (Relax) Do you ever use alcohol or drugs while you are by yourself Alone? (Alone) Do you ever Forget things you did while using drugs or alcohol? (Forget) Do your Family or Friends ever tell you that you should cut down on your drinking or drug use? (Friends) Have you ever gotten into Trouble while you were using alcohol or drugs? (Trouble).” Two or more positive answers are considered an indicator of a possible problem with alcohol or drug use. Research with adolescents indicates that the CRAFFT demonstrates 92% sensitivity and 64% specificity.

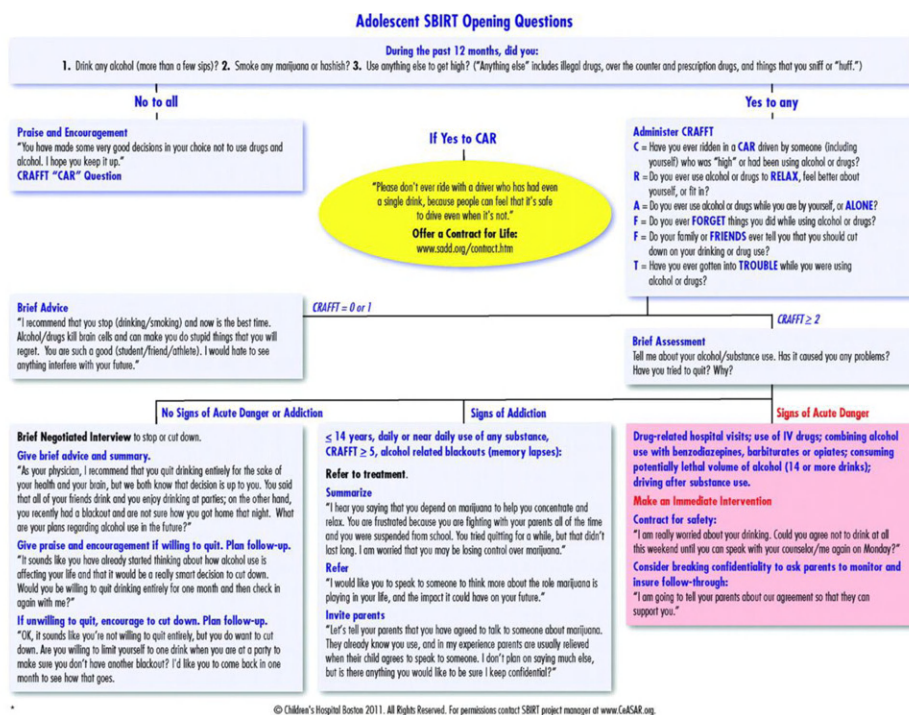

Brief standardized questionnaires and semi-structured interviews above provide effective, time-sensitive tools for health care professionals to use to gain the most relevant information in contexts where multiple health

concerns are to be addressed. They also structure and reduce the amount and length of training needed to insure a wide range of providers (e.g. physicians, nurses, health care assistants) are competent to assess these issues in an effective manner, and allow for more standardized assessment of substance-related care needs of patients presenting to health care venues. These assessment tools may be used alone, and particularly in systems/clinics where more formal screening policies have not been established. They are likely most useful when incorporated into structured/semi-structured screenings and interventions applied system wide.

Below is a decisional flow chart, Fig. 80.1, from the guidelines of the American Academy of Pediatrics, Committee on Substance Abuse. It demonstrates the application of an adolescent SBIRT algorithm for practitioners to follow for assessing the stage of use, choosing a recommended brief intervention, and guiding the providers’ referral strategy. The algorithm starts with a 2-step method of screening using the CRAFFT screening tool followed by a semi-structured brief intervention by the primary care provider and then appropriate referral, as indicated. The CRAFFT is a well validated and developmentally appropriate screening tool that, while easy to administer, has demonstrated good discriminative properties for assessing the level of risk and presence of substance use disorders in adolescents screened in the primary care and ED settings. Results of the CRAFFT screen identify adolescents without use, with no signs of acute danger or addiction, signs of addiction, and signs of acute danger within the SBIRT algorithm, supplying suggested intervention for each level of risk/severity.

Psychosocial Intervention Guides for Screening

The 2011 Policy on Substance Use Screening by the AAP recommends using existing psychosocial intervention schemes, such as Goldenring and Cohen’s HEADSS (or HEEADSSS) or SHADESS, when incorporating SBIRT into primary care settings. As with CRAFFT, the HEADSS title represents the items for screening and the acronym itself can be used to guide the interview through questions about Home, Education, Activities, Drug and alcohol use, Sexuality, and Suicide/depression (HEEADSS adds an Eating and Safety assessment). The SHADESS interview framework further leverages patients’ resilience by identifying patients’ perceived and realized strengths before exploring environment context and risks. These guides also emphasize the importance of a discussion about confidentiality – both assessing the adolescents’ understanding of confidentiality and providing a confidentiality statement based on the particular situation.

Motivational Approaches to SBI and SBIRTs

Approaches to intervention in medical settings differ, typically based on theoretical orientation and beliefs about substance use and treatment. For discussion purposes we can talk about interventions that stress motivational enhancement, based on the work of Miller and Rollnick, and those for which motivational interviewing (MI) approaches are not specifically incorporated (e.g. Johnson intervention). As MI is gaining traction in the substance abuse treatment community, motivational enhancement has been incorporated in many interventions, some more directly acknowledging MI techniques and some less. TrEAT (Trial for Early Alcohol Treatment) and BASICS (Brief Alcohol Screening and Intervention for College Students), discussed below are motivational approaches that have been either developed for, or applied to, adolescent populations. In addition, much of the research for development and testing of screening and brief motivational interventions for alcohol in adolescents and young adults has been conducted with college students (and not in a medical context) and therefore programs are primarily implemented in college (non-medical) settings. While college students are at heightened risk

for binge drinking (approximately 42% binged in the past month in 2010 in the NSDUH sample), same-age adolescents, not in college, also engage in high rates of binge drinking (36%) further emphasizing the need to address this age group in primary care and emergency department medical settings.

The majority of research on brief motivational interventions (e.g. SBI, SBIRT) conducted in medical settings target populations 18 and older, which includes individuals characterized as both young adults and adolescents based on somewhat different definitions. These studies speak to the effectiveness of the interventions generally, and may somewhat characterize alcohol-using adolescents over the age of 18. More recent investigations have specifically targeted adolescent populations in health care settings yielding important findings that are applicable to individuals under 18. For example, Bernstein and colleagues evaluated a brief motivational interview in a pediatric ED with adolescents aged 14–21, randomized to conditions designed to examine assessment reactivity in addition to the effectiveness of a peer-conducted motivational intervention with referral to community resources and treatment, when indicated.

NIAAA and TrEAT

Project TrEAT examined the efficacy as well as the cost-effectiveness of a two-session intervention of 10–15-min counseling visits with problem drinkers (age 18–65) using a scripted workbook. Twelve-month follow-up data from the initial randomized control trial demonstrated significant reductions in 7-day alcohol use, number of episodes of binge drinking, and the frequency of excessive drinking compared to the control condition. Analyses of economic costs and benefits presented in subsequent reports indicated that the project TrEAT intervention demonstrated positive benefit–cost ratios with benefits such as subsequent reduction in hospital and emergency department use, fewer criminal and legal events, and fewer motor vehicle incidents.

The NIAAA Task Force on College Drinking offers online training curriculum for health care providers. This curriculum is comprised of four teaching modules covering epidemiology and prevention strategies, screening and assessment, brief intervention, and MI and can be used to train providers in a wide range of training settings (e.g. grand rounds, day-long seminars). The goal of the curriculum is to provide clear and comprehensive training materials for the training of a broad range of health care professionals (e.g. physicians, nurses, social workers, health educators) to identify and treat students at risk for, or having, alcohol-related problems. Materials are freely available as a web-based course for trainers with materials for both the training of medical professionals, and materials for use directly with students in medical settings. For example, the curriculum provides an intervention workbook, based on the TrEAT brief intervention, available to download and print for use with students.

Brief Alcohol Screening and Intervention for College Students (BASICS)

The BASICS approach is quite consistent with MI principles. The intervention consists of two sessions, approximately 45–60 min each. In the initial session, information about the student’s alcohol use is gathered and self-monitoring cards are given for the student to complete in between sessions. At the second session personalized feedback regarding the student’s alcohol consumption is provided, and the student’s perception of other students’ alcohol consumption is compared to actual data. The intervention discussion includes normative information regarding blood-alcohol levels and discussion regarding students’ beliefs about alcohol, consequences, risk factors, and the use of a tool called the “readiness ruler.” Developed for nonmedical settings (e.g. for high-risk students entering college), the intervention has more recently

been implemented in the health care arena (e.g. student health centers).

To date, few studies have examined the use of motivational SBIs in college medical settings, in any manner (e.g. see work by Matt Martens and colleagues). Outside medical settings, data from motivational SBIs (e.g. BASICS) suggest that addressing students’ motivation/readiness for change and protective strategies appears to be important in reducing problematic alcohol use. The early empirical studies of motivational SBIs applied in medical settings suggest that these interventions can be feasibly provided in a university student health center, reduce quantity and frequency of alcohol consumption, and further reduce negative consequences of use among college student populations. Ehrlich and colleagues, in the first randomized control trial of BASICS in a medical setting, demonstrated that the intervention delivered in a student health center was effective across demographic characteristics assessed and students’ history of abuse, reducing quantity and frequency of alcohol consumption, and negative consequences of drinking.

Due to variations in the age ranges considered as adolescent or young adult, studies of intervention with adult patient populations (i.e. age 18 or greater) may have indications for older adolescents and young adults. However, without separate analyses of individuals in the adolescent/young adult age category (e.g. 18–25), ability to apply findings to adolescents is problematic. A smaller group of studies have been conducted that look at these age ranges more specifically, and these results can be interpreted with greater confidence. For example, Monti and colleagues compared a brief motivational interview to standard care among 18–19-year-old ED patients. Follow-up interviews at both 3 and 6 months indicated that patients in the MI condition reported a lower incidence of drinking and driving, were less likely to have been cited for a motor vehicle moving violation and were less likely to have an alcohol-related injury. Reported alcohol consumption in this study decreased in both groups. This study speaks to the efficacy of intervention older adolescents presenting for emergency care. Spirito and colleagues examined patients aged 13–17 treated in an ED for alcohol-related events/injuries. Adolescents in the MI condition with a baseline Adolescent Drinking Inventory score suggestive of problematic alcohol use reported a lower frequency of alcohol consumption and binge drinking during a 12-month follow-up period as compared to a standard care condition. Thus, preliminary studies of screening and intervention with adolescents under the age of 18 as well as 18–25-year-old young adults in medical settings indicate that motivational SBIs appear effective for targeting problematic alcohol.

WHY INTERVENE IN MEDICAL SETTINGS?

The importance of therapeutic relationship in the delivery of behavior-change interventions has been well established, and may be particularly beneficial as a jumping off point in medical settings. Primary care providers and team members can utilize established relationships with patients as well as their role as potentially trusted experts to improve tailoring, relevance, and impact of SBI. Patients are generally willing to work with their physician or other health care provider to reduce alcohol use, and the acceptability of this approach may increase as the Medical Home (discussed below) approach spreads.

The strongest evidence for SBIs in medical settings includes trials where the patient's personal physician or nurse has delivered the intervention. While an adolescent or young adult is unlikely to receive treatment from a known provider in the ED settings, the urgency of the situation and authority of the health care provider could be impactful. Further, and as medical records become more available across sites, ED providers could make primary care teams aware of the visit and possibly set a follow-up primary care appointment while in the ED – an additional opportunity to provide SBI in a time period close to an emergency event.

Situations in which patients receive acute medical services for an alcohol-related injury (e.g. MVA) are considered by many to be unique teachable moments when substance-using individuals may be particularly open to intervention. Although it has been demonstrated that practitioners consider performing these interventions to be feasible and acceptable, lack of time is still cited as a frequent reason that the screens do not get performed in emergency care settings. Although ED visits present an opportunity to address problematic substance use, patients receiving care for physical injuries are often distracted by pain, treatment procedures, communicating with family members, or continued intoxication. In addition, after waiting for and receiving care, patients seen in the ED typically leave quickly after receiving care for their physical injuries, limiting opportunities for intervention or limiting the quality of intervention able to be provided. However, for patients who are hospitalized after arriving in the ED, interventions delivered at the hospital bedside in the days following the admission can be impactful.

In an influential study addressing these issues (not specifically targeting adolescents and young adults), Longabaugh and colleagues conducted an investigation with three conditions. Patients in the ED who screened positive for problematic drinking either received the ED standard care, a brief intervention, or a brief

intervention followed by a booster session 7–10 days later. The booster session was added to overcome the time limitations and distractions often present in the delivery of emergency care. At the 1-year follow-up, ED patients who received the intervention plus booster had fewer alcohol-related problems and injuries compared to patients receiving the ED standard care. However, patients who received the brief intervention without a booster did not differ in alcohol-related negative consequences compared to the patients receiving the ED standard care. The application of booster sessions may be most useful in situations where time and ability to focus are constrained. Interventions for practitioners in ED settings have been developed that can be performed in 10 min or less. Offering subsequent booster sessions may be an important way to enhance the effectiveness of these interventions and include patients who might otherwise not be served. Other methods are being considered, as well, to address limitations of time in ED settings, such as computer-based approaches that make use of patients' waiting time for health promotion and to target patients at risk for varied health problems.

REFERRAL

The most empirically based treatments for adolescent individuals with established alcohol and other substance use disorders include group-based cognitive-behavior therapy, multidimensional family therapy, and functional family therapy. In medical settings, referral for treatment of adolescents is complicated by both physician- and age-related factors. It is suspected that most adolescents who receive treatment for alcohol and substance abuse treatment receive family therapy, 12-step programs, and therapeutic communities (long-term treatment, 12–18 months, for adolescents who have multiple severe problems). Most physicians and health care providers are unaware that many treatment options for problematic alcohol use have not been empirically tested nor evaluated for relative efficacy. Much of what is understood in popular culture about the treatment of alcohol and other drug problems come from television and film depictions. Even "reality television" conveys the message effective treatment necessitates that one must leave society for a period of 28 days or more in order to receive treatment for a substance use disorder. Often providers may be pressured to send a young adult to an inpatient rehabilitation facility or to stage a confrontational intervention, as families dealing with addiction issues in their children are, understandably, very concerned and emotionally aroused and feel comforted by what they view as the most intensive of treatments. While pressure from family and

colleagues may be present, the role of the provider in this context is to help identify the best route for the patient and family, with the understanding that the most effective strategy may not be the route that the family expects. Adolescent patients are particularly unlikely to have detox needs that warrant inpatient hospitalization. Primary care doctors are still rarely trained to provide outpatient alcohol detoxification to their patients. Unfortunately, some patients needing alcohol detoxification end up in psychiatry inpatient units, which are not only costly, but may convey the message to the patient and family that the patient is incapable of managing themselves or their problem without hospitalization. This message may undermine future attempts to change problem behavior with outpatient support.

ROADBLOCKS TO SCREENING AND BRIEF INTERVENTION IN HEALTH CARE SETTINGS

Health Care Coverage

A limitation of delivery of SBI for young adults in the US is that their health care often changes when they leave home, and this is further restricted by limitations on insurance coverage for young adults (only recently extended to age 26 for young adults attending college and being covered by parental employer insurance). Young adults are among the healthiest group in the nation physically, but as discussed earlier, are at a critical time period for the prevention and treatment of mental health and alcohol problems. While providing insurance coverage for all adolescents/young adults may seem costly given relative good health, nationwide health and long-term health costs could be positively impacted by a commitment to screening, prevention, and intervention for mental health and addictive behaviors in this age group.

Confidentiality

Another potential roadblock to assessing and addressing alcohol use issues is the need, not only for general confidentiality of health-related information, but also for protection of specific information related to issues such as reproductive and sexual health, mental health, and drug and alcohol use for patients under the age of 18. Specific protections are in place to support adolescents' willingness to seek treatment for, and provide information related to, sensitive concerns. However, statutes addressing confidentiality of sensitive health information vary from state to state. Having protections in place also does not guarantee that adolescents will either be knowledgeable of their rights or

confident in the mechanisms to protect information from being shared with parents, teachers, and other school staff, or others that the minor fears will gain access to information. Therefore, efforts should be aimed at education and empowerment of adolescents, not only regarding services available, but also regarding their health care rights.

Health Care Cost

Health care costs are well identified as a pressing national issue in the US. Because it is difficult for prevention interventions to show immediate cost savings, they may be sidelined by insurance providers to prioritize programs that result in more immediate cost savings to the for-profit insurance industry. Therefore, at the core of successful assessment, prevention, and secondary intervention for substance use disorders is a well-integrated system of service delivery that has long-term accountability for quality and cost of care. An integrated delivery system is a network of health care providers and related organizations which coordinates to provide a continuum of care to its targeted population(s). Ideally, a fully integrated delivery system would be a single integrated entity providing a full range of services covering the entire spectrum of health and mental health needs that are well-integrated with the communities that it serves. Coordination of services is of interest to health care providers, as integration reduces redundancy in services, centralizes administrative tasks which reduces staffing needs, allows for a broader range of services/specialties offered, and facilitates a higher level of strategic planning and generation of policies to better serve communities and consumers. These shifts help to reduce costs of care delivery and direct costs to the consumer. The strengths of such a well integrated system go beyond increased productivity, efficiency, and cost-effectiveness. An integrated system facilitates continuity of care through more seamless referrals in a system that facilitates communication between providers and allows for tracking and accountability of referrals for specialty care. Integrated services help insure continuity of care and increase the likelihood of treatment engagement, treatment adherence, and improved quality of care.

Limits and Benefits of SBI in ED Settings

Some experts contend that the MI approach is not feasible for primary care and emergency settings due to the training and time needed to provide effective MI type interventions. Of note, even when providers in ED settings have the skills and time to provide such interventions, high levels of intoxication may preclude the usefulness of any "in the moment" type of intervention. If an

individual presents in the ED with heavy intoxication, it is possible that the patient might not remember the motivational intervention delivered at that time. Although valid, these concerns should not curtail efforts for the development, testing, and dissemination of interventions in ED settings. It is well established that learning that occurs closer to the behavior targeted for change is more likely to lead to changed behavior. Further, patients often naturally abstain from alcohol for a time period following an ED visit or hospitalization due to an injury where alcohol was a contributing factor. In addition to person-to-person interventions, web-based interventions have been suggested as being possibly more adaptable for health care settings. In managed care organizations, for example, the combination of medical record tracking and payment structure could be utilized to incentivize such interventions. For example, if a young patient presents in an ED setting, they could receive a BAC test and if indicated, a follow-up intervention via secure e-mail messaging to address alcohol use. If the patient completed the intervention and followed up with their primary care doctor, their ED visit fee could be waived.

ALCOHOL, TRAUMA, AND SBIRTs

Excessive alcohol use, ranging from binge drinking to longstanding alcohol dependence, has been found to be a leading risk factor in admissions to hospitals for trauma. Hence, there has been an organized effort to institute screening and brief intervention in trauma-related injuries treated in Level 1 Trauma centers/hospitals. Chafetz and colleagues, in the first report on the use of brief interventions delivered in a hospital emergency department setting, indicated that interventions successfully motivated alcohol-dependent individuals to engage in subsequent treatment for their disorder. Harborview Medical Center in Seattle, in an effort to examine alcohol-related admissions to its trauma unit, found that alcohol screening and brief intervention delivered in the emergency department reduced the rate of alcohol use and repeated admissions for trauma by nearly 50%. Cost-benefit analyses conducted as part of this trial indicated that, if instituted nationwide, such interventions could lead to an annual direct medical cost savings of almost \$2 billion. Results from this CDC-funded research led to a mandate by the American College of Surgeons to require that Level 1 trauma hospitals provide alcohol screening for all injured patients arriving in emergency rooms and brief intervention for individuals who screen positive for problematic alcohol use. More specifically, trauma centers can test BAC when patients arrive with trauma. If the patient is subsequently hospitalized, the BAC information can then be used to provide personalized intervention delivery.

FORWARD THINKING

Patient-Centered Medical Home Models

One approach to improve patient care and lowering health care costs is the Patient-Centered Medical Home – an organization model for the delivery of the core components of primary health care. In 1967, the American Academy of Pediatrics first introduced the idea of a “medical home,” in order to provide a central location for children’s medical records. In 2002, the AAP expanded this concept by identifying “Joint Principles.” The Patient-Centered Medical Home model is a team-based approach to care emphasizing patient support and empowerment, coordination and continuity of care, ease of communication between the patient and his or her and health care team, timely access to care, and “whole person” care. Whole person care assumes that the physician and his or her team are responsible for providing or arranging patients’ care across the lifespan and considering patients’ cultural traditions, personal preferences and values, family situations, social circumstances, and lifestyles. Each patient has a personal physician with whom they have an ongoing care relationship. This physician works with a team who collectively are responsible for the patient and includes a primary focus on quality and safety of care. Whole person care systems focus on prevention of costly ED visits and hospital stays, increasing one-to-one time with patients, patient-provider communication via alternative methods (secure e-mail and telephone), treating to target (having a tracking system for identifying those not within targets for health, such as depression scores, blood pressure ratings, and body mass index), and identifying those lost to follow-up. Whole person care further includes integration of the Chronic Care Model, a model that engages patients with chronic conditions to become more informed and active self-managers, and does so through a prepared, proactive primary care team and supportive delivery system design. The Joint Principles included an emphasis on the importance of reimbursement for physician care management, which is conducted outside of the office visit, a further benefit to the consumer. Because the medical home model is appropriate for organizations where health care delivery and coverage are combined into a single system, such systems have strong incentives to focus on both greater quality of care and cost of care.

Alcohol and Mental Health Screening

Literature largely from research with college students indicates that there are important relationships (we suggest transactional) between mental health problems

(such as symptoms of depression and anxiety), drinking-related consequences, alcohol consumption, and drinking that is motivated to manage negative moods. Individuals with mental health problems are at greater risk for drinking to manage the moods associated with these problems and in turn are more likely to experience significant consequences due to their alcohol use. Although alcohol-related consequences cannot be totally disentangled from severity of alcohol use problem, these relationships are still important to consider. Individuals should be screened via PHQ-9 and GAD-7 (the Patient Health Questionnaire and Generalized Anxiety Disorder, respectively, seven items self-report, free online) at the same time as they are screened for alcohol use disorders. Above all, we recommend that health care practitioners emphasize (especially for young patients with mental health problems) the importance of avoiding drinking while in a negative mood state or for the purpose of managing mood, because of the numerous associated problems. Whiteside and colleagues have recently published research on an SBI (incorporating mental health feedback and coping skills training from dialectical behavioral therapy) for young adults experiencing both mental health and alcohol problems. Results of this pilot intervention indicate reductions in mental health symptoms and alcohol-related problems.

SUMMARY

Groundwork has established a platform for refining brief interventions in the medical arena for adolescent populations. Medical care settings have been identified as an important potential mechanism addressing the unique needs of adolescent populations. Although roadblocks and complicating factors are clearly evident, identifying these issues is key to development of services to maximize the potential for intervention with this age group. The potential psychosocial and economic benefits far outweigh costs of screening for alcohol-related problems and offering motivation for behavior change. Primary care and emergency department venues are key points of contact for alcohol screening to identify risk of developing alcohol-related problems and intervene early with individuals who may never otherwise seek alcohol or mental health treatment. Such interventions hold the promise that brief, cost effective interventions during youth can positively influence health trajectories and reduce substance-related issues over the lifespan.

EPIDEMIOLOGY OF COLLEGE STUDENT DRINKING

By the time young adults enter college in the United States (US), over 70% have consumed alcohol at least once, over 50% have “been drunk” on at least one occasion, and approximately 4% report drinking on

a daily basis. Over a third of college students at least occasionally misuse alcohol, engaging in heavy episodic or *binge* drinking. A binge episode is typically denoted as consumption of five or more standard drinks by a man or four or more standard drinks by a woman during a single drinking occasion. In the US, one standard drink is currently defined as

0.6 oz of 100% pure (or 200 proof) alcohol, which is equivalent to 12 oz of beer (5% alcohol by volume (ABV)), 5 oz of wine (12% ABV), or 1.5 oz of liquor (40% ABV). However, this definition has changed over time and differs from country to country.

Despite the fact that most college students mature out of heavy drinking around age 21 or 22, the harmful consequences of alcohol use, in particular, chronic heavy drinking and binge drinking, can have lasting effects. Acute alcohol-related consequences, such as impaired academic, athletic, and work performance, physical injury, weight gain, blackouts, and unplanned pregnancies, can divert students' natural developmental course, contributing to lost potential and long-term harm. Students who misuse alcohol are at higher risk for these and other more severe consequences including academic failure, alcohol dependence, sexual victimization, infection and disease, accidental death, and suicide. Although the damage caused by alcohol is often greatest to the individual drinker, others are frequently affected. Consequences of student alcohol misuse are also evident at the institutional and societal level including costs associated with property damage, student attrition, healthcare utilization, and involvement in the legal system. Collectively, the damage attributable to college student drinking makes it a significant public health concern.

COLLEGE STUDENT DRINKING PREVENTION

Myriad preventive and interventional approaches have directly targeted college student drinking in an effort to stem the tide of harmful consequences. These efforts can be roughly divided into two categories: (1) environmental and (2) individual-focused. Environmental programs aim to reduce drinking and associated harms by modifying the drinking context, with the intent of changing the broader drinking culture within which individual drinking occurs. By comparison, individual-focused programs aim to reduce drinking and associated harms by modifying drinker-specific factors, with the intent of changing a specific individual's drinking behavior. Individual-focused programs that have demonstrated evidence of efficacy in reducing college student drinking are grounded in (1) an understanding of the individual factors contributing to the initiation and perpetuation of alcohol consumption and (2) broader theoretical frameworks that postulate how behavior is maintained and can be modified through manipulation of these factors. More prominent etiological models of college student drinking are subsequently discussed.

Etiological Factors Related to College Student Drinking

Perceived Risk for Alcohol-Related Consequences

Awareness and educational campaigns assume that students abuse alcohol due to a lack of knowledge or awareness of health and legal risks, and that remediation of this knowledge gap will result in behavior change. This assumption is largely unsupported. In fact, students are often acutely aware of the possible consequences of drinking, and in particular, the more extreme negative outcomes such as alcohol poisoning, traffic fatalities, and legal involvement. However, a large body of research suggests that individuals tend to perceive that they are at lower personal risk for negative consequences relative to others and relative to their actual level of personal risk. Available theory suggests that perceived susceptibility to harm may therefore be more influential in the choice of behavior.

Cognitions

Beliefs about the effects of alcohol on behavior, also known as *alcohol expectancies*, have been repeatedly shown to influence drinking. These expectations may be particularly important in determining drinking behavior in social situations, as many of the most common positive expectancies cast alcohol as a social lubricant. Other common expectancies include that alcohol will increase confidence/assertiveness, increase sexual attractiveness/prowess, reduce inhibition, and reduce negative mood states like boredom, worry, or stress. Expectancies are often directly related to personal motivations or reasons for drinking. For example, a student who normally feels shy may specifically choose to consume alcohol in order to reduce social anxiety. Experimental manipulation of alcohol expectancies in laboratory studies has demonstrated a direct association between expectancies and alcohol consumption, such that increasing positive expectancies leads to increased alcohol consumption and increasing negative expectancies leads to decreased alcohol consumption.

Social Influences

Social influences on drinking behavior are primarily related to peers, including peer modeling of inappropriate use and direct or indirect pressure to use, and inaccurate perceptions overestimating the prevalence and acceptability of drinking in the college culture at large (e.g. beliefs such as "all college students drink") and more proximal peer groups (e.g. "all my friends drink, and they drink more than I do"). Misperception of drinking norms is often considered a cognitive etiological factor, but it is grounded in selective observation of actual peer behavior. Students who are drinking may engage in other behavior (e.g. sustaining an injury,

causing a disturbance) that is more likely to be noticed and to bother nondrinkers and drinkers alike, making drinking look more prevalent due to the ease with which such events are brought to mind. Moreover, students tend to estimate norms based on the behavior of proximal peer groups who most often engage in similar drinking behavior. Students who estimate drinking norms based only on their proximal peer group are ignoring the large percentage of students whose drinking behavior they have not observed. Studies suggest that approximately 20–30% of US college students abstain from alcohol use, and these individuals are the most likely to be discounted when students try to estimate the behavior of “typical college students.”

Coping or Protective Behavioral Skill Deficit

Unlike other behaviors, such as driving a car, young adults typically do not receive explicit instruction on how to drink safely. Students often learn how to drink through passive observation of others’ drinking behavior, and thus their skill repertoire for moderating consumption may be limited. Students who lack the ability or self-efficacy (perceived ability) to judge their level of intoxication (estimate their blood alcohol concentration (BAC)) and limit their consumption (e.g. refuse drinks, pace and space drinks, set and adhere to a predetermined limit) are at greater risk for misusing alcohol. Students may also be at greater risk for misusing alcohol if they lack general life management skills, such as stress management, and instead rely on alcohol as a primary coping mechanism.

Motivation

Low motivation to change behavior is a key factor in the maintenance of risky drinking. Many students are inherently ambivalent regarding their drinking behavior. On the one hand, they may see the potential harms and have personally experienced undesirable consequences, while on the other hand, they often experience immediate positive benefits that reinforce their drinking (e.g. I want to get good grades, but I do not think hanging out with my friends would be as fun without alcohol). It is often assumed that motivation is a stable trait of the individual – someone either possesses motivation or they do not – and that intervention is not possible until the person “finds” the motivation on their own to receive and make use of the help available. In contrast, certain theoretical perspectives view motivation as a product of the interaction between individuals (e.g. a therapist and client). This perspective forms the basis for humanistic, person-centered approaches such as Miller and Rollnick’s motivational interviewing (MI), which is rooted in the transtheoretical model of change. The transtheoretical model of change and MI are described along with other theories of

behavior and behavioral interventions, respectively, in subsequent sections of this chapter.

Biology

Students may be predisposed to alcohol misuse due to genetics. Unlike the aforementioned etiological factors, genetic risk is not directly modifiable via intervention. However, knowing about a student’s family history can help to elucidate an individual’s own behavior. Children of alcohol-dependent individuals (COA) may exhibit acute sensitization and/or acute tolerance to alcohol. Acute sensitization refers to an increased sensitivity to alcohol’s subjective stimulating effects, whereas acute tolerance refers to a decreased sensitivity to alcohol’s depressant effects on the central nervous system. In essence, the person may experience “higher highs” and “diminished lows.” As a consequence of finding alcohol use to be pleasurable without necessarily experiencing the negative physiological consequences (e.g. nausea) students may be more likely to drink heavily and develop an alcohol-use disorder. The finding that COA are more likely to develop an alcohol-use disorder themselves is consistent within the literature, and the role of genetic factors in this risk is evident. Research suggests that COA may differ from children of nonalcohol-dependent individuals in other potentially important ways including personality (e.g. impulsivity, negative affectivity), behavioral tendencies (e.g. hyperactivity, antisocial behaviors), and cognitive factors (e.g. lower verbal and problem-solving abilities, greater positive alcohol expectancies). However, findings are not consistent, and it is less clear if these differences are due to genetic or environmental influences.

Theories of Behavior Related to College Student Drinking

The etiological models discussed above rely on broader theories of behavior to postulate how these individual factors may individually and interactively contribute to college student drinking. These theories include classical learning theories (classical conditioning, operant conditioning, and Bandura’s Social Learning Theory), as well as extensions and variants of these models including Prochaska’s and DiClemente’s Transtheoretical Model of Change, Rosenstock’s Health Beliefs Model, and Ajzen’s Theory of Reasoned Action and Theory of Planned Behavior. This section reviews some of the basic tenants of these theories.

Classical Conditioning

Learning that occurs through classical conditioning is based on pairing. Classical conditioning can occur

intentionally or unintentionally. When done intentionally, a neutral stimulus (e.g. ringing of a bell) that does not evoke the desired response is purposefully paired with an unconditioned stimulus (e.g. meat powder) that naturally evokes the desired response in all members of the organism's species (e.g. salivation in all canines). For maximum learning, the neutral stimulus is consistently presented immediately before and in conjunction with the unconditioned stimulus. In this way, the organism learns that the presentation of the unconditioned stimulus is contingent on presentation of the neutral stimulus, and it produces a conditioned response (e.g. salivation) when presented with the formally neutral, now conditioned, stimulus because it anticipates the presentation of the unconditioned stimulus.

With respect to alcohol use, unintentional learning occurs when external stimuli (e.g. tastes, smells, surroundings, friends/peers) get inadvertently paired with alcohol consumption. As alcohol use naturally produces physiological changes associated with subjective feelings of stimulation and disinhibition, the body activates opposing processes in order to maintain homeostasis. Over multiple pairings, the sensory and social stimuli that frequently precede and co-occur with alcohol consumption come to evoke these opposing processes before alcohol is even consumed. That is, the individual develops tolerance, which prompts greater consumption of alcohol in order to elicit the desired subjective feelings of stimulation. Classical conditioning methods may be used to extinguish alcohol use by pairing alcohol with stimuli that naturally evoke an aversive response. This method of aversive counterconditioning is most often seen in the use of medications that produce physical illness when alcohol is consumed.

Operant Conditioning

Learning that occurs through operant conditioning is based on reinforcement and punishment. Edward Thorndike's Law of Effect suggests that operant conditioning is generally unintentional. That is, behavior is initially performed at random, and behaviors that are followed by desirable consequences are repeated whereas behaviors that are followed by undesirable consequences are discontinued. Of course, operant conditioning can be used to intentionally increase desired behaviors through application of reinforcers or to extinguish undesirable behaviors through withdrawal of reinforcers (or application of punishment). Reinforcers and punishers are not absolute or universal within a species, and as such are defined functionally within a given organism. A reinforcer is any consequence desirable to the individual that increases the likelihood the behavior will be repeated. Conversely, a punisher is any consequence undesirable to the

individual that decreases the likelihood the behavior will be repeated. Reinforcers and punishers are deemed positive or negative depending on if something is added to or subtracted from the individual.

Operant conditioning underlies most cognitive-behavioral models that suggest that alcohol consumption is coupled with positive and/or negative reinforcement (e.g. increased perceived enjoyment, acceptance by peers; decreased social anxiety), which serves to maintain the behavior despite intermittent negative consequences (i.e. punishers). At the level of intervention, alcohol's operant function is explored through discussion of perceived benefits and consequences of drinking, and behavior change may be supported through substitution of alternate behaviors that provide similar positive reinforcement without associated harms.

Social Learning Theory

Unlike classical and operant conditioning, Social Learning Theory holds that neither pairing nor direct reinforcement is necessary for learning to occur. Instead, according to this theory, individuals are capable of learning indirectly through observation of others' behavior and ensuing consequences; the anticipation of reward or punishment is sufficient to shape behavior. In addition, this theory holds that learning may occur without being evident in subsequent behavior. That is, someone may learn how to drink and form expectations for how alcohol affects individuals through observation of proximal (e.g. parents, peers) and distal (e.g. media) models without directly engaging in drinking themselves. The influence of this learning is posited to subsequently emerge if and when the individual decides to engage in drinking. This model underlies cognitive-behavioral models that suggest alcohol use is initiated and maintained due to positive expectancies and underlies intervention approaches that challenge these expectancies and perceived norms for peer-drinking behavior.

Transtheoretical Model of Change

Fundamentally, the transtheoretical model of change suggests that motivation for behavior change is a state, rather than a trait, and lies along a continuum with five distinct stages. Individuals who are comfortable with the status quo are considered to be in the precontemplation stage. That is, they have no motivation for behavior change and are not considering altering their behavior. Individuals who recognize that their behavior has both pros and cons may feel ambivalent, simultaneously wanting the benefits and preferring not to experience the harms. These individuals are considered to be in the contemplation stage. Once this decisional balance is tipped in the direction of behavior change, individuals enter the preparation stage, wherein they amass the

resources necessary to change their behavior. With respect to alcohol use, preparation may involve exploration of alternative activities to drinking or renewal of friendships with peers who would support decreased drinking. When ready, individuals enter the action stage and actually change their behavior, for example, reducing the amount they drink or the time spent drinking. An individual is thought to enter the final stage of maintenance when behavior change is sustained for an extended period of time, usually 6 months.

Health Beliefs Model

The Health Beliefs Model suggests that individuals will alter their behavior if they perceive that (1) they are susceptible to a negative health condition resulting from the behavior, (2) that the condition resulting from the behavior is severe, (3) that they possess the requisite resources to prevent or mitigate the condition, and (4) that the benefits of changing their behavior outweigh the costs. Applied to alcohol use, this model assumes that individuals must be aware of the consequences of use; perceive that they are likely to experience these consequences and that the overall outcome is significantly detrimental to their well-being; feel a sense of self-efficacy to avoid or lessen these consequences as well as possess any necessary external resources to support decreased alcohol use; and perceive that their life will be better overall if alcohol use is reduced. This model informs intervention approaches that address perceived risk for alcohol consequences, reinforce benefits of alternate behaviors, and teach skills to reduce the likelihood of drinking-related harm.

Theories of Reasoned Action and Planned Behavior

The Theory of Reasoned Action and the Theory of Planned Behavior share an emphasis on perceived subjective (injunctive) norms (i.e. perceptions related to the approval of behavior by a relevant reference group) and personal attitudes about engaging in a behavior as predictors of intentions to engage in the behavior. Several researchers have recommended extending the Theory of Planned Behavior to include perceived objective (descriptive) norms (i.e. perceptions of the degree to which a relevant reference group engages in a specific behavior). Research with college students indicate the greater one's perception of others' drinking, the greater the occurrence of drinking and related problems for the individual. Research also reliably indicates that alcohol use is associated with overestimation of how frequently and how much other people drink. This model underlies normative reeducation approaches that juxtapose an individual's perception of drinking norms and actual drinking norms to highlight this overestimation. Correcting this misperception has been shown to result in reductions in perceived

norms and reductions in the individual's drinking behavior consistent with the revised norm.

INDIVIDUAL-FOCUSED PREVENTIVE INTERVENTION APPROACHES

This section describes individual-focused preventive interventions, rooted in the etiological models and behavioral theories discussed above that have been applied to college student drinking. These interventions can be roughly divided into four broad categories based on their primary target: (1) educational/awareness-based, (2) cognitive-behavioral skills-based, (3) motivational/feedback-based, and (4) pharmacological. However, interventions are increasingly blurring the lines between these categories, incorporating elements from various efficacious programs. For example, although historically focused primarily on alcohol education, recent versions of multicomponent alcohol education-focused interventions have included elements of motivational/feedback-based approaches, including graphic presentation of the individual's drinking behavior, correction of normative misperceptions of others' drinking behavior, and tips regarding protective behavioral strategies that serve to reduce harmful drinking consequences. This overlap between the content of different interventions notwithstanding, each of the four broad intervention categories and representative exemplar programs are described below.

Educational/Awareness Programs

Information/Knowledge Programs

As previously mentioned, programs that focus on alcohol-related information and knowledge tend to highlight the type of negative consequences that may be experienced as a result of alcohol use. These programs are solely didactic (instructive) and may also include information on the likelihood of experiencing specific consequences. However, more often than not these programs give emphasis to the severity of consequences, rather than likelihood, as severity and likelihood are often inversely related (e.g. death is the most severe consequence of alcohol use, but the percentage of individuals who die from all alcohol causes each year is comparatively low relative to the percentage of individuals who experience more minor consequences such as nausea). These programs also frequently include information on the range of BACs associated with specific alcohol effects, and directly challenge commonly held myths regarding how alcohol is absorbed and oxidized (e.g. coffee may decrease subjective intoxication, but will not decrease actual BACs).

Values Clarification Programs

In comparison to traditional information/knowledge programs, values clarification programs are typically more interactive. They may contain general alcohol information, but they focus on helping students to consider their own personal values (e.g. being a good student, being financially responsible) and evaluate how choices related to alcohol use may facilitate or hinder attainment of specific goals related to these values (e.g. scholastic achievement, saving money). For example, a prototypical values clarification program may include exercises that help students to define and determine the relative importance of their values, recognize and appreciate the interindividual diversity of values, increase awareness of discrepancies between their values and current behavior, and develop plans to promote greater consonance between their values and future behavior.

Normative Reeducation Programs

Although normative reeducation programs often rely on didactic presentation of factual information about alcohol, the focus is almost exclusively on the actual frequency and acceptability of drinking behavior within a circumscribed reference group (e.g. college students at a given campus). For example, students may be told that less than a certain percentage of students on their campus (e.g. 10%) engage in binge drinking or that more than a certain percentage of students on their campus (e.g. 80%) perceive that public intoxication is not acceptable. When used as a primary prevention strategy, reeducation programs are often referred to as social norms campaigns, and would be considered an environment-level intervention. Individual-focused normative reeducation programs contain the same information as social norms campaigns but additionally highlight discrepancies between personally held perceptions of drinking behavior and the actual behavior of the reference group. Personalized normative feedback (PNF) interventions share many common elements with normative reeducation programs, but as subsequently detailed in the motivational intervention section differ in important ways.

Cognitive-Behavioral Skills-Based Programs

Cognitive-behavioral skills-based programs tend to blend elements of information/knowledge, values clarification and normative reeducation programs with didactic skills instruction and/or interactive skills practice. As the name implies, these skills target cognitive and behavioral factors that promote or maintain high-risk drinking. Some programs focus on teaching specific skills, while others focus on teaching a broader constellation of related skills.

Specific Alcohol-Focused Skills Training

These programs typically focus on teaching a single skill directly related to alcohol use with the intent of decreasing drinking and/or bringing it under greater conscious control. For example, behavioral self-monitoring assumes that excessive behavior will decrease if brought into conscious awareness through consistent tracking. Students are taught the definition of a standard drink; how to calculate the number of standard drinks in various beverages; strategies for keeping track of their alcohol intake in social situations (e.g. placing tokens such as bottle caps in their pocket when a beverage is consumed); and how to document their drinking behavior for later examination (e.g. keeping an alcohol diary). Documentation is usually most accurate and effective in reducing behavior when it is done contemporaneously with the target behavior, but this is usually not preferred by students due to the perceived stigma of recording drinking behavior and may be complicated by the CNS depressant effects of alcohol (e.g. cognitive impairment, lethargy) if done at the end of a drinking occasion. As such, determining a covert strategy for tracking alcohol use that the student is willing and confident in using is paramount to the success of this intervention.

BAC discrimination is another specific alcohol-related skill. This approach trains individuals to determine their approximate BAC using external information (e.g. BAC chart, breathalyzer) and internal cues associated with different levels of BAC. Use of external information and internal cues are both necessary as alcohol reduces attentional capacity, restricting the individual's ability to recognize and make use of available information (e.g. individuals may fail to recognize how extensive their motor coordination is impaired despite having fallen down or knocked over their glass), and internal cues associated with different BACs change as the person increases or reduces his/her level of tolerance to alcohol. BAC discrimination is most useful for regulating alcohol intake to achieve an "optimal level" of intoxication in which the stimulant effects of alcohol are maximized and the negative consequences associated with the CNS depressant and biotoxic effects of alcohol are minimized (approximately equal to a BAC of 0.05–0.06 g%). Past this point, the negative effects are much more dominant and no greater stimulant effects can be achieved.

Alcohol expectancy challenge (AEC) programs specifically focus on evaluation of personally held beliefs about the effects of alcohol. Students are guided to consider which effects are truly attributable to the pharmacological effects of alcohol versus which effects are produced by an individual's expectations on how alcohol will affect them. This challenge may be conducted experientially (in vivo), by proxy, or via didactics and discussion. In vivo AEC comprises actual and

perceived alcohol administration to different students in a group setting. Students who merely perceive that they received alcohol typically exhibit the same social effects as those who actually received alcohol (e.g. being more talkative), which serves to demonstrate the influence of expectancies on behavior. Because alcohol is served, this intervention is only appropriate for students who are of legal drinking age. In comparison, AEC by proxy involves watching a video of another group of students undergoing an in vivo AEC, and may be used with students of all ages. Finally, AEC may be conducted through didactic presentation and group discussion alone. As detailed later, not all AEC protocols are equally effective.

Multicomponent Alcohol Skills Training

In contrast to specific alcohol skills training programs, multicomponent programs provide instruction on a range of alcohol-related skills. These skills include, but are not exclusive to, combinations of the specific alcohol skills detailed above. For example, the Alcohol Skills Training Program incorporates elements of all of these specific skills into a one-to-eight session didactic protocol. Students learn a given skill or set of skills each week and are encouraged to practice skills between sessions. Multicomponent programs also target real and perceived deficits in general life skills. For example, students who feel socially inept may report using alcohol to facilitate social interaction, or students who have difficulty balancing multiple role responsibilities may experience stress, which they choose to alleviate through alcohol use due to perceived lack of, or low confidence in the efficacy of, alternative options. The World Health Organization (WHO) defines life skills as those “abilities for adaptive and positive behavior that enable individuals to deal effectively with the demands and challenges of everyday life.”¹ The WHO suggests that these skills include decision-making, goal-setting, and problem-solving; creative and critical thinking; effective communication, empathy, assertiveness, negotiation and other interpersonal skills; and intrapersonal skills including maintaining self-esteem, awareness and concordance of personal values with behavior, adaptive coping and emotion regulation. When used, these skills are thought to help students make informed, responsible choices with respect to their drinking behavior.

Motivational/Feedback-Based Approaches

Motivational/feedback-based approaches may include elements of information/knowledge, values clarification and normative reeducation as well as

cognitive-behavioral skills training. However, their hallmark is a focus on increasing students’ readiness to change problematic behavior through use of motivational enhancement strategies and personalized feedback regarding behavior.

Brief Motivational Interventions

Brief motivational interventions (BMIs) are usually delivered over one or two sessions. They are facilitated by a trained interventionist whose goal is to increase the student’s motivation and commitment to change high-risk drinking. The interventionist may be a clinical professional, a paraprofessional, or a peer. The most important element is that the interventionist uses a MI style when discussing alcohol use.

MI is a therapeutic approach built around a core “spirit,” or a way of being, that is denoted by (1) fostering collaboration, (2) supporting/respecting autonomy, and (3) evoking versus imposing motivation/goals on others. The MI spirit is embodied in action that serves to (1) express genuine empathy, (2) develop discrepancy between an individual’s values/goals and their current behavior, (3) roll with resistance to change, and (4) support the individual’s self-efficacy. Application of MI requires strategic use of four specific skills: (1) asking open-ended questions, (2) affirming individuals’ strengths/values, (3) listening reflectively, and (4) summarizing individuals’ responses. Adherence to MI style serves to elicit self-motivational statements known as “change talk.”

Within MI, motivation is viewed as a mutable state that can be strengthened or weakened through the verbal and nonverbal behaviors of the individuals involved. Certain behaviors, such as argumentation, blaming, and prescribing solutions, tend to evoke resistance or psychological reactance. That is, when people believe an outside force is threatening their freedom of choice (“You need to stop drinking.”), they will act in a way that is opposite of the outside force (“No I don’t.”). Conversely, other behaviors, such as acceptance, empathy, and asking permission to offer solutions, pull for open discussion, leaving room for the individual to find reasons for change.

The actual content of a BMI is usually structured around a personalized feedback form, ranging from one to several pages in length depending on the number of target behaviors and level of detail included. Personalized feedback may include the individual’s self-reported drinking behavior and related consequences; their perceptions of others’ drinking behavior and the acceptability of drinking; their expectancies regarding, and motives for, drinking; their familial risk for alcohol-use disorders; strategies that they have used to minimize

¹http://www.who.int/school_youth_health/media/en/sch_skills4health_03.pdf

harms associated with drinking; and domains in which they feel more or less confident to resist drinking.

With the student's permission, general alcohol education is usually provided in tandem with discussion of personalized feedback (e.g. information regarding the cognitive effects of alcohol, the impact of alcohol expectancies on behavior, gender differences in BAC, and defining a standard drink). Depending on the student's readiness for change, the session also includes discussion of alcohol-specific coping and harm reduction skills and/or general life skills (e.g. how to moderate drinking and associated BACs; how to reduce tolerance; how to avoid high-risk situations; adaptive coping strategies for managing stress). Regardless of what specific elements are discussed within the session, all students are provided with a copy of their personalized feedback form along with written material covering general alcohol education and harm reduction tips. The Brief Alcohol Screening and Intervention for College Students (BASICS) program is a prototypical example of a BMI (see Further Reading section for BASICS-related resources).

Personalized Feedback Interventions

The personalized feedback component of BMIs can be used as a stand-alone intervention without the benefit of an interventionist. Like the personalized feedback used in BMIs, personalized feedback interventions (PFIs) provide a written summary and graphic representation of an individual's drinking behavior, including his/her typical and peak frequency, quantity and calculated BACs; a comparison of the individual's behavior with his/her perceptions of the drinking norm and the actual drinking norm for a given reference group; positive beliefs about alcohol use; an enumeration of self-reported alcohol-related negative consequences; and other protective and risk-related behaviors. As the information in a PFI must speak for itself, information on an individual's typical and peak BACs is typically presented in relation to BAC-specific effects, such that risk for specific consequences (e.g. impaired judgment and motor coordination, blackout, respiratory depression, coma) is apparent. Additionally, relevant general alcohol education and harm reduction tips may be incorporated directly into the feedback or optional links to this information may be offered to students if the PFI is delivered in an electronic or web-based format. Stand-alone PFIs include, but are not exclusive to, commercially available programs such as eCHECKUP TO GO (a.k.a. eCHUG) and BASICS Feedback. Free web-based programs are also available, such as Check Your Drinking.

Personalized Normative Feedback

The PNF component of a personalized feedback form in a BMI or a PFI can also be used as a stand-alone

intervention. As in a BMI or PFI, PNF contrasts the student's self-reported drinking behavior with that of the typical drinking behavior of a relevant reference group (e.g. typical female student, typical fraternity member). Inclusion of PNF facilitates examination and development of discrepancies between an individual's perception of his or her drinking as "typical" and actual drinking behavior of other college students, which is generally much more moderate. As indicated previously, PNF shares similarities with normative reeducation programs insofar as it presents accurate drinking norms for a given reference group. However, PNF differs from normative reeducation programs in that it juxtaposes an individual's personal drinking behavior with his/her perception of the drinking norms for the reference group and the accurate drinking norms. Many normative reeducation programs also incorporate discussion of the acceptability of drinking behavior in addition to its prevalence whereas this information is not typically included in PNF.

Multicomponent Alcohol-Education-Focused Programs

These programs represent a relatively new hybrid of traditional alcohol information/knowledge-based programs and efficacious elements of BMI, PFI, and PNF interventions, such as personalized feedback, normative reeducation, challenge of positive drinking expectancies, and tips for harm reduction. These programs could also be considered multicomponent skills-based interventions. However, their inclusion of personalized feedback makes them more similar to stand-alone PFI and PNF interventions than more skills-focused programs. They are most often delivered via an electronic medium, either a CD-ROM or over the web. These programs include, but are not exclusive to, commercially available interventions such as College Alc, Alcohol 101, AlcoholEdu and Alcohol Wise (which directly incorporates eCHECKUP TO GO as an intervention component). Earlier versions of some of these programs were almost exclusively focused on alcohol information/knowledge, and as such should be considered separately from more recent versions that incorporate the elements of BMI, PFI, and PNF enumerated above.

Intensive Treatment and Medication

For individuals with more extensive alcohol-related problems who exhibit diagnosable alcohol abuse or dependence, more intensive treatment may be required. This treatment may take the form of inpatient detoxification, inpatient rehabilitation, intensive outpatient chemical dependency therapy, individual outpatient therapy, participation in 12-step focused or other support groups,

and/or medication. Approval of medication for alcohol dependence varies by country. Within the US (which has historically tended to be among the most conservative countries with respect to drug approval), four medications are currently approved for the treatment of alcohol dependence: disulfiram (Antabuse[®]), oral naltrexone, extended-release naltrexone (Vivitrol[®]), and acamprosate (Campral[®]). Disulfiram produces immediate physical discomfort and nausea when alcohol is consumed, leading to aversive counterconditioning. In comparison, naltrexone blocks opiate receptors, diminishing the stimulating effects of alcohol, leading to operant extinction (lack of reinforcement). Acamprosate's mechanism of action is less well understood, but it appears to restore homeostasis between excitatory (glutamatergic) and inhibitory (GABAergic) neuronal pathways in the brain, which is disrupted through chronic alcohol use. More intensive forms of treatment and use of medication have not been well studied in college student populations. Targeted use of naltrexone (i.e. on isolated days in anticipation of drinking events) may serve to further enhance the effects of brief motivational interventions but considerably more research is needed before this can be firmly established.

EVIDENCE OF EFFICACY FOR SPECIFIC INDIVIDUAL-FOCUSED PREVENTIVE INTERVENTION APPROACHES

Current State of the Science

Prevention science is constantly advancing, leading to somewhat different conclusions over time about which preventive intervention approaches are most efficacious. At the time this chapter was written, three intervention approaches had sufficient evidence to warrant classification as efficacious among college students. Specifically, (1) cognitive-behavioral multi-component skills-training approaches, (2) BMIs incorporating personalized feedback and normative reeducation (PFI/PNF), and (3) AEC intervention protocols. Evidence supporting the efficacy of these programs has been documented in numerous qualitative and quantitative literature reviews. These reviews have additionally demonstrated support for the efficacy of stand-alone PFIs and PNF interventions, although more research is needed.

The support for AEC approaches, although considerable, has been less consistent and points to particular efficacious modalities and potential moderators of intervention efficacy. Specifically, *in vivo* (experiential) AECs appear to work well for men, may work for women when delivered in a gender-specific format, and tend not to work when delivered by proxy or via didactics/

discussion only. Other specific alcohol skills programs, including BAC feedback/discrimination training and self-monitoring, have also demonstrated efficacy, but evidence supporting these approaches is considerably more mixed, perhaps due to the high variability of content and administration protocols evident across these approaches.

There has consistently been an absence of support for programs solely including alcohol education. These programs produce changes in alcohol knowledge, but not alcohol-related behavior. In comparison, multicomponent alcohol-education-focused programs that include educational elements in conjunction with personalized feedback and normative reeducation components inherent to BMIs, PFIs, and PNF interventions have started to amass greater support, but evidence of efficacy ranges greatly within and across different programs. Part of the variability in the evidence of efficacy for a given electronic program may be due to evaluation of different versions of the same program (e.g. a study may show no support for version 7.0 of a program, but strongly support version 9.0 of the same program because it included additional or refined intervention elements). Additional variability in efficacy may be due to differences across studies with respect to target population (e.g. all students regardless of age vs. only students age 18 or older) and intervention intent (e.g. universal vs. indicated prevention). As such, more research is needed to determine what specific configuration of intervention elements (i.e. program version), for what students, and under what circumstances such programs may be most efficacious.

As previously indicated, research evaluating the efficacy of intensive treatment and medication for college student drinking has been limited. To date, targeted use of naltrexone in combination with a BMI has been tested in a single open-label trial. Although the findings are promising, significantly more research is necessary before firm conclusions can be drawn regarding efficacy.

Barriers to Intervention Implementation

Barriers exist that may impede or complicate implementation of efficacious individual-focused alcohol interventions on college campuses. First, with the exception of commercially available programs, most intervention protocols are not easily accessible or immediately useable by key stakeholders (e.g. campus health professionals, peer interventionists, college administrators). Although a published manual and measures necessary to generate personalized feedback are available for the BASICS program, campus personnel may not have adequate human resources (e.g. staff with expertise in MI who can deliver the intervention and/or provide

supervision), data (e.g. campus-specific drinking norms), or technological resources (e.g. access to programs that can generate personalized feedback) to implement the program with sufficient fidelity.

These barriers can be lessened through interdepartmental coordination, connecting campus health professionals with academic faculty who have expertise with program implementation and evaluation. Personalized feedback can be developed within basic word processing and spreadsheet/database programs, and normative data can be gleaned from secondary sources (e.g. national epidemiological and behavioral health monitoring research studies) or through implementation of routine alcohol screening in campus health centers. Finally, existing methods for distance learning (e.g. video or web-based conferencing) could be adapted to support implementation of in-person facilitated BMI protocols (e.g. provide initial training and ongoing supervision).

Future Research Directions

Although the balance of the published evidence supports the efficacy of BMIs, more research is needed to elucidate for whom in-person BMIs are more or less efficacious in comparison to PFI/PNF-only interventions. The absence of intervention effects on alcohol behavior and consequences in some studies of BMIs and PFIs/PNF interventions may indicate a failure to include critical intervention components, a lack of fidelity in delivery of the intervention, and/or the presence of potential moderators of intervention effects (e.g. gender, Greek or athletic affiliation, mandated student status). Additionally, despite growing support for the efficacy of PFI/PNF-only interventions, further research is necessary to determine which specific elements and/or delivery modalities are associated with change in alcohol-use and/or -associated consequences.

Both BMIs and PFIs/PNF interventions have demonstrated variability in the duration of effects on alcohol outcomes, ranging from weeks to years. Short-term reductions in drinking behavior (e.g. changes lasting 1–6 months) are far more common and future research is needed to determine how to extend these effects and enhance the impact of these interventions on negative alcohol-related consequences. Recent research suggests that effects on alcohol-related consequences may emerge subsequent to changes in alcohol use behavior. Preliminary evidence suggests these emergent effects may be most related to in-person BMIs, but further research with longer follow-up periods is necessary for other intervention approaches. Additional research is also needed to evaluate the efficacy of BMIs in combination with interventions targeting environmental drinking factors, parental communication regarding alcohol use,

and psychiatric comorbidity (e.g. depression, anxiety, other substance use, disordered gambling). Ultimately, no single approach may be sufficient and multiple intervention strategies may be required to produce lasting effects on college student drinking and related harm.

Finally, the existence of barriers to implementation suggests that further research focused on increasing the reach of evidence-based alcohol intervention approaches is warranted. Specifically, more research is needed to (1) develop efficacious approaches to train intervention providers and evaluate the fidelity of intervention delivery, (2) increase the effect of interventions delivered in written or electronic form in the absence of a trained facilitator, and (3) test the necessity for, and efficacy of adaptations of, existing efficacious programs to reach college students from varying cultural backgrounds and educational contexts (e.g. community college, minority-serving institutions, online distance learning programs).

HISTORY OF STIMULANT USE

Stimulants are a class of substances that represent the most misused products in the world. This class of drugs range from widely used and accepted over-the-counter products such as caffeine and nicotine, to prescription medications used to treat medical conditions such as attention deficit hyperactivity disorder (ADHD), obesity, and narcolepsy, to illicit drugs such as cocaine and methamphetamine. While all of these drugs result in increased energy and vigilance, the capacity of some of these substances to create a “high” involving a sense of euphoria, gregariousness, and excitement has resulted in them being sought after by humans for thousands of years, resulting in stimulants comprising one of the largest categories of drugs of abuse.

Use of legal stimulants such as caffeine can be traced from the discovery of tea in China in 2750 BC to the

present annual per capita consumption of coffee in the United States. Today, caffeine finds its way into a variety of products ranging from soft drinks to ice cream to candy, with the average adult consuming 200 mg of caffeine a day. Use of nicotine, another stimulant found in tobacco, could be traced back over 2000 years with over 20% of Americans smoking cigarettes. While products such as coffee, tea, and tobacco have addictive properties and (especially in the case of tobacco) associated health concerns, they have not been associated with the personal and societal destruction of more powerful stimulants such as cocaine and illicit and prescription amphetamines.

Use of cocaine can be traced back to 3000 BC to the inhabitants of the Andes Mountains. To the Incas of Peru, cocaine, because of its ability to increase energy and elevate mood, was viewed as a gift from the Gods. Cocaine use consisted of chewing coca leaves,

a process that would likely have delivered between 200 and 300 mg of cocaine to the brain over a 24-h period. However, with the development of organic chemistry in the 1800s and the introduction to cocaine to Europe, pure forms of cocaine became available and quickly started showing up as medicinal products (e.g. toothache drops) or in retail products ranging from wine to soft drinks. As with the Incas of Peru, cocaine was initially touted as a panacea for a variety of ailments, marketed as an “intellectual beverage” as Coca Cola and endorsed by a number of influential people ranging from Pope Leo XIII to Thomas Edison. However, the addictive qualities of the drug soon became apparent, resulting in governmental regulation (i.e. Harrison Act of 1914) and eventual (1970) classification of cocaine as a Schedule II drug (a drug with some medical use, but high potential for abuse and dependency) in the US.

Use of cocaine significantly declined in America for over half a century. However, there was resurgence in cocaine use in the mid to late 1970s when it was again viewed as a safe drug. In fact, in the 1980 edition of the *Comprehensive Textbook of Psychiatry*, Grinspoon and Bakalar opined, “Chronic cocaine abuse usually does not appear as a medical problem.” During the 1980s, new forms of delivering cocaine to the brain such as freebasing and crack emerged, increasing addiction potential and personal destruction by delivering higher doses of the drug with a reduced latency from ingestion to drug effects. Modern technology now provided users with dosages of cocaine reaching the brain up to five times higher than that of the Incan, delivered to the brain in seconds rather than hours. This deadly combination led to a cocaine epidemic of unparalleled proportion and associated violence and mortality that ripped at the fabric of American society.

Use of Ephedra majung, a plant with stimulant and appetite suppressant properties can be traced back to 3000 BC in China. The active ingredient of amphetamine was first synthesized in 1887 from a series of plant compounds related to ephedrine. A related compound, methamphetamine, was synthesized in Japan in 1918. While structurally similar to amphetamine, methamphetamine differs from amphetamine in that at comparable doses, higher levels of methamphetamine get into the brain; thus making it a more potent drug. Both drugs are classified as Schedule II drugs.

Amphetamine had little medicinal use until the mid-1930s when it was marketed as a decongestant and treatment for narcolepsy. Known for creating a sense of alertness, energy, and euphoric properties, it was widely used to counter fatigue in combat troops in World War II. Its ability to suppress appetite resulted in it being marketed as a weight loss agent known as Dexedrine beginning in the mid-1940s. However, its

addictive properties soon became apparent and legislation regarding its use and distribution started to emerge in the 1950s.

Amphetamine and methamphetamine became popular in 1960 both in terms of legal prescription and as part of the 1960s drug culture in the US. These substances were used by people ranging from truckers to students to housewives for increased stamina, alertness, and appetite suppressant qualities. Between 1958 and 1970, the US production of amphetamine pills grew from 2.5 billion to over 10 billion, greatly exceeding the legitimate medical demand. Known by a number of street names including speed, ice, meth, bennies, etc., these substances quickly became popular drugs of abuse with an estimated one half to two-thirds of the pills manufactured between 1960 and 1971 being sold on the black-market.

The Controlled Substances Act of 1970 greatly restricted the availability of traditional sources of amphetamine related drugs. In fact, an analysis of black-market street drugs in the mid-1970s revealed that less than 10% of samples actually contained amphetamine. Users were now turning to clandestine laboratories of amateur chemists who “cooked” available over-the-counter products such as ephedrine, commonly found in cold medicines, and other compounds into D-methamphetamine using a “pseudoephedrine reduction” process, the recipe for which is readily available via the Internet.

More recently, users have begun to abuse stimulant medications used to treat attention deficit disorders. These medications (Adderall, Ritalin, etc.), when used in the proper dosage, increase central nervous system arousal and attention in ADHD patients. These drugs are becoming more popular among high school and college students as a study aid due to their ability to improve stamina and focus. However, when used in higher dosage, these medications can produce the same euphoric effects seen with other amphetamines. Rates of ADHD drug abuse mirror that of the increase in prescriptions for the medication; both of which increased over 75% between 1998 and 2005.

CURRENT EPIDEMIOLOGY OF STIMULANT USE

Historical analysis of cocaine use indicated rampant use in the early 1900s with a sharp decline following government control over the drug. Use of these drugs began to increase in the 1970s when it was perceived to be relatively safe and nonaddictive. However, during the late 1970s and early 1980s the use of cocaine dramatically increased.

Use of cocaine among 12th grade students dramatically increased in the late 1970s and remained fairly stable until the mid-1980s. After a sharp decline, cocaine use increased again during the mid-1990s when rates again increased. Since 2009, cocaine use among 12th graders has slowly declined with 12-grader use in 2009 being 3.4%.

Use of cocaine by youth is affected by a variety of factors that can provide valuable information for prevention programming. One of the factors associated with use is that of the perceived risk of the drug. Perception of cocaine as dangerous by 12th grades was relatively low during the 1970s and mid-1980s. However, in 1987 perceived risk significantly increased. This was likely associated with the death of NBA first round draft, Len Bias, following his first use of cocaine. Perceived risk remained high until the 1990s, consistent with the above noted increase in use. Since 2000, perceived dangerous of cocaine has increased, again mirroring decline in use.

Cocaine use may also be tied to perceived availability. For example, while 33% of 12th graders reported that cocaine was “fairly easy” or “very easy” to obtain in 1977, 59% so responded in 1989. In 2009, 39% of 12th graders endorsed these categories.

Tables 82.1 and 82.2 clearly show the inverse relationship between perceived risk and use.

Trends in amphetamine use indicate peak usage by 12th graders in 1981 with 26% reporting use within the past year. There was then a gradual decline until the early 1990s when use of a variety of illicit drugs increased. Rates of abuse again began to peak after the mid-1990s and have steadily declined to the present time with 7.8% of 12th graders reporting use within the last year in 2009. Again, similar to that of cocaine, usage rates of amphetamine are inversely related to their perceived dangerousness.

Use of methamphetamine rose from 1.9% of 12th graders in 1976 to 3.7% by 1981. It was not until 1990 that the Monitoring the Future questionnaire began asking questions specific to crystal methamphetamine use. As illustrated in Table 82.3, crystal methamphetamine use

TABLE 82.2 Amphetamine Use and Perceived Risk*

peaked in the late 1990s and has steadily declined over the last 5 years with the 2009 12th grade use remaining at 1%. Again, usage rates decline as perceived dangerousness of the drug increase.

Use of stimulants by young adults (aging 18–25 years) and adults (age 26 and older) are similar to those observed as with the 12th graders. Cocaine use by young adults within the last month declined between 2002 and 2008 from 2.0 to 1.5%, while amphetamine and methamphetamine in this group declined from 1.3 to 1.1% and 0.6 to 0.2%, respectively. Cocaine, amphetamine, and methamphetamine use among adults have remained relatively stable with 0.7% reporting cocaine use and 0.3% reporting methamphetamine use within the last month.

Rate of abuse of prescription stimulants such as Adderall and Ritalin are more difficult to calculate. However, there is clear evidence that these medications, primarily used to treat ADHD, are increasingly being used for nonmedical use. In 2000, 19 million prescriptions for ADHD drugs were written, a 72% increase from 1995, and 34% of children 11–18 years who were on these drugs reported being approached by peers to sell or trade their medication. Research on college students reveals that 6.4% admitted to using the ADHD stimulant Adderall nonmedically within the past year. While these drugs are not associated with abuse when used within their prescribed dosage, in excessive amounts they can create the same euphoric

and energizing effects as other stimulant drugs of abuse.

NEUROBIOLOGY OF STIMULANTS

Of the thousands of chemical compounds available, only a small number are abused by people. All drugs of abuse share the common property of being able to cross the blood–brain barrier (BBB) and affect the action of neurotransmitters within the brain leading to the core of all addictions, brain reward.

The concept of brain reward is complicated and involves several brain areas and multiple neurotransmitters. While a thorough discussion of this process is beyond the scope of the present chapter, a brief explanation of the process will help the reader understand why these substances are so addictive. Once in the brain, stimulants like cocaine and amphetamine affect the release of various neurotransmitters within the brain. Neurotransmitters are chemicals within the brain that allow communication between neurons. Neurotransmitters released by one neuron flow across a space between neurons called a synapse, and then they attach to another neuron. Much like a lock and a key, different neurotransmitters have specific sites on neurons to which they can attach. This process stimulates various parts of the brain, some of which produce feelings of energy and euphoria. Once the action has taken place, the neurotransmitters must then be reabsorbed back into the sending neuron for later use in a process known as reuptake. Amphetamine-type drugs achieve their euphoric effects primarily through their impact on the release or reuptake of the neurotransmitter dopamine in specific structures in the brain, known as the “reward pathways.” These areas, which include structures such as the nucleus accumbens (Nacc), ventral tegmental area, substantia nigra, and amygdala are present in the brain so that certain behaviors important to the survival of the species, such as eating and sex are rewarding, leading to an increase in the probability of the occurrence of those behaviors. However, drugs of abuse like stimulants hijack this area of the brain by having more impact on neurotransmitter release. Thus, it is not surprising that individuals addicted to these drugs often forgo typical survival behaviors such as eating or sex in favor of drug use.

While cocaine, amphetamine, and methamphetamine affect the action of dopamine (DA) within the brain, they do so differently. Cocaine achieves its increase in DA in the brain primarily by blocking the reuptake of DA at the synapse. While methamphetamine also blocks DA reuptake, it increases the release of DA at the synapse. This leads to higher concentrations of DA at the synapse, which accounts for the increased neurotoxicity of

methamphetamine to the nerve terminals compared to cocaine.

A number of different delivery systems are used to supply cocaine and amphetamine to the brain. The various routes of administration are important in that they play a significant role in drug effects and addiction. For example, 96 mg of cocaine administered intranasally (snorted) results in peak venous plasma levels of 150–200 mg ml⁻¹ within 30 min, while intravenous use of 32 mg of cocaine produces peak venous plasma levels of 250–300 mg ml⁻¹ within 4 min. Smoking 50 mg of crack cocaine produces a pattern similar to intravenous use. Methamphetamine can be used in pill form, intranasally, intravenously, or smoked in a form often referred to as “ice.” Similar to cocaine, smoking or injecting methamphetamine produces a faster and more intense high, although because of its longer half-life, a methamphetamine high tends to be longer than those experienced from cocaine. Prescription stimulants such as Adderall, taken orally, reach peak plasma concentrations in approximately 3 h. Unfortunately, individuals using these drugs also snort and inject them with effect profiles similar to that of cocaine and methamphetamine.

TREATMENTS

Research has identified a variety of evidence-based treatments for cocaine and amphetamine addiction. These include traditional 12-step recovery programs, pharmacotherapy, and behavioral interventions. Given the widespread knowledge of 12-step models, this chapter will focus on pharmacologic and behavioral therapies.

Medical Treatments for Cocaine Addiction

Immunization

One approach involves the use of “super” cholinesterase or immunotherapy designed to reduce brain exposure to ingested cocaine through increased metabolism or preventing cocaine from crossing the BBB. While these approaches are promising, research is still limited.

Agonist Medications

Another approach involves the use of agonist medications. Agonists are chemicals that function similar to neurotransmitters by attaching to a specific neurotransmitter receptor (e.g. DA) and mimicking the action of that neurotransmitter. In other words, they function like a spare key that goes into the keyhole and opens the lock. These therapies involve the use of oral cocaine (e.g. tea, tablets), psychostimulants (e.g.

methylphenidate, levodopa), and DA monoamine uptake inhibitors (bupropion) designed to retain some aspects of cocaine's effects while reducing abuse potential and toxicity. Results have been variable and often contradictory and confounded by the presence of comorbid psychiatric issues. There is also concern that the use of these drugs may perpetuate the reinforcing effects of cocaine in the brain.

Agonist/Antagonist Medications

Another pharmacologic approach to the treatment of cocaine addiction involves the use of agonist and antagonist medications in relapse prevention. Unlike agonists, antagonists attach to a specific neurotransmitter receptor but do not result in the activation of the receptor as the actual neurotransmitter would. This action is analogous to a key which will fit into a lock but not result in the opening of the lock. These medications that involve use of cannabinoid receptor antagonists, DA agonists and antagonists (e.g. atypical antipsychotics), gamma-aminobutyric acid (GABA) agonists, and opiate agonists are designed to reduce the perception of cocaine euphoria and relapse triggered by stress of drug-associated cues. Results have been mixed. While opioid agonists appear to provide some efficacy and cannabinoid antagonists and some DA agonists (D1) show some promise, other interventions such as atypical antipsychotics or GABA agonists appear ineffective or result in contradictory outcomes.

Medical Treatments for Amphetamine Addiction

Agonist Medications

Similar to cocaine treatment, agonist therapy is available for amphetamine addiction. Research has shown that use of D-Amphetamine generally leads to a decrease in drug use, injecting behavior, and dependence severity. Similar results were also found for methylphenidate. While amphetamine agonist replacement therapies do appear to be successful in treating amphetamine dependence, this approach, similar to that of opioid replacement in heroin users, is controversial and may never gain wide acceptance due to clinician reluctance to use amphetamine derivatives to treat methamphetamine dependence. Medications like bupropion, however, appear to having less potential for abuse than other opioid agonists, while still having the potential to reduce their use in amphetamine-dependent patients.

Use of GABA agonists is thought to have an antagonizing effect on dopaminergic systems under the inhibitory control of GABA. While patients using medications such as baclofen and gabapentin did not show

a statistically significant difference in terms of negative methamphetamine urine samples, the baclofen group negative urine samples were in the predicted direction (i.e. 50% negative for baclofen versus 38% negative for placebo).

Agonist/Antagonist Medications

Antagonist treatments have involved the administration of compounds that directly or indirectly antagonize the effects of amphetamines on the monoamine systems of the brain. These have included the use of atypical antipsychotics, such as risperidone (Risperdal) and aripiprazole (Abilify), GABA agonists, opioid agonists, and the use of calcium channel blockers. While these medications tend to attenuate the behavioral effects of amphetamines, they have demonstrated little efficacy in the treatment of amphetamine dependence. In fact, some research indicates that these interventions may actually decrease the success of treatment outcome through the dropping out of patients who dislike the sedating effects of the drugs.

The discovery of opioid receptors in the Nacc and ventral tegmental areas of the brain and the evidence of interaction between the central DA and opioid receptors raises the possibility that opioid antagonists such as naloxone could have an impact of stimulant addiction. Opioid antagonists such as naltrexone have been shown to attenuate DA levels in amphetamine-induced increases in DA as well as reducing the behavioral effects of amphetamine. While research has been limited, findings do suggest that opioid antagonists may be effective in managing amphetamine dependence, with treated patients evidencing decreased use and cravings compared to placebo patients.

PSYCHOLOGICAL INTERVENTIONS FOR COCAINE AND AMPHETAMINE ADDICTION

Contingency Management

Another intervention for cocaine and amphetamine-dependent patients involves an array of behavioral approaches and interventions. One intervention involves contingency management techniques based on psychological principles of operant conditioning. In these models, reinforcers, usually involving vouchers redeemable at local stores, are provided based on some predetermined desired behavior (e.g. negative urine drug screen). Contingency management techniques are successful in initiating abstinence from a wide variety of drugs including cocaine and amphetamines. Meta-analytic studies consistently demonstrate the effectiveness of these interventions, with results indicating that

the magnitude of the incentive is positively correlated with the rates of abstinence.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) techniques have also been used with stimulant-dependent patients. These strategies help the patient examine cognitive distortions (erroneous beliefs) related to their drug use. CBT also helps individuals by providing increased problem-solving and stress management skills. Research has shown that CBT is an effective method for dealing with stimulant abuse. Research comparing CBT to contingency management interventions generally indicate the latter to be more effective in the treatment of stimulant dependence.

PREVENTION

Prevention is an important component of any comprehensive substance abuse program. Not surprisingly, most of the prevention programming has focused on adolescents. This is not surprising in that research is clear that most individuals who develop substance-use disorders began their drug use in adolescence or young adulthood. Obviously, there is no need to direct treatment resources to address something that has never occurred. Thus, preventing someone from ever using a substance will guarantee no need for later treatment. Research has shown that every dollar effectively utilized in prevention of drug use saves \$10 dollars in treatment costs.

The research literature and clinical experience are clear that age of initiation of use is related to later severity of substance-related problems. Whether examining alcohol or illicit drugs, students who started their substance use in high school or college had lower substance-related problems than those who began in elementary or middle school. This phenomenon may be due to several factors. First, research is clear that the human brain continues to develop, especially within the frontal lobes, well into the mid-20s. Thus, the earlier the drugs are introduced into the brain, the larger the potential for impaired development. Second, the earlier the adolescent uses substances as a coping behavior, the less likely they are to develop other problem-solving skills; thus making them more reliant on the substance in the future.

Early prevention models, which began in the 1920s, focused on informing youth on the dangers of drugs through vivid exaggeration. The 1936 film, *Reefer Madness*, was a movie about a group of teens who went insane from marijuana use. In the 1970s, programs such as *Scared Straight* targeted youth who had delinquent

or drug offenses and exposed them to inmates in an attempt to deter further problematic behavior. However, research on programs that attempt to deter drug use through the creation of fear and catastrophic consequences do not appear to have long-term beneficial effects, with some studies actually indicating an increase in the undesired behavior.

Another strategy in drug prevention has been providing youth and society information regarding the negative effects of drug use. These programs, the most popular of which is D.A.R.E (Drug Abuse Resistance Education) with over 3 million participants, have not been particularly effective, and in some studies have actually shown an increase in substance use over time.

Before examining the various prevention strategies employed for stimulants, it is worthwhile to look at some basic philosophical differences in the prevention movement. The first issue has to do with what is the ultimate goal of the prevention program. While most programs are designed to bring about total avoidance/use of the drug (abstinence), this is not the only approach. There are experts in the field who see the goal of such programming as not general prohibition of any drug use, but rather the reduction of harm, suffering, and long-term negative consequences associated with drug use. This model proposes that these strategies may be more effective in a population that has witnessed substance use by peers without long-term negative consequences. These interventions, while encouraging abstinence, focus on identification of harmful use patterns. While some literature suggests that this type of approach may have more saliency with youth in terms of their own goals and expectations, it is fraught with several major problems. First, much of the variability identified in addiction, as indicated above, is based on brain neurobiology and genetically determined personal vulnerabilities. Because it is not possible at this time to determine who does or does not possess vulnerability to a particular drug, the program may attempt to solicit use in moderation in a group that is incapable of such use. The second problem is that these programs are difficult to implement due to illegal status of the drugs, political pressures, and the unwillingness of parents, schools, and communities to adopt such a model, fearing such programming as a direct or indirect acceptance or even promotion of drug use.

There are several systems for the classification of prevention programs. The Substance Abuse and Mental Health Services Administration and the Center for Substance Abuse Prevention classify prevention programs on six dimensions. These include information, education, alternatives, problem identification and referral, community-based process, and environmental change. The Information component involves printed or multimedia material on various substances, addiction

and consequences of substance use. While ineffective in isolation, Information is useful when part of a more comprehensive prevention model. The Education component differs from Information in that there is a communication process between the presenter and the audience. This type of intervention involves skill building (e.g. assertiveness training, coping strategies, etc.). Alternative programming seeks to provide youth with alternative activities that are incompatible with drug use or provide a healthy environment and include programs such as athletics, after school programming and job training. Problem identification programs focus on individuals who have already engaged in substance use and refer them to an intervention program consistent with their needs.

The last two classifications, Community-based Process and Environmental intervention focus more on larger system intervention. The Community-based approach identifies and incorporates stakeholders in the community to provide an integrated, comprehensive resource for combating substance use. The Environmental classification looks like a public policy both written (e.g. laws) and unwritten (e.g. community attitudes) that can affect substance use.

Prevention programs can also be classified in terms of the overall population goal. The Institute of Medicine created a classification in 1994 based on Universal Prevention Strategies (i.e. programs that target the whole community, regardless of risk factor – the entire school). Selective prevention strategies target subsets of the population determined to be at some special risk (e.g. failing students, abused children, etc.). Indicated prevention strategies focus on specific individuals such as children who have already started using drug court, etc.

Most comprehensive drug prevention programs adhere to several accepted tenets of intervention. Some of the basic beliefs involve recognition that drug abuse represents a complex relationship between risk and protective factors and that prevention programs should reduce risk while promoting protective factors. Effective programs also recognize the importance of the family and the school and seek to utilize, nurture, and enhance these constituencies in any programming. Effective programs are also identified as being specific to the community within which they will be implemented of sufficient intensity and duration for change and cost effective.

Examples of selective prevention efforts include targeting nonmedical use of ADHD drugs by college students. These programs incorporate drug-free activities, social norms that reject stimulant use and limit availability through working with campus police, government policy makers and campus health professionals.

Research is clear: prevention programs that meet the above criteria of work. For example, cocaine prevention programs implemented early in the school process have been shown to reduce later cocaine use between 10–50%, depending on the particular model and length of follow-up. Similar effectiveness has been seen in treatment programs for other stimulants, including methamphetamine. One study that utilized the Life Skills Training and Strengthening Family Programs for Parents and Youth examined the effectiveness of these programs in 667 families, and found that none of the 12th graders who participated in the program had abused methamphetamine in the following years compared to 3.2% of controls who used the drug.

CONCLUSIONS

Abuse of stimulants such as cocaine and amphetamine are, unfortunately, seen throughout human history. Like most drugs of abuse, these substances are seen as safe and even recommended for improving various human maladies. However, society soon becomes aware of much physical, psychological, and social devastation associated with the drug use. At this point emphasis is placed on education, treatment, and prevention of use of the drug. This usually leads to a reduction in drug use.

Unfortunately, lessons learned by one cohort are soon forgotten and it is not long before another generation succumbs to the same deception of the safety of the substance, starting the process again. Review of epidemiological data suggests that the last decade has seen a general decline in cocaine and amphetamine use among youth as effective education and prevention programs have alerted them to the danger of the drugs. However, the use of a new class of prescription medications for treating ADHD may be emerging as a new threat.

This chapter identified how stimulants “hijack” the brain by altering neurotransmitter function. This leads to changes in behavior and cognition and a “new brain” where presence of the drug is now “normal” and absence of the drug is abnormal. In this case, most users fail to achieve the brain reward associated with their initial use of the drug, and engage in current use partly to maintain the status quo of the “new drug adapted brain.”

While addiction is devastating to the user, their families, and society in general, the good news is that there are proven treatments that can help the person free themselves from their chemical dependency. In addition to proven psychosocial interventions, new medications are being developed that can help to minimize the effects of cocaine and stimulants on the brain.

The most powerful treatment, however, is prevention. Over the last 20 years, researchers and clinicians have developed prevention programs that can have an impact upon convincing youth never to try these dangerous substances as well as reduce relapse in people who have been treated. What is clear is that prevention is not an event, but a process. The most successful programs utilize a variety of components, enlist community support and provide follow-up prevention over time. While these programs are expensive, they are economic bargains when one examines the financial and human cost of drug abuse.

List of Abbreviations

DA dopamine
GABA gamma-aminobutyric acid
Nacc nucleus accumbens

Glossary

Attention Deficit Hyperactivity Disorder (ADHD) a psychiatric diagnosis marked by either symptoms of inattention or symptoms of hyperactivity and impulsivity. Prevalence rates range from 3–7% in school age children. Common treatment includes use of stimulant medication.

Blood–Brain Barrier (BBB) a naturally occurring network of blood vessels and cells within the brain that prevents many substances from crossing from the blood system into the capillaries of the brain. All drugs of abuse have the ability to cross the barrier.

Cognitive-Behavioral Therapy (CBT) a form of psychotherapy that is based on the premise that faulty or maladaptive thinking leads to maladaptive behavior and emotional distress. The therapy focuses on changing these thoughts into more adaptive and effective cognitive patterns.

Crack cocaine Powder cocaine that has been mixed with water and another substance such as ammonia or sodium bicarbonate and then boiled. The resulting substance is then dried and cut up and sold into 0.1–0.5 g pieces called rocks. The rock is then smoked in a special glass tube pipe. It supplies a faster, more intense, but shorter-lasting “high.”

Methamphetamine a stimulant drug similar to amphetamine. However, its chemical structure is slightly different and the addition of the *N*-methyl group alters its characteristics, allowing it to penetrate the blood–brain barrier easier and resulting in more intense brain effects. It metabolizes down in the body to amphetamine.

Reuptake a process that involves the reabsorption of a neurotransmitter back into the neuron after it has transmitted a neural impulse. The process involves special transporters that attach to the neurotransmitter and take it back into the presynaptic neuron. Many drugs of abuse affect this process by attaching to the transporter, leading to increased presence of neurotransmitters in the synapse.

Marijuana use among college students has gained research attention in recent years. Despite studies suggesting that marijuana use can lead to a multitude of consequences in the collegiate context, there are few empirically based interventions that address abuse of marijuana among students. This chapter reviews the available research on the etiology of marijuana use in college and provides suggestions for future research work needed to help inform the development of empirically supported interventions. The available literature on marijuana intervention research with adults and adolescents is reviewed, and suggestions for the transfer of empirically based alcohol interventions in college are presented.

PREVALENCE AND DEVELOPMENT OF MARIJUANA USE AMONG COLLEGE STUDENTS

Prevalence

Marijuana is the most common illicit drug used among US college students. Most recent data from 2010 indicate that approximately 33% of college students reported any marijuana use in the past year. Approximately 18% of students report past 30-day use, with 4.4% reporting daily use. As in the United States, marijuana, or cannabis, has the highest prevalence of illicit drugs in other countries, such as Australia, the

United Kingdom, and Canada. For example, cannabis use was found to be more prevalent among Australian tertiary students than in the general Australian population, with monthly use rates higher than in the United States. Other countries have found lower rates of marijuana use among college students compared with US college samples (e.g. Austria, Spain).

College students are typically within the age range when initiation of marijuana use may occur and patterns of use can develop. Use of marijuana is typically initiated and at its heaviest during late adolescence and young adulthood, with the most frequent users between ages 19 and 22. While marijuana use may begin prior to college for some, approximately one-third of US college students reported initiating use at age 18 (i.e. likely during first year of college).

Risk during Transition

The transition to college may place individuals at increased risk for developing heavier marijuana-using patterns. Increased freedoms during college may influence substance use behaviors. For example, students may live away from home in on-campus residence halls or with friends in apartments. This independent living may lead to increased freedom and reduced parental supervision. Increased access may also contribute to the initiation and development of use patterns, with peers being a major source of influence over decision making among young adult college students. College students are also in a developmental stage where peers serve an important component in identity formation and the choice to engage in substance use contributes to identities connected to such use.

Researchers have suggested that approximately half of marijuana users report their first opportunity to use marijuana as occurring in late adolescence or young adulthood. Additionally, a substantial proportion of young adults who are offered marijuana eventually try the drug. Studies have also suggested that first-year college students may be at particular risk and may even use to a greater extent than upperclassmen. In an examination of developmental trends, researchers outlined six different marijuana use trajectories among young adults from high school graduation to age 24 over four assessment periods. The trajectories included students who abstained from using throughout the duration of the four assessment periods, those who used infrequently, those who experienced a period of frequent use at one point during the assessment periods, those who increased their use over the assessment periods, those who decreased their use over the assessment periods, and those who used frequently throughout the assessment periods. While three-quarters of the 20 000 participants in the study reported

abstinence or infrequent use over the four waves of data collection, 5% reported continued heavy use throughout the assessment, with an additional 5% reporting increased use over time. Compared to noncollege graduates, graduates were overrepresented in the group that increased over the assessment period.

Fortunately, many students who use marijuana or other substances in college substantially reduce or quit using once they graduate and mature into adult roles (e.g. marriage/family, career). In addition, the long-standing claim that marijuana serves as a “stepping-stone” or “gateway” to other harder drugs such as opiates and cocaine has not been sufficiently supported by empirical data. However, it is estimated that approximately 9% of those who have tried marijuana may go on to develop cannabis dependence and marijuana is the illicit drug with the highest rate of past year dependence.

DEPENDENCE RISK AND MARIJUANA-RELATED CONSEQUENCES

Cannabis Dependence Symptoms and Prevalence

According to the *Diagnostic and Statistical Manual for Mental Disorders, Fourth Edition, Text Revision (DSM-IV-TR)*, cannabis dependence symptoms include tolerance (i.e. needing more of the drug to feel the effect), physical withdrawal (e.g. anxiety, loss of appetite), unsuccessful attempts to cut down or quit, reducing other activities to use the drug, spending a good amount of time using, obtaining, or recovering from the drug, using in greater quantities than intended, and using the drug despite knowledge that it could exacerbate a psychological or physical problem (e.g. smoking marijuana despite problems with breathing/lung damage). Most recent estimates of cannabis dependence in the general population aged 12 and older was 4.3% in 2010.

Within the general population, prevalence rates of cannabis dependence in the United States are highest among youth and young adults aged 15–24. In addition, college students may be at risk for developing a cannabis use disorder during college. One recent small study found that 10.1% of first-year students who had used marijuana at least once in the past year met criteria for cannabis dependence (according to the *DSM-IV-TR*), while 14.5% met criteria for cannabis abuse. Those who used marijuana at least six times in the past month reported dependence and abuse rates of 38.6 and 28.6%, respectively. In further work, researchers found that 19% of students tracked over 3 years of college met criteria for cannabis dependence during at least 1 year of the study. Of the students meeting criteria for substance

use disorders involving both alcohol and marijuana, only 11% took steps to actively seek help (e.g. entered treatment). None of the students reporting struggles with marijuana use only sought help.

Risk for Consequences

While dependence risk may not be a concern for all students who use, students who use marijuana are at increased risk for a variety of short- and long-term consequences, such as injuries and accidents, decreased academic performance and missed classes, cognitive difficulties such as memory loss, risky sexual behavior, physical complications such as poor lung capacity and difficulty breathing, lower self-confidence and self-esteem, and psychological difficulties such as increased depression and social anxiety. Marijuana-related problems have been shown to increase across the transition from high school to college and marijuana users who use alcohol report heavier drinking and more substance-related consequences than drinkers who do not report marijuana use. Marijuana users who report frequent use consistently from senior year of high school through the age of 24 reported higher rates of consequences such as interpersonal aggression, risk taking, criminal behavior, and heavier use of alcohol. Despite the complications, students who report use generally do not believe marijuana will lead to significant risk of consequences. In fact, those who use marijuana tend to rate use-related consequences as less negative than do those who abstain (who perceive the consequences more negatively). Heavier users cite the perceived low risk associated with smoking marijuana as a reason for choosing to use. Thus, as initiation and development of marijuana use begin for many during the college years, college students represent a population in need of prevention strategies to reduce the short- (e.g. academic complications) and long-term consequences (e.g. risk for cannabis dependence) of using marijuana.

INTERVENTION AND PREVENTION PROGRAMS FOR COLLEGE STUDENTS

Limited Available Intervention Studies

Alcohol abuse has received substantial attention among researchers and funding agencies, with dozens of prevention and intervention studies aimed at reducing the harms associated with heavy drinking among college students. However, marijuana interventions for college students have received much less attention. To date, there appears to be only one randomized clinical trial primarily targeting marijuana use among college students. In this study, researchers developed and

evaluated a web-based personalized feedback intervention for incoming first-year college students who indicated current marijuana use (defined as any use in the last 90 days). The intervention was based on many of the components in the harm reduction-based, alcohol-focused intervention, Brief Alcohol Screening and Intervention for College Students (BASICS), and utilized a motivational framework for presenting information. The web-based feedback was individually tailored and based on student responses to a prior baseline assessment. Feedback for current users included information about their marijuana use (e.g. pattern of marijuana use, amount of money spent on marijuana), experienced consequences of use, perceived and actual descriptive norms for marijuana use, perceived pros and cons of using marijuana, and participants' own cost-benefit scale. Results indicated no overall reduction in marijuana use as a function of the web-based intervention relative to control at either 3-month or 6-month follow-ups. However, results did provide some promise for students who reported a family history of drug use, and to a smaller extent those who had greater readiness to change at baseline. While there are several commercially available web-based projects on the market for college student marijuana use (e.g. electronic THC Online Knowledge Experience [e-TOKE]), to date these programs have not been evaluated for efficacy. Encouraging results for reducing marijuana use have been found among a few selective and indicated programs targeting college student drug use in general in the United States and the United Kingdom (e.g. McCambridge and Strang, 2004; Miller et al., 2001; White et al., 2006).

Possible Considerations for Marijuana-Focused Interventions

Since there appears to be only one randomized clinical intervention study for marijuana use among college students, researchers have the choice of looking at three areas for ideas to design effective preventive interventions with college students. These areas include (1) the efficacy studies targeting adolescent marijuana use (i.e. high school and middle school students), (2) the efficacy studies targeting cannabis use disorders among treatment-seeking adults, and (3) the extensive literature on efficacious components of interventions targeting college drinking behavior.

Efficacious Interventions Targeting Adolescent Marijuana Use

"CHECK-UP" MODELS

There have been multiple trials examining the efficacy of brief and long-term interventions with marijuana-using adolescents. Because only a minority of

adolescents abusing marijuana voluntarily seek treatment, there is a need to create programs designed to encourage heavy marijuana users who do not identify as “in need of treatment” to self-refer. The Teen Marijuana Check-Up (TMCU) is a motivational enhancement therapy (MET) intervention adapted from the Drinker’s Check-Up. The TMCU is aimed at eliciting voluntary participation from heavy marijuana-using adolescents and includes a tailored advertisement strategy and a two-session intervention. The advertisements for TMCU emphasize elements of the program designed to decrease barriers to participation, including the brevity of the intervention, confidentiality, as well as the fact that the program is not labeled as “treatment” but rather as an “opportunity to take stock” of use and is for “people who have questions or concerns about their use.” Originally delivered in high schools, recruitment included educational presentations made to classes about marijuana. At the end of the presentation, details of the TMCU study were shared, and students could indicate in a confidential manner to the presenters if they were interested in learning more about the program. Sessions were held at school during regular class hours.

The MET intervention consisted of a computerized assessment and two individual sessions with a counselor. Counselors utilized principles and techniques of motivational interviewing (MI), such as open-ended questions, reflective listening, developing discrepancy between where one is presently and where one wants to be (e.g. the teens state they want to go to college and also are falling behind in their grades due to using), and building self-efficacy (e.g. helping teens believe in their ability to change their behavior). In the second session, the counselor reviewed a personal feedback report (PFR) that was created for each person from his or her individual responses to the assessment questions. The PFR consisted of a history of marijuana use; recent use patterns of marijuana, alcohol, and other drugs; normative data on marijuana; problems related to marijuana use; potential costs and benefits of reducing marijuana use; situational confidence in avoiding marijuana; and life goals. The PFR was printed in booklet format with graphics and accompanying descriptions of risk factors for developing problems with marijuana. The PFR booklet was reviewed with the counselor utilizing MI skills throughout the session.

Two pre–post design pilot studies have evaluated the acceptability of this model in the United States and Australia. Both demonstrated that nontreatment-seeking adolescents could be attracted to voluntarily participate in the TMCU and that reductions in marijuana use were evident. A randomized clinical trial involving 97 high school students who used marijuana heavily was conducted to determine if the MET

intervention could produce reductions in marijuana use greater than an assessment control condition. Both conditions reported lower marijuana use at a month follow-up assessment, and the lack of differential effect between conditions raised questions about whether the pre-intervention assessment accounted for the reductions in use. The assessment package in the study was carefully constructed to include questions involving both the positive and the negative aspects of marijuana use, and in some ways it was similar to a writing exercise to explore the pros and cons of marijuana use, that is, a decisional balance that is a potential active ingredient in MI. Similar findings were reported with an Australian sample recruited from the general community. Lack of a comparison group to control for counselor contact and other nonspecific factors was a limitation of both studies. Less is known about the durability of a MET intervention’s effect due to the short follow-up periods in these studies.

While findings are encouraging, perhaps an important component of these models to use with college students stems from researchers’ ability to recruit young people via “the check-up” model. College students who report marijuana use (and those who meet the criteria for a substance use disorder) generally report little interest in treatment. In addition, many do not see marijuana as a particularly harmful drug and report that positive effects of the drug are more likely to occur than negative ones. Thus, it may be important for preventive and intervention approaches to consider motivational factors around decreasing use. Presenting interventions as “check-ups” may help recruit particularly resistant populations who may indeed benefit from intervention. Considering the stages of change model, which suggests individual’s cycle through a series of motivation stages when considering behavior change, helping to motivate college students to reach higher levels of change readiness (e.g. moving individuals from contemplation into action) using MET techniques may help prepare them for lasting behavior change. As shown in the only published marijuana intervention with college students, those with greater readiness to change behavior responded best to the online intervention. “Check-up” models with brief motivational components may assist college students to begin exploring their decisions and ambivalence regarding marijuana use.

Efficacious Interventions Targeting Treatment-Seeking Adults

Despite the prevalence of marijuana use throughout the world, there are limited interventions solely targeting cannabis dependence and cannabis abuse among adults. Interventions for marijuana are even more important, as recent research has demonstrated the

physical withdrawal effects of marijuana, thereby refuting the claim that marijuana has no physiological addiction risk. Although continued research is warranted, efficacious interventions do exist and show promise; of particular interest are behavioral interventions based on MET, cognitive-behavioral skills training, and contingency management.

MET, COGNITIVE-BEHAVIORAL SKILLS TRAINING, AND CONTINGENCY MANAGEMENT

Randomized control trials of MET have been efficacious in reducing marijuana use among treatment-seeking adults. Although studies have supported both short- and long-term MET interventions, these interventions appear to work best when combined with cognitive-behavioral skills training.

Cognitive-behavioral skills training interventions based on relapse prevention ideals have also shown some promise with marijuana-using adults. These interventions generally help individuals to recognize triggers for use and to learn and practice coping skills for dealing with risky situations (e.g. going for a walk instead of using marijuana when stressed). Interestingly, researchers have documented equivalent success between a 28-h, 14-session support group and a 3-h, 2-session MET in targeting abstinence from marijuana. Also, researchers have found a relapse prevention intervention to successfully support abstinence rates comparably to a support group with minimal didactic training. Contingency management interventions, in which participants receive vouchers for cash or prizes in increasing value the longer they remain abstinent, have also been shown to be efficacious alone, but appear to support longer term abstinence rates when coupled with both MET and relapse prevention approaches.

These studies suggest that a combination of the three approaches (MET, cognitive-behavioral skills training, and contingency management) may lead to more sustained abstinence. As contingency management predicted better abstinence rates initially, perhaps these approaches are more successful in helping individuals enter treatment and begin working toward goals (i.e. tangible rewards), while MET and relapse prevention components help build motivation for lasting change while individuals learn skills for coping with risky situations once the contingencies diminish. When working with students, perhaps it may be helpful to offer some form of incentive for entering treatment, particularly since so few students seek treatment for marijuana use. Perhaps advertising and offering treatment as “a check-up,” as in treatment studies successfully recruiting adolescent marijuana users and adult drinkers, may help spark student interest in exploring personal use. Once students are available and interested, using MET may help build motivation to further explore their

choices around marijuana use. Indeed, even single-session interventions utilizing MI have the potential to reduce both established patterns of use and future intentions to continually abuse marijuana.

Will What Works for Preventing College Alcohol Abuse Work for Marijuana?

In an effort to design efficacious interventions to prevent marijuana use and resultant negative consequences with college students, it may be helpful to consult the vast literature on alcohol use interventions with college student drinking. Examining the successful components of these interventions and empirically investigating if these components will translate across substances may be helpful in the prevention effort. These components include utilizing motivational enhancement techniques, discussing personal reasons for use, correcting misperceived norms of peer behavior, challenging expectancies, discussing marijuana’s impact on mood and anxiety, and providing psychoeducation about physiological effects.

MOTIVATIONAL ENHANCEMENT TECHNIQUES

In alcohol research, the most efficacious alcohol interventions with college students have come from a harm reduction standpoint. Harm reduction approaches state abstinence as an ultimate goal, but any reductions in use are seen as important steps toward reducing harms from substance use. As stated previously, these harm reduction approaches utilize the style and techniques of MI, a client-centered approach to help individuals change behavior by exploring ambivalence, reducing resistance, and supporting self-efficacy through the expression of empathy and reflective listening. Reviews of alcohol interventions with college students have cited MI-based interventions as the most efficacious in reducing and preventing heavy and risky drinking behavior.

BRIEF ALCOHOL SCREENING AND INTERVENTION FOR COLLEGE STUDENTS BASICS has been recognized by the National Institute on Alcohol Abuse and Alcoholism (NIAAA) as an empirically based effective intervention for college student drinkers. The program, based within a harm reduction framework, combines an MI approach with cognitive-behavioral skills training in a two-session, one-on-one intervention with personalized feedback tailored to the individual’s needs and interests. There is strong research evidence supporting BASICS in individual and modified group formats. Thus, modifying the components of BASICS intervention and adapting them to target marijuana use may be an important first step in addressing marijuana use among college students.

Before applying or extending interventions such as BASICS to other substances, it is important to examine

the mechanisms behind each component of these interventions to determine whether marijuana use would be similarly impacted. The following includes a review of the components included in alcohol interventions that may be translatable to marijuana. In more cases than not, more research is needed to determine whether what works for reducing college alcohol use will also help reduce college marijuana use. While in reviewing the research below we may suggest ideas that may be helpful when working with students, clinicians and other individuals working with students are cautioned against using any practice that does not have empirical support as an efficacious treatment technique.

DISCUSSING PERSONAL REASONS FOR USE

Motivational models of substance use suggest that behavior is motivated by different reasons (e.g., social enhancement and affect regulation), leading to theoretically distinct behaviors that are important for understanding the context and circumstances of marijuana use. Until recently, research examining motivations for marijuana use has been based on measures designed for alcohol use. Research highlighting differences in the nature of alcohol and marijuana use motives supports the need for marijuana-specific research. Recently, 12 unique motives related to marijuana have been identified based on college students' self-reported reasons for using marijuana. There are several reasons why a student may use marijuana, and these motives differ depending on context. This research also highlights differences in motives across substances. Among a large sample of incoming first-year college students, several motives for marijuana use were identified, including the perception of marijuana being a low-risk substance, enjoyment, assistance with sleep, altered perceptions, relief of boredom, celebration, coping, relief of social anxiety, availability of marijuana, conformity, alcohol-related reasons, and experimentation. More specific results indicate that when controlling for other reasons, enjoyment, boredom, altered perceptions, relative low risk, and sleep were uniquely related to more marijuana use among college students, whereas experimentation and availability were uniquely related to less use.

Focusing on the different reasons students have for using marijuana may be helpful in carrying out college student interventions. That is, helping students to understand their personal reasons for using may be helpful as they gain more insight into their patterns of use. For example, a student may not recognize that they only smoke marijuana when in social situations. Combining the MET approach with cognitive-behavioral skills training can help others understand how their reasons for use may be particularly more harmful than they think (e.g. using marijuana to sleep

and learning that cannabis disrupts the rapid eye movement (REM) sleep cycle).

CORRECTING MISPERCEIVED NORMS OF PEER BEHAVIOR

Given that college students are representatives of the "Emerging Adult" population, a developmental period that focuses on peer acceptance and fitting in, it has been theorized and empirically supported that students' own alcohol use is impacted by how they perceive their peers' drinking behavior. Targeting alcohol use specifically, efficacious interventions have been designed both within multicomponent interventions and as stand-alone personalized normative feedback presentations.

MISPERCEPTIONS OF MARIJUANA USE NORMS Perceptions of marijuana use, however, may function differently than those of alcohol in the college environment. There are clear misperceptions of the prevalence of marijuana use (or "descriptive" norms). Studies document that less than 10% of students accurately estimated that the average student does not use marijuana. One study indicated that although 67% of students never used marijuana (and, therefore, "students in general" typically do not use), 98% of students perceived "students in general" to use at least once per year. Additional research suggests that there are more pronounced misperceptions about the prevalence of marijuana use among those who use marijuana than among nonusers. Research indicates that perception of the use of one's friends and of students in general is associated with one's own frequency of use, and that these perceptions are also predictors of drug-related consequences. However, the relationship between "injunctive" norms (e.g. how acceptable you think typical students feel about using marijuana often) and behavior is less clear. The few studies that have looked at injunctive norms have found that these perceived attitudes have generally been associated with actual marijuana use to a lower degree than perceived descriptive norms (i.e. behaviors). Among a sample of Australian university students, cannabis users perceived higher approval of their use among close friends, siblings, parents, and workmates compared to those students who didn't use cannabis. Those with beliefs that marijuana use was both deviant (i.e. low descriptive) and undesirable (i.e. low injunctive) reported the greatest degree of abstinence. These findings suggest that beliefs that others use infrequently and that others would be disapproving of such behavior may influence one's decision to abstain from the behavior.

Although there is some evidence to suggest that perceived descriptive and injunctive norms are influential components of use in college students, the research is nascent and the connection between perceptions and

actual behavior is not as fully understood as it is in the alcohol literature. Theorists assert that for individuals who smoke marijuana more than occasionally, being a marijuana smoker may be an integral part of their self-identity. They may view their behavior as deviant and yet choose to engage in the behavior despite knowing that others may be less accepting of the behavior. Since social norms interventions are based on the idea that individuals care about what peers think about their behavior, marijuana users who perceive themselves as different from the general student population may not be influenced to use less if they learn they are in the minority. Thus, while some evidence supports the utility of targeting misperceived peer norms during preventive interventions with college students, there is not enough available research to suggest that perceived norms have the great influence over behavior as they do for alcohol use.

WILL NORMS INTERVENTIONS WORK FOR MARIJUANA USERS? More research is needed to examine how presenting students with information to challenge their beliefs about perceived peer norms can be helpful in preventing or reducing marijuana use. Studies show that incoming first-year college students already have skewed misperceptions about marijuana use on campus. This suggests the potential benefit of efforts to correct misperceived norms immediately upon entering college or perhaps during late adolescence. It is possible that selective studies (e.g. collecting a random sample of data from students and presenting marijuana prevalence rates to students within interventions only) would be one possibility for impacting norms. Given the importance of peer acceptance in young adulthood, learning that approximately 85% of young adults disapprove of daily marijuana use could potentially have an important impact on some students' use. It may be more useful for students to learn about actual norms early on in college (or in high school) before they initiate stable patterns of use that may lead to their identifying with others with similar patterns.

CHALLENGING EXPECTANCIES

Individuals may expect marijuana and other drugs to have a particular effect on their behavior, mood, cognitions, or affect. In alcohol research with college students and young adults, challenging expectancies about the positive and negative effects of drinking behavior through experimental manipulations has had some short-term success in reducing drinking rates. These "placebo studies" use a 2 × 2 balanced design whereby some students are told they are drinking alcohol but are actually consuming nonalcoholic drinks. Participants in these studies believe and act as if they had actually consumed alcohol.

MARIJUANA-USE EXPECTANCIES Young adults also have expectancies regarding the positive and negative effects of marijuana. Studies have shown that young adults who reported primary use of marijuana (compared to primary users of alcohol or primary user of stimulants) expected marijuana to lead to less negative effects (e.g. cognitive and behavioral impairment) and more positive effects (e.g. relaxation and tension reduction). Additional studies have found a link between relaxation/tension reduction expectancies and frequency of use among college students, as well as between general positive expectancies (e.g. social and sexual facilitation, enhancement) and use.

Using a balanced placebo design, researchers recruited 20 college students to pilot-test the experimental manipulation of expectancies for marijuana. All participants who were told they had smoked marijuana but in actuality received a placebo reported a belief that they had smoked marijuana. Rates of satisfaction were impacted by what students expected (i.e. overall, those who were told they were using marijuana reported greater satisfaction) and what they received (i.e. overall, those who received marijuana reported greater satisfaction), with no significant interactions. This study demonstrated that experimental manipulation with marijuana is possible, and suggested that additional research is needed to explore ways in which such expectancy challenges could be used.

MARIJUANA'S IMPACT ON MOOD AND ANXIETY

Using marijuana to cope with stress has been linked to greater marijuana use, and more frequent users report more depressive and anxiety symptoms than occasional users. Social anxiety was revealed to serve as a risk factor for marijuana dependence even when controlling for other Axis I disorders. Additionally, social anxiety has been linked to the experience of marijuana-related problems among undergraduate users – a finding that was mediated by reasons for using marijuana related to coping with negative affect. These studies indicate that social anxiety may have more of an association with marijuana use problems than actual frequency of use. This finding suggests that students using as a way to connect with peers are struggling to avoid problems from their behavior – perhaps due to the findings that negative expectancies (impairment and global negative) functioned as a mediator for the relationship between social anxiety and marijuana use problems.

Although research supports a clear connection between marijuana use and anxiety, it is still unclear whether more anxiety leads one to use marijuana or if using marijuana leads one to develop anxiety. Multiple physiological studies indicate that use of marijuana can induce panic-like anxiety symptoms. Researchers have observed that more frequent marijuana users

with high anxiety sensitivity experienced increased general anxiety symptoms, while marijuana users with greater anxiety sensitivity reported more catastrophic thinking (e.g. I may go crazy, I may act foolish) than non-users with similar high levels of anxiety sensitivity. Examining a large community sample of adults, researchers found a predictive relationship between cannabis dependence and panic attacks. With regard to symptoms of panic specifically (e.g. increased heart rate, hyperventilation, feelings of unreality), one hypothesis is that once someone experiences the anxiety sensitivity resulting from marijuana intoxication they may begin to notice subtle changes in their physiology (e.g. breathing, heart rates) and believe that these changes are precipitating a panic attack.

It is likely important to target negative mood states during preventive interventions with college students. For social anxiety, students may learn how to connect with new peers through the use of marijuana. Teaching social skills and developing a plan for engaging their peer environment without the use of substances may be an important topic to discuss with students. Those with higher levels of panic disorder can be helped to understand that marijuana use may perpetuate the fear cycle of perceived threatening bodily sensations. That is, it may be important to help students with panic symptoms to realize that using marijuana only exacerbates the anxiety symptoms they may experience. In addition, if students are using regularly to reduce incidences of depressed mood or anxious effect, a discussion about the negatively reinforcing power of marijuana may be important. As in Relapse Prevention approaches, helping students develop alternative activities and behaviors to engage in when feeling stressed, down, or anxious may be a helpful component of prevention approaches.

PROVIDING PSYCHOEDUCATION ABOUT PHYSIOLOGICAL EFFECTS

A range of consequences associated with marijuana use could be relevant to a college student considering the impact of use. While a positive association exists between marijuana use and negative consequences, students who smoke marijuana may not think this behavior poses any significant risk. Thus, consistent with a motivational enhancement theoretical framework, presenting students with one-sided information about the harmful effects of marijuana will likely not lead to changes in use. In alcohol intervention research, information-only approaches are typically ineffective, and a healthy balance of didactic and motivational components (e.g. BASICS) appears to be the most effective.

IMPORTANCE OF OBJECTIVE PRESENTATION OF EFFECTS When discussing the effects of marijuana use with college students during interventions, presenting them with information straight from the federal government (e.g. National Institute on Drug Abuse (NIDA)) may be dismissed by students or may be perceived as one-sided or as a scare tactic. Thus, while the information presented in such reports is accurate, clear, and accessible, students may dismiss the information if presented without a motivational enhancement framework. Conversely, referring students to pro-marijuana websites with one-sided information about the health benefits of marijuana will likely strengthen their belief that marijuana is a harmless drug. Therefore, presenting students with an objective review of the research evidence on physiological effects may help reduce resistance. For example, there are objective books presenting marijuana research on memory, learning, and cognitive effects in three categories representing tasks that are probably unaffected by marijuana use, possibly affected by use, and probably affected by use. Objective sources such as this may be helpful references to distribute to students if they are interested in learning more about the effects of marijuana.

Perhaps the most objective way to discuss the effects of marijuana with students is to review the source of the scientific research. That is, students can review with counselors relevant research literature targeting the effects the student may find particularly interesting. Rather than teaching students about the effects of marijuana that they may care little about, counselors can find out what information students would like more about and refer them to relevant sources for objective materials regarding one's specific interests. Suppose through the course of a discussion with a user that the student mentions having recently noticed some impairment in his memory. In MI style, the counselor could ask the student if he would be interested in learning about some of the effects of marijuana and memory and collaboratively find and critique research evidence discussing these effects.

CHALLENGES

Study and prevention of marijuana abuse poses several challenges. Related to research on marijuana use and consequences, continued development of assessment tools and measures is indicated. A particular challenge involves assessment of quantity of use; unlike alcohol, in which standard drinks can be defined, the numerous ways in which marijuana can be used (and the inability to confirm potency on the part of the person using the substance) lead to many assessments focusing

on frequency only. Additionally, any concerns students might have about the confidentiality or intent of a screening or study, combined with existing possible limitations to self-report data, contribute to research challenges.

College and university administrators may be concerned that directing resources or attention toward marijuana in some way suggests that there may be a “problem” at the institution. However, with rates of past year marijuana use exceeding rates of past year tobacco cigarette use, it is evident that some response is warranted. Although clearly misperceptions surround the prevalence of marijuana use, there are less clear guidelines as to how to correct and address these misperceptions effectively across campus. The social norms mass media campaigns that continue to be evaluated for impacting alcohol perceptions would likely not work in the same way for marijuana. Instead of acknowledging that “most” students abstain or use moderately, the message with marijuana could exclusively be a focus on those who abstain compared to those who use. However, colleges would be documenting, quite publicly, prevalence of a Schedule I illicit drug, which could have implications for liability, funding, and public perception. Finally, in view of marijuana’s illicit status, there may be challenges for adoption of prevention or intervention efforts that focus on reducing the risks or harm for those who do choose to use marijuana. Clearly, additional research is indicated to help overcome these challenges and to advance understanding of addictive behaviors, especially marijuana use and abuse.

CONCLUSION

Many of the efficacious treatments and techniques used to target marijuana use among adolescents and treatment-seeking adults may be translatable to the college population. However, further research is needed to determine whether empirically supported multicomponent interventions for alcohol abuse (e.g. BASICS) will work just as well for marijuana use. Although some of the empirically supported techniques used to reduce risky drinking behavior among college students could possibly be adapted to target marijuana use, research is needed to examine the specific components that may help prevent risk for a different substance. The reviewed literature suggests that exploring students’ personal motives/reasons for using marijuana, correcting their perceptions about what others around them think and do regarding use, challenging their expectancies about what effects they believe will result from use, exploring the mood and affective components related to use, and helping them

understand the physiological effects and consequences resulting from use may assist in the prevention effort. Research can identify and determine whether multicomponent interventions can effectively reduce use or whether single-component interventions (e.g. expectancy challenges) are successful within this population. Furthermore, utilizing interventions based in efficacious MET, release prevention, harm reduction, and contingency management ideals should be examined within the college population.

INTRODUCTION

The transition through adolescence into young adulthood involves rapid biological, psychological, and social changes, setting the stage for adult physical, psychological, and social function. This transition also provides

the context in which secondary and postsecondary student drug use, specifically, performance-enhancing drug (PED) use, is embedded. During this period, adolescents and young adults exhibit increased susceptibility to peer influence and adult (nonparental) role models as they establish their identity in relation to the

world around them. Concerns regarding adolescent and college student PED use emerge not only from these developmental tasks and vulnerabilities, but also the potential for exogenous hormonal PEDs, most notably anabolic-androgenic steroids (AAS), to disrupt brain development with long-term repercussions. Tragedies associated with the use of PEDs and public condemnation of high-profile athletic role models who have allegedly used PEDs to “cheat” in sports have also been focused attention on PED (mostly AAS) use. To understand and address PED use during this stage requires an examination of its context, prevalence, and consequences.

THE SOCIAL CONTEXT

Society values performance, whether cognitive/academic, emotional/social, sexual, or athletic/physical. Cognitive/academic performance enhancement, even for normal function, via supplements (e.g. *Ginkgo biloba*) or drugs (e.g. methylphenidate, modafinil) is generally accepted. Licit (e.g. paroxetine, alcohol) and illicit (e.g. marijuana) drugs modulate emotional/social performance. A profitable industry offering enhanced sexual performance to older adults has also spread to young adults. Surgical and pharmaceutical treatments are used to enhance youthfulness. Beta-blockers are used by musicians to improve audition performance. Performance enhancement strategies are ubiquitous and historically documented transculturally. Despite shared moral/ethical issues, none has achieved the notoriety of PED use; “performance enhancement” is synonymous with athletic/appearance enhancement. PED use is embedded in this sociocultural context, as drugs are used for specific functional purposes.

Appearance/Performance-Enhancing Drugs

PEDs fall within the larger class of performance-enhancing substances (PES) encompassing both dietary supplements (e.g. creatine, protein) and prescription drugs such as hormonal products (e.g. AAS, human growth hormone (HGH)). AAS, which are man-made variations of testosterone, the primary male sex hormone or “androgen,” are available in oral, topical, and injectable drug forms. Thus AAS have androgenic (e.g. masculinizing or virilizing) effects as well as anabolic/muscle-building effects. AAS administration over a period of weeks or months increases protein synthesis to build skeletal muscle. HGH is produced in the body by the pituitary gland and is available as an injectable, synthetically produced drug. It is sometimes used concomitantly (“stacked”) with AAS.

Among PEDs, hormone abuse presents the greatest potential for harm and AAS have dominated PED research. Dietary supplement use poses less or no risk (beyond issues of purity), but often evokes discussions of the Gateway Hypothesis. That is, supplements (or strength training) might “cause” later AAS misuse, as marijuana hypothetically provides a “gateway” to “hard drugs.” Although intuitively appealing, such causation has not been demonstrated. Supplement use or weight training may typically predate AAS use, but a vast majority of weight trainers or supplement users do not subsequently use hormonal PEDs.

PREVALENCE OF PED USE

Understanding the risk and prevention of PED use requires examining prevalence. Concerns over rates of PED use, primarily AAS, emerged in the mid-1980s when high school use was first reported. Population estimates of adolescent AAS usage are routinely obtained via surveys administered in school environments.

Monitoring the Future

The most highly regarded national survey of drug use among young people in the United States is the Monitoring the Future (MTF) study, which annually surveys approximately 50 000 8th, 10th, and 12th grade students. Since 1989 MTF has asked: “Steroids, or anabolic steroids, are sometimes prescribed by doctors to promote healing from certain types of injuries. Some athletes, and others, have used them to try to increase muscle development. On how many occasions (if any) have you taken steroids on your own – that is, without a doctor telling you to take them ...?” (In 2006, the text “to promote healing from certain types of injuries” was changed to “to treat certain conditions”.) Although non-AAS PED use is not assessed, MTF provides over two decades of information on prevalence of adolescent steroid use.

Lifetime prevalence of AAS use among all grades peaked about 8–10 years ago in the United States and has generally declined since. Among 8th graders, lifetime use peaked at 3.0% in 2000, declining every year thereafter to a record low of 1.1% in 2010. Among 10th graders, it declined consistently from a high of 3.5% to an all-time low of 1.3% in 2009 with a slight rebound in 2010 (1.6%). Among 12th graders, the decrease was from a high of 4.0% to a steady 2.2% in 2007 through 2009 and further to 2.0% in 2010. This overall decline in lifetime prevalence belies concerns of a recent

epidemic; the percentage of 8th–12th grade students who have ever used AAS have fallen by roughly half over the last decade, even with a slight increase in 10th grade lifetime prevalence in 2010 recently.

Youth Risk Behavior Survey

The Centers for Disease Control and Prevention's Youth Risk Behavior Survey (YRBS) monitors health-risk behaviors among 9th–12th grade students in the United States. However, anomalous AAS prevalence estimates from the YRBS have raised validity concerns. For example, YRBS lifetime prevalence estimate of AAS use among 9th grade girls was 7.3% in 2003, sparking justifiable concern of an epidemic among adolescent girls. However, if valid, a 7.3% lifetime rate among 9th grade girls would, of necessity, yield a similar or greater estimate among 11th grade girls 2 years later (i.e. would reflect the 7.3% of 9th graders (2003), plus initiators in the intervening 2 years). Yet, 2005 lifetime estimates for 11th graders were only 2.8%. Consensus in the literature suggests that lifetime prevalence of AAS use among adolescent females is likely less than 1%.

The 2009 YRBS estimated that 3.3% of students (4.3% of boys and 2.2% of girls) had "taken steroid pills or shots without a doctor's prescription" during their lifetime using a single question that asks "how many times" the respondent has used "steroid pills or shots without a doctor's prescription." The term "anabolic steroid" is not defined or clarified, allowing confusion with corticosteroids or other medicines or even dietary supplements with suggestive "steroid-like" names. Some respondents may even confuse nonsteroidal performance-enhancing supplements (e.g. creatine) with AAS due to media misreporting and misleading advertising copy. Still, despite these concerns, trends in overall YRBS estimates are consistent with MTF trends, showing an approximate 50% decline, from a high of 6.1% overall in 2003 to the current level of 3.3%.

Prevalence of Adolescent Steroid Use Compared to Other Drugs

The most recent (2010) MTF figures reveal that, compared to AAS, three to four times as many 12th graders have used ecstasy (7.3 versus 2.0%), cocaine (5.5 versus 2.0%), or hallucinogens (8.6 versus 2.0%); over 20 times as many have used marijuana/hashish (43.8%). Over 16% of 8th graders reported consuming alcohol to intoxication, and more have used crack (1.5%) and powder cocaine (2.6%) than AAS (1.1%). Such comparisons do not mitigate concerns over teen

AAS misuse, but provide a reference for interpreting the prevalence of AAS use and potential for relative harm.

Use of Nondrug PESs

In 2005, data from the Growing Up Today Study were analyzed to examine the use of AAS and non-AAS PESs including dietary supplements. Boys ($n = 4237$) and girls ($n = 6212$), 12–18 years of age, reported their use of protein powder/shakes, creatine, amino acids, dehydroepiandrosterone (DHEA, an adrenal androgen), HGH, or anabolic/injectable steroids to improve appearance, muscle mass, or strength. While 12.3% of boys and 8.4% of girls had used at least one product in the past year, fewer (4.7 and 1.6%, respectively) used them weekly, suggesting use was not consistent across the year. The most popular products were protein powder/shakes; 10.2% of boys and 8% of girls had used them in the past year, while 3.4 and 1.4%, respectively, used them weekly. Creatine was used by 4.3% of boys during the past year, but only 0.4% of girls. Use of hormonal PEDs was very low: Only 0.7% of boys and 0.2% of girls used DHEA, HGH, or AAS in the past year.

Summarizing Adolescent Prevalence

Adolescent AAS use is rare, both overall and compared to vast majority of other illicit drugs, and has largely and consistently declined over the past decade. Use of nondrug PESs, while more common, is also a low base rate phenomenon. Although a major concern, adolescent AAS use has shown an encouraging decline in recent years.

Prevalence among College Students

Many studies of prevalence among college students reflect specific campuses or geographical locales, which may not generalize to the wider population, and single point estimates that preclude an examination of trends. However, national college data suggested that nonmedical use of AAS was rare (lifetime prevalence <1%) and fairly stable during the 1990s. Approximately 2% of males and 0.2% of females reported lifetime use. As with adolescents, AAS use prevalence was lower than rates for nonmedical use of other drug classes. Interestingly, the overall estimate (<1%) is lower than MTF lifetime estimates for 12th graders, although this sample excludes high school students not matriculating. Collegiate athletes' use was slightly higher (1.4% in 2001) but had declined from 4.9% in 1989.

ETIOLOGICAL CONSIDERATIONS

Risk Factors

The pathway to PED use is complex and the literature on risk for PED (most often AAS) use relies mostly on case studies, convenience samples, and cross-sectional methods that fall short of explaining etiology. This section briefly reviews factors *associated* with AAS use among adolescents and college students. The true utility of this work lies in mitigation of harm via identifying risk and building protective factors.

Gender

Predictably, males are two to six times more likely to use AAS than females. Females are more likely to use fat-burning PEDs than AAS, although males may be more likely to use both. Although female AAS use is rare it poses even greater risks due to possible masculinization.

Sports

Although the efficacy of some PEDs has been questioned, AAS' muscle-building properties are well-documented. Consequently, adolescents and young adults involved in strength-dependent sports, where muscle and strength are desirable, are at higher risk for use. It is crucial to note that this does not mean nonathletes are not also at risk.

Peer Influence

Those offered AAS or associated with AAS users exhibit greater risk, although not all such instances need result from pressure; some adolescents may seek out such associations. Hence, indirect pressure may be felt when aspiring athletes are exposed to or competing against peers with superior natural abilities or who are using AAS. Further, pressure may be implicitly or explicitly exerted via questioning one's dedication to a team if they fail to "do whatever it takes" to win. Each possibility may lead to active drug-seeking.

Social Pressures

Parents, coaches, and communities place considerable pressure on athletes to perform, even at younger ages. Culture imparts early lessons on success, whether actively, via parental expectations, or subtly, through exposure of young males and females to unrealistic images (e.g. anorectic models, action figures, cartoons) that affect body image and risk for PED use. Considering also the need for success, approval, recognition of achievements during this period, the popular exhortation to "be all you can be" taps into this desire to excel, or self-actualize. To fulfill this desire western cultures have, in many areas of performance, subscribed to "better living through chemistry" and these messages

are not lost on young adults, who, while potentially ambivalent regarding use, may value short-term success over nuanced moral arguments and distal and uncertain negative social or physical outcomes.

Media

Broad exposure to scandals involving seemingly healthy elite professional athletes may normalize, if not justify, PED/AAS use. Media coverage often contains mixed messages, highlighting PED use as physically harmful and morally aberrant, yet normative and seemingly accepted among successful and fit athletes. Thus, young adults may come to overestimate the likelihood of use and positive outcomes among both models and peers.

Prior Use of Dietary Supplements

Supplement users are more likely to endorse intentions to use AAS and, as noted above, supplement use may precede AAS use. However, intentions only marginally predict future use and although supplement use does not cause later AAS use, it may increase or co-occur with exposure to activities (e.g. weight training in gyms) and associations with users, thus increasing risk and signal the appropriateness of increased vigilance for signs of emerging PED use. Another important consideration is the possibility of mislabeled or poorly manufactured supplements.

Individual Characteristics

Signs of risk for adolescent/college student drug use, such as increased risk taking and low harm avoidance, low self-esteem, high self-monitoring or poor academic performance, are also associated with AAS use. These individual characteristics predict a wide range of risky behaviors and, rather than specific risk indicators, may, in combination with more AAS-specific indicators (e.g. weight training, body image concerns) suggest further assessment and monitoring.

Summary

The above factors indicate risk, but are not etiological in nature; they are not perfect predictors and their sensitivity and specificity have not been definitively determined. For example, sport participation is associated with AAS use. However, more than 50% of high school students play sports while current lifetime AAS use among 12th graders is 2%. Perhaps up to 1/3 of adolescent AAS users are not playing organized sports, but engage in weightlifting. Other processes are also involved.

Reasons for Use

Desire for enhanced performance can be alarming; as many as 15% of 12th grade males expressed willingness to take a supplement that would promote their fitness

goals even if it harmed their health; >8% would take it even if it would shorten their life span. Although this may baffle adults, it typifies many young adults' "here and now" thinking and reflects societal trends toward the use of drugs with potential aversive outcomes as a means for meeting ever-growing demands and accruing more proximal or salient payoffs. These reasons, motivations, or expectancies (anticipated effects) for PED use have etiological implications, suggesting a pathway from risk to use. The rewards for sports excellence or physical attractiveness may be highly valued and PEDs may represent a means that is anticipated to achieve them.

Adolescents and young adults consistently list increased muscle mass and strength as major reasons for using AAS, reflecting AAS' true effects and the perception of their functional use by aspiring athletes. However, aesthetics and appearance are also primary reasons; muscularity motivates the nonathlete as well. Given the developmental tasks of identity formation and the establishment of social position, the desire for improved physical performance, appearance of health, and increased stature is clear; lean muscle and body size signal dominance and social status.

Expectations for desirable outcomes from alcohol predict both initiation and levels/style of drinking (and can inform prevention). Adolescents' AAS expectancies remain uninvestigated, but are clearly reflected in the reasons cited (appearance/athletic improvement). Positive expectations predict college students' AAS use and negative expectancies appear protective. College-aged users expect positive psychological effects (e.g. assertiveness, confidence, positive outlook, and enhanced sexuality) as compared to nonusers. The effects of these expectations can be seen when young adults have exhibited both increased strength and changes in observed psychological function in response to placebo administration.

Maintaining Factors

Most drugs of abuse have immediate primary reinforcing effects i.e. they are naturally/biologically reinforcing. Secondary reinforcers function via association with specific reinforcing stimuli, such as praise from a boss that predicts a raise. Of course, money is not inherently reinforcing, but is a generalized reinforcer; it allows access to (is associated with) a broad range of reinforcing stimuli. Although most drugs of abuse are primary and secondary/generalized reinforcers, abuse/dependence potential is most often attributed to primary processes. This distinction is crucial to understand AAS use.

Evidence of AAS' primary reinforcing properties derives from animal models. Laboratory animals learn

to prefer contexts in which AAS are administered and will, to varying degrees, self-administer AAS/testosterone via oral, intravenous (IV; into a vein) and intracerebroventricular (ICV; i.e. injected into the ventricles of the brain) routes. Reinforcement from AAS appears similar to mild drugs such as nicotine, caffeine, and benzodiazepines (a Schedule IV drug; AAS are listed under Schedule III), and significantly lower than highly addictive drugs (e.g. heroin, cocaine).

Experiments using animal models often do not mimic real world human use. For instance, humans do not self-administer AAS through IV and ICV routes and most use considerably lower dosages over substantially shorter percentages of their lives compared to animal experiments using high-dose regimens that may extend across the full pubertal period. Furthermore, the processes underlying a pleasurable neural response to AAS have yet to be definitively identified, although dopaminergic pathways, which modulate most reward learning, have been implicated. Of course, AAS reinforcement may not result from psychoactive effects, but rather from somatic (e.g. quicker recovery time, reduced fatigue) enhancement. This highlights another difference between human use and animal models; unlike research animals, humans use AAS in pursuit of goals.

Human participants consistently deny a "rush" or "high" from AAS. This makes sense that given standard modes of administration; intramuscular (IM; into the muscle) and oral ingestion offer slowed absorption/onset. Most commonly IM-injected AAS release into the body over a period of days. Those psychoactive drugs that are considered the most addictive employ routes of administration (e.g. IV, inhalation) and formulations that rapidly reach peak plasma levels (within seconds/minutes). Humans endorse using AAS to improve appearance, strength and size, not for an immediate high. Such findings suggest that AAS are best viewed as secondary or generalized reinforcers; the reinforcement derived from AAS is most likely indirect – they are reinforcing as a means toward status, recognition, or reward.

Negative reinforcement (escape from or avoidance of noxious stimuli) also serves to maintain use. Drug use disrupts the body's homeostatic processes and, upon cessation, can create a state of withdrawal. To ameliorate this condition, many readminister the abused drug or one with similar properties. For instance, nicotine addiction is based less on gratification than amelioration of cravings. After weeks of AAS use, the body's natural production of testosterone is reduced and the unpleasant cognitive, emotive, and/or vegetative effects that emerge upon cessation may motivate readministration to alleviate symptoms. Many AAS users prepare for this "postcycle crash" which is discussed later.

CONSEQUENCES OF PED USE IN ADOLESCENTS AND YOUNG ADULTS

If the complete pharmacopeia is considered, a broad range of potential adverse events is associated with PED use. Although many PEDs garner little attention with regard to prevalence or risk, medical knowledge of their effects can inform a discussion of potential adverse events. It is unfortunate that, as AAS-associated adverse events have garnered the greatest attention due to editorial and political concerns, attention and resources may have been diverted from other PED-related issues (e.g. stimulants for weight loss, sustained attention and wakefulness, beta-blockers for anxiety management).

Most pharmaceutical PEDs are therapeutic medicines when used in the proper population at the recommended dose. Their effects follow a dose–response curve; greater effects emerge as the dose increases. Adverse effects are also dose dependent, particularly in hormone-based PEDs, although problems can also appear with doses that might be considered therapeutic in clinical settings; therapeutic effects of hormones may be considered adverse (e.g. virilization of females, premature closure of growth plates limiting skeletal growth) when used in a contraindicated manner.

Adolescence is a period of fluctuating sex steroid hormones and male pubertal changes may mirror some adverse drug effects. Excessive androgens can result in adverse levels of estrogen. For example, supraphysiologic (levels beyond physiological normal) dosages of AAS are associated with gynecomastia (the growth of glandular breast tissue in males) in adult men, due to conversion of androgens to estrogens via the enzyme aromatase. Similarly, pubertal gynecomastia can emerge in teenaged boys experiencing periodic surges in testosterone. Non-PED drugs also can induce gynecomastia, including certain antidepressants, and must be ruled out when evaluating cases of gynecomastia as adolescent antidepressant use is not uncommon.

Beta-adrenergic stimulants mimic the effects of adrenalin. As PEDs, they reduce fatigue, increase contractile force (strength), and quicken response; they are often a component of weight loss drugs. In excess, beta-adrenergic drugs can induce tachycardia (fast heart rate), tremors, irritability, and elevated body temperature. Deaths associated with ephedrine–caffeine product abuse/misuse caused the withdrawal of several effective over-the-counter (OTC) weight loss products in the United States, although the combination has been shown safe and effective when offered as a prescription medication or used in specified doses and timing. Many “energy” drinks are also often high in caffeine and other stimulants. As stimulant nutritional supplements, certain OTC medicines, and certain asthma medications may be accessible to

teens and young adults, it is nearly impossible to prevent exposure to this class of PED. Thus, it is vital that the signs of stimulant toxicity above be noted and medical attention sought if warranted. Further, stimulant PEDs are used recreationally, for weight loss, to counter sleep deprivation, and socially, expanding concerns beyond sports or performance use. Stimulant-induced deaths are typically cardiac in nature, and thus immediate.

AAS are the most commonly detected and reported PED at all levels of sport. Testosterone is an androgen, and a precursor to dihydrotestosterone (DHT; a potent androgen responsible for changes in secondary sexual features) and estradiol (the primary estrogen in males and females). Excesses in testosterone can therefore result in adverse changes from elevations in DHT and/or estradiol. Elevated testosterone and DHT can produce features in females that can be considered disfiguring (clitoral enlargement and deepening of the voice) and persist beyond cessation of AAS use. Endocrine disruption of the hypothalamic–pituitary–ovarian axis can result in amenorrhea (absence of menses). Facial hair growth, breast atrophy, and acne are the transient changes with significant potential impact on a young woman’s self-esteem and social acceptance. If AAS are used during pregnancy, the potential for ambiguous genitalia in the fetus exists. Alterations in physiology or psychology resulting from in utero exposure to elevated maternal androgens or estrogens are suggested by certain animal data.

Elevated androgen presence can also affect male adolescents, inducing early puberty, and acceleration of progress through the stages of secondary sexual development, severe acne, as well as increased impulsiveness and aggression. Some animal models have administered large doses of testosterone across the full pubertal period and observed behavioral effects (e.g. aggression) that persisted even after the drug administration has been ceased. Abnormally elevated hormone levels at this critical time might disrupt brain organization and have lasting effects, although, as noted above, extrapolation to human use requires caution.

Estrogen excess is more of a factor for male AAS users, although premature closure of growth plates in the long bones can limit linear growth (height) in both sexes. Males can experience gynecomastia, as previously mentioned; water retention, adipose accumulation, and mood alteration can also be attributed to estradiol excess. Both DHT and estradiol can suppress natural testosterone production, leading to testicular atrophy and delayed restoration of normal gonadal function; rare cases of chronic hypogonadism (diminished gonadal hormone production) and infertility in adult male AAS users have been reported. This has implications for both continued use (as noted above) and treatment (noted below).

AAS can affect the structure/function of the liver. Oral AAS are particularly harmful due to chemical

modification called 17-alpha alkylation that allows the drug to be effective when ingested orally (otherwise it is "deactivated" by the liver). Prolonged or excessive exposure is associated with benign and malignant tumors of the liver, as well as signs of organ dysfunction and cellular stress (e.g. elevated liver enzymes, cholestasis – disrupted flow of bile from the liver). Interestingly, liver toxicity of oral agents is the main reason why AAS users prefer IM injection. However, any mode of administration which involves injection (IV or IM) has the risk of blood-borne or injection-site infections, although this is rare. Needle and multiuse vial sharing between AAS users is relatively uncommon and therefore, even though IM use has the potential for such transmission, it, in reality, poses little risk for this.

The lipid profile is a minor risk factor used in calculating vascular health including fractions of cholesterol and triglycerides. Certain AAS are associated with deleterious changes in (good) *high-density lipoprotein* (HDL)-cholesterol, though some reports have shown improvements with testosterone use in hypogonadal (abnormally low testosterone) adult males. The changes seen during AAS use appear to be transient, returning to baseline within weeks, making it difficult to determine the long-term harm that may follow limited AAS use. The heart is a muscle, but dissimilar to skeletal muscle in many ways. Nonetheless, it responds to AAS, augmenting the tissue-building effect of exercise on ventricular wall thickness.

The range of adverse effects highlighted within drug education programs demonstrate the diverse spectrum of tissue types affected by AAS. Although considered to be a two-dimensional hormone, affecting muscle and sexual features, testosterone and related AAS can affect nearly every tissue in the body, from classic changes, including those described above, to more covert changes rarely considered in young persons (e.g. elevated red blood cell volume, male pattern balding). Due to the wide range of PED-associated adverse effects, it is important to obtain a full and honest patient history when presented with a possible case. Due to social and legal repercussions, this is best handled in a nonjudgmental atmosphere during a medical or mental health encounter, treating the revelations as privileged communication. This can be accompanied by complex issues associated with privacy and confidentiality when working with minor children.

TREATMENT AND PREVENTION OF PED USE

Heightened awareness of the signs of risk or early onset of consequences can facilitate early detection of individual use. However, some signs of PED misuse/

abuse are less familiar or more subtler, making it vital that athletic trainers, nurses, and team physicians aid in monitoring for emergence of risk. Clearly, adolescents should be educated on the proper use of supplements and the potential problems associated with tainted or mislabeled supplements, and both parental and regulatory agency monitoring is appropriate. Given identification of use or risk for use, especially of AAS, concern shifts toward treatment (safe termination of use) and prevention (primary and secondary) strategies for AAS.

Treatment

The dependence-producing potential of AAS is a matter of ongoing investigation. Although the Diagnostic and Statistical Manual (DSM) allows diagnosis under "other substance dependence," the International Classification of Diseases considers AAS as "nondependence producing" (classified similar to the DSM Substance Abuse). The DSM criteria for dependence reflect more immediate psychoactive properties and may not account for, among other things, the cyclic nature of AAS use, including planned alternating periods of use and abstinence. AAS use is also absent with the spontaneous loss of control typical of dependence. This disparity partially reflects the distinction between primary versus generalized reinforcement from AAS.

Ultimately, diagnostic considerations are a secondary concern; the suicides of teens and young adults terminating the use of AAS and suggestions that a significant minority of AAS-using adults have difficulty in controlling planned cyclic use have highlighted the need for empirically supported treatments of the desisting AAS user. Unfortunately, little empirical research exists on such treatment and no consensus treatment exists besides abstinence, which has the attendant issues previously noted. Also, such cases will likely be seen by general practitioners who may be ill-prepared to help such a patient; ineffective treatment may even exacerbate symptoms (such as antidepressant treatment which might enhance suicide potential) and adverse events.

As alluded to earlier, AAS are exogenous versions of testosterone and, via myriad feedback mechanisms, their use reduces or halts natural production of testosterone. However, most adult users are embedded in a subculture that has "trained them up" to use various patterns of administration (e.g. cycling on and off AAS, gradually "pyramiding" (escalating doses up to a peak concentration, followed by a taper to termination)) and ancillary drugs (e.g. antiestrogens, aromatase inhibitors) that favorably affect hormone levels and ratios to manage this dysregulation during and after use. Adolescents and younger adults may be less aware of or likely to

rely on such strategies. When AAS use is abruptly halted, the body cannot readily increase testosterone production to compensate, resulting in a period of lower than normal testosterone, which can lead to physical malaise, muscle atrophy and depression, hopelessness, and potential suicide. Hence, treatment may require use of ancillary therapies to ameliorate these deficits and avoidance of treatments that might exacerbate potential negative outcomes, as well as close monitoring for and supportive treatments of emerging depression and suicidal ideation. As opposed to conventional wisdom in the treatment of other drug dependence, it may also involve controlled administration of testosterone analogs. Therefore, treatment of desisting AAS users is both a specialized area of expertise and a matter of great debate and contention, fraught with obstacles.

Prevention

Few empirically tested PED prevention programs exist. Some theory-based proposals incorporate the Transtheoretical (stages of change) model to conceptualize how adolescents and young adults might move toward use, what might be done to reduce their likelihood of use (e.g. early intervention) or, if using, how they might be motivated to cease use (hence requiring treatment). It has also been suggested that ambivalence in the decisional balance for use of PEDs might be capitalized on; attitudes toward PED use versus abstinence are not exclusive. Adolescents may have positive attitudes toward both use and abstinence and, while such ambivalence may enhance susceptibility to risky influences, it may also be useful in promoting behavioral decisions forestalling use. Another crucial factor may be parental education on early indicators of risk and problems; if parents know what to look for, parental monitoring and even intrusiveness can have protective effects against drug use and related problems.

Urinalysis has also been used in deterrence/prevention. Some states (e.g. Florida, Texas) instituted large scale AAS testing in high school athletic programs. However, high costs and rare positive tests have led many to rethink the effort. For instance, 3 years of tests in Texas revealed only 21 positives out of 51 000 tests costing \$7 million. Research on the deterrent effects of urine testing also is less than supportive. The Student Athlete Testing Using Random Notification (SATURN) study found no consistent deterrent effects of random urinalysis, but did observe potential increases in some risk factors for future use (e.g. perception of attitudes of authority figures). Responses to detection may inadvertently support this attitude by removing individual responsibility; blame for detected use is often immediately leveled toward an unethical coach, role model, or dealer. Despite the popular appeal of drug testing, great

benefit from it has not resulted and numerous ethical questions remain with regard to the use of mandatory urine testing among high school students.

Perhaps, the most researched program for PED prevention is the Adolescents Training and Learning to Avoid Steroids (ATLAS) program, intended to educate young men on PED use. A similar program, Athletes Targeting Healthy Exercise and Nutrition Alternatives (ATHENA), targets healthy nutrition, exercise, knowledge of drug use and its effects, media education, and depression prevention among young women.

Adolescents Training and Learning to Avoid Steroids

The ATLAS program combines elements of several theories of human behavior change (e.g. social learning theory and the health beliefs model), providing education on sports nutrition and exercise-based alternatives to the use of PEDs, drug-refusal skills, and active participation in the creation of health-promoting messages. Sessions are led by peer educators and facilitated by coaches and strength trainers. Short-term reductions in intentions to use AAS have been reported, although actual use reduction was not significant. Other drug use (including alcohol), drinking and driving, and supplement use declined, while nutritional habits improved. Although prevention research suggests that increases in knowledge rarely predict decreased initiation of drug use, ATLAS appears to affect a number of risk indicators via increased knowledge and perceived severity of AAS effects.

The ATLAS program may capitalize on the ambivalence noted earlier, providing education on alternatives, such as proper nutrition and training strategies, may have a positive effect on acceptance of PED abstinence, while also diminishing positive attitudes toward drug use. To the extent such a procedure can introduce appropriate ways to fulfill the goals inherent in PED use, without unintentionally highlighting potential positive effects of the drugs, beneficial effects might accrue. Nonetheless, efficacy for reducing actual use, as opposed to intentions, remains to be validated. In addition, such programs must be mindful of the fact that there may be few universally negative consequences; what an adult might consider aversive (e.g. anger, aggression) may be a desirable outcome to some adolescent males; additionally, most aversive consequences are distal, while positive outcomes are proximal.

Athletes Targeting Healthy Exercise and Nutrition Alternatives

The ATHENA program addresses young females' disordered eating and use of drugs for body-shaping motives. It is a peer-led program incorporated within normal sports team activities. It has been shown to increase

a wide range of healthy- and safety-oriented behaviors (e.g. use of seat belts) and reduce a number of unhealthy practices (e.g. disordered eating), as well as the intention to use, initiation and ongoing use of PEDs. Many of these changes persisted over periods as long as 3 years.

Other Prevention Targets

Many other possible prevention targets might inform a multimodal approach. Of particular relevance may be motivations for use and expectations of AAS effects. General expectations for positive effects of AAS among college students predict risk; college students who believe they are taking an AAS exhibit strength increases as compared to known inactive placebo and similar effects have been seen for some psychological outcomes. Positive beliefs about the effects of AAS differentiate users from nonusers. Given these findings and the fact that methods for challenging alcohol expectancies have demonstrated utility in reducing alcohol use among college students and risky expectancies among elementary students, procedures that not only increase negative expectations but also decrease risky positive AAS expectancies might be a useful preventive component.

Criminalization

The classification of AAS as controlled substances under federal and nearly all state laws was motivated in large part by concerns over adolescent usage. In 1990, Congress placed AAS in the same legal class (Schedule III) as barbiturates, ketamine, LSD precursors, and narcotic painkillers (e.g. Vicodin), making simple possession without a valid prescription of crime subject to arrest, prosecution, and imprisonment. This "criminalization" of the end user has been a favored US legislative approach to steroid prevention, but some commentators have been critical of this strategy and its militaristic enforcement. For example, reminiscent of alcohol prohibition, one effect of steroid criminalization has been the increased manufacture and distribution of black market products including homemade counterfeits and dubious or even contaminated foreign veterinary products. Further, criminalization may discourage illegal users, including teens, from admitting their steroid usage to physicians, thus exacerbating the physical dangers. It should also be noted that following, and despite, the enactment of the federal criminalization legislation in 1990, lifetime adolescent steroid use generally increased, peaking in 2000–2002 (MTF).

Harm Reduction

Given that, despite attempts to prevent PED use, a small percentage of adolescents and college students

continue using them, how might we prevent the harm their use may cause? Although often raised as a viable or even preferred option, and one that has recently made inroads into American culture, harm reduction strategies are often controversial, whether applied to risky sexual behavior (e.g. provision of condoms to prevent spread of sexually transmitted diseases) or IV drug use (e.g. needle exchange programs). Harm reduction is not a substitute for primary or secondary prevention, but an acknowledgment of their partial success. Clearly not an option for younger adolescents, among AAS-using young adults, harm reduction may take the form of needle exchanges as a means to reduce blood-borne infections. In fact, needle exchanges initially established for opiate injectors have served AAS injectors. Concerns that harm reduction approaches will increase risky behavior and drug use have largely been unfounded; conversely, evidence suggests that they significantly reduce negative outcomes. Although this approach, more widely accepted in several other countries, has begun to gain some acceptance in the United States, it has not yet made an impact on AAS treatment wherein moral judgments and legal sanctions of drug use (themselves a potential source of harm) have thus far hindered its adoption.

DISPELLING THE MYTHS OF PED USE

A wide range of substances is used by a minority of adolescents and college students to enhance appearance and performance. Most often they are dietary supplements that have few serious adverse consequences and do not inevitably lead to use of "hardcore" PEDs. This review has focused mostly on AAS, as they are both the most well-researched and notorious of the PEDs. Additionally, their efficacy as appearance/PEDs is settled science. Lastly, tragic teen suicides and tribulations of tarnished sports heroes have pointed the spotlight clearly at AAS. These concerns and suggestions that exogenous androgens may have long-lasting effects on brain development among adolescents, and thus adult behavior across several domains, have justifiably led to increased scrutiny.

It is a positive sign that AAS use is rare and has recently grown rarer among adolescents in general; lifetime prevalence rates are lower than those for other drugs of abuse and have largely and steadily declined over the past decade. Available US data suggest that lifetime prevalence among college students is also relatively low and stable, although more and more recent data would clarify trends. Individual factors associated with AAS use seem to fall into two general categories; those that are general risk indicators for drug use and risky behaviors (e.g. gender, low harm avoidance,

disinhibition) and those that might be more specific to PEDs (e.g. body image concerns, sport participation, PED-using peers). Motivations for use center on the documented effects of these substances; increased muscle and improved body composition.

While most of our knowledge of prevalence and risk for PED use reflects the relative focus on AAS, our understanding of the potential consequences of the range of PEDs is more complete, given an understanding of their physiological effects and the history of most as therapeutics. Although of paramount importance, the literature on treatment and prevention, while it encompasses much speculation, may be the least evolved of all. It is not at all clear precisely what factors underlie the fortuitous decline in AAS use in recent years; perceptions of great risk from use as assessed in MTF do not mirror this trend. Ultimately, an understanding of established risk factors can be applied to foster early monitoring/identification of those in jeopardy for potential harm and knowledge of motivations and maintaining factors can inform our prevention efforts. Still, accepting that perfect prevention of PED misuse is improbable (as it has proven for other drug use), of potentially greater import is the possibility of putting moral considerations and legal sanctions aside in favor of reducing harm among those who use despite our best efforts. This does not suggest tolerance, acceptance, or promotion of use, only recognition that although PED use can never be perfectly prevented, its potentially tragic consequences can often be averted.

OVERVIEW OF SUBSTANCE USE PREVENTION

Prevention Definitions and Classifications

Substance use prevention interventions are programs tailored to address the needs of specific groups and are often designed for use in a particular setting or settings. Different prevention programs are tailored for persons

at various points across the life span. In general, the goal of these programs is to prevent drug use and abuse from occurring (i.e. of alcohol, tobacco, or other drugs; ATOD). Chronologically, prevention programs have been delineated into “primary prevention” (before the problem behavior starts), “secondary prevention” (before the disease starts), and “tertiary prevention” (before death occurs). Substance use prevention may

also be considered as “universal” (to affect the general population), “selective” (to affect subgroups at elevated risk for developing a drug problem; e.g. children of alcoholics), or “indicated” (to affect high-risk subgroups already identified as having some detectable signs or symptoms of a developing drug problem). Selective and indicated programs, taken together, also have been referred to as “targeted” programs. There are several parameters of prevention programming, as is presented next.

Prevention versus Cessation Programming

Both drug prevention and cessation approaches encourage adoption of alternative, healthy behaviors and prevention of premature death. However, prevention work focuses its impact on antecedents (e.g. neurobiological, cognitive, social, or large physical and social environmental variables) of the problem behavior, whereas cessation work focuses on stopping a current behavior from continuing to arrest ongoing consequences, helping sufferers to learn to live with some experienced consequences, and permitting recovery of functioning.

Drug use prevention programs teach participants how to anticipate the impacts of antecedents (e.g. such as desiring to feel good or accepted by others) and counteract potential influences with instruction of protective cognitions, behaviors, or access to protective social units (e.g. drug-free communities). Cessation programs instruct participants how to cope with psychological dependence on a drug and with physiological withdrawal from a drug. Cessation activities can appear with prevention activities in the same program to maximize program effectiveness since some youth may already be abusing or addicted to a substance (e.g. cigarette smoking), but may not be using or dependent on another substance (e.g. alcohol).

Message Content, Modality of Delivery, and Implementer Type

Message Content

Message content refers to the various strategies offered to prevent or stop drug abuse. Hansen hypothesized 12 mediating variables that act as change agents in substance use prevention programs, most of which have shown to have potential effects to prevent the onset of drug use (see Table 85.1). Certainly, there are many types of substantive content areas addressed in prevention programs, which are presented later on in this chapter, grouped by level of analysis: neurobiological, cognitive, micro-social, and macro-social and large physical environment.

Modality of Delivery

Modality of delivery involves utilization of the different settings or contexts within which the programming is offered. Prevention programming has been implemented primarily in schools, and it has also been utilized in medical clinics, prisons, family based home or agency settings, other community-based settings (e.g. boys and girls clubs), and various media-based settings (e.g. computer-based, television, print ads).

Implementer Type

Implementer type is the term used in characterizing the persons who deliver prevention programming. Implementer selection is important in maintaining good quality delivery of drug abuse prevention programs, which, in turn, is relatively likely to achieve preventive effects. For example, in school-based prevention work, high-fidelity implementation of prevention programs is positively associated with implementer characteristics including having favorable attitudes toward the program, comfort with program content and approach, perceived self-efficacy to implement the program, independence, innovativeness, a confident and nonauthoritarian teaching style, good overall teaching skills, and other personal characteristics such as being outgoing, adventurous, and well-organized. Implementers who build interactive methods into their teaching (as opposed to using a didactic approach) also tend to be more likely to achieve program effects, because an interactive process reduces youths’ resistance to messages and encourages discussion and consensus among group members.

Consideration of Age of Program Recipient

Many researchers believe that prevention programs should be delivered to young adolescents since tobacco and alcohol experimentation increases dramatically during this critical period. Moreover, the younger a person is when he or she starts smoking or using other drugs, the more highly drug dependent he or she is likely to become, making it more difficult to quit later in life. Most drug use prevention programs therefore have focused on combating social influences, relatively immediate antecedents of drug use during young adolescence.

Others have argued that prevention should focus on the very young (preschool or elementary school age), so that those at high risk for drug abuse can be recognized early and receive assistance. Researchers have found early intervention to be beneficial in directing individuals away from problem behaviors and to prosocial activities. In particular, teaching youth how to bond with institutions and family members has been found to be an important early preventive function.

TABLE 85.1 Twelve Mediating Variables as Change Agents in Substance Use Prevention Programs

Mediating variables	Description
1. Normative beliefs	Perceptions about the prevalence of drug use among close friends and same-age peers at school, and the acceptability of substance use among friends
2. Lifestyle/behavior incongruence	The degree to which an individual views substance use as incongruent with personally held current lifestyle and future aspirations
3. Commitment	Effortful, possibly public commitment regarding not using substances
4. Social, psychological, and health beliefs	Individual's beliefs about, for example, what it means to be a part of a group, what it means to have fun, and one's conception of health risk behaviors
5. Resistance skills	The perceived ability to identify and resist pressure to use drugs
6. Goal-setting skills	The degree to which one is able to engage in goal-setting behaviors
7. Decision-making skills	The degree to which one understands and applies a rational strategy for making decisions
8. Alternatives	Awareness of and participation in enjoyable activities that do not involve substance use
9. Self-esteem	The degree to which one feels personal worth and perceives possessing characteristics contributing to a positive self-evaluation
10. Stress management skills	Perceived skills for coping with stress including skills for relaxing as well as for confronting challenging situations
11. Social skills	The ability to establish friendships, be assertive with friends, and get along with others
12. Assistance skills	The degree to which an individual believes in one's ability to give assistance to others who have personal problems

Note: See Hansen (1992).

Yet, others suggest that drug abuse prevention programs would also be effective if implemented when drug misuse was truly beginning to become problematic, among older teens for most people. If the person continues to use drugs, then motivation enhancement to not misuse drugs, skills to engage in other nondrug-related activities, and decision-making to take effective action appear to be important strategies for successful prevention.

Possibly, targeting youth with different types of prevention programming at different points in development would bolster overall effects, though such an assessment remains for future research. However, there is some consensus that substance use prevention programs are found to be most beneficial when an individual is developmentally able to learn specific material, when the content of the material is meaningful and relevant to the individual, when the material is provided in contexts that permit exposure to most of the material, and when implemented by highly trained or effective facilitators.

History of Drug Abuse Prevention Programming

Drug education programming for adolescents and youth in the United States can be traced at least as far back as the early 1900s when every state and territory

in the United States had passed legislation mandating some form of temperance instruction to be taught in the public schools. This instruction focused on the moral evils of using alcohol, tobacco, opium, and other drugs. Since then, different drug use prevention strategies have been developed and implemented (see Table 85.2). In the 1960s, most of the prevention programs were based on the premise that if youth knew why drug use was bad for them, they would choose to not start using. However, the effects of these programs were found to be either ineffective or equivocal. More recently, comprehensive social influences/life skills programs were developed and evaluated, showing effects lasting an average of 5 years post-program. These programs are conceptualized primarily at a micro-social level, as is discussed later on.

SUBSTANCE USE PREVENTION FOR YOUTH: A MULTI-LEVEL APPROACH

The following sections discuss prevention programming strategies from four general substantive perspectives: neurobiological relevant, cognitive processes, social groups, and the large social and physical environment. For each perspective, an overview of the perspective is provided, and evidence-based strategies or potentially effective strategies from within that perspective are provided. In practice, many prevention

TABLE 85.2 Timeline for Substance Use Prevention Program Message Contents

Drug use prevention program	Key concepts
1900s	
Temperance instruction	Focuses on the moral evils of using alcohol, tobacco, opium, and other drugs
Scare tactics	Use of graphic descriptions of physical consequences and moral degradation associated with drug use
1930s	
Responsible use programs	Waiting until one is grown up (18 years of age) so that one can make a responsible, mature choice
1960s	
Fear-based model	If youth were frightened about the potential negative effects of drugs, then they would not want to experiment with drugs
Information-based model	Providing youth with factual information about drug use would prevent them from engaging in the behavior
Affective or values-based model	Addresses global attitudinal changes such as enhanced self-esteem, improved decision-making and goal-setting, and clarification of one's life values
1970s	
Social influence-based programs	Expose young people to social pressures involving tobacco or other drug use in a safe environment and to teach them skills that could then be transferred to the real-world; expanding to include general life skills and coping enhancement

programs are composed of elements of each of these domains, so the division herein provides insight into assumptions behind different strategies rather than delineating different programs per se. In addition, it is likely that some strategies may impact multiple substantive perspectives. Thus, some strategies presented in the following sections are repeated across perspectives.

Neurobiological Relevant Prevention Programming

Overview

Some individuals are more susceptible to the reinforcing effect of drugs due to variation in phenotypes of neurobiological systems. Therefore, prevention programs may need to be tailored to these at risk people. For example, sensation-seeking individuals may require fast-paced programming and healthy sensation-seeking alternative behaviors, whereas anxiety-sensitive individuals may require emotional learning or mood management programming including behavioral, contextual, or medication options. Approaches discussed herein that might be considered neurobiologically related include: emotional learning, sensation-seeking strategies, self-control strategies and a targeted motivation-skills-decision making prevention model. Certainly, neurobiological-related prevention programming is only recently being directly investigated and relatively little empirical support is available.

Emotional Learning

It is becoming more evident that social and emotional competence is important in successful neural development. Some believe that prevention programming should be applied to very young children to enhance social and emotional learning when the brain is still rapidly developing. At this time, developing the ability to competently express oneself emotionally and socially through education programs that provide instruction on emotional regulation may help individuals minimize a sense of emotional discomfort that might otherwise promote drug use. There are some evidence-based programs suggesting such effects. An example of a program for young children that focuses on social and emotional learning is the I Can Problem Solve (ICPS) program. Words that are precursors to understanding consequences and problem-solving are instructed. Some research indicates that through the ICPS, young children learn alternative ways to solve interpersonal problems.

Sensation-Seeking

Youth may attend to and process information differently due to variation in neurobiologically based traits. The reinforcing effects of drugs play a key role in promoting continued drug-use behavior, especially for sensation-seeking and novelty-seeking individuals. Since individuals higher in sensation-seeking may have a neurobiologically based need for stimulation, it is

likely that drug abuse prevention messages need to be novel and exciting enough to get their attention. For example, Palmgreen and colleagues utilized sensation-seeking as a risk factor for drug misuse in the development of a mass media marijuana-use prevention campaign. Five professionally produced 30-second television spots that involved material likely to appeal to youth high in sensation-seeking (e.g. fast-paced and novel) were produced and aired extensively. After program development was completed, the campaign was implemented and evaluated using a controlled interrupted time-series design in two matched communities. The campaign reversed upward developmental trends in 30-day marijuana-use among high-sensation-seeking individuals; in other words, about a 10% decrease in use was observed the year following the campaign.

Self-Control

Executive cognitive functions are mediated by prefrontal brain regions implicated in behavioral regulation and decision-making processes. Brain-based neurocognitive functions implicated in behavior regulation and decision-making may moderate prevention program outcomes. Findings from studies on neurological development suggest that youth decision-making ability and emotion-regulation skills are not fully developed. However, relatively poor executive cognitive functioning has been found to be associated with current drug and alcohol use, lower social competence, and predicts the onset of drug-use disorders among adolescents. Training of self-control skills may include instruction on assertiveness, impulse control, and anger management. For example, in assertiveness training, youth may learn, through modeling, behavioral rehearsal and role-play instruction, statements that include in combination acknowledgment of the other person, self-statements of preference, and action statements. By learning assertiveness, the youth may be able to better inhibit neurobiological tendencies to express anger. Youth may also be instructed to learn to think ahead and anticipate problem situations, as well as avoid high-risk situations. Some prevention programs that include such strategies do find effects on drug use; however, these strategies generally are included along with many others and component effects have not been isolated. A few research studies have shown that pre-existing neurocognitive proficiency may enhance prevention outcomes, whereas neurocognitive deficits may attenuate program effects. Therefore, prevention programs might need to consider supplemental materials for youths with neurocognitive deficits who do not respond as well to the general core curriculum.

Targeted Drug Abuse Prevention

While not well-grounded in neurobiological research, some researchers and practitioners assume that targeted programs are neurobiologically relevant because they target at risk youth (who may be more vulnerable to later drug abuse). Sussman and colleagues reviewed 29 evidenced-based, targeted drug abuse prevention programs and concluded that effective targeted programming (1) motivates the at-risk recipients to not desire to misuse drugs, (2) teaches skills to bond to more conventional venues, and (3) trains at-risk recipients in decision-making to tie motivation material to skills material and take self-fulfilling action. This has been labeled a motivation-skills-decision making model of drug misuse prevention.

Cognitive Processes in Prevention Programming

Overview

Cognitive processes can influence behaviors through both rational and nonrational motivations. Many researchers view drug abuse as unlikely to be motivated by (only) rational decision-making. Therefore, some cognitive-based prevention strategies include both rational and nonreflective cognitive processes. This section addresses drug abuse prevention strategies that focus on counteracting (1) cognitive-information errors, (2) cognitive processing limits, (3) belief-behavior congruence errors, and (4) contextual/situational distortions.

Cognitive-Information Errors

Cognitive-information errors associated with youth drug use include drug use prevalence overestimates and error-related myth formation. Drug use prevalence overestimates can be counteracted through an "overestimates reduction" prevention activity. For example, youth can self-report their drug use in the past week and poll their perceptions of the numbers of peers who have used the drugs over the same period of time. Then a comparison of the actual prevalence of drug use among peers derived from their own self-reports (in a group setting) with the mean perceived estimate of peer drug use prevalence are presented to them. By becoming aware that they tend to overestimate their estimates of their peers' drug use (a cognitive-information error, due in part to a biased encoding of novelty-type inputs), youth may be able to reduce their prevalence estimates and also reduce their expectations that they should use drugs in the future. A conservative shift in cognitive information/beliefs is an important preventive effort, and in general, relatively low prevalence estimates are predictive of less drug use in the future. While perhaps a primarily cognitive-based

strategy, prevalence overestimates reduction has been found to be a main mediator of the impact of comprehensive social influences/life skills drug abuse prevention programs (such as the Alcohol Abuse Prevention Trial and the Midwestern Prevention Project).

Elaborative processing of information can be used to counteract cognitive-information error-related myth formation. For example, as used in the curriculum, Project Towards No Drug Abuse (TND), a discussion about the “kernel of truth” is provided for popular drug-use myths (e.g. when one no longer gets sick after trying cigarette smoking couple of times, one has subjectively “gotten used to the effects”). Youth discuss the myth and then discuss why the myth is, in fact, a myth (e.g. no longer getting sick means that the body is no longer providing danger signals about poisons invading the body and is the beginning of addiction). In order to construct meaningful memories, it is important to elaborate the difference between more immediate subjective gratification and the impact of longer-term negative consequences of drug use. One caveat needs to be noted in presenting myths and truths to youth: myths might be retained as facts after the program is completed if memory processes are not considered. For example, it has been shown that myths about alcohol use can be retained as facts after 24 hours. Therefore, it is important to use elaborative processing strategies so that myths are more likely to be retained in memory over time as being myths.

Cognitive Processing Limits

As discussed in the neurobiological section, executive functions are higher order cognitive constructs that are involved in the planning, initiation, and regulation of goal-oriented behavior. Executive functions are related to inhibitory control over behavior and counteracting the influence of more spontaneous cognitions and implicit processes. To enhance the effects of prevention interventions, newly learned program information must compete with relatively automatic, existing memory associations. Drug use prevention materials often encourage executive planning and judgment in high-risk, drug-related social situations. Program material that helps youth cope with cognitive challenges faced in high-risk situations, for example, practice in self-instructional training (to elicit protective cognitions when needed) may be an important element of drug use prevention programs.

The Promoting Alternative Thinking Strategies (PATHS) project provides elementary school youth with opportunities to practice self-control strategies including verbal mediation (self-talk) and inhibitory control via curriculum lessons and the integration of a “Control Signals Poster.” The red light signals “Stop-Calm Down”, yellow light signals “Slow Down-

Think”, and green light signals “Go-Try My Plan.” Students significantly improved their perceived efficacy in managing emotions and problem-solving skills. While there is some evidence that various self-instructional training strategies decrease impulsive behavior among youth (e.g. Meichenbaum’s Self-Instructional Training protocol, the PATHS project stoplight protocol), research is needed to assess more specifically cognitive mediation skills application to drug abuse prevention.

Belief–Behavior Congruence Errors

Belief–behavior discrepancies occur when an individual engages in self-destructive behaviors that may be contrary to their basic beliefs about themselves – because they often do not think about how their beliefs relate to different behaviors. There are three classroom-based strategies that attempt to make youth aware of their own belief-behavior discrepancies and be induced to reduce these discrepancies through healthful action. These three activities are contained in Project TND. The *stereotype activity* consists of having youths explicitly stating the discrepancy between how deviant they view themselves versus how deviant they think others view them and their peers (generally youth see others as viewing them and their peers as more deviant than they actually are). Then youths consider reacting against a self-fulfilling prophesy by not acting more deviant, and decreasing drug use. The *attitudinal perspectives activity* is one where youth identify their general sense of self as a moderate person (most people view themselves as moderate people). When they engage in an exercise that places drug use on a traditional, moderate, radical continuum, they may realize that to continue to view themselves as moderate person, they need to decrease their drug use (which tends to be viewed as radical behavior). Finally, the *health as a value activity* involves asking youths what they want to accomplish in the near future. Most will say that they want to improve their lives (e.g. through continued education). They are asked to consider how important their health is to reach their goals. Then they are asked to consider if drug use will injure their health. Youth realize that to achieve their goals they may need to maintain their health and decrease their drug use (see Table 85.3).

Contextual/Situational Distortions

People prone toward drug misuse may distort situations to make them seem more positive than they are. For example, stories about youths being drunk and losing their car for a couple of hours often are told as if they are humorous rather than being difficult situations. These distorted meanings of behavior, or mystification processes, may be counteracted by direct confrontation. For example, humorous cartoons can be presented and

TABLE 85.3 Strategies to Increase Awareness of Belief-Behavior Discrepancies

Strategy	Description	Examples
Stereotyping	Tendency to rebel against the stereotype when discrepancy is brought to awareness	Counteracting stereotype by engaging in pro-social action and informing others of one's healthful pursuits
Attitudinal perspective	Tendency to change behaviors rather than change self-perception as a moderate person	Recognizing a specific attitude that drug use is consensually considered radical behavior so that one should not engage in drug use in order to be a moderate person
Health as a value	Tendency to not want to give up life goals so that health as a value becomes more important, and one thinks more seriously about drug misuse as health deterring	Considering what they want to accomplish in the future and whether health is important to accomplish these goals and whether drug use can interfere with their health

discussed in a group setting; that reveal situational distortions. Also, use of psychodramas or "talk shows" (a social group activity that can induce a cognitive change) can assist in eliciting responsibility and consequences information and achieving healthy changes. These two strategies are instructed in Project TND.

Social Group-Related Prevention Programming

Overview

Applying prevention programs in social settings (e.g. in groups) is essential to induce and maintain change among youth. It not only can help correct youth's cognitive misperceptions, but also provide a venue for practicing newly learned behavioral skills with corrective input from educators and feedback from peers that may mimic real-world social situations. This section discusses several prevention program strategies that involve social groups, including the elements of comprehensive social influences/life skills programs and community unit-based involvement.

Elements of Comprehensive Social Influences/Life Skills Programs

These programs aim to create awareness of the impact of social influences on behavior and to counteract these influences by enhancing social skills (e.g. listening and communication skills training, refusal assertion training, social decision-making, and activism skills) and correcting social misperceptions (e.g. correction of use prevalence overestimates, normative restructuring, and media literacy; see Table 85.4).

Project Towards No Tobacco Use (Project TNT) is a model comprehensive social influences/life skills tobacco use prevention program that targets young adolescents. The 10-day, classroom-based core curriculum provides detailed information about health consequences of tobacco use and addresses topics including building self-esteem, active listening, communicating effectively, refusal assertion learning and practice,

noncompliance coping to enhance self-confidence and decrease perceived social influence to use tobacco, counteracting advertising images and social activism to change norms, and decision-making/public commitment. Five homework assignments, classroom group competitions, and a two-lesson booster program provided the following year are used to maintain student involvement.

To evaluate the Project TNT curriculum, 6716 7th grade students from 48 junior high schools in Southern California were randomized into five conditions (four programs and one control). Four curricula were developed and examined. Three were designed to counteract the effect of separate (single) program components (normative social influence [direct pressures to be liked by using tobacco], informational social influence (indirect pressures to adopt beliefs facilitative of tobacco use), and physical consequences). The fourth was a comprehensive curriculum that designed to counteract all these three components. The comprehensive curriculum showed the largest effects on behavior and is now being disseminated throughout the United States. Compared to the control group, this program exerted significant effects at 1- and 2-year follow-ups on initiation (30% relative reduction) and weekly use (60% relative reduction) of cigarettes and smokeless tobacco. More recently, the comprehensive curriculum was found to be effective over a 1-year period when delivered among 6th and 7th graders in 14 East Texas countries, and it has been demonstrated to be cost-effective.

Community Unit-Based Involvement

Most social influence-based prevention programs occur in the school classroom setting. There is evidence showing that school-based programming can be successful. Indeed, school-based programming is a central means of delivery since youth are a captive audience to this type of programming. However, as introduced earlier in this chapter, other community units may exert preventive effects. In particular,

TABLE 85.4 Eleven Components of Comprehensive Social Influences Programming

Components	Description
1. Listening and communication skills	To improve listening and communication skills by demonstration of appropriate behavior, modeling of appropriate behavior, behavioral rehearsal, and feedback components
2. Refusal assertion	Training on how one might best refuse a drug offer or request of someone else (e.g. to refuse drug offers assertively but not aggressively or passively)
3. Short- and long-term physical consequences information	Although not directly addressing social influences, group activities are used to discuss short- and long-term physical consequences of substance use and to explain why it is important to not misuse drugs
4. Peer group unacceptability of drug misuse	Use group activities to make it known among group members that drug misuse is not as widely accepted by their peers as they may perceive (e.g. taking group polls on acceptability of drug misuse among peers)
5. Correction of use prevalence overestimates	Activities to reduce prevalence of use overestimates which involve clarifying the true prevalence of drug use among peers and correct overestimates of perceptions of drug use prevalence among peers
6. Awareness of adult influences	Discussions with the focus on adult drug use as a problem behavior with grave consequences among youth since youth often attempt to copy adult role models when they use drugs
7. Media literacy	Make youth aware of adult advertising influences so that they are less likely to yield to pro-drug use images portrayed in the media
8. Activism	Encourage youth to participate in anti-drug use activism (e.g. writing letters to tobacco and alcohol industry) in order to personalize knowledge, become active learners, and encourage belief change in society
9. Self-confidence building and decision-making	Information on cognitive techniques such as making positive affirmations to self and others, and help youth learn how to rationally combine information to make positive decisions in different problem areas
10. Making a commitment to not use drugs	Encourage youth to make public commitments (e.g. before a group of peers) not to use tobacco and other drugs with the assumption that such commitments put their self-respect at stake in order to discourage them from drug use
11. Smoking and other drug use cessation materials for older teens or adults	Provide materials to older teens or parents who are regular smokers or drug users and need information on how to cope with withdrawal symptoms

regarding the micro-social climate, it is important to recognize the influence of the family unit because of the close and historical patterns of interaction within the unit. Family involvement-based programming is a relevant way of providing prevention material outside school and can lead to a 15% relative effect in compliant families (e.g. the Strengthening Families Program and Family Matters are two examples). Strategies to strengthen family dynamics in such programs include instruction in family skills training and resource acquisition instruction, family therapy, cognitive and behavioral parent training, contingency management, stimulus control, and family support training to prevent drug use.

Large Social and Physical Environment Prevention Programming

Overview

Available research suggests that program effects are most likely to be maintained by utilizing multifaceted approaches to prevention, whereby youth receive a consistent message across community contexts and over time. For example, tobacco and other drug use access reduction, family programming, mass media programming, involvement of community organizations, and school-based programming may combine to achieve a system-wide approach for the largest

intervention effects (possibly doubling effects achieved by single-unit programs). Prevention programming that permeates the larger social environment can have wide-ranging influences since it could affect various micro-groups and individual perceptions, attitudes, and behaviors through monopolization of messages being provided to youth. However, much research still remains to determine which modalities, administered for how long, are needed to increase system-wide prevention programming effectiveness.

Large physical and environmental influences on drug use include presence or level of drug manufacturing and distribution channels and presence of pro-social/physical environmental resources. Pro-social resources availability such as teen centers and libraries, might lead youth to seek out options other than drug use. In addition, supply reduction approaches (e.g. policy enactment and enforcement) may decrease or redirect drug distribution, thus, drug use may decrease. This section discusses larger social and physical environmental approaches to drug use prevention programming including use of community coalitions, mass media-based prevention programming, obtaining social and physical environmental resources, and supply reduction.

Community Coalitions

Large community interventions may involve a range of program channels (e.g. schools, family groups, media, community agencies, local governments, church, and health groups) that demand coordination to provide consistent and sustained prevention messages. *Coalition building* involves formation of partnerships among key organizations and individuals, regular meetings among partners, and action planning to carry out change. Hallfors and colleagues examined 12 coalition sites that were involved in a large-scale drug and alcohol demand reduction program in the United States and found that strategies aimed at youth or community outcomes failed to have significant effects, and many coalitions did not last very long. For coalitions to be most effective, they should be well-organized, focused on specific goals, manageable, select evidence-based prevention programs to promote, and obtain expert assistance while facilitating implementation of these programs. In addition, to make sure that appropriate actions are taking place at each step of coalition building and action, coalitions should consider their role as being primarily to coordinate units, restrict environmental access, and maintain good communication with researchers, health educators and evaluators. Community Anti-Drug Coalitions of America (CADCA) is an umbrella organization for more than 5000 antidrug coalitions that began in 1992. It holds numerous media events, anti-drug gatherings, engages in information dissemination through newsletters, engages in lobbying efforts, and coordinates

partnerships with other coalitions and anti-drug organizations. While research is needed, CADCA's coordination efforts may have an important, indirect/coordinating effect on drug use prevalence among youth.

Mass Media-Based Prevention Programming

The mass media can affect a very large range of social regions because of its potentially very broad reach. Media literacy strategies that enhancing youth's logical responses to media messages (e.g. movies that appear to glorify alcohol use) and raising their awareness of their own emotional responses have been shown to help prevent a variety of risky behavior outcomes, including substance use, among middle and high school students, as well as among elementary school students. It has been found that for mass media campaigns to have the strongest effects on drug misuse, the contents may depict a dramatic true consequence of drug use, take an activism stance, advocate for greater autonomy experienced by non-drug use lifestyles, appeal to sensation-seeking youth by fast-paced material with descriptions of exciting activities (e.g. as was described in the neurobiological section), attempt to provide a media literacy impact, or correct misperceptions of drug use norms.

Internet-based prevention programming provides a very pragmatic way of surveying and intervening with various populations since its use is inexpensive and convenient, and information can be processed quickly. A study by David Buller and colleagues to test the effectiveness of Internet-based programs to reduce smoking prevalence and positive smoking-related outcome expectancies found a decrease in 30-day smoking prevalence and lower expectation for smoking in the future among its Australian but not American adolescent subjects, respectively (behavioral results were obtained only in the Australian sample, a 26% relative reduction). In addition, newer technology interventions are being considered in ongoing research such as virtual reality simulations, interactive computer and other communication devices, and portable computer devices (e.g. the use of cell phones, text messaging).

Obtaining Social and Physical Environmental Resources

A meta-analysis of the Center for Substance Abuse Prevention high-risk youth and family programs suggests that increases in drug use have resulted from engagement in certain recreational activities such as rock band concerts, sports that involve peer or adult drug users, and some vocational or community-service activities (e.g. housing construction and house painting, where adult drug users might be involved with youth). On the other hand, academic achievement and aspiration-related activities, religious activities, anti-drug

activism-related involvement and active personal hobbies are inversely related to drug use. Therefore, establishing facilities that provide youth opportunities to obtain access to pro-social (e.g. drug-free recreation alternatives/hobbies, jobs) and physical environmental resources (e.g. libraries, gymnasiums) may be an effective community-level strategy. In addition, direct instruction, modeling, and structured practice in resource acquisition skills may also help youth to increase their knowledge and self-efficacy on how to obtain pro-social resources and to readily access resources when needed. Certainly, research is needed on manipulation of resource acquisition and drug use prevention effects.

Supply Reduction

Supply reduction involves legal regulation of substances and can be accomplished by environmental prevention strategies such as prohibitory policy mechanisms (of production or distribution) and regulatory policy mechanisms (setting conditions of use, information about use, sanctions). Some other regulatory manipulations include the use of large warning labels (which actually is a demand reduction-oriented regulation), and enforcement of underage use laws at convenience stores. For example, Reduce High-Risk Drinking is an environmental intervention to increase community awareness, prevent access to alcohol for underage drinkers, and enforce laws regarding alcohol use and sales. This project has reported that individuals living in the intervention community sites reduced drinking compared with individuals living in comparison sites (51% relative decline in self-reported drinking over the legal limit, 6% reduction in DUIs).

Supply reduction or regulation strategies not only reduce access; they may alter demand in the larger social climate (e.g. that drug use is good or bad because it is legal or illegal). Until recently, the primary supply reduction method was interdiction (i.e. forbid use by actions of authorities). However, interdiction has been expensive and not very successful. Domestic enforcement costs four times more than treatment for a given amount of user reduction, seven times more than consumption reduction, and 15 times more than societal cost reduction.

SUMMARY

This chapter addressed different approaches for drug use prevention programs targeting school-aged youth, considered from the lens of neurobiological, cognitive, social group, and large social and physical environmental-related perspectives. A focus on implementing interventions that address neurobiologically based trait

variations for individuals who are highly vulnerable to reinforcing drug effects and incorporating components that address cognitive mediators and moderators of drug misuse may provide preventive program impact at the individual-level. Micro-social group strategies also impact individuals' cognitions and behaviors, and are key foci of programming. Aggregated, macro-social level effects may be larger than the impacts of individual community units. In addition, larger social and physical environmental climates "set the stage" for culturally expressed group and individual perceptions and attitudes that impact illicit drug use policy change and make resources available for drug use prevention programs. Future research and programmatic efforts may be guided by considering all the above four perspectives.

INTRODUCTION

Problem drinking, in all its facets, lies at the heart of a major health and socioeconomic burden worldwide. Individuals whose alcohol consumption exceeds the accepted guidelines for low-risk drinking can be defined as problem drinkers. Various gradations of substance use disorders may underlie their alcohol consumption. (see [Box 86.1](#) for an overview of specified alcohol use disorders, and see *Alcohol Use Disorders and Symptoms and Course: Alcohol Use Disorder in Adulthood*.)

Screening and brief intervention procedures (SBIs) have been found to be cost-effective in curbing adult problem drinking notably in primary care populations. Yet the number of problem drinkers reached by SBIs in primary care is very small (5–10%). This is due largely to a host of implementation barriers, including time, money, professional training constraints, and the fear of many general practitioners of confronting patients with their drinking habits. The uptake of SBIs by problem drinkers themselves is also low. Many feel shame and loss of privacy, and such perceptions inhibit them from seeking professional help. From a public

BOX 86.1**ALCOHOL USE DISORDERS**

- Abstinence is defined as refraining from drinking alcoholic beverages.
- Moderate use is conceptualized as drinking less than 21 drinks per week for men and less than 14 drinks per week for women.
- Heavy use is defined as drinking levels in excess of 21 drinks per week for men and in excess of 14 drinks per week for women.
- Hazardous use [ICD-10 code Z72.1] is a pattern of heavy drinking and/or binge-drinking that carries with it a risk of harmful consequences to the drinker. These consequences may be detrimental to physical or mental health, or have adverse social consequences to the drinker or others. Other potential consequences include worsening of existing medical conditions or psychiatric illnesses, injuries caused to self or others, due to impaired judgment after drinking, high-risk sexual behavior while intoxicated, and worsening of personal or social interactions.
- Harmful drinking [ICD-10 code F10.1] is a pattern of drinking that is causing damage to health. The damage may be either physical (e.g. liver cirrhosis from chronic drinking) or mental (e.g. depressive episodes secondary to drinking). Harmful patterns of use are often criticized by others and are sometimes associated with adverse social consequences of various kinds. Harmful drinking has persisted for at least 1 month or has occurred repeatedly over the past 12-month period; subject does not meet criteria for alcohol dependence.
- Alcohol dependence [ICD-10 code F10.2] is determined if the drinker has at least three of the following: tolerance; withdrawal symptoms; impaired control; preoccupation with acquisition and/or use; persistent desire or unsuccessful efforts to quit; sustains social, occupational, or recreational disability; use continues despite adverse consequences.

Based on the publication by Saunders et al. (1993)

health perspective, then, the current impact of SBIs in the real world is limited. SBIs not only need to be effective in themselves, but large populations of problem drinkers would have to use them before the envisioned health and economic gains could be achieved.

Broad public access to the Internet has now opened new avenues to reach out to the large but yet uncontacted group of problem drinkers. One such opportunity involves Internet-delivered screening and brief intervention programs (ISBIs) aimed at curbing adult problem drinking and other substance use disorders. The availability of such ISBIs, especially those for problem drinking, has meanwhile expanded rapidly in many high-income nations, including the United States, Canada, Australia, and many Western European countries. These have both high levels of Internet penetration and a strong public health focus on problem drinking. This chapter discusses ISBIs designed for adult problem drinkers (*see Adolescent Substance Use: Symptoms and Course, Developmental Risk Taking and the Natural History of Alcohol and Drug Use among Youth, Screening and Assessment of Substance Use Disorders in Youth and Young Adults, Individual Prevention of College Student Alcohol Misuse and Substance Use Prevention Approaches for School-aged Youth for young people*). For the prevention of illicit drug use, our chapter deals with ISBIs for both adults and adolescents.

INTERNET-BASED SCREENING AND BRIEF INTERVENTION RESOURCES FOR ADULT PROBLEM DRINKING

Screening and brief intervention procedures (SBIs) are available in different modalities, including face-to-face encounters between a health professional and an individual or a group of problem drinkers. These procedures can also be delivered by telephone or mail. More recently, screening and brief intervention programs have been provided by the Internet on PCs or smart phones. Like the more conventional SBIs, these ISBIs target adolescent and adult individuals that consume alcohol. Such groups may also be targeted via specific environments, such as school, community, workplace, or primary care settings.

Universal, Selective, and Indicated ISBIs

The various ISBIs may be distinguished into universal, selective, and indicated interventions, in accordance with Marzek and Haggerty's classification of prevention strategies from 1994. *Universal* ISBIs are designed to inform everyone in a particular population (such as a school or community); in relation to alcohol, this implies all individuals, regardless of whether and how much they consume. National alcohol awareness campaigns providing links to

online resources are examples of universal prevention strategies (see, for instance, the US site <http://www.samhsa.gov/>). *Selective* ISBIs target subgroups of specific populations that are at additional risk for problem alcohol use. Web-based self-help interventions designed for pregnant women in the community would be an example of selective ISBIs, given the greater health risks of alcohol to both mother and baby. *Indicated* ISBIs are focused on people who already drink alcohol in amounts that exceed the recommendations for low-risk drinking, but who do not have a clinical diagnosis of alcohol abuse or dependence (such as from *DSM-IV*). Examples of indicated prevention for problem drinkers are the Dutch ISBI entitled *MinderDrinken* and the Canadian *Drinker's Check-Up* (DCU), both of which are designed to help problem drinkers curb their alcohol use and diminish alcohol-related problems.

Minimal and Extended ISBIs

ISBIs are available in minimal and more extended formats. *Personalized normative feedback* (PNF) interventions consist of screening and self-help, often in a single session. Participants receive personalized feedback based on their personal alcohol consumption as compared to recommended guidelines for low-risk drinking. Often this includes normative feedback, whereby problem drinkers compare their own drinking patterns (in terms of frequency, quantity, or other measures) to those in their peer group. One purpose of PNF interventions is to correct misperceptions that problem drinkers often have about low-risk drinking guidelines or about drinking prevalences among their peers. More extended forms of ISBI include *protocol-driven self-help treatments* based on principles of behavioral self-control, cognitive-behavioral therapy (CBT), motivational interviewing, or a combination (see *Motivational Enhancement Approaches, Cognitive Behavioral Therapies, Twelve-Step Facilitation Therapy, Contingency Management* for a detailed description of treatment principles). Self-help refers here to a type of psychological treatment in which participants work through the procedure more or less independently. Although the exact components may differ for each intervention, most contain several common elements. These include (1) self-assessments of alcohol consumption patterns, (2) psychoeducation on cognitive and behavioral change strategies, (3) goal setting for alcohol moderation or abstinence, (4) self-monitoring of daily alcohol consumption, (5) strategies to maintain alcohol reduction patterns, and (6) relapse prevention techniques. ISBIs often also make use of online, moderated peer-to-peer discussion groups. The recommended duration of use for extended ISBIs is 4–6 weeks, a time frame in which positive behavioral changes in problem drinking are expected to occur.

Unguided and Guided ISBIs

Online prevention and treatment for problem drinking can be delivered with different amounts of support from health professionals. At one end of the continuum we find *online self-help interventions without professional guidance*. Unguided ISBIs are currently being delivered on a broad scale in routine alcohol prevention practice. At the other end of the scale there are *therapist-guided online therapies* consisting of multiple sessions and self-help exercises. The guidance may take place in asynchronous web-based communication (e.g. e-mail exchanges) or in real time through web-based chat sessions. Such guided online treatment is only available on a very small scale as of yet, for example, in the Netherlands. ISBIs with more limited guidance by coaches or therapists have scarcely been implemented for adult problem drinking, in contrast to their use for disorders such as depression and anxiety. ISBIs may also be used as a component of face-to-face SBIs or more intensive treatment (as a partial replacement or as an adjunct), in order to expedite the therapeutic process, improve its quality, and/or reduce costs. Guided ISBIs can be provided by different types of certified professionals (GPs, counselors, psychotherapists, substance use prevention workers), depending on the nature and intensity of the desired therapy and the prevailing legal requirements.

PROS AND CONS OF ISBIs

Screening and brief interventions delivered over the Internet have a number of advantages over other modes of SBI delivery (face-to-face, postal, or telephone). Advantages involve user acceptability, aspects of service delivery such as cost savings and intervention quality, and research optimization.

User Acceptability

ISBIs can potentially reach broad groups of problem drinkers without regard to geographical distance or time (24/7). Participants can work with the programs in their own time, at their own speed, and often free of charge. They can perform them in virtual anonymity, allaying fears of stigmatization and privacy violation. The high level of privacy may help persuade large groups of problem drinkers to work on their alcohol problems, something they might not have done in a more traditional SBI.

Intervention Qualities

Timely accessibility is not only an important feature from the standpoint of participant convenience, but it

serves a therapeutic goal as well. Help-seeking behavior and motivation to change are often fleeting in nature. In many cases, an actual decision to seek help is a consequence of unforeseen situations, adverse effects of alcohol use, or both. Giving problem drinkers access to help at the right moment may therefore strengthen their motivation and thereby their likelihood of successful change. ISBIs make this timely access possible. Other qualities of ISBIs relate to the delivery of the intervention as intended. Treatment fidelity is high for ISBIs, owing to the protocol-based, structured, and automatic features that minimize delivery differences. ISBIs can provide immediate automated feedback on self-reported information. They can automatically monitor and report on participants' progress, both to the participants themselves and (in guided treatment) to the facilitating professionals. The Internet also facilitates various options that may heighten the appeal of ISBIs to participants, such as graphic, audio, and video features to complement text-based components.

Service Delivery and Research

Although the costs of developing ISBIs may be considerable, most programs, especially those without guidance, offer cost benefits, as they can be delivered to large numbers of problem drinkers at a low marginal cost per additional user. Even if they provide therapist support, ISBIs still may save time for both therapists and participants when delivered as stand-alone interventions or as components of face-to-face therapies (e.g. by reducing the number of sessions needed). Other features that increase the economic attractiveness of ISBIs include shortened waiting lists and saved traveling time. ISBIs also greatly simplify the process of effectiveness research, as both participant recruitment and data collection can be carried out automatically through the Internet.

Disadvantages

Some of the current disadvantages of ISBIs are likely to be overcome through future research and practice. Web-based interventions may not be suitable for all problem drinkers, such as those that are computer illiterate or have low reading levels. Others may find online help disagreeable or inconvenient, whether it is with or without professional support. For yet another group, the complexity of the alcohol problems may preclude treatment with ISBI, and more intensive or inpatient treatment may be required. Some coaches or therapists may also not possess the specific skills needed for giving online therapy.

AVAILABILITY, ACCEPTABILITY, AND USER PROFILES OF ISBIs

Internet-delivered SBIs have grown rapidly in number, particularly in the United States, Canada, Australia, and in European countries such as the United Kingdom, Finland, Sweden, and the Netherlands. Since 2000, process evaluation studies have reported on the availability, user acceptability, and user profiles of (mainly unguided) ISBIs for adult problem drinkers in the general population. These studies afford ample evidence that a sizable adult population seeks web-based help for problem drinking and is satisfied with that type of intervention. To illustrate, it is not uncommon for an ISBI to reach 10 000 participants within a very short time. Such successful outreach has never been achieved with conventional modes of SBI delivery. These numbers should not only be compared to the reach of the usual prevention or treatment strategies but also to the potentials of the various modes to reach the overall intended group. A conservative estimate in 2009 found that a single low-cost, unguided self-help intervention could reach around 2.5% of the target group, even without active recruitment. This is high, as the overall percentage of this population of problem drinkers reached by health care services is only 5–10%.

ISBIs generally appear to attract similar groups of problem drinkers in terms of sociodemographic profiles and severity of alcohol use. The majority of adult participants belong to the 35- to 55-age group. They are relatively more likely to be female, with an ISBI gender participation ratio of 1:1, as compared to a male–female ratio of 4:1 in problem drinking prevalence in many Western societies. In comparison to the general population, ISBI participants have relatively high educations, high incomes, and stable relationships. Those who actively take part in ISBIs, and especially in the extended self-help interventions after screening, drink well above the guidelines for low-risk alcohol consumption, having a mean weekly alcohol consumption from 30 to 50 standard units (of 10 g of ethanol). Their mean scores of 18–22 on the Alcohol Use Disorder Identification Test (>8 AUDIT) reveal a strong likelihood of alcohol abuse or dependence (*see* Alcohol Use Disorders and Internet Screening and Intervention Programs). Most participants are first-time-help seekers and are usually self-referred. Hence, ISBIs for problem drinkers indeed appear to address an unmet public health need.

ARE ISBIs EFFECTIVE IN CURBING ADULT PROBLEM DRINKING?

A limited number of randomized controlled trials have assessed the effects of ISBIs in reducing alcohol

consumption among participants. For unguided self-help in comparison to nonintervention, available evidence from meta-analyses suggests small- to medium-effect sizes (Cohen's $d = 0.40$) for alcohol reduction up to nine months postintervention (for an explanation of effect sizes and Cohen's d , see Evidence-Based Treatment). These results translate to a very favorable number needed to treat (NNT) of 5, indicating that about five drinkers must receive an ISBI to generate one positive intervention response. A fading of effect size differences in the longer term (12 months or more) has been observed, but more studies are needed to verify it. Even so, within-group differences still indicate that a substantial group of problem drinkers are consuming less alcohol at follow-up than at baseline. The small- to medium-effect sizes for unguided ISBIs compare well with those reported for face-to-face adult brief interventions in primary care and for unguided postal self-help.

Extended unguided self-help ISBIs show a medium impact in meta-analyses ($d = 0.60$), greater than that of minimal PNF-based unguided ISBIs, which have effect sizes in the small range. Such findings were not confirmed, however, in a large-scale randomized controlled trial ($N = 7935$) published in 2011. It found no significant difference in terms of alcohol reduction between a group receiving minimal psychoeducational information only and a group receiving an extended self-help ISBI procedure at any of the three assessments (at 1, 3, and 12 months). Both groups decreased their mean weekly alcohol consumption by 20 units (from 46 to 26), thus suggesting potential benefit from access to either minimal or more extended ISBIs. Differences in findings compared to other studies might possibly be attributable to differing study designs. One striking difference involves the blinding of participants to their group allocation. In most studies on unguided ISBIs, researchers inform participants to which group they will be assigned as they inform them about study aims during recruitment. Nondisclosure of group allocation is preferable, as such knowledge may influence treatment outcomes and bias results.

The effectiveness of Internet-based multiple-session therapist-guided self-help treatment has also been assessed in two studies in comparison with nonintervention. One of these found a medium effect ($d = 0.59$) for chat-based therapy, and the other found a large effect ($d = 1.21$) for asynchronous e-mail therapy in terms of weekly alcohol consumption and conformity with low-risk guidelines at 3 months after the start of treatment. Such outcomes may be initial evidence for a potentially stronger impact of guided self-help treatments as opposed to unguided ones. A 2011 study found that although unguided self-help was as effective as guided chat-based treatment at 3 months, the chat-based group fared better at 6 months in terms of a further reduction in mean weekly consumption. The medium to large effects

found for guided online treatment are similar to those found in meta-analyses for face-to-face treatments ($d = 0.80$). More research is still needed to try to replicate findings that compare guided online treatment to unguided online interventions in terms of alcohol consumption and related outcomes.

ISBIs for Problem Drinking at the Workplace

Work environments seem to be promising venues to deliver screening and brief intervention, as they potentially afford easy access to large groups of problem drinkers. It is this large population of problem drinkers in employment that is responsible for the bulk of the health and economic burden associated with alcohol misuse. Only a few studies have assessed the user acceptability or the effectiveness of workplace interventions; their outcomes are not overwhelmingly positive. One explanation for the disappointing results lies in the low percentage of employees who are willing to participate. They may fear loss of privacy or other negative consequences if they disclose themselves as problem drinkers at their place of work. ISBIs could help to overcome some of their fears, as confidentiality can be much better safeguarded in ISBIs than in conventional SBIs. When ISBIs are delivered via the workplace (mainly done up to now in large US or Australian companies), they are often components of overall employee health programs. Such ISBIs target the general employee population with preventive messages and with screening for problem drinkers and at-risk employees. Not surprisingly, such ISBIs are particularly effective for problem drinkers, delivering small to medium effects in terms of reduced alcohol consumption. Yet studies on ISBIs at the workplace are hampered by constraints similar to those affecting conventional SBIs, including limited sample sizes due to recruitment difficulties. Like conventional SBIs, ISBIs appear more acceptable to employees in work settings where alcohol use is strictly regulated, such as in the military. One study has illustrated the positive impact of two ISBIs among military personnel: Alcohol Savvy, a universal, primary prevention program aimed at adults in the workplace; and the PNF-based Drinker's Check-Up. The latter was found more effective than Alcohol Savvy, and both were superior to nonintervention.

SUMMARY, FUTURE DIRECTIONS, AND CONCLUSIONS

Summary

Internet-based screening and brief intervention programs (ISBIs) are effective, feasible, and acceptable

for delivery to many problem drinkers in the general population. The majority of people who actively use ISBIs drink well above the recommended guidelines for low-risk drinking. Most are adults between 35 and 55 years of age, relatively well educated, and in paid employment; most are first-time help seekers. Overall, ISBIs not guided by a professional have been found to produce small to medium effects compared to nonintervention. Studies of online guided treatment resources are scarce, but results suggest they may have a greater impact than unguided ISBIs. Whether the intensity of treatment will predict treatment outcomes and whether particular groups of problem drinkers will respond better to particular kinds of ISBIs needs to be examined further. The effectiveness of unguided ISBIs in reducing problem drinking is apparently comparable to that of face-to-face or telephone SBIs in primary care and of SBIs delivered by mail to adults in the community. The longer-term (more than 1 year) effectiveness of ISBIs has yet to be assessed. Differences between the outcomes of groups receiving unguided ISBIs and nonintervention control groups appear to narrow over time, though both groups tend to moderate their alcohol consumption.

Studies also show that a substantial percentage of ISBI participants do not succeed in reducing their alcohol intake. Even if they do, not all of them manage to stay below the low-risk guidelines. Yet even a reduction of one standard unit per person per day would generate substantial health and economic gains if large numbers of drinkers could be reached at low costs. Negative consequences of alcohol misuse, such as traffic accidents, injuries, and work absenteeism, could be diminished. Long-term detrimental health effects, such as cirrhosis of the liver, cardiovascular disease, major depression, and suicide, could also be mitigated. ISBIs could thus prove to be a viable component of an overall public health approach to problem drinking. That is especially true of ISBIs that require no professional guidance, as these can be disseminated on a wide scale with minimal investments of time and money.

Future Directions

Evaluating and expanding the evidence base for ISBIs requires further research. The robustness of current insights needs to be tested, and many questions remain unanswered. Most findings are still not generalizable to the average problem drinker, based on the characteristics of existing ISBI participants. It is also unclear for which types of problem drinkers ISBIs might be more effective and in what settings ISBIs might be most successfully delivered. Improvements in study design and conduct should also make the results more generalizable to daily practice.

For Which Problem Drinkers Are ISBIs Effective?

ISBI user profiles based on study participation data suggest that most users would have relatively high income and education levels. It is therefore not clear to what extent the outcomes of the currently available studies can be generalized to groups that are insufficiently reached at present, such as people of low socioeconomic status, the elderly, or ethnic minorities. Reaching such groups may require interventions with different formats or modalities as well as innovative recruitment strategies. Predictor studies that investigate whether low education or income is a barrier to successful engagement with ISBIs have yielded an incomplete picture, as have those that assess whether ISBIs might be less effective for very heavy drinkers than for moderately heavy ones (as has been found for offline SBIs). More research is therefore needed on these issues. Studies on mediators and moderators of behavioral change in problem drinking and on the most effective components of ISBIs might create more insights. Incorporating diagnostic interviews into randomized controlled trials of ISBI participants (in addition to the current self-report screening measures) could produce more in-depth knowledge about many of these issues and about the severity level of the individual drinking problem. Research on additional aspects of ISBIs, such as the possible role of natural recovery mechanisms and the potential adverse effects of unguided interventions (including the postponement of professional help), will further strengthen the ISBI evidence base.

Improving Treatment Compliance and Discouraging Dropout

Most ISBI studies are hampered by high dropout rates and low intervention adherence by participants. Study dropout is often well over 40%, while as few as 15% of participants may actually complete the intervention as intended. Dropout rates of this magnitude may bias study outcomes even if missing data are accounted for statistically. Improving adherence and reducing sample attrition will enhance the validity of research results and decrease the likelihood of bias. Some studies have reported contradictory associations between the level of adherence and the severity of problem drinking: Some found that the more serious the problem, the greater the engagement of the participants; others found that study dropouts had significantly greater alcohol-related problems than completers. Other reasons for dropout or noncompliance could be that participants attain their goals early or are dissatisfied with the ISBI itself. Although one might understandably presume that low adherence means poorer treatment results in ISBIs (as has been shown for offline SBIs), any such relationship needs to be substantiated in research. These investigations, too, will contribute to the

evidence base for the rapidly growing field of Internet screening and brief intervention for problem drinking.

Assessing the Cost-Effectiveness of ISBIs

Several economic studies have evaluated the cost-effectiveness of brief face-to-face interventions for problem drinking, and most have found favorable benefit-to-cost ratios. Although comparable studies on ISBIs are very few in number, these, too, suggest promising economic outcomes in terms of both the low delivery costs of ISBIs and the indirect cost savings accruing from reduced production losses and improved job performance by problem drinkers. Further studies are required to investigate the economic implications of ISBIs more rigorously.

Conclusion

Internet-based screening and brief intervention (ISBI) is a feasible and effective strategy to curb adult problem drinking. Its potential could be enhanced by integrating such online intervention resources into approaches that combine public health prevention strategies with treatment strategies in primary and secondary care. Such approaches could be based on a “stepped-care” model to address problem drinking. Unguided, free-access ISBIs would be a cost-effective first step. Problem drinkers might then move up to guided interventions, if necessary, or even to more intensive treatment and medication. Low-threshold monitoring of client progress is, however, a key requisite for successfully implementing a stepped approach. Monitoring would ensure that treatment for problem drinkers is stepped up in a timely and efficient manner. More intensive treatment might consist of guided ISBIs or face-to-face treatment modalities, or combinations of both. Adjunctive online peer support may enhance the effectiveness of ISBIs throughout all such stepped-care stages. Studies on the use of ISBIs by primary care providers or hospital emergency departments are still rare, and it is not yet known whether ISBIs could help overcome the general constraints of SBIs in such settings. Given their demonstrated advantages, we expect they may do just that. The study and implementation of ISBIs may therefore help to build a public health strategy that provides a full range of effective prevention and care services for problem drinkers in a cost-effective manner.

INTERNET INTERVENTIONS FOR ILLICIT DRUG USE

This section reviews the literature on web-based interventions to assess the progress and the evidence regarding the effectiveness of Internet intervention for

illicit drug use and the misuse of licit (e.g. prescription or over-the-counter) drugs. The potential benefits of ISBI found for problem alcohol consumption are likely to extend to interventions for illicit drug use. Although this field lags behind the developments of ISBI for alcohol, there are still examples of universal, selective, and indicated programs that have been evaluated. Given the range of substances under investigation and the current stage of development, this section includes programs evaluated in both adult and adolescent settings.

A search for peer-reviewed papers on Internet interventions revealed reports of interventions that covered a wide range of target groups – from universal preventive approaches to those targeting people fulfilling DSM-IV criteria for substance use disorders. Most studies reported outcomes for several classes of drugs (often including alcohol and tobacco), but there were specific interventions for users of benzodiazepines, cannabis, cocaine, and opioids.

Interventions for illicit drug use have adopted a range of methodologies, including computer-generated letters and facilitated video conferencing, but generally they are used to deliver programs in a standard fashion to replicate the input from a therapist. These draw on a number of theoretical or treatment frameworks, including social learning theory, motivational interviewing, community reinforcement approach, family interactional approach, and CBT.

INTERVENTIONS FOR CANNABIS USE

Cannabis is the most widely used illicit drug in the world with about 4% of the adult population having consumed cannabis in the last year. This compares about 1% for opiates, cocaine, and amphetamine-type stimulants combined with the prevalence in the developed world ranging from 0.1% in Japan to 16.8% in Canada. Unlike the interventions for alcohol, among the interventions that included cannabis use as an outcome, there were diverse theoretical approaches underpinning the programs. This diversity may reflect the age range of participants. First, as with alcohol, among adults, cognitive-behavior therapy and motivational approaches were used. Personalized feedback alone did not appear to be effective. Brief interventions that include incentives, produce short-term improvements, and extended intervention can be successful in reducing cannabis use to 12 months. Other interventions have involved mother and (teenage) daughter dyads, and via extended programs based on family interaction theory, these have achieved significant reductions in cannabis use to 24 months, plus reductions in measures of other substances. Further trials with extended interventions

include educational approaches, which show little effect and programs drawing on social influence and social learning theory that were successful in reducing cannabis consumption to 6 months.

INTERVENTIONS AS ADJUNCTS TO PHARMACOTHERAPY

Opioid substitution therapy for heroin dependence with methadone or buprenorphine is well established. However, this requires the collection of medication on a (near) daily basis from a clinic or pharmacist. Attendance for psychotherapy would be an additional burden, especially as agonist therapies are meant to permit recipients to return to everyday activities, such as employment or education. The provision of Internet-based therapy would alleviate this burden while providing an additional support in the transition away from heroin dependence. However, initial research has only provided limited support for this proposition. Studies published in 2008 and 2009 by Bickel and Chopra found that contingency reinforcement for drug-free urine samples improved abstinence whether delivered by therapists or computers compared with standard care. A comparison of video conferencing with face-to-face care found no significant difference in outcomes, albeit with a small sample.

LIMITATIONS OF EXISTING RESEARCH

These studies typically have had small samples, with the median being 120 participants. As a result, there has been little opportunity to evaluate the key characteristics of successful interventions or to identify whether there are critical features of those who would benefit most from face-to-face interventions or computer support. In addition, these interventions often use short-term outcomes, with the median follow-up being 6 months, ranging from as little as 2 weeks to 24 months. Although, most studies had rates of attrition that would be considered low for Internet interventions, these should be considered in light of the length of follow-up. Furthermore, some studies included incentives (such as medication or voucher contingency schemes) or were delivered in combination with methadone or buprenorphine maintenance programs. Nevertheless, retention of over 90% at 24 months, as reported for one German program, would be meritorious in any circumstance. Most studies used self-reported drug use, which is often used as an outcome measure in the substance use field. However, some of the studies, especially those including drug substitution programs, were able to

include “objective” measures such as urine screening tests to provide a more rigorous outcome.

CONCLUSIONS

Internet interventions for substance use are still in their infancy, although the initial reports appear to be favorable. Characteristic of this stage is the diversity of approaches, even though these were typically underpinned by the notion of replicating existing face-to-face therapies. However, the development of interventions that use multiple features of web content (e.g. blogs, chat, games) and have the potential to create a new paradigm in treatment still seems to be problematic.

Concerns exist about the cognitive capacity of substance users to benefit from treatments such as CBT that require insight and complex cognitive tasks. The use of computer-aided treatment, particularly if it requires strong literacy skills or lacks the potential to clarify misunderstandings, could be a further barrier to effective treatment. Nevertheless, the potential for exercises to be repeated as required, progression at the participant’s own pace, and the presentation of multiple vignettes modeling behavior could be beneficial compared to face-to-face interventions.

In sum, the breadth of target groups, ranging from universal prevention to those with dependence, suggests considerable utility of this approach. However, the universal prevention approach is the most likely to exploit the advantages of computerized interventions with greatly extended reach and fidelity compared with standard care. The ISBI approach can be successfully integrated into the school curriculum, but it remains to be seen whether this explicitly harm-minimization model will be acceptable in all jurisdictions, such as the United States, where abstinence models predominate.

Overall, the use of ISBI has yet to establish a strong empirical basis for its use as either a treatment or an adjunct to pharmacotherapy among illicit drug users. However, the potential benefits offered by this approach warrant further investigation, in particular its use in universal prevention (e.g. within the school curriculum) and as a means of engaging marginalized and stigmatized client groups, which are currently reluctant or unable to access conventional treatment.

INTRODUCTION

For some students, alcohol consumption begins after college matriculation. For others, it represents a continuation of established behavior. Further, there is evidence that some alcohol-related consequences increase in older students aged 21–24 years. In response, more intensive campus and community programs have been implemented. In spite of these efforts, college student alcohol problems in the United States have not decreased significantly.

Numerous factors have been implicated in college alcohol misuse. These include expectancies and motives, environment, and background factors. In addition, drinking attitudes and peer norms are among the strongest correlates of alcohol abuse. While peer influences are significant predictors of alcohol socialization, a growing literature has emphasized the importance of parents. Although some reports show that parents'

influence may recede, others suggest the continued value of parental involvement.

To date, there is no review on the role of parents in college student alcohol etiology and prevention. Thus, the aim of this article is to fill this gap in the literature. Our analysis is organized into three sections. Section 1 focuses on the role of parents in the etiology of college student drinking. This section covers parental approval and permissibility of teen drinking (Is it okay for parents to permit their teens to drink?), parental communication (Can and do parents communicate effectively with their college students about alcohol use?), parental monitoring (How do parents keep in touch with their sons and daughters?), parental modeling of alcohol use (Are there certain types of modeling behaviors that are risky or protective?), family history of alcohol abuse and alcoholism (Is there evidence that parental history of alcoholism is uniquely harmful to college students?), parenting styles (Are there specific styles that increase or

reduce harm?), and gender (Is there a difference between mothers and fathers when it comes to college student drinking?). Section 2 focuses on the literature examining the efficacy of parent-based interventions (PBI) designed to reduce the onset or usage of alcohol (Are parents an important part of comprehensive prevention efforts and effective as targets for prevention?). Finally, Section 3 is a discussion of the current state of parenting research in relation to college student drinking, limitations, and future directions.

THE ROLE OF PARENTS IN THE ETIOLOGY OF COLLEGE STUDENT DRINKING

Parental Approval/Permissibility of Drinking

The topic of parental approval and permissibility of underage drinking has been recently associated with two opposite viewpoints. One viewpoint is that the legal age of 21 is appropriate and parents who permit underage drinking may be increasing their child's risk of engaging in risky drinking behavior. The opposing second perspective is that it is better to supervise underage teens in order to teach them to drink in a responsible manner as they transition into adulthood. While this debate is prominent in media outlets, the scientific evidence consistently supports the positive relationship between parent permissibility of alcohol use and students' risky drinking behavior in college.

Research has shown that parental approval of underage alcohol use is related to increased consumption and related consequences among college students. Abar and colleagues found that college students whose parents were more permissive about drinking while they were in high school (as measured by limit setting and approval of drinking in general and in special circumstances) were more likely to engage in alcohol misuse and experience more consequences than students who had less-permissive parents. Further, complete parental disapproval of alcohol consumption was the optimal strategy to reduce high-risk consumption among students during their freshman year. Interestingly, no gender effects were observed. In a longitudinal study conducted by Livingston and colleagues, the authors examined whether parents allowing their daughters to drink alcohol at home during senior year of high school reduced the risk of heavy drinking in college. The authors examined the following three types of permissibility: not permitted to drink at all, allowed to drink at home during family meals, and allowed to drink at home in the company of their friends. The findings indicated that students who were allowed to drink at home during high school in both categories (during family

meals and with friends) engaged in more high-risk drinking during the first semester of college than those who reported not being allowed to drink at all. However, students who were permitted to drink at home with friends reported the heaviest alcohol consumption. Further, the relationship between alcohol permissibility and college drinking was mediated through perceptions of parental alcohol approval. Research has also examined the relationship between parent and peer approval and college student drinking and found that both are significant predictors. Additional research has shown that if a large disparity between parent and peer approval of drinking exists, individuals with friends who approve of drinking and parents who disapprove are at a higher risk of drinking heavily and experiencing problems.

In sum, research demonstrates a consistent positive relationship between parental permissibility and approval of alcohol use and high-risk drinking in college. Students of parents who disapprove of underage drinking are at a lower risk of engaging in high-risk drinking and related problems. No research to date has shown increased parental approval or permissibility of alcohol consumption to be protective against harmful drinking in college. In addition, studies have indicated the importance of consistency between normative reference groups. Specifically, parents can promote responsible alcohol behavior by encouraging their son or daughter to choose friends who share their value system.

Parental Communication

Communication is another avenue through which parents may influence their children's alcohol use. Researchers have examined alcohol-specific parental communication and found that it is associated with less drinking and fewer alcohol-related consequences. On a related note, general positive communication between mothers and their teens has been identified as protective against high-risk college drinking. Conversely, negative parent-teen communication has been linked to negative alcohol outcomes among college students. One study found that parent-child communication conflict was linked to alcohol-related consequences in a sample of college students. Conflict with fathers was more strongly predictive of consequences than conflict with mothers for male students. However, the association between conflict and alcohol-related consequences was stronger for female students.

The specific content of alcohol-related communication may also be important. Turrise and colleagues found that among a sample of college student athletes, communication about the legal, social, and academic consequences of alcohol use was actually linked to heavier drinking. On the other hand, communication

about the physical consequences of alcohol use was associated with less drinking. Another study found that parent–student communication about the negative effects of alcohol use was unexpectedly associated with more excessive drinking in a sample of college students. It may be that overly negative parental messages about alcohol cause their teens to discredit them. Future research could help identify specific communication content that is most protective with respect to reducing high-risk college student drinking.

While it is clear that parent communication about alcohol is important with respect to college student drinking, further clarification is necessary to determine the relevance of timing of communication. Parents may initiate conversations about alcohol during high school, in the summer prior to college matriculation, or while in college. One paper has examined frequency of communication at these different time points; however, college student alcohol use was not examined as an outcome.

Similar to alcohol-specific communication, general openness to communication may also be protective. Open communication between parents and their children could be an indicator of overall relationship quality, which in turn influences student drinking. For example, children who report an established pattern of good communication may be more likely to communicate with their parents when they are faced with decisions about drinking or choice of peers. While there is little in the literature addressing overall tone of communication between parents and college students, one study found that students' perceptions of family openness to communicate were associated with parent–child discussions about alcohol, which in turn were related to fewer risky drinking behaviors in one sample of college students.

In sum, both alcohol-specific and general parent communication have been consistently linked to less drinking and fewer consequences among college students. Future directions should explore content and timing of communication to determine their relevance to drinking outcomes.

Parental Monitoring

Parental monitoring is generally conceptualized as parents' knowing where their children go at night, what their children do during the day, and also what they try to know about their children's drinking. Monitoring of students' activities, and also specifically drinking, has been shown to be related to lower first-year college student drinking. Another study examined parental monitoring and two types of college alcohol outcomes. The first binomial model examined the influence of parental monitoring on initiation of drinking and

experiencing consequences. The second linear regression model tested monitoring as a predictor of drinking and consequences, which were continuous outcomes. Students who perceived greater parental monitoring during the summer before college entrance were less likely to report experiencing consequences in the binomial analysis and reported less binge drinking and fewer consequences in the linear model.

Specific factors that have been identified as important in the relationship between monitoring and alcohol use outcomes are drinking history and peer influences. Researchers have found that parental monitoring was protective against drinking in college and this relationship was explained by high school drinking. The authors also found that students who resided in their parents' home while attending college consumed less alcohol. With respect to peer influences, research has shown that the impact of parental monitoring on second semester college alcohol use is mediated by friends' alcohol use. This suggests that one way in which parents exert indirect influences on their college students' alcohol use is by monitoring their choice of friends. Similarly, Wood and colleagues found that the relationship between monitoring and alcohol-related consequences was moderated by number of alcohol offers from peers. At lower levels of monitoring, alcohol offers significantly predicted consequences, but at higher levels of monitoring, there was no such association. Finally, students who perceived that their parents had both an awareness of their drinking and cared about their drinking tended to drink less in terms of both quantity and frequency during the first semester of college.

In sum, parental monitoring has consistently been linked with reduced alcohol use and related consequences among college students. The majority of this work has focused on monitoring prior to college entrance or during the first semester of the freshman year; therefore, future efforts could elucidate the impact of longer-term monitoring throughout the college experience.

Parental Modeling

Research investigating the parental modeling of alcohol use has primarily focused on adolescent samples, and the literature on modeling's impact on young adults is limited. One longitudinal study followed adolescents into their early 20s, and the authors used growth curve analysis to model trajectories of alcohol use. They found that parental modeling of alcohol use was a stronger predictor of teen drinking than parenting behavior itself, such as monitoring. Mother's modeling was more predictive than father's modeling, indicating that mothers and fathers have independent and distinct influences on their teen's drinking.

There is scant research investigating the parental modeling of alcohol use specifically among college students. Abar and colleagues examined parental modeling and alcohol use among first-year college students and did not find a significant association. However, their measures of modeling captured drinking quantity and frequency only and did not include other alcohol-related behaviors (e.g. reasons for drinking, risky or protective drinking behaviors such as drinking shots or pacing drinks, or behavioral consequences such as drinking and driving).

Despite the body of work investigating the parental modeling of alcohol use among adolescents, there is very little examining modeling among college students. In addition to determining the relationship between modeling and college student drinking, future directions could include more detailed measures of modeling that capture behaviors beyond drinking itself. A second area that requires further exploration is how modeling impacts antecedents of college student alcohol use, such as alcohol-related expectancies or willingness to drink.

Family History

The link between family history of alcoholism and college student alcohol use is well documented. More specifically, *parental* history of alcoholism is also related to alcohol use and problems among college students. Authors examined parental history of alcoholism and found that it significantly predicted alcohol use disorders in a sample of college students.

Parental risk for alcohol-related problems may be transmitted through different pathways. Two pathways that have been identified are expectancies and personality characteristics. In one study investigating expectancies, positive parental history of alcoholism was significantly related to greater alcohol problems. This relationship was moderated by positive expectancies for alcohol use such that students with a positive parental history and more positive expectancies were at greatest risk. Another study in a sample consisting primarily of college students examined personality factors (social deviance and excitement-seeking) and found that these characteristics accounted for a significant proportion of the variance in the association between parental alcoholism and alcohol abuse.

A third possible mechanism through which parental alcoholism transmits risk to college-age children is exposure to childhood stressors. Scientists examined a sample of college students with and without a history of paternal alcoholism. They found that those with an alcoholic biological father were more likely to have experienced childhood stressors related to their fathers' drinking, such as verbal or physical abuse. The effect

of paternal history of alcoholism was stronger for women than for men, suggesting that females experience more stress related to their fathers' alcoholism than males. Exposure to childhood stressors was significantly related to later problems with alcohol; again, this effect was stronger for women with respect to certain stressors. These childhood stressors partially mediated the relationship between paternal history and development of problem drinking during young adulthood.

To summarize, parental history of alcoholism has been identified as a risk factor for high-risk college drinking. Possible mediators of this pathway are cognitive and personality factors and exposure to stressful experiences in childhood.

Parenting Styles

Parenting styles encompass many of the factors previously discussed, including monitoring, communication, and approval of alcohol use. Baumrind identified four types of parenting styles: (1) authoritative, (2) authoritarian, (3) permissive, and (4) indifferent. These four parenting styles can be conceptualized in terms of warmth and structure. Authoritative parents provide both warmth and structure. Authoritarian parents also set rules and boundaries; however, they are not as warm and are more punishment focused. Permissive parents are very warm and supportive but provide few rules or structure. Finally, indifferent parents provide little warmth, support, or structure. There is a rich literature focusing on parenting styles in relation to child and teen development; however, less is known about the relationship between parenting style and drinking behavior during emerging adulthood.

In a recent study, scientists observed the presence of all four parenting styles among college students. Nearly half of the parents in the sample were classified as authoritative (48%), while the following percentages represented the rest of the sample: authoritarian (14%), permissive (27%), and indifferent (11%). Further, the study found that individuals with authoritarian parents were at a significantly higher risk of heavy episodic drinking during their freshman year compared to the other groups.

The work of Patock-Peckham and colleagues has explored the relationship between parenting styles (authoritative, authoritarian, and permissive) and drinking behavior in the context of mediating and moderating variables. Findings from these studies are summarized below.

1. *Authoritative Parents.* The authoritative parenting style has been shown to be a protective factor in relation to college student alcohol consumption and problems. For instance, both males and females with authoritative parents have lower rates of alcohol

problems. Specifically, males with an authoritative father report less impulsiveness and depression, a stronger parental bond, and increased autonomy, resulting in fewer alcohol-related problems. Males with authoritative mothers also have fewer alcohol problems mediated through higher self-esteem and lower depression. Females with authoritative mothers have higher self-regulation and drinking control that are related to reduced alcohol outcomes. Similarly, females with authoritative fathers report fewer alcohol problems mediated through depressive symptoms.

2. *Authoritarian Parents.* In contrast to authoritative parents, research has found that authoritarian parenting is significantly associated with increased risk and has no protective qualities. For males, having an authoritarian father is associated with increased alcohol-related problems that are mediated through increased neurotic symptoms and depression. Females with authoritarian mothers report more impulsivity and those with authoritarian fathers have higher rates of depressive symptoms, both resulting in increased alcohol-related problems.
3. *Permissive Parents.* Studies have shown that permissive parenting can have risky and protective qualities in relation to college alcohol use. In terms of risk, males who have a permissive father tend to be more impulsive and have lower self-regulation, resulting in increased alcohol use and problems. Females with a permissive mother exhibit the same pattern. In contrast, both males and females with permissive parents had increased autonomy. For both genders, fathers' permissive parenting style was associated with lower levels of depression as mediated by increased autonomy. Depression was positively associated with alcohol problems.

Interestingly, Patock-Peckham and colleague's work showed that there were differences in terms of which parent was more influential, which varied depending on the gender of the target child, the personality construct under study, and the parenting style. These findings make a strong case for examining mothers' and fathers' independent influences on their college students' drinking.

Gender

As suggested above, the issue of parent gender is becoming more salient in both etiological and intervention research among college students. A large portion of previous work that examined parental influences on adolescents' drinking outcomes did not account specifically for gender. Studies are now more consistently examining differences between mothers and fathers in

terms of impacting young adult alcohol use. Studies that have included gender have shown mixed results in terms of which parent is more influential. Some authors have found that mothers tend to be more influential figures than fathers in relation to adolescent and young adult behavior. Other recent research examining family history and parenting styles has highlighted the distinct influence of both mothers and fathers on emerging adult drinking behaviors. More research examining the unique influence of gender influences in terms of both parents and children is needed.

EXAMINING THE EFFICACY OF PBI

Several studies have been conducted over the past decade examining the efficacy of PBI to prevent the onset of or reduce previously established drinking tendencies. In this body of research, the format of the PBI was an informational handbook that was developed to assist parent communication about drinking with their emerging adult children. The theoretical underpinnings of the handbook were heavily influenced by psychosocial theories of behavioral decision-making (e.g. intentions, attitudes, and norms toward drinking and the alternative behaviors) and the specific format of the handbook contained different sections to increase parental motivation to communicate, bolster parenting skills (e.g. communication, assertiveness training, dealing with resistance, decision-making), and alcohol knowledge. Fidelity of the PBI is assessed through parental evaluations of the interest, value, readability, utility, and ease of comprehension for each of the sections and self-reports on whether they had talked with their teen about each of the major topics discussed in the handbook. Typically, it has been observed that an overwhelming number of parents discussed the different topics with their sons and daughters (e.g. over 80%) and the evaluative ratings of the handbook were universally positive. The studies that have implemented the PBI will be reviewed in turn.

In the earliest study focusing on a PBI for emerging adults, Turrise and colleagues examined the effect of the intervention on college freshman drinking tendencies approximately 3 months post-baseline. Despite the fact that all respondents were below the legal age for drinking, approximately one in three individuals indicated that they drank alcohol weekly and consumed five or more drinks 2 weeks prior to the data collection. Comparisons between treatment group and controls, controlling for baseline drinking and gender, were all significant in the hypothesized directions. For example, individuals in the treatment condition had lower levels of drinking and drunkenness episodes, lower perceived

parent and peer approval of drinking, and experienced fewer alcohol-related consequences. Follow-up comparisons at approximately 9 months post-baseline (spring semester assessments) revealed no significant time by condition interactions suggesting the effects did not decay across the first year of college.

Researchers conducted an in-depth analysis examining variables from the theoretical models underlying the original Turrisi PBI. Attitudes toward diverse drinking and nondrinking activities (e.g. drinking at a sporting event, bar, or party; getting drunk at a sporting event, bar, or party; going to a sporting event, campus event, or coffee shop, and not drinking) were included as mediators. First, the analyses of the PBI and the mediators revealed that individuals in the control condition had more favorable attitudes toward the drinking activities and less favorable attitudes toward the nondrinking activities. Second, in the analyses of the mediators and the drinking outcomes, it was observed that as individuals' attitudes toward drinking activities became more favorable, their drinking increased and as individuals' attitudes toward nondrinking activities became more favorable, their drinking decreased. Finally, the comparison of analytic models controlling for and not controlling for the mediators revealed that the effect of the PBI was partially mediated by the attitudinal constructs, suggesting that the PBI also had an impact on emerging adult drinking via factors other than decision-focused constructs.

In another extension of the original PBI research, Turrisi and colleagues examined a PBI in combination with an individually delivered motivational enhanced intervention (BASICS) with a high-risk subgroup (athletes). Athlete status, by comparison to the other risk factors, had been relatively under-examined in college student alcohol interventions. Participants ($n = 1275$) were randomized to one of four conditions (BASICS, parent, combined BASICS and parent, or assessment-only control) using a computerized algorithm. The follow-up assessment was conducted at approximately 10 months post-baseline (spring semester; 85.5% retention). Analysis of covariance examined mean differences in drinking outcomes at follow-up by treatment condition, controlling for baseline drinking. Results indicated that participants randomized to the combined condition reported significantly less drinking and consequences compared to the control group. Participants in the combined group also reported significantly fewer consequences. Beliefs about alcohol, attitudes toward drinking, descriptive norms, and injunctive norms with respect to both peers and parents were explored as mediators of intervention efficacy and drinking outcomes at follow-up. Results revealed that descriptive norms and injunctive peer norms were significant mediators of the relationship between the intervention and all

drinking outcomes. Relative to the control group, those who received both the parent and BASICS intervention perceived that typical college students drink less and perceived their peers to be less favorable toward their drinking behaviors and in turn reported drinking fewer drinks per week, fewer drinks per weekend, experiencing fewer consequences, and were estimated to have a lower peak blood alcohol concentration (BAC) at follow-up.

In a secondary analysis of the combined intervention for college athletes study, latent profile moderator analyses determined whether there were parent subgroups for whom the interventions were more effective versus less effective on peak drinking BACs. The latent profile analyses revealed a four-class solution, with consistently high probabilities (all >0.86) that participants were assigned to the most likely class. The first profile, labeled authoritative, was characterized by high relationship quality, monitoring, and alcohol knowledge, and below average negative communication and approval of underage drinking. The second parent profile, labeled permissive, consisted of low negative communication, monitoring, and alcohol knowledge, and high relationship quality and approval of underage drinking. The third parent profile, labeled authoritarian, consisted of low relationship quality, approval of underage drinking, and alcohol knowledge, and high negative communication and monitoring. The final parent profile, labeled indifferent, was characterized by low relationship quality, monitoring, and alcohol knowledge; high negative communication; and average approval of underage drinking. Follow-up analyses revealed that control participants in the authoritarian and permissive profiles had a significantly higher mean peak BACs compared to the combined intervention participants in these profiles (no significant differences were observed for authoritative or indifferent parenting styles). Together these findings suggest that the interventions had the largest impact on those students who came from authoritarian and permissive parents.

Ichiyama and colleagues examined the efficacy of the original Turrisi PBI in the context of environmental risk. In this study, approximately 95% of the sample resided on campus near a documented environmental risk factor: close proximity to the border of the United States and Mexico, where studies have reported higher than average rates of college student high-risk drinking and alcohol-related consequences. First-year students were randomly assigned to the PBI or the no-PBI condition and assessed on drinking outcomes prior to college and again 4 and 8 months post-baseline. There was an active comparison condition in which all first-year students' parents received materials on alcohol policies, consequences of policy violations, and information on college drinking during orientation, and

were encouraged to be actively involved in conversations with their students. An analysis of a latent growth mixture model revealed that female students in the PBI condition were significantly less likely to shift to drinking; however, the growth for males was nonsignificant. Thus, the trial seemed to replicate the benefits of the original PBI, at least for females. The authors cited the lack of a true control group, the possible confounding influence of an environmental risk factor, and the differences in the proportions of students who were commuters versus residents as plausible reasons for the differences in findings from the original study.

Modifications to the Original Turrisi PBI

As noted above, there have been several studies conducted on modified versions of the Turrisi PBI. Researchers examined the efficacy of a modified PBI in combination with an individually delivered brief motivational intervention (BMI) based on the BASICS program for a universal college sample. Modifications of the PBI included reduced emphasis on drinking abstinence and increased emphasis on protective factors (e.g. clear expectations about alcohol use, monitoring, and drinking-specific communications). In addition, the design of the study included a 2-year post-baseline follow-up. With these notable innovations, the findings were similar to those of the original study. The lowest level of alcohol-related harm was observed for individuals receiving both the PBI and the BMI interventions, relative to either the PBI-only or the BMI-only interventions.

Testa and colleagues examined the efficacy of an adapted version of the PBI designed to increase mother-daughter communication to reduce alcohol-involved sexual victimization. The study had four conditions: traditional PBI, enhanced PBI (adding a component covering college dating, sexual assertiveness, and partner selectivity), assessment-only control, and a post-assessment-only control. Assessments of drinking and sexual victimization were conducted at pre-intervention baseline prior to college matriculation and during the fall and spring semesters of the first year in college. The findings revealed that both PBI conditions were associated with lower incidences of incapacitated rape relative to controls. Path analyses also revealed that the intervention increased parent-student communication, which in turn influenced lowered drinking and incapacitated sexual victimization.

In sum, taken together, the PBI studies indicate some benefits of targeting parents alone or in combination with other evidence-based intervention efforts. These findings are very promising as administrators and public health officials are seeking potential solutions to

reducing the high-risk drinking and consequences that are so common on our campuses.

DISCUSSION

During the past two decades, both etiological and prevention research has shown that parents are influential in college students' alcohol use. Prior to the year 2000, the accepted view was that parents were largely irrelevant in terms of impacting college student drinking behavior and much of the research examined peer influence in relation to college student drinking. However, as highlighted in the current review, parents can and do impact students' alcohol consumption by virtue of their approval, communication, monitoring, modeling, style, and history, and are also an efficacious mode of intervention delivery.

Overall, the current review highlighted ways in which parental behaviors can serve as both protective and risk factors in relation to risky drinking among their sons and daughters as they transition to college. In summary, with regard to parental approval, research consistently found that students whose parents approve of and are permissive of underage alcohol consumption are at a higher risk of engaging in risky drinking behaviors. No study to date has supported the idea that parents supervising or "teaching" their sons or daughters how to drink responsibly is beneficial in reducing excessive consumption. Research has also found that students who engage in more general and alcohol-related communication with their parents drink less and experience fewer consequences, particularly if the communication is more positive in nature. Increased parental monitoring in high school and during the first semester of college has been associated with less drinking and fewer problems in students' early transition to college. In addition, research suggests that parental modeling of alcohol use is positively associated with students' alcohol consumption; however, more work is needed to better understand this relationship. A parental history of alcohol problems has been identified as a risk factor for problematic drinking in college; however, more work is needed to explore mediators of this relationship in order to better understand these underlying mechanisms of influence. Finally, studies examining parenting styles tend to indicate authoritative parenting as a protective factor in preventing high-risk drinking among college students. Research was somewhat variable in this area based on gender and personality differences among both the parents and their children.

The research to date on the role of parents in prevention efforts is also promising. The majority of trials in the area have shown benefits of engaging parents and

emphasizing the benefits of communication. Further, there is emerging evidence that parent-based efforts that are initiated during the teen years may have long-lasting benefits into college. It is interesting to note that almost all the literature in this area has focused on first-year college students. The role of parents needs to be examined beyond the first year, as do efforts to involve parents in the prevention of drinking.

LIMITATIONS AND FUTURE DIRECTIONS

Although the literature on parenting and college student drinking has grown significantly over the past decade, a relative lack of research in this area in comparison to other life stages remains. In addition to the gender differences mentioned previously, areas that need future attention include understudied constructs that are important in the development of risky or protective drinking behaviors, time course and measurement issues, and a more inclusive examination of different college populations.

The majority of parenting research up to this point has focused on a limited variety of student outcomes, such as quantity and frequency of drinking or consequences, or both. Future work should explore parenting factors as they relate to correlates of drinking and consequences, such as drinking attitudes and beliefs, and consequence-specific constructs. Another future direction would be to examine how parenting might relate to engagement in protective behaviors that have previously been identified in the literature, such as alternating drinks with water.

With respect to time course, the majority of previous work has studied parenting behaviors immediately before college entrance and, in some cases, into the fall of freshman year. Similarly, student drinking and consequence outcomes have been shorter term and have generally not been assessed beyond the freshman year. Future work should examine the influence and changing dynamics of parenting in relation to longer-term student outcomes throughout the entire college experience.

A third limitation of the previous body of literature is the prevalence of teen-reported measures of parenting. While teens' perceptions of their parents' behavior are certainly important, parent-reported experiences, attitudes, beliefs, and behaviors would provide a useful and more comprehensive picture of the parent-student relationship during the college years.

Finally, future work could benefit from a more inclusive definition of the college student population. Previous studies have focused exclusively on traditional 4-year college students who attend college away from home and live on campus. Almost no literature on

parenting and students attending community colleges or technical schools exists. In addition, due to the convenience of using registrar data to contact students for research purposes, most previous studies have ignored students who leave or transfer from school. Future work should address parenting and teen alcohol use in the context of school leaving, re-entry, and transfer.

In sum, the body of research in this area indicates that parents significantly impact students' drinking behavior and alcohol-related consequences, are important targets of future efforts of study, and warrant inclusion in comprehensive intervention efforts.

OUTLINE

Gambling and Pathological Gambling among Youth	875	Indicated Prevention	879
Universal Prevention	877	Conclusion	880
Selective Prevention	879		

The topic of gambling and pathological gambling is an area of study that has increased its field of expertise over the years. Thirty years ago, knowledge of gambling was still very small, but the arrival of the 2000s coupled with increased gambling offerings and availability of gambling activities via the Internet have led many researchers to look at this problem and simultaneously allowed significant growth of knowledge in this field. Thus, we know quite well the characteristics of adults with gambling problems, the consequences that this problem may bring to the gambler, his social network and society, as well as the factors associated with the development of problem and pathological gambling in adults. However, despite an increasingly large and diverse literature, relatively little is known yet about how pathological gambling takes place among youth and how the presence of such a problem is reflected in their lives. As a consequence of the relatively few epidemiological studies estimating the prevalence of pathological gambling among youth conducted in recent years, prevalence rates currently available may poorly reflect the situation of 2012. The arrival of Internet gambling, cell phone gambling, and the rise of poker in recent years require further studies to establish the

actual picture of the needs for prevention and intervention for youth. Despite this fact, previous research continues to guide preventive actions. This chapter aims to present a portrait of preventive practices that can be implemented with youth as well as some examples of preventive interventions that are already in place. We invite readers to consult the article entitled "Preventing the Incidence and Harm of Gambling Problems" published in 2008 by Dickson-Gillespie, Rugele, Rosenthal, and Fong in the *Journal of Primary Prevention*. This paper presents a comprehensive model of the different prevention possibilities targeting public health and different clientele.

GAMBLING AND PATHOLOGICAL GAMBLING AMONG YOUTH

When talking about gambling, we think of an array of diverse activities. In fact, the word "gambling" includes all activities for which a person may bet or wager money or an object of value. In general, we can divide gambling activities into two categories: the "legal" gambling activities and "private" gambling activities. Legal gambling

activities are usually managed by the State or by a private enterprise and are controlled by legislation or regulation that has to be followed by managers of these activities. These legal gambling activities refer mainly to lotteries, horse racing, video lottery terminals, and casinos. In regard to the second category of gambling activities, the private gambling activities, it includes all the activities done with family or friends and for which no or very little legislation is in place to control them. Besides playing cards or playing dice with friends that spontaneously come to mind, private gambling activities may also include a variety of more or less unusual activities; for example, betting money on sporting events, on the result of a monopoly game, on the result of a video game, on the speed of an automobile, on the number of flies that will arise on the table in 10 min, on the result of an exam, etc. Thus, this is not the activity that defines the presence of gambling, but rather the context surrounding its practice. In fact, three elements must be present to determine the activity an individual participates in is a gambling activity. The person (adolescent or adult) must wager money or something that has value on the result of the activity. The result must be based wholly or partly on chance (as in cards, for example) and the bet must be irreversible, so that nobody can recover their money if they lose.

The use of such a broad definition of gambling activities allows us to better understand how participation in gambling may be present in the lives of youth. Based on the previous definition, several everyday activities can become gambling activities that are readily available for youth. Once accepted the idea that the bet can be a valuable thing (in the owner's perspective), the more limited financial resources of youth are no longer an obstacle to gambling, because they can bet valuable items such as iPods, MP3 players, clothing, food, or cigarettes if they do not have money. It is therefore utopian to believe that the regulations that restrict youth access to the legal gambling activities prevent them from gambling participation. In fact, most studies conducted among youth indicate that approximately 80% of them have already participated in gambling activities while between 24 and 65% of high school students report having annually participated in these activities.

Obviously, not all young gamblers will develop pathological gambling. However, it is possible to believe that gambling in childhood or adolescence may lead young people to develop a positive attitude toward this activity, which will continue throughout the adulthood. In fact, one of the few longitudinal studies conducted among youth demonstrated the stability of the proportion of young regular gamblers between 16 and 23 years of age (Winters et al., 2002).

The criteria currently used to determine whether an individual, young or adult, presents or not pathological gambling are those listed in the DSM-IV-TR. There are 10 criteria and the diagnosis of pathological gambling is present when the gambler meets 5 of these 10 criteria. This diagnosis should be assigned in a face-to-face interview with the gambler. However, as it is difficult to make a face-to-face assessment in population studies, the latter typically use screening questionnaires, which are completed through telephone interview or self-reported questionnaires during group meetings (e.g. in schools). The questionnaires currently used in most of the studies addressing the prevalence of pathological gambling among youth are the *DSM-IV-J* or its *MR-J* version (Fisher, 2000), the *South Oaks Gambling Screen-Revised Adolescent* (SOGS-RA) (Winters et al., 1993), and the *Massachusetts Gambling Screen* (MAGS) (Shaffer et al., 1994). All these questionnaires are based on the diagnostic criteria for pathological gambling listed in earlier versions of the *Diagnostic and Statistical Manual of Mental Disorders* and they give an estimate of the intensity of the gambling problem. While the *Diagnostic and Statistical Manual of Mental Disorders* classifies gamblers in terms of pathological or nonpathological gamblers, screening questionnaires have the advantage of distributing the respondents into several distinct categories depending on the intensity of the negative consequences they have to face because of their participation in gambling. The classifications most often encountered in epidemiological studies counted four categories and are placed on a continuum. These are as follows:

1. Nongamblers: People who never participate in gambling activities.
2. Occasional or recreational gamblers: People who gamble primarily for fun and socializing and who do not suffer consequences because of their participation in gambling activities.
3. At risk gamblers: People who gamble above average (more frequently or more money) and who have few negative consequences because of their participation in gambling activities.
4. Probable pathological gamblers: People who suffer several negative consequences because of their participation in gambling activities. It should be noted that the term "probable" is used to clarify that the assessment was done by questionnaire and that it is an estimate and not a formal diagnosis.

Besides these standard categories, it is also common to find the expression "problem gamblers" which, according to the authors, put together in one category at risk and probable pathological gamblers, or place all the gamblers in a single group who reported at least one negative consequence related to their gambling participation.

Population studies conducted with youth indicate that between 1.7 and 8% of them met the criteria for probable pathological gambling and between 4 and 14% are at risk of developing gambling problems. It is important to note here that in the last few years, the field of youth gambling has hosted several debates concerning both the criteria that is used to assess the presence of gambling problems among youth and the questionnaires used to do this assessment. The most important arguments were the lack of the definition of pathological gambling adapted to youth and the youth's difficulties in understanding the screening questionnaires. This is perhaps not unrelated to the fact that prevalence studies among youth have declined in quantity in recent years. Because gambling now occupies an important media space and activities such as poker appeal particularly to young people, it is quite possible that the prevalence rates currently available are not representative of what the reality really is. Further epidemiological studies will be needed in coming years in order to draw a picture of the recent situation of youth and ensure that preventive interventions that would be implemented continue to meet the needs. The arrival of a new screening questionnaire for problem gambling among youth could help do this. Indeed, as the items that compose the *Canadian Adolescent Gambling Inventory* (CAGI) (Tremblay et al., 2010) were developed following focus groups with youth, many of the items retained in the final version target impacts that a youth may suffer due to an important participation in gambling activities. In addition, the CAGI having been part of an exhaustive process of validation in both English and French, there is every reason to believe that future epidemiological studies that will use it, will allow a better overview of the youth's gambling profiles.

Despite all the methodological and ideological debates surrounding the epidemiological studies and prevalence rates of gambling among youth, it is important to remember that abusive/excessive/pathological gambling can lead to serious consequences that could impinge the cognitive, personal, social, and academic development of youth. Although not all young people who participate in gambling activities will develop gambling problems during their adolescence or adulthood, the fact remains that exposure to gambling activities is the first step towards acquiring such a habit. It is to reduce the likelihood that youth develops gambling problems so that prevention programs were developed and implemented over the years. One way to classify preventive interventions is to divide them in terms of universal, selective, and indicated prevention based on the populations targeted by the interventions. The universal prevention strategies are designed to reach the entire population, without regard to individual risk factors, and aims at preventing or delaying the beginning or abuse of

gambling; selective prevention strategies target subsets of the total population that are deemed to be at risk for gambling problems by virtue of their membership in a particular population segment. Indicated prevention interventions identify individuals who are experiencing early signs of gambling abuse and other risk factors associated with pathological gambling and target them with special programs. An approach, like the harm reduction approach is also part of the preventive approaches introduced in recent years and it is predominantly found in the indicated preventive intervention category.

The next sections focus on each of the three categories of preventive interventions and, when possible, provide examples of interventions that have been proved effective. It is, however, important to note that although all preventive interventions should be evaluated before being implemented on a large scale, yet few interventions targeting the prevention of gambling were assessed and published in the scientific literature so far. This document is not an exhaustive presentation of every preventive intervention actually available. It is rather meant to describe the types of preventive interventions available to youth under 18 years old.

UNIVERSAL PREVENTION

Universal prevention strategies are designed to reach the entire population, without regard to individual risk factors. These programs are intended to reach a very large audience and aim to prevent or delay the onset or the abuse of gambling. Universal prevention programs targeting gambling problems may have different objectives. Indeed, some of these programs will aim to provide nonerroneous knowledge about gambling activities in order to help youth better understand what are the real odds of winning, while others aim to raise awareness about the consequences of an abusive participation in gambling and about the resources available if the youth or his or her relative needs help. However, regardless of the proximal goal of universal prevention programs, their distal goal is always to prevent or lessen the risk that youth develops a gambling problem.

Often implemented in schools, universal prevention programs targeting youth attempt to reach all the students and convey a consistent message to all, and this in a relatively short period of time. As these programs are relatively easy to implement and they easily reach many people, it is not surprising that they are the type of preventive intervention that can be found the most frequently.

Although the basic assumption of universal prevention is to reach all youth, it might be important to question the age at which these programs should be introduced and the type of information they should transmit. A study from Messerlian and Derevensky (Messerlian et al., 2005) showed that youth would not be affected by the same type of message depending on their age and gender. According to these researchers, girls are more sensitive to prevention campaigns based on emotions, while boys prefer more direct messages that present statistics and use humor. These researchers also noted that the younger teens prefer prevention messages including humor while older ones prefer more dramatic messages. Besides this difference on the content of the message that varies with age and gender, it is also important to question the relevance of meeting students of all ages as part of gambling prevention initiatives. Indeed, studies conducted with teenagers and pathological gamblers indicated that participation in gambling begins around 10–11 years of age and that most parents of children 5–17 years old gamble with their children (92%) and listen to television lottery shows with them (72%). Such statistics are indicative of the place that gambling activities takes in everyday life and of the trivial characteristic that is associated to this activity. However, although these figures include many young people, they do not indicate that all 10 year olds know and participate in gambling activities. Depending on the family environment in which youths are raised, it may happen that 10 year olds do not have contact with gambling. The great diversity of individual experiences thus leads to an additional problem regarding the age when universal preventive intervention should be initiated. It would indeed be inappropriate to have to teach kids how to play poker in order to demystify the role of chance and knowledge in this activity!

Although few prevention programs are evaluated, some experiments have shown interesting and positive results for youth. The *Dacey Dealings* program developed and implemented in some schools in Australia in 2004 is one of them. The evaluation of this program (Department of Education and Children's Services, 2005) involving a control and an experimental group showed that youth who received the intervention had gained a better understanding of chances of winning in gambling activities and a better knowledge of the resources available to gamblers, while reducing the number of their erroneous beliefs related to gambling. Despite the positive impacts of the program at the cognitive level, it has not succeeded to reduce the gambling behavior of youth. Apart from this Australian experience, other preventive interventions implemented in schools have also been tried and most of those which were evaluated showed positive

impacts on knowledge and attitudes toward gambling but did not have an impact on youth gambling behaviors. To our knowledge, only one preventive intervention addressing problem gambling in a universal approach has reduced the gambling behavior of participants. This program is called *Gambling: A Stacked Deck*. It has been evaluated with high school students (Grade 9–12) and showed a reduction of the time spent on gambling and the money wagered 3 months after completing the intervention (Williams et al., 2003).

The results obtained with the prevention programs evaluated clearly demonstrate the importance of ensuring the impact of those programs prior to broadcasting them to a wider audience. Prevention of gambling among youth is relatively new and it is important to learn from prior experiences of prevention in the field of addiction because some of them revealed that an intervention aimed at reducing the occurrence of a behavior might in fact increase its occurrence or the curiosity for it. As mentioned by Shaffer, Hall, and Vander Bilt (1997), "The need for program evaluation is dictated by a simple premise: unless a program is evaluated, we do not know whether it is producing positive, neutral or negative results." However, in order to have this information one needs to conduct the assessment over a period of time long enough so that youth would be faced with the possibility of gambling. Moreover, to estimate the effectiveness of a preventive intervention it is also important to determine the extent of what would be "acceptable" gambling involvement to conclude whether there has been a positive impact of the intervention. Will it be considered effective if youth have not started gambling 1, 5, 10, or 15 years after the intervention? Will it be considered effective if youth gamble without reaching the at risk or pathological gambling levels? This great difficulty maybe explains why there is still no universal prevention program for gambling among youth that was evaluated long enough to demonstrate its effectiveness on the gambling behavior.

As demonstrated by the results of evaluations, universal prevention programs are highly effective in changing knowledge and attitudes of youth toward gambling, but the lack of long-term evaluation does not allow an assessment of their impact on eventual participation in gambling that would or not meet the criteria for at risk or pathological gambling. Furthermore, individual differences in the age of initiation, experience, and exposure to gambling activities vary extremely from one youth to another. Therefore, exposing all the youth of the same age to the same preventive intervention may translate to a first exposure to gambling for some of them. A selective prevention approach is therefore an interesting avenue for

gambling. More difficult to implement than universal prevention, it could however allow better results.

SELECTIVE PREVENTION

Selective prevention strategies target subgroups of the general population who are deemed to be at risk for gambling problems by virtue of their membership in a particular population segment. Generally, these programs do not take into account the level of risk of developing a gambling problem. They are more interested in the belonging of the participant to a specific subgroup. It should be noted that the choice of the subgroup that would be targeted by the intervention would color the content of the selective preventive intervention.

The scientific literature on gambling identifies several risk factors associated with the development of gambling problems. These factors are numerous and the main ones are among the demographic and personal characteristics of youth. Thus, being a boy, being young, having only completed primary or secondary school, and having school problems are all well-documented demographic characteristics. Other risk factors related to personal characteristics associated with the presence of gambling problems are impulsivity, sensation seeking, drug, alcohol and cigarettes use, and having done illegal acts and delinquency. Besides these factors, there are also economic factors (e.g. having a family allowance), social factors (e.g. having friends who gamble, having easy access to gambling activities), and familial factors (e.g. low parental supervision, having a family member who has or had a problem with alcohol, drugs, or gambling). Risk factors directly linked with the gambling history are also often seen as being precursors of a gambling problem. Among these, we find the gain of a large amount of money at the beginning of gambling participation, the type of gambling activities engaged in, and the early onset of gambling involvement.

While all youth with these risk factors could benefit from preventive interventions tailored to their needs, there are still no guidelines supporting the choice of who should be privileged among these subgroups. Without being contradictory, opinions are still quite varied. For example, Derevensky and colleagues (2005) underlined the importance of targeting youth with multiple risk factors, because the accumulation of risk factors in one individual is linked to the development of a gambling problem. Other researchers put more emphasis on the importance of focusing prevention efforts on children whose parents or siblings have a problem with gambling or substance abuse.

Like previous reviews, our research did not identify selective preventive interventions conducted with youth who have been empirically evaluated and published. (This does not mean that no intervention of this type is currently available. Several organizations are implementing preventive interventions that are not advertised or available through scientific journals.) Although it is difficult to explain the rarity of this type of intervention with youth, the fact that they are more difficult to implement than universal programs is probably no stranger to this. A school that wishes to organize a preventive intervention for a subgroup of at risk youth on regular school hours would face several challenges including the need to remove youth from class on regular school time. Moreover, the same intervention established outside the regular school hours would require the organization to organize a transportation service for the targeted youth. Despite these difficulties, the selective prevention approach remains an interesting option because it allows a focus on subgroups of youth who share similar experiences and therefore allows a more personalized response.

INDICATED PREVENTION

Indicated prevention programs aimed at youth who show signs of excessive gambling and at youth who have risk factors for developing gambling problems without meeting criteria for pathological gambling. Unlike youths who participate in universal prevention programs, those targeted by the indicated programs will be screened before being included in these programs. Although the purpose of indicated prevention, as of any prevention program, will always be to prevent the development of gambling problems, the measures implemented to achieve the goal as well as the program content will vary depending on the characteristics of the youths that we want to reach.

Here, the first selection criteria is the extent of youth gambling participation and the importance of the negative consequences experienced as a result of gambling participation. Thus, youths who meet the criteria of at risk gambling (which may lightly vary depending on the questionnaire used) would be privileged under indicated prevention programs. According to data currently available, they account for 4–14% of youth in the general population.

As for selective prevention, the scientific literature on gambling does not contain any indicated prevention experience for the youth clientele. Again, the difficulty of implementing this type of intervention in a school setting may explain why these programs are hard to find among youths. The relatively low prevalence rate of at risk or pathological gamblers among youth also

makes it difficult to set up an indicated intervention when few youths in the same sector could attend the intervention. However, there are several examples of this type of preventive intervention available for adult casino gamblers. Many of these programs use a harm reduction approach in putting forward controlled gambling or responsible gambling to ensure that the gambler remains or returns to an area of nonpathological gambling causing him or her little or no negative consequences. A similar approach could also be an option for youth gamblers because the majority of youth who gamble do not develop gambling problems and remain recreational gamblers. It would therefore be interesting to study the impact of the harm reduction approach with youth at risk and pathological gamblers.

CONCLUSION

Although years of research on youth gambling habits have improved the knowledge toward this population, yet today most prevention programs designed for them use a universal approach and are introduced in school settings. Following the information gathered to write this chapter, we can only underline the absence of evaluated selective and indicated prevention programs in the scientific literature. We believe that this situation is mainly due to the fact that there are still few prevention programs for which the effectiveness is evaluated and even less which are published in scientific journals. The field of gambling prevention, however, needs that prevention efforts be evaluated, because only the results of such evaluations could confirm whether or not a program is effective and which components of the program are really effective. It is worth noting Williams et al. (2003) who were able to identify elements of their prevention program that were associated with decreased gambling behavior. Such information is valuable and can guide the development of new preventive interventions. Thus, although the evaluation of preventive interventions takes time and is sometimes difficult to implement, dissemination of the results is necessary to improve future preventive interventions addressing gambling.

Glossary

Youth the term “youth” used throughout this chapter includes all individuals aged 18 and under as well as all young adults who

study on a full-time basis, who are under their parents/guardians’ responsibilities, or have a way of living that meets what one would actually expect from adolescents.

GAMBLING OVERVIEW

Gambling Definitions

Gambling is placing something of value (typically money) at risk on an event with an element of chance in the outcome, with the potential to win a substantially larger prize. Gambling requires one to bet on the outcome of some event or specific game such as lottery tickets, cards, bingo, slots, machines, instant scratch tickets, races, animal tracks, sporting events, dice, and roulette. The list could be endless of the ways in which one could bet. This chapter uses the term *disordered gambling*, coined by Howard Shaffer and colleagues, to refer to a range of gambling behavior, from behavior that places individuals at risk for developing more serious problems (subclinical) to those behaviors that would meet *Diagnostic and Statistical Manual of Mental*

Disorders (Fourth Edition) (*DSM-IV*) diagnosable criteria for pathological gambling (PG). The term *disordered gamblers* refers to individuals who engage in gambling behavior within this range.

Disordered Gambling as a Mental Health Disorder

Although problem gambling has been around for centuries and was described by one of the founders of modern psychiatry, Emil Kraepelin, as “gambling mania,” it was not officially recognized as a mental disorder until the American Psychiatric Association’s publication of their *Diagnostic and Statistical Manual of Mental Disorders* (Third Edition) in 1980. In the past 27 years, the criteria have evolved from their inception, based solely on the clinical work of Robert Custer, to the

use of a more evaluative process involving surveying 222 self-identified compulsive gamblers and 104 substance-abusing social gamblers as the controls. Lesieur and Rosenthal conducted cluster analyses to identify a set of nine symptom criteria, which would distinguish between the two groups. After national and international meetings, many experts suggested a 10th criterion of “loss of control over gambling.” A follow-up study was conducted with 453 subjects using these 10 criteria to attempt to correctly identify pathological gamblers. While the “loss of control” criterion was found not to significantly improve the diagnosis of PG, the item remained in the current set of 10 criteria used to define PG. Currently, according to the American Psychiatric Association’s *DSM-IV* (Text Revision), PG is classified as an impulse control disorder, not elsewhere classified. The disorder is defined by the 10 symptom criteria designed to capture persistent and recurrent maladaptive gambling behavior, not better explained by a diagnosis of bipolar disorder, manic episode. An individual’s gambling is determined to meet the threshold for diagnosis of PG if he/she meets five or more of the following: (1) is preoccupied with gambling (e.g. preoccupied with reliving past gambling experiences, handicapping or planning the next venture, or thinking of ways to get money with which to gamble); (2) needs to gamble with increasing amounts of money in order to achieve the desired excitement; (3) has repeated unsuccessful efforts to control, cut back, or stop gambling; (4) is restless or irritable when attempting to cut down or stop gambling; (5) gambles as a way of escaping from problems or of relieving a dysphoric mood (e.g. feelings of helplessness, guilt, anxiety, depression); (6) after losing money in gambling, often returns another day in order to get even (“chasing” one’s losses); (7) lies to family members, therapist, or others to conceal the extent of involvement with gambling; (8) has committed illegal acts, such as forgery, fraud, theft, or embezzlement, in order to finance gambling; (9) has jeopardized or lost a significant relationship, job, educational, or career opportunity because of gambling; and (10) relies on others to provide money to relieve a desperate financial situation caused by gambling (American Psychiatric Association 2000).

Despite relatively stringent criteria in the *DSM-IV* for a diagnosis of PG, most clinicians and researchers recognize the existence of subclinical symptoms of PG and have used the terms “problem,” “compulsive,” or “potential PG” to refer to excessive gambling resulting in subclinical levels of negative consequences. A continuum model suggested by Korn and Shaffer conceptualizes gambling occurring along a continuum, ranging from no gambling (level 0) or nonproblem gambling (level 1), to at-risk gambling (level 2), to diagnosable PG (level 3). Disordered gambling refers to all

gambling at level 2 (at risk) or greater, which would include those individuals meeting *DSM-IV* criteria for PG. The most commonly used screening measure for disordered gambling is the South Oaks Gambling Screen (SOGS). The standard use of this measure suggests that a cutoff score of 5 or more indicates probable PG. Individuals scoring 3–4 have been termed at-risk or problem gamblers.

Despite being categorized as an impulse control disorder, PG is similar to other addictive behaviors in both its description and treatment. As addiction experts prepare for revising the *Diagnostic and Statistical Manual of Mental Disorders* for version 5, several have suggested recategorizing PG alongside substance use disorders, based on similarities in diagnosis and assessment, comorbidity, neurobiological overlap, and treatment practices. Regarding assessment, the diagnostic criteria for PG has more in common with substance abuse and dependence criteria than with the other impulse control disorders of intermittent explosive disorder, kleptomania, pyromania, and trichotillomania. Four of the 10 criteria for PG closely resemble the substance abuse criteria, including preoccupation, needing to gamble with increasing amounts of money to achieve the desired excitement (equivalent to tolerance), repeated unsuccessful efforts to cut down, and irritability when attempting to cut down (equivalent to withdrawal).

Recent biological studies have found a number of neurobiological features in common between pathological gamblers and substance users as identified by biochemical, functional neuroimaging, and genetic studies. Similarities between gambling and substance use disorders have been found in the neurotransmitter systems including dopamine, serotonin, and gamma-aminobutyric acid. Collectively, this evidence is being used to propose upcoming changes to the American Psychiatric Association’s *Diagnostic and Statistical Manual of Mental Disorders* (Fifth Edition) in which PG is moved from the Impulse Control Disorders to a new category currently proposed to be called Behavioral Addictions.

PREVALENCE OF COLLEGE STUDENT GAMBLING

North America

Transitioning from adolescence to adulthood makes college students a unique population worthy of attention. College students have been found to gamble more than the general adult population. The current generation of college students has grown up in a culture with widespread legalization and promotion of

gambling as a socially acceptable behavior. Two meta-analyses conducted in 1997 and updated in 2001, including 19 college studies, estimated the prevalence rates in the United States and Canada as 10.88% of college students classified as at-risk gamblers and 5.56% classified as pathological gamblers. For example, Lesieur and colleagues in the early 1990s surveyed six universities and found that 85% of students gambled, 23% gambled once a week or more, and 10% experienced some problems associated with their gambling. More recently, studies not included in the Shaffer and Hall meta-analyses have reported somewhat higher rates of disordered gambling, perhaps fueled by the campus craze of poker play.

Winters and colleagues conducted a three-wave longitudinal study of 305 Minnesota mid-adolescents (time 1 [T1] in 1992, time 2 [T2] in 1994, and time 3 [T3] in 1997–98) through young adulthood (mean ages were 16.0, 17.6, and 23.8), and reported two main findings: (1) the prevalence at wave 3 (young adulthood) of problem gambling, defined as 4 on the SOGS, remained unchanged from the previous two waves (adolescence) and (2) there was a significant increase from adolescence to young adulthood of at-risk gambling, defined as an SOGS score of 2–3. Winters and colleagues expanded on these findings by examining individual trajectories over the three-wave assessment. They classified their sample into five categorical behavioral patterns, which included resisters, persistors, desistors, new incidents, and others. Resisters were the largest group and made up 60% of the sample. Resisters never reached the threshold of problematic gambling over the three time points. Some of the resisters did engage in gambling, but report of their gambling behavior was consistently infrequent and nonproblematic. The least common behavior pattern, termed “persistors,” represented 4% of the sample. Persistors were individuals whose status was at risk or problem gambling at all three time points. Their typological feature involved regular or frequent gambling; most reported gambling weekly. Thirteen percent of the sample was categorized as desistors. Desistors followed a behavioral pattern of at-risk or problem gambling at time 1 (mid-adolescence) but never reported gambling problems at either time 2 or 3. Three percent of the sample was considered other, in that their gambling behavior appeared more episodic and variable in pattern. These individuals reported problematic gambling twice in the three-wave assessment but with an interrupted period of nonproblem gambling during the second wave. The second largest group was the new incidents (21%), which supports that early adulthood seems to be a particularly important age period when gambling-related problems emerge in the form of at-risk

gambling. This suggests that young adults (including college students) are a population in need of further prevention programming.

In contrast to studies showing higher rates of disordered gambling among young adults and college students, some studies have questioned if these rates are inflated. Slutske and colleagues in 2003 reported following 468 first-time freshmen as part of a larger longitudinal study of alcohol use patterns at the University of Missouri–Columbia. The data used for the longitudinal analyses correspond to ages 18–19, 21–22, 24–25, and 28–29, and assessed students during the years 1987–88, 1990–91, 1993–94, and 1997–99. The rates of past year and lifetime incidence of problem gambling remained stable over the 11-year period. Two to three percent of the sample reported experiencing gambling-related problems in the past year, 1–2% experienced a gambling-related problem for the first time in the last 3–4 years at ages 18, 21, 24, and 28, and about 3–5% of participants had experienced a gambling-related problem in their lifetime. While the rates of disordered gambling were found to be lower than the 10% found in previous studies, these rates were still higher than the general adult population. Although the study had a strong, longitudinal methodology, the results might be outdated, given that the assessment period coinciding with college attendance was during the late 1980s and early 1990s, before the media explosion of college student poker and Internet poker took hold of college students’ attention. In addition to the study’s timing, location of the campus and regional differences might also have been factors in the lower rates for this particular study. Recently, Welte and colleagues conducted a national telephone survey and found that the South had the lowest rates of gambling and problem gambling compared to the rest of the country.

LaBrie and colleagues surveyed 10 765 college students from 119 scientifically selected US colleges included in the 2001 Harvard Public Health College Alcohol Study. Their results indicate that 52% of males and 33% of females reported that they gambled at least weekly in the last school year. Those students older than 21 years were more likely to gamble, and students gambled more in those states in which they had greater availability of gambling venues such as casinos and card rooms. Despite these findings, the authors suggested that previous rates of disordered gambling among college students may have been overestimated. The study is commendable for its size and depth of analyses; however, the fact that the study assessed only gambling frequency and type of gambling (rather than symptoms of disordered gambling) warrants tempering of conclusions drawn from this study, especially given that over half of the men and one-third of the women in the sample endorsed weekly gambling.

Research suggests that frequent gambling (i.e. weekly) is associated with an increased risk of gambling problem severity.

In light of the mixed results regarding college student prevalence rates, the most recent meta-analysis was conducted in 2007, focusing solely on US college student populations. The analyses included 15 studies and found the rate of PG (SOGS ≥ 5) to be 7.89%. This estimate is slightly higher than the rates found by Shaffer and colleagues published 10 years earlier. The authors suggest that the increase in the prevalence rate could be due to the surge in gambling availability and an increase in the popularity of poker and other casino games among college students in the past 10 years. There is support for this hypothesis in that college students are in closer proximity to casino environments than ever before. Closer proximity to gambling venues has been shown to be a strong predictor of disordered gambling.

Another study of college student gambling attempted to define behavioral indicators associated with disordered gambling among college students. The authors concluded that gambling more than 1.2 times per month, gambling more than 2.1 hours per month¹, intending to wager more than 6.1% of monthly income, and wagering more than 10.5% of monthly income represented thresholds above which likelihood of disordered gambling increased. The combination of psychological distress, gambling frequency, and a history of parental gambling problems was significantly associated with diagnosis of PG in college students.

Other Countries

Gambling has proliferated around the world with a variety of ways to gamble, including government-sponsored lotteries, casinos, pari-mutuels, sports betting, and online gambling appearing throughout Asia, Australia, Europe, South America, and regions of South Africa. However, the particular issue of college student gambling or specifically disordered gambling within this population does not appear prominently in the research literature from studies conducted outside North America or Australia at this time. The current international research literature on disordered gambling has tended not to focus on college students per se but rather on college-aged young adults (ages 18–26). The nascent international research literature that does exist suggests that this segment of the population does tend to report higher rates of problems compared to the general adult population, a finding that could be attributed to broader developmental issues for this population. For example, the results of the British Gambling Prevalence Study conducted in 2010 reported that problem gambling estimates were higher among

college-aged men compared with older populations, 2.8 versus 0.4%, respectively. Among college-aged women, problem gambling estimates were 1.3% for those aged 16–24 years and 0.2% among those aged 65–74 years. Similar findings have been reported in several European countries, Australia, and Asia, suggesting that this age range may be more prone to gambling problems; however, more research needs to be conducted to see if the university environments may add unique contributing factors that add to the risk for this group.

Prevention programs aimed specifically at college student gamblers in other countries also do not appear in the published literature, perhaps due to the scarcity of research on the issue of disordered gambling among young adults outside North America or because of lack of awareness of disordered gambling in this age group as a public health issue. The lack of information on college student gamblers from around the world suggests that this is an area ripe for rigorous research to be undertaken.

ETIOLOGICAL FACTORS RELATED TO COLLEGE STUDENT GAMBLING

Behavioral Theories

Behavioral accounts of gambling overlap with behavioral psychology because of the principles of variable reinforcement, response costs, magnitude of reinforcement, and immediacy of reinforcement of gambling behavior. The writings of Ferster and Skinner describe the powerful technique of variable ratio schedules in training animals to press levers. A variable ratio delivers a reinforcer after a random number of responses, but based on a predetermined average. Rewarding the animal with food, an average of every fifth push on the lever increased the likelihood of the animal continuing to push the lever. The exact same principles of varying the ratio of reward can be found with gambling, especially slot machines. Ferster and Skinner also established that once initiated and learned by the animal, the behavior becomes hard to extinguish. Priming, in which a learned connection can be accessed via an unearned reinforcer, can trigger the original behavior. In the case of gambling, a disordered gambler who is abstinent can relapse to gambling based on environmental cues or apparently irrelevant decisions landing the gambler back in the casino.

Schneider discussed the limits of reinforcement in terms of magnitude. For example, most gamblers would not place a bet of \$100 if the payout were \$110. Hence, the gambling industry has found that using games that

are low cost with high magnitudes reinforces more play than high costs–low magnitude. Hence, this may explain why at casinos the penny slot sections are filled with more patrons than the high rollers slot sections. Likewise, gambling can also be maintained by modeling and second-order conditioning. Television, movies, and advertisements all provide models of gambling behavior, typically displayed as happy, successful gamblers with few or no negative consequences related to gambling. Money receives its value through a social construct agreed upon by members of a society, called a secondary reinforcer, since it is in fact merely paper and ink. Secondary reinforcers can be near wins or small payouts that can encourage continued gambling.

Immediacy of reinforcement is also an important factor in determining effects of a reinforcement schedule. For example, if a rat presses a lever but the reward is delayed more than 30 s, the rat does not associate the lever press with the reward. Similarly, gambling reinforcement immediacy is related to disordered gambling. The majority of people seen for treatment for disordered gambling engage in casino gambling, typically slot machines/video poker (which deliver immediate reinforcement) compared to lottery gambling (which is associated with delayed reinforcement).

There is also evidence that gambling can serve as a negative reinforcer. A negative reinforcer is one that takes away aversive stimuli. With disordered gamblers, this could be negative emotional state such as feeling sad, depressed, or bored. Research suggests that those who gamble to cope with negative effect have higher scores on gambling severity.

Biomedical Theories

Biological or biomedical theories of disordered gambling grew out of the psychodynamic approach, given that most psychoanalysts are trained in psychiatry or come from a medical background. The biomedical approach views disordered gambling as occurring due to a disease process or biological risk factors inherent in the person. This model has served to develop various theories of organic systems that could explain the difference between recreational and disordered gamblers. Early research focused on arousal and how gambling could influence the physiological systems involved in arousal. Studies have demonstrated that gamblers do report becoming aroused when involved in gambling. There are also corresponding physiological reports that have demonstrated that gambling behavior can increase heart rate and other measures, such as electromyographic activity and skin conductance level, and assays of endocrine response including salivary cortisol.

While results to date suggest that gambling and physiological arousal are connected, what that connection is remains to be established, as the findings and interpretations regarding the determinants and effects of arousal are not always consistent. Gambling severity is found to be associated with degree of arousal, but not always. Several studies have demonstrated that winning is more arousing than losing and that winning real money (versus chips or playing just for fun) is more arousing. While the results have been mixed, there does appear to be a connection between arousal and gambling behavior, which may have a biological component.

Other research on the biological basis of disordered gambling has focused on structural or abnormal brain functioning that might affect information processing systems of the brain. Pathological gamblers have been found to have reduced hemispheric differentiation compared to controls according to electroencephalography readings, which has been suggested to mediate impulse control. The study, however, did not fully describe the eight pathological gamblers for substance use or other histories of psychiatric disorders, which have been associated with similar abnormalities. More recent neurocognitive work has found impaired concentration, memory, and executive function and non-left hemispheric language dominance in gamblers compared to non-gamblers. The results suggest that these abnormalities could be the result of early brain damage, given that 81% of the 17 gamblers tested positive for brain injury.

Other biological evidence has begun to focus on the serotonergic, noradrenergic, and dopaminergic neurotransmitters; endogenous opioid systems; and the mesolimbic reward pathway as potential causal mechanisms in disordered gambling and addiction in general. The studies of these systems suggest that there may be genetic or functional abnormalities, which result in either structural or functional differences between gamblers and disordered gamblers. The current studies in the literature lack any randomized clinical trials, are generally based on small and often not well-described samples, and make causal inferences tenuous at best. Rarely do biological findings lend themselves to behavioral prevention strategies.

Cognitive Theories

Cognitive theories of human behavior and decision-making models became popular in the early 1970s and 1980s as a response to behaviorism. The cognitive theories relevant to gambling focus on cognitive distortions related to gambling. The psychological literature supports that human beings maintain several thought distortions especially about gambling. *Illusions of control*

refer to a belief that one has a greater amount of control on the gambling outcome than would be expected. Early experimental work found that people would behave differently if given the appearance that they could control the outcome. For example, Langer demonstrated that people who picked their number for a lottery ticket placed higher monetary value on that ticket than people whose tickets had already been randomly chosen for them, despite the fact that the outcome would be completely determined by chance and the expected value of both tickets is therefore identical. A second type of cognitive distortion relevant to gambling situations is commonly known as attribution bias. Wagenaar demonstrated that people who won on a series of hands of blackjack would attribute their wins to their skill, as compared to those who lost several hands, who would not make a personal skill attribution. There has been some support for the contention that disordered gamblers have significantly more cognitive distortions or qualitatively differ in the types of distortions made compared to non-disordered gamblers. However, other studies have not found support for differences in the frequency of erroneous statements made by disordered or non-disordered gamblers. Overall, cognitive distortions appear to be common regardless of gambling severity.

Social Influences

Normative beliefs, also called social norms, have been significantly influential and central to several theories of behavior and behavioral change based on social psychology concepts, such as Bandura's Social Learning Theory, Jessor and Jessor's Problem Behavior Theory, and Ajzen's Theory of Planned Behavior. The common thread between these psychological theories is the central tenet that cognitive processing of normative information or beliefs drives individual behavior and decisions to change that behavior. The term "social norms" often has two different ways of use in the literature. Descriptive norms refer to perceptions of actual behavior of others, whereas injunctive norms refer to perceptions of the appropriateness of a behavior. Research suggests that both types of norms are related to individual risk behaviors, and research further indicates that these norms are often misperceived. In particular, individuals tend to misperceive the descriptive norm as being higher than it actually is across a wide variety of health risk behaviors, including alcohol use, tobacco use, and a variety of other substances. Larimer and Neighbors examined college students' perceptions of peer gambling (descriptive norms) and their views on the acceptance of this behavior (injunctive norms) and found a similar pattern of misperception. Findings indicated that gamblers overestimated the descriptive

norm, assuming that other students gambled more often and with more money than students actually engaged. Both descriptive and injunctive perceived norms were related to self-reported gambling quantity, frequency, and negative gambling consequences in this study.

Integrated Pathway Model

The integrated pathway mode of PG builds an explanatory model of disordered gambling, which integrates psychological and social environmental factors. Blaszczynski and Nower offered a pathway model integrating empirical findings from biological, personality, developmental, cognitive, learning theory, and ecological determinants of problem and PG. The proposed model suggests three pathways, which add on to each other to create a subtype classification of disordered gamblers. In each of the pathway models, they suggest that the ecological factors of availability and accessibility must be present. The first pathway is a strict behavioral model, suggesting that operant and classical conditioning leads some people to form gambling habits, resulting in losses, which lead to chasing behavior and disordered gambling. The second pathway is the emotionally vulnerable model, similar to pathway 1 but with the addition of a biological abnormality leading to physiological resting states of hyper- or hypoarousal, and a history of negative childhood experiences, which interact and are influenced by the behavioral reinforcers inherent to gambling. This interaction again leads to disordered gambling. The third pathway is the impulsivity model. Similar to pathway 2 gamblers, this subgroup possesses both psychosocial and biologically based vulnerabilities, and features of impulsivity and antisocial personality disorder distinguish this third group. While the theoretical model provides a plausible explanation, given some of the existing literature, it remains to be scientifically tested.

HARMS ASSOCIATED WITH GAMBLING

Gambling Problems

Attempting to review all the health implications for gambling is beyond the scope of this chapter, and most of the research on health-related issues is conducted on older adults rather than college students. For many college students, gambling is an enjoyable pastime. Most college students will not experience serious problems or go on to develop disordered gambling from their gambling activities. Yet, for some students, gambling can lead to a variety of negative

consequences. Disordered gambling has also been linked to having higher rates of other mental disorders, including substance/alcohol abuse/dependence, eating, mood, anxiety, and personality disorders. Gambling activities along with the other risky health behaviors associated with gambling can promote a more sedentary and stressful lifestyle. Disordered gambling has also been linked to poorer health outcomes in several studies of later adulthood. Specifically, disordered gamblers have been found to have significantly higher rates of tachycardia, angina, cirrhosis, and other liver disease. Other studies have found that pathological gamblers suffered from minor respiratory ailments, high blood pressure, intestinal distress, migraine headaches, fatigue, and insomnia. It should be noted that these physical health issues do not typically appear during one's college years, but many of these individuals may have started gambling in college or earlier; thus, the long-term health outcomes may be attributed to gambling behaviors that started in one's college years but do not impact health until years later. Further research is needed to evaluate the contributing factors that appear to link disordered gambling to impacts on physical health.

Beyond physical health consequences, gambling has been linked to a host of social and economic consequences. There is very little in empirical research on the link between college student gambling and legal problems. Several anecdotal stories have appeared in the media, highlighting the legal issues that have arisen due to students' gambling problems, including theft, bank robbery, check and credit card fraud, insurance fraud, embezzlement, selling illicit drugs, illegal sports betting or book making, underage gambling or frequenting a casino, and college athletes fixing games.

Academic and work performance can suffer due to gambling and personal relationships as well. For many college students, the extended period of time at school presents a new freedom. Many students move away from the family home and engage in new activities such as gambling. However, if a student's gambling becomes problematic, it can put a strain on relationships with family and friends. Disagreements over finances and confrontations about gambling behavior can arise, causing stress to both the student and loved ones. It can be especially difficult for the student as they may withdraw from relationships and lose their support systems.

Perhaps the most common problem for disordered gamblers is the financial issues that arise from chasing losses. Many problem or PG college students bet away large sums of money needed for tuition or living expenses. There has been some research to show that credit card debt also provides the easiest way for players

to finance their gambling, which may allow the problem to fester for months to years without being addressed. Credit card debt among college students could potentially set up college students for financial difficulties later in life.

Again, there is very little empirical research on how gambling behavior affects students' academic performance. There have been a handful of college student studies conducted in the United States and Canada, showing that disordered college student gamblers report lower grades than non-disordered gamblers; however, no longitudinal studies have examined this question or offered a potential causal mechanism for this outcome. Some have suggested that as disordered gamblers spend more time gambling and less time studying, the result is poor grades. No studies have examined dropout rates of college students due to gambling-related issues. It is possible that some students leave college due to their gambling behavior and anecdotal stories have circulated of students leaving college in order to pursue life as a "professional gambler," typically to pursue their interest in poker.

GAMBLING PREVENTION

Indicated Prevention Programs

Prevention programs are designed to alter behavior or change the trajectory, by either increasing positive health behaviors (i.e. getting more sleep, eating more vegetables) or decreasing negative health behaviors (i.e. reducing alcohol consumption, stopping smoking) in order to reduce or avoid future problems, thus leading to better outcomes than if nothing was done. In 1990, the Institute of Medicine described three-tiered classification levels of prevention based on the target populations. Universal prevention targets the entire population regardless of their individual experience with the problem. Selective programs target a specific population due to the group's status as high risk, again regardless of individuals' experiences with the problem. Indicated prevention targets individuals who are already experiencing indications of the problems at either subclinical or clinically significant levels. Typically, individual interventions focus on targeting risk and/or protective factors believed to be contributing to the problem behavior. The intervention is designed to either reduce the individual's risk or enhance their protective behaviors when being exposed to the problem.

Prevention programming can take many forms and many levels such as policy approaches aimed at preventing problems through the implementation of laws

and regulations. For example, setting the legal age to gamble is a policy intervention. While this does impact college students, most prevention programming to date has not specifically focused on college students despite the evidence that they are an at-risk population for disordered gambling.

Despite the relative dearth of evidence in the area of college student gambling prevention, three recently published randomized trials evaluated the efficacy of prevention programming with disordered gambling college students. All three prevention programs approach college student prevention using a combination of motivational interviewing (MI)/enhancement and cognitive behavioral principles to guide their development. MI, developed by Miller and Rollnick, views ambivalence about behavior change as typical, and the intervention is designed to highlight the discrepancy between one's current problem behavior (status quo) and personal goals (future ideal self) in order to reduce ambivalence. The goal of prevention facilitators is to have the participant voice their need to change, thus engaging their intrinsic motivation to change the problem behavior. All three programs also incorporate normative feedback components to some degree as part of their prevention program. Normative feedback is based on a social psychology principle that people who engage in a behavior tend to overestimate the actual norm of a behavior, and this overestimation is in part driving their own behavior. Correcting the misperception should enhance an individual's motivation to reduce their gambling to be more in line with normative behavior. In this case, those who gamble problematically think that others gamble more often and lose more money than they actually do, and presenting the actual norms on gambling in a nonjudgmental framework may aid in reducing a participant's actual gambling behavior.

Two of the existing prevention studies based their prevention approach on an adaptation of efficacious alcohol prevention programming with college students, a program called Brief Alcohol Screening Intervention for College Students (BASICS). BASICS uses an MI framework combined with cognitive behavioral skills training to reducing harms associated with alcohol consumption. The findings of the studies varied in the degree in which students reduced their gambling frequency and quantity of associated negative consequences.

Takushi and colleagues conducted one of the first indicated prevention studies on gambling for college students. Their pilot study focused on adapting the BASICS intervention to reduce at-risk gambling for college students. Participants were randomized to either the intervention or the control group. The prevention program had an assessment phase in which participants completed a series of paper-pencil measures and

returned the following week to meet a program facilitator for a one-on-one personalized feedback session. A personalized feedback sheet that contained a summary printout of participants' data combined with psychoeducational information for reducing alcohol and gambling harms was provided for each participant. Program facilitators reviewed each participant's feedback sheet as a guide for a discussion on gambling and alcohol use, using a MI style. Participants were followed up 6 months later to assess their level of gambling and alcohol use. The study was underpowered to show treatment effects, but results indicated that participants in the intervention group reduced their concurrent episodes of drinking and gambling compared with those in the control group. Data suggest that those who drink alcohol and gamble concurrently are more likely to gamble with more money, lose money faster, gamble for longer amount of time than they intended, and experience greater negative consequences compared to those who do not drink and gamble concurrently.

Petry and colleagues conducted a randomized prevention trial for college students, comparing three different types of prevention programs to an assessment-only control (AOC). The interventions tested included a brief advice condition; a brief Motivational Enhancement Therapy (MET) session, similar to the one described above by Takushi and colleagues; and an MET + four-session Cognitive Behavior Therapy (CBT). The brief advice condition was a 10–15 min discussion, which involved the facilitator assessing the student's involvement with gambling (frequency and quantity) and providing some general college student norms comparison data regarding how often and how much other college students gambled, ways to identify risky gambling behavior, and specific tips for reducing risky gambling (i.e. setting a budget, setting a time limit, and not to think of gambling as a way to make money). The MET condition was 50 min, focusing on the pros and cons of the student's gambling, providing a handout that contained national norms of gambling for college students, and completing a change plan worksheet aimed at reducing gambling-related harms. The MET + CBT condition was four, 50-min sessions. The first session was the same as the MET session, plus three additional CBT sessions focusing on (1) identifying triggers (internal and external) for gambling, (2) coping with internal triggers, and (3) coping with external triggers. Participants were followed over 6 weeks and 9 months. At the end of the study, those in any prevention groups reported less gambling severity and days spent or dollars spent on gambling compared to AOCs at the 9-month follow-up. Surprisingly, there were no differences on outcomes between the three conditions, suggesting that a 10–15 min of brief advice intervention

was as effective as the four sessions of MET + CBT prevention programming.

The third empirically based prevention program was a follow-up to Takushi and colleagues program conducted by Larimer and colleagues. This program, called Project Chance, combined both gambling and alcohol prevention programming. Participants were a random sample of undergraduates who completed a screening survey, using a score of 3 or greater on the SOGS (lifetime timeframe) as the indicator of at-risk gamblers for inclusion in the study. Invited participants completed a longer baseline assessment, then were randomly assigned to receive one of three groups that were the following: an individual, in-person, single-session personalized feedback intervention (PFI) similar to the approach used by Takushi and colleagues; a four- to six-session group cognitive behavioral intervention (CBI) similar to Petry and colleagues; or AOC. Participants were followed up 6 months later.

Results suggested that the prevention programming of either the PFI or the CBI was efficacious for reducing gambling frequency, amount spent (lost) on gambling, and negative consequences compared to AOCs. The study also tested theoretically driven mediators of these interventions. Those in the PFI condition were expected to improve if normative misperceptions of gambling were reduced, whereas those in the CBI intervention were expected to improve via reductions in their cognitive distortions regarding gambling. However, only the correction of normative misperceptions was found to mediate the intervention effect for the PFI group. Though cognitive distortions were improved following CBI intervention, this did not appear to be the mechanism through which the CBI intervention impacted gambling outcomes. While there remains significant work to be done in the area of college student gambling prevention, there does appear to be emerging evidence that interventions based on sound psychological theory and incorporating elements of MI style, personalized normative feedback, and cognitive behavioral approaches such as cognitive correction and protective behavioral strategies may be efficacious in reducing gambling frequency, quantity, and harms. Further, there is some evidence to suggest that a single session of brief advice or motivational feedback may be more feasible and similarly efficacious to multisession, multicomponent approaches.

CONCLUSIONS

Although most students who gamble appear to do so without significant consequences, gambling nonetheless represents a significant public health concern among college students due to increased rates of disordered

gambling in college students and college-aged individuals relative to the general adult population. Research on gambling in young adults and college students is in its infancy, and there is relatively little research on this topic outside North America and Australia. Three recent randomized controlled trials in the United States demonstrate that brief interventions can be efficacious in reducing gambling frequency, amount, and harmful consequences of gambling among college students. Additional research is needed to better understand the prevalence, etiology, and prevention of gambling among college students and college-aged young adults worldwide.

		Need for More Research	900

Research has identified multiple risk factors that, when present, increase the likelihood of substance use among youth and young adults. These conditions or experiences include individual characteristics (e.g. displaying aggression at a young age or believing that using drugs is not harmful), peer influences (e.g. having friends who use drugs or who believe that drug use is acceptable), family experiences (e.g. drug use by parents or siblings or inadequate monitoring of children by parents), school factors (e.g. academic failure or having a low commitment to school or education), and neighborhood experiences (e.g. availability of drugs or community norms that support drug use). Protective or promotive factors, which ameliorate the negative influences of risk factors or directly reduce the likelihood of drug use, also exist in all areas of individuals' lives (e.g. attachment to prosocial others, having a resilient temperament, or having healthy beliefs and clear standards regarding substance use).

Prevention efforts aimed at reducing rates of substance use typically do so by minimizing one's exposure to harmful risk factors and/or by enhancing

protective/promotive factors in order to reduce the negative impact of risk factors. While many prevention efforts have been found to reduce tobacco, alcohol, and drug use using this type of approach, these strategies are often limited in addressing risk and protective factors from just one developmental period or socialization domain. Most focus on the most proximal causes of drug use, such as peer or family influences, rather than targeting the larger contexts in which youth and young adults live. This narrow focus may reduce the overall impact and long-term effectiveness of drug use prevention strategies, given that multiple factors affect substance use and because the effectiveness of any intervention is likely to be compromised if the environments in which individuals live are unfavorable to or do not support intervention goals and activities.

Community-based efforts offer broad potential for impacting rates of substance use. Such programs rely on multiple strategies intended to change a variety of factors that place individuals at risk for engaging in substance use, thus potentially increasing their likelihood of success. Most also seek to alter the long-term,

structural, and environmental influences that are associated with drug use and abuse, along with more proximal influences, which increase their potential to make a significant and long-lasting impact on drug prevention. By saturating the environment with prevention strategies and messages, community-based efforts aim to reach many more individuals and thus have the potential to achieve population-level reductions in substance use.

Another potential advantage of community-based strategies is their reliance on members of the local community to plan, implement, and monitor prevention activities, usually via coalitions comprised of stakeholders from diverse organizations and backgrounds. By actively involving the community in the prevention effort, these approaches may enhance community buy-in for prevention activities and may help to ensure that services are a good fit with local needs, resources, and norms. Levels of elevated or depressed risk and protective/promotive factors vary across communities, and what is most needed in one community to reduce youth drug use may not be what is needed in another community. Thus, prevention efforts that are based upon assessing local needs (i.e. risk and protective/promotive factors faced by individuals in the community) and implementing prevention strategies that are best suited to address these needs may be more effective than implementing a single prevention program across all communities. Mobilizing the community also has potential for pooling information and resources across agencies and individuals, minimizing duplication of services, and potentially offering more cost-effective services that are better implemented and more likely to be sustained.

WHAT DOES IT MEAN TO MOBILIZE COMMUNITIES TO PREVENT DRUG USE?

Existing community-based drug prevention efforts are flexible and adaptable to local circumstances, which make it difficult to identify the specific components that define this type of approach. Nonetheless, community mobilization efforts have in common the goal of reducing drug use by changing the larger environment using approaches that are owned and operated by the local community. Most rely on coalitions of community stakeholders to collaboratively plan and coordinate prevention activities, which typically take one of two forms. In some cases, coalitions focus on implementing, in a coordinated fashion, multiple, discrete prevention programs and practices that seek to decrease elevated risk factors and enhance depressed protective/promotive factors related to drug use. Others focus on transforming the environment via changes in local

ordinances, norms, and policies related to drug use. These efforts target a more limited number of risk factors; in particular, community norms and laws related to drug use, the availability of drug use in communities, and individual attitudes favorable to substance use. Some community-based efforts rely on a combination of these strategies.

WHAT COMMUNITY-BASED STRATEGIES WORK TO REDUCE DRUG USE?

A review of evidence from controlled and well-conducted evaluations of community-based interventions implemented in the United States has identified 12 community-based initiatives that have been shown to reduce rates of tobacco, alcohol, or drug use among youth and young adults. [Table 90.1](#) lists these interventions and provides a brief description of each program, the population for whom the intervention was evaluated, and the program's significant effects in reducing drug use. These initiatives were identified via a systematic review of the literature. Programs were eligible for inclusion in the review if they included a substantial community-based component, and were evaluated using a quasi-experimental or true experimental design that involved, at a minimum, one intervention group (implementing the strategy) and one comparison group, and collected data on drug use outcomes at least two times during the research project (e.g. before and after the intervention was conducted).

The findings from the review indicate that a common feature of successful community-based prevention approaches is reliance on local coalitions to select and implement with fidelity preventive interventions that have evidence of effectiveness. The inclusion of universal, school-based drug prevention curricula is also associated with reductions in substance use. Environmental strategies, such as changing laws, norms, and policies related to alcohol access and use, do not appear to reduce alcohol use among adolescents when implemented independently of other community-based strategies. However, they have been a part of successful multicomponent interventions and, implemented on their own, have reduced the availability of alcohol in communities and lowered drunk-driving arrests among young adults.

RELIANCE ON COMMUNITY COALITIONS TO PREVENT DRUG USE

All of the effective community-based initiatives listed in [Table 90.1](#) relied on local coalitions to plan and

TABLE 90.1 Community Mobilization Strategies with Evidence of Effectiveness in Reducing Substance Use

Study	Description	Study population	Significant effects
Kentucky Incentives for Prevention	Coalition-based prevention strategy targeting risk and protective factors related to drug use with effective programs	19 coalitions in Kentucky; 25 032 students in Grades 8 and 10	Reduced smoking, drinking, and binge drinking among 10th graders
New Directions	Coalition-based prevention strategy targeting risk and protective factors related to drug use with effective programs	23 coalitions in Vermont; 24 932 students in Grades 8–12	Reduced past month smoking and marijuana use
Communities That Care (CTC)	Coalition-based prevention strategy targeting elevated risk and depressed protective factors related to drug use with effective programs	24 communities in seven states; 4407 students in Grade 5	Reduced the initiation of smokeless tobacco, smoking, and alcohol Reduced past month use of smokeless tobacco, alcohol, and binge drinking
PROMoting School –community–university Partnerships to Enhance Resilience (PROSPER)	Coalition model relying on school and university staff to implement school-based and family-focused programs targeting risk and protective factors related to drug use	28 school districts in Iowa and Pennsylvania; 12 022 students in Grade 6	Reduced the initiation of marijuana, inhalants, meth, ecstasy, gateway drugs, and illicit drugs Reduced past year use of marijuana and inhalants
Midwestern Prevention Project	Combines community mobilization strategies with the implementation of school-based prevention curricula	42 schools in Kansas City; 5065 students in Grades 6 and 7	Reduced past month smoking and drinking
Project SixTeen	Combines community mobilization strategies with the implementation of school-based prevention curricula	16 communities in Oregon; 4438 students in Grades 7 and 9	Reduced smoking, drinking, and marijuana use
Project Northland	Combines community mobilization strategies with the implementation of school-based prevention curricula	24 school districts in Minnesota; 2953 students in Grade 6	Reduced binge drinking and alcohol sales to minors
Native American Project	Combines community mobilization strategies with the implementation of school-based prevention curricula	27 tribal and public schools in the Midwest; 1396 students in Grades 3–5	Reduced smokeless tobacco, alcohol, and marijuana use
Minnesota Heart Health Program	Combines community mobilization strategies with the implementation of school-based prevention curricula	Two communities in Minnesota; 2401 youth in Grade 7	Reduced smoking
DARE Plus	Combines community mobilization strategies with the implementation of school-based prevention curricula	24 schools in Minnesota; 7261 students in Grade 7	Reduced past year and past month smoking and drinking for boys and having ever been drunk for girls
Communities Mobilizing for Change on Alcohol	Coalition-led activities seeking changes to community policies, practices, and norms related to alcohol use	N = 15 school districts in MN and WI; 4506 students in Grade 12 and 3095 18–20 year olds	Reduced the provision of alcohol to minors and arrests for drunk driving among 18–20 year olds
Community Trials Project	Coalition-led activities seeking changes to community policies, practices, and norms related to alcohol use	N = 6 communities in CA and SC	Reduced heavy drinking among adults, alcohol sales to minors, and alcohol-related car crashes

implement prevention activities. This evidence indicates that to be successful, community efforts must ensure the presence of active, broad-based groups of individuals who believe it is possible to prevent drug use and who are willing to engage in collaborative prevention activities. Although coalitions vary in their structure, size, goals, and activities, a defining feature of such groups is their focus on facilitating desired changes through collaborative action. While the specific members of a coalition may vary depending on the focus of the group, coalitions usually seek to be broad based and to unite diverse stakeholders and key leaders from key agencies and sectors of the community that have a stake in creating a change. Coalitions focused on preventing drug use may include members from law enforcement, local government, health and human service agencies, youth service groups, business, religious groups, youths, and parents. Coalitions are typically formed around a common vision that inspires and motivates their actions. By working together to bring about change, coalitions allow intervention approaches to be tailored to local needs, as identified by coalition members. They also increase political alliances, foster communication among community members, and coordinate human and financial resources.

Although coalitions are a common element of effective community-based prevention, not all coalition efforts have produced significant changes in drug use. Some coalition initiatives have failed to reduce rates of drug use among youth and adolescents, even when groups were well funded and members were well intentioned and willing to make changes. Two evaluations of coalition efforts, the Fighting Back and Community Partnership initiatives, for example, both evidenced failures in bringing about changes in youth drug use. The evaluations indicated that the coalitions involved in these projects had insufficient guidance in how to enact prevention strategies, varied widely in the nature and amount of prevention services provided, and largely relied on locally created prevention strategies which likely had not been previously evaluated for effectiveness in reducing drug use. These studies suggest that the mere presence of an active, well-intentioned coalition is not enough to prevent drug use; that is, simply gathering local stakeholders and asking them to collaborate to do their best to solve local drug problems do not produce desired changes.

The evidence suggests that to be successful, coalitions must set clearly defined, focused, and manageable goals; have adequate planning time; base prevention decisions on empirical data about what needs to change in the community and on evidence from scientifically valid studies of what has worked to address those needs; implement prevention policies, practices, and programs that have been tested and shown to be effective; and carefully

monitor prevention activities to ensure implementation quality. Two programs that exemplify these principles are the Communities That Care (CTC) and the PROMoting School–community–university Partnerships to Enhance Resilience (PROSPER) coalition models. Evaluations of these initiatives have shown reductions in the initiation and prevalence of youth drug use.

CTC and PROSPER provide proactive training and technical assistance to community coalitions to ensure that they select and implement with fidelity prevention strategies that have been previously demonstrated as effective in reducing youth drug use. The CTC model involves a structured and guided intervention process involving five phases, in which coalitions (1) assess community readiness to undertake collaborative prevention efforts; (2) form a diverse and representative prevention coalition; (3) use epidemiologic data to assess prevention needs; (4) select evidence-based prevention policies and programs that target these needs; and (5) implement the new policies and programs with monitoring to ensure fidelity and evaluation to ensure that goals are being met. The coalitions are structured, ideally with chairs, co-chairs, and workgroups; employ at least a half-time coordinator; and are broad-based. Prevention activities selected and implemented by communities can take place in a variety of settings and may target individual, family, school, peer, and/or community risk and protective/promotive factors related to drug use. Community coalitions select prevention strategies from a menu of options that includes only policies and programs that have been shown in at least one study using a high-quality research design to significantly change risk and protective factors and reduce rates of drug use.

Unlike the CTC model, which makes no stipulations regarding the agency or individual best suited to lead the coalition, the PROSPER model is initiated by local university Cooperative Extension Service agents, who partner with school district personnel to facilitate coalition activities. Coalitions receive technical assistance from state-level extensive staff who are supported by university research scientists. PROSPER coalitions do not undertake an extensive needs assessment as is done in CTC. The PROSPER model assumes that youth in all communities will benefit from family- and school-based prevention programs, and communities select evidence-based prevention programs from a menu of options limited to these areas. Thus, prevention activities are centered in the school and involve the implementation of school-based prevention curricula and workshops for parents and/or children that focus on increasing parental supervision and effective discipline of youth, enhancing parent–child communication, and providing children with tools to effectively resist drug offers.

Several evaluations of the CTC coalition model have been conducted, including a randomized experiment involving 24 communities in seven states, which were randomly assigned to either implement the CTC system ($n = 12$) or to serve as control communities ($n = 12$). Intervention sites received training in the CTC model, proactive and intensive technical assistance, and funding for 5 years to plan and implement tested and effective prevention strategies. This study indicated that, after 4 years of the intervention, students in CTC communities had lower rates of substance use compared to students in control communities. They were less likely to initiate cigarette, alcohol, and smokeless tobacco use as well as delinquent behavior by Grade 8. In addition, 8th grade students in the intervention communities reported lower rates of drinking, binge drinking, smokeless tobacco use in the past month as well as delinquent behavior in the past year compared to students in the control communities.

An experiment testing the effectiveness of the PROSPER model involved 28 communities in Iowa and Pennsylvania which were randomly assigned to implement PROSPER ($n = 14$) or to act as control communities ($n = 14$). Eighteen months after the intervention began, when students were finishing Grade 7, significantly fewer youth in the PROSPER communities had initiated the use of marijuana, inhalants, methamphetamine, and ecstasy compared to those in the control communities. Students in the PROSPER communities also reported significantly less marijuana and inhalant use in the past year compared to students in the control communities.

These studies indicate that when local community coalitions are provided with proactive training and technical assistance, have clear goals and guidelines, and ensure that they effectively implement prevention strategies that have prior evidence of effectiveness, they have the potential to significantly reduce substance use community wide. The particular strategies that are implemented appear to matter less than the process by which programs are selected and the manner in which they are implemented. That is, coalitions may enact a variety of previously tested and proven prevention policies and programs targeting a variety of risk and protective factors and still be successful, as long as efforts maintain the focus on using methods that have themselves been demonstrated effective and ensure that prevention activities are carefully implemented, monitored, and coordinated.

INCLUSION OF SCHOOL-BASED CURRICULA IN COMMUNITY-BASED EFFORTS

Implementation of universal, school-based drug prevention curricula as part of the larger community

effort appears to predict reduced rates of substance use among middle and high school students. All of the community-based initiatives listed in Table 90.1 that were effective in preventing or reducing youth substance use involved the implementation of a school-based curriculum. In the PROSPER and CTC initiatives, for example, school programs were selected by community coalitions as one element of their comprehensive prevention strategies. The PROSPER coalition model mandates the implementation of such curricula in order to reach a large percentage of the youth population and to target individual-, peer-, and school-related risk and protective factors. While the CTC prevention system does not require the use of school curricula, all of the coalitions involved in the randomized evaluation of CTC implemented a school curriculum during the study in order to target particular risk factors identified as too high or protective factors identified as too low by the local coalition.

Other successful community-based prevention initiatives have involved the implementation of a particular school curriculum offered to students in conjunction with the implementation of environmentally focused strategies targeting community risk factors related to drug use. An evaluation of the Project Northland program in Minnesota, for example, demonstrated the reduced rates of drug use in communities that implemented a multiyear school curricula and made changes to local policies and practices associated with youth alcohol use. The school program focused on decreasing students' views regarding the acceptability of alcohol use, increasing students' skills in refusing drug offers, and increasing parent-child communication about alcohol use through homework, assignments, and information mailed to parents. Environmental strategies included increased identification checks by retail liquor establishments and legal consequences for selling alcohol to minors. The evaluation of Project Northland found that, after receiving services in both middle and high school, students in Project Northland communities had lower rates of binge drinking (i.e. drinking five or more alcoholic beverages on one occasion) compared to students in control communities. In addition, retail establishments were less likely to sell alcohol to minors in intervention versus control communities.

A similar combination of activities is advocated in the Midwestern Prevention Project (MPP). This program involves the implementation of a 2-year middle school curriculum to promote students' drug resistance skills, along with parent education, media campaigns to reinforce antidrug messages throughout the community, and local policy changes to reduce demand and supply of drugs. When implemented in schools in Kansas City, MPP demonstrated reductions in past month smoking and alcohol use for students receiving the intervention

compared to students in control schools. Long-term effects were also found on past month tobacco and marijuana use when students were in Grades 9 and 10.

In Project SixTeen, small communities in Oregon implemented a five-session school-based program targeting reductions in youth tobacco use, along with media campaigns and responsible beverage training for alcohol retail outlets. The evaluation showed a significant reduction in past week smoking and marijuana use for 7th and 9th grade students in intervention compared to control communities, and less alcohol use among 9th graders. A similar initiative, the Minnesota Heart Health program, combined the implementation of a 1-year school-based program focused on tobacco prevention with 5 years of community education and mobilization efforts intended to improve diet, exercise, and reductions in smoking among community residents. An evaluation of this program found significantly less smoking among students in the intervention versus control communities at the end of high school.

These studies indicate that the inclusion of school-based prevention programs in comprehensive, community-based initiatives can contribute to reductions in drug use among adolescents. These results are not particularly surprising, given that a variety of school-based prevention programs have shown evidence of effectiveness when evaluated independently of other prevention efforts occurring in communities. These curricula target an array of risk factors for drug use using a variety of methods, but also have certain characteristics in common. Most successful school-based programs move beyond teaching students about drugs and their consequences using primarily didactic teaching techniques. Instead, they rely on interactive teaching strategies that engage students in the material and allow them to practice mastery of new skills. Rather than simply delivering content or seeking to increase knowledge, such programs focus more broadly on increasing general social and life skills, such as enhancing students' ability to effectively communicate with others, make good decisions, set goals, positively cope with stressful situations, and skillfully refuse offers of drug use. While they may include information about drugs and their harmful effects, such programs tend to focus on short-term rather than long-term consequences of drug use. They also aim to change students' normative beliefs about drug use; for example, by providing students with statistics regarding the actual rates of adolescent drug use in order to counteract teenagers' perceptions that the majority of their peers are using drugs.

Currently, most schools in the United States provide some type of drug prevention programming to students, but not all school districts implement strategies that have evidence of effectiveness, despite the fact that the

Safe and Drug Free School (SDFS) legislation mandates the use of effective substance use prevention curricula. Coalitions can help school districts fulfill the SDFS mandate by helping them identify and adopt strategies that are effective and by helping to ensure that the new programs are well suited to addressing the needs of local students. In addition, coalitions can partner with schools to find the needed resources to initiate and sustain new effective prevention strategies and can help oversee the implementation of the new strategy to ensure that it is well implemented. Inclusion of school-based programs in a larger community prevention initiative thus provides multiple advantages, including the ability to reach much of the youth population and thus increase the potential of achieving community-level changes in desired outcomes.

TARGETING ENVIRONMENTAL RISK FACTORS FOR SUBSTANCE USE

The initiatives just described combined the implementation of school curricula with community mobilization efforts that target environmental risk factors in order to reduce the availability of and demand for tobacco, alcohol, or other drugs. Such efforts include changes to community-level policies, practices, and norms, such as creating ordinances to restrict smoking in public settings, increasing alcohol pricing, creating drug-free zones, limiting alcohol sales in venues easily accessible to youth, requiring keg registrations, and increasing the use or severity of community laws related to drug use by minors or adults. Changes to community practices may involve responsible beverage service training; that is, educating merchants about the negative consequences of providing tobacco or alcohol to minors or serving intoxicated patrons, encouraging identification checks, and ensuring that merchants who violate rules are appropriately sanctioned. Media campaigns may also be used in conjunction with these activities to educate the public about the negative effects of drug use, increase support for drug prevention, and counter norms favorable to drug use. Media increases public awareness by saturating the community with print, radio and television advertisements, mailing informational fliers to businesses or homes, or by holding community forums to discuss substance use issues.

Evidence is mixed regarding the effectiveness of environmentally focused prevention strategies. As discussed in the previous section, when offered in conjunction with school-based prevention curricula, they appear to be effective in reducing rates of youth substance use. However, efforts that focus exclusively on changing environmental risk factors, without also

targeting more proximal risk factors related to drug use, have *not* been associated with reductions in alcohol use among youth under the age of 18. For example, an evaluation of Communities Mobilizing for Change on Alcohol (CMCA) found no changes in drug use among 12th grade students or 18–20 year olds in communities implementing CMCA compared to those in control communities. In this project, community coalitions coordinated a variety of activities aimed at limiting alcohol sales to minors, increasing enforcement of under-aged drinking laws, and changing alcohol policies at community events, as well as increasing public attention to problems associated with under-age drinking. Although rates of alcohol use were not changed by the intervention, the evaluation showed that 18- to 20-year-old youth from intervention sites were less likely to provide alcohol to minors and were less likely to be arrested for drunk driving compared to those in control sites.

The Community Trials Project used similar environmentally focused prevention strategies to reduce alcohol use and related risky behaviors among young adults. A quasi-experimental evaluation of this program in six communities indicated no differences in rates of drinking among youths less than 18 years old in intervention versus comparison sites. Among adults (those aged 18+ years), a *greater* proportion of those in communities implementing the program reported having one or more drinks in the past year versus those in comparison communities. However, among those who reported any drinking, adults in intervention sites had lower rates of heavy drinking and drunk driving. The evaluation also showed fewer nighttime injury car crashes and drunk-driving crashes and fewer sales to minors by alcohol sales establishments in intervention versus comparison sites.

The mixed evidence for environmentally focused strategies makes it difficult to draw firm conclusions regarding their ability to reduce substance use. Among those under 18, there have been effects in existing studies only when they included a school curriculum. There have been very few evaluations of community-based prevention efforts that rely solely on changing community policies, practices, and norms, and more research is needed to assess the impact of environmental strategies when used independently and when combined with other types of prevention strategies.

CHALLENGES OF COMMUNITY MOBILIZATION EFFORTS

There is much public support for community mobilization efforts that seek to reduce substance use, and many communities have coalitions in place to coordinate

community-based prevention strategies. However, implementing, evaluating, and sustaining such efforts can be challenging. Ensuring the adoption and high-quality implementation of a single prevention program or practice is demanding, and problems are likely to be multiplied when adopting a multiple-component strategy enacted in a variety of settings by numerous service providers. It is often difficult to engage and ensure collaboration among community members from diverse backgrounds who may have different skills, needs, resources, and ideas about what is needed to prevent substance use. Compared to single prevention programs, community-level strategies are likely to be costlier to implement and evaluate, as they entail more components and require longer term interventions in order to achieve community-wide outcomes. It can also be difficult to recruit entire communities to participate in research studies and to measure processes and outcomes that may vary across communities. Community-based prevention strategies are intended to be owned and operated by the community, which can create tension between local practitioners and scientists who may differ in their ideas about what is most needed to prevent drug use.

The many challenges related to the implementation of community-based prevention efforts are likely responsible for the relatively small number of interventions that have demonstrated evidence of success, as seen in Table 90.1. In addition, evaluations of some community prevention programs have failed to demonstrate significant effects on substance use, sometimes due to problems related to program implementation and intensity. For example, the initial evaluation of the Project Northland program in Minnesota indicated that the 3-year intervention implemented in middle schools was not enough to lead to sustained effects on drug use, and additional services were added in high school, which reduced rates of alcohol use through Grade 12. A replication of this program in Chicago failed to produce positive effects, which led the evaluators to recommend that in lower income, urban populations, in which problems other than youth drug use (e.g. gangs, violence, and housing) may take precedence, longer term and more intense community-based strategies may be needed to bring about change.

The Project Northland replication in Chicago and other evaluations have noted that implementation challenges, such as difficulty in engaging community members in the initiative and challenges in moving from planning to action, may compromise the ability of community-based efforts to produce significant effects. Nonetheless, evaluations of the CTC and PROSPER prevention systems have shown that communities can successfully mobilize volunteers, create high functioning and goal-driven coalitions, and ensure the high-quality implementation of prevention strategies

that target salient risk and protective factors. Success is more likely when community coalitions are provided with proactive and high-quality training and technical assistance from system developers. Establishing close relationships between research scientists and community practitioners can be mutually beneficial. By observing firsthand the challenges and successes faced by the community, researchers gain a better understanding of how their interventions work and can make refinements as needed. At the same time, direct access to program developers allows practitioners to have their questions answered, feel supported when problems arise, and ensure that the intervention is well aligned with their particular needs and resources. In the absence of training and technical assistance, common implementation challenges are likely to threaten implementation and the likelihood of realizing desired reductions in drug use.

NEED FOR MORE RESEARCH

While this review has identified 12 community mobilization strategies with the evidence of effectiveness in reducing substance use, more research is needed to clarify the particular types of community-based strategies that are effective and to identify new models that may also reduce drug use. Most of the initiatives reviewed involved a combination of prevention strategies, and more studies are needed that can scientifically compare the relative effectiveness of these components in order to identify the particular strategies and/or sets of strategies that are most likely to lead to reduced drug use. Ideally, these and other evaluations will employ a true, randomized experimental research design which can best assess the effectiveness of the intervention. Additional information is needed to assess the extent to which interventions have different effects for different groups of individuals (e.g. males versus females) or for different types of communities (e.g. urban versus rural). Some of the programs included in this review did identify variation in effects; for example, some found greater reductions in drug use for males versus females, or for individuals who had already initiated drug use prior to the intervention. More complete information about how and for whom interventions work can reveal whether or not programs have iatrogenic effects (i.e. leading to *increased* rates of drug use) for certain individuals, can aid in the selection of programs by communities, and can be used by program developers to refine their interventions.

Finally, further research is needed to provide information on the financial costs versus benefits of community-based efforts. The National Center on Addiction and Substance Abuse (CASA) (2009) estimated that

over \$467 billion was spent in the United States in 2005 in responding to the negative consequences of drug abuse and addiction. Only two of the programs included in this review have been rigorously evaluated for cost-effectiveness, and in both cases, fiscal savings were demonstrated. According to the Washington State Institute for Public Policy, for every dollar spent on Project Northland in Minnesota, the program produced a savings of \$2.45 in later treatment, morbidity, mortality, and criminal justice costs, while the Midwestern Prevention Project produced a savings of \$1.27. Given that cost is a major factor influencing community decisions to adopt new programs, information on financial benefits may help to increase the dissemination of community-based prevention strategies, and, in turn, their potential to substantially reduce the rates of drug use among young people.

INTRODUCTION

Alcohol use among college students is associated with many problems, including traffic crashes, falls, fights, sexual assaults, poor grades, and alcohol overdose. Rather than focusing on preventing each type of problem individually, the most efficient approach to reducing these problems simultaneously is to reduce rates of alcohol use and/or change drinking patterns among college students. Alcohol control policies can effectively change drinking rates and patterns among the entire population of student drinkers.

Some college students drink very heavily on a regular basis; and some of these students may meet diagnostic criteria for alcohol abuse or alcoholism. These students are at a very high risk for experiencing alcohol-related problems and require some type of intervention. However, other college students are also at risk for alcohol-related problems. In 2008, approximately 40% of college students in the United States reported binge

drinking – in other words, they consumed five or more drinks in a row on at least one occasion in the past 2 weeks. While some students who binge drink meet a diagnostic criteria for alcohol dependence, the majority of these students do not. However, these students are also at risk of experiencing alcohol-related problems; in fact, these binge-drinking students account for the largest number of alcohol-related problems and the majority of damage, deaths, and societal costs related to college student drinking.

The drinking behavior of the entire continuum of college student drinkers may be affected by implementing policies that influence access to alcohol. Research shows consistently that as access to alcohol increases, rates of alcohol use and related problems also go up. Following an assessment of the research literature in the early 2000s, the National Institute on Alcohol Abuse and Alcoholism (NIAAA) recommended that colleges and surrounding communities implement a variety of policies and enforcement practices that reduce college

student access to alcohol. At that time, most of the research evidence pertained to the general population rather than the college student population specifically. Since that review, alcohol policy research focusing on the college student population has significantly increased.

In this chapter, we provide an overview of policies affecting alcohol access among both underage students and among all students in general. We also review several other campus policies, such as alcohol advertising restrictions that can shape the degree to which a campus environment encourages or discourages heavy alcohol use. The policies described in this chapter can be implemented at the campus, community, state, and/or federal levels.

Once a policy is enacted, it also needs to be actively enforced to maximize the policy's effectiveness in reducing college student drinking and related problems. Enforcement actions that increase the perceived certainty of getting caught for violating a policy are most effective, but meaningful consequences for this violation that are swiftly applied should also be addressed.

Table 91.1 provides a list of policies identified to reduce alcohol access among underage college students; Table 91.2 provides a list of policies identified to reduce alcohol access among all college students in general; and Table 91.3 describes other promising policies addressing college student drinking. A brief description and rationale for each policy are provided in these tables as well as information about the possible levels at which the policy could be implemented (college, community, state, and/or federal levels) and whether research studies have addressed the policy. When research studies have addressed a particular policy, we summarize the research findings in the text. Finally, while it is important to consider each of these policies individually, combinations of policies may be necessary to create sustained reductions in college student alcohol use and related problems. We also provide a brief summary of research evaluating the effects of multipolicy interventions.

POLICIES TO REDUCE ACCESS TO ALCOHOL AMONG UNDERAGE COLLEGE STUDENTS

The minimum legal drinking age is one of the most well-evaluated alcohol policies. Many studies have found that when the legal drinking age was lowered during the 1970s in the United States, consumption and traffic crash deaths increased among 18–20 year olds; when the drinking age was raised to 21 in many states, consumption and traffic crashes

decreased. Although all states in the United States currently have a minimum legal drinking age of 21, underage youth and young adults continue to drink alcohol and experience alcohol-related harms. One reason is that legal drinking age laws – including laws that restrict purchase, possession, and consumption of alcohol as well as provision and sales of alcohol to underage individuals – are often not well enforced. Hence, underage individuals can obtain alcohol from various sources including social sources and commercial sources. Social sources are individuals (either over or under the age of 21), who illegally provide alcohol to underage persons. Social access to alcohol among underage college students may occur at parties, in residences, at campus or community events, in bars and restaurants, and in public areas such as parks, beaches, or outside of stores that sell alcohol. Commercial sources are retail alcohol establishments such as restaurants, bars, and liquor stores that sell alcohol illegally to underage patrons. While research studies have shown that most underage individuals obtain alcohol through social sources, the likelihood of underage individuals purchasing alcohol from establishments increases with age. Also, underage individuals who are able to purchase large quantities of alcohol (e.g. a beer keg) may then illegally provide that alcohol to other underage individuals. Policies, and active enforcement of these policies, are needed to reduce social or commercial access to alcohol among underage college students (Table 91.1).

Reduce Social Access to Alcohol

As indicated in Table 91.1, a variety of policies can be implemented to reduce social access to alcohol among underage college students. These policies may reduce social access to alcohol through several mechanisms, including: (1) prohibiting alcohol in certain locations (e.g. residential halls) where underage drinking may occur, (2) prohibiting alcohol at parties or other campus events, (3) placing restrictions on alcohol use and service at campus events (e.g. not allowing self-service of alcohol), (4) deterring adults from providing alcohol to underage students, and (5) enabling police to break up underage drinking parties. Of these policies, we only identified research pertaining to policies designed to deter adults from providing alcohol to underage persons.

To decrease the likelihood that individuals will illegally provide alcohol to underage individuals, it is important to increase the likelihood that they will be caught and penalized for this illegal provision of alcohol. To help identify individuals who provide alcohol to underage individuals at parties, communities and states can implement beer keg registration laws that

TABLE 91.1 Policies That May Help Reduce Access to Alcohol among Underage Students

Policy	Policy description	Policy level	Policy rationale	Research evidence for underage persons?	
REDUCE SOCIAL ACCESS TO ALCOHOL					
Prohibition of alcohol in certain locations	Alcohol is prohibited from being consumed or brought into certain public locations where monitoring of underage drinking may be difficult (e.g. community and state parks)	S, L, C	Fewer locations allowing alcohol consumption = fewer underage parties, less access	None	
Prohibition of alcohol at campus events	Alcohol use is prohibited at all campus events or at events where underage students are present	C	No alcohol at events where underage students are present = less access	None	
Restrictions on service and use of alcohol at campus events	<ul style="list-style-type: none"> Self-service of alcohol is prohibited at events 	C	<ul style="list-style-type: none"> Requiring alcohol to be served rather than available for self-service can ensure only students of legal drinking age have direct access = less access 	None	
	<ul style="list-style-type: none"> Alcohol service is limited to one drink per person per request 		<ul style="list-style-type: none"> Limiting the number of drinks students are served will reduce opportunities to obtain extra drinks for underage students = less access 	None	
	<ul style="list-style-type: none"> Alcohol consumption is allowed only in specified areas restricted to individuals 21 and older 		<ul style="list-style-type: none"> Not allowing underage students in areas where alcohol is consumed = less access 	None	
Legal deterrence for providing alcohol to underage <ul style="list-style-type: none"> Keg registration laws 	<ul style="list-style-type: none"> A unique ID is required on each beer keg; ID number is recorded at the time of purchase along with purchaser information 	S, L	<ul style="list-style-type: none"> Because law enforcement can identify who purchased the keg, adults will be deterred from buying kegs for use by underage students = less access 	Limited: General population	
	<ul style="list-style-type: none"> Shoulder tap campaigns 		<ul style="list-style-type: none"> Under the supervision of law enforcement, an underage person approaches an adult outside a store and asks the adult to purchase alcohol for them. If the adult provides alcohol he/she is subject to citation 	<ul style="list-style-type: none"> Perceived certainty of being caught will deter adults from purchasing alcohol for an underage individual = less access 	Limited: General population, College students
	<ul style="list-style-type: none"> Social host laws 		<ul style="list-style-type: none"> If an adult illegally serves alcohol to an underage person, and the underage person injures themselves or someone else, the offending adult may incur civil and/or criminal penalties. Social host laws may also require hosts to pay for enforcement costs 	<ul style="list-style-type: none"> Due to legal risk, fewer people willing to provide alcohol or host a party = less access 	Yes: General population
Noisy assembly laws	Law stipulates that parties exceeding a specified noise level may be subject to search and citation by law enforcement	S, L	Restrictions on noise level may deter large parties; landlords and property owners held accountable for parties will be more strict = less access	None	

(Continued)

TABLE 91.1 Policies That May Help Reduce Access to Alcohol among Underage Students—cont'd

Policy	Policy description	Policy level	Policy rationale	Research evidence for underage persons?
REDUCE COMMERCIAL ACCESS TO ALCOHOL				
RBS training requirements	Managers and servers of alcohol establishments are required to receive training in how to check age identification and refuse sales to underage customers	S, L, C	Managers/servers less likely to allow alcohol sales to underage individuals = less access	Yes: General population
Minimum age requirements to serve/sell alcohol	Employees under a specified age are not permitted to serve or deliver alcohol	S, L, C	Older employees are less likely to sell alcohol to an underage person = less access	Yes: General population
Compliance checks	Under the supervision of law enforcement, an underage person attempts to purchase alcohol from on- and/or off-premise serving establishments. If alcohol is sold to underage person, server and/or license holder is penalized	S, L	Consistent ID verification when establishments are routinely checked for compliance = less access	Yes: General population
Dram shop liability laws	Individuals are able to sue alcohol serving establishments for injuries sustained after illegal alcohol sales to an underage person	S	Fewer sales to underage individuals if threat of lawsuit exists = less access	None
Prohibition of home deliveries	Retailers are prohibited from delivering alcohol to individuals at their homes	S, L	Reduce the likelihood of delivering alcohol to underage persons = less access	None
Identification card design requirements	State requirements that ID cards for underage persons have a unique design that is difficult to falsify	S	Alcohol sellers/servers can more clearly identify and refuse sales to underage individuals and they are less likely to have false age identification = less access	Limited: College students

Note: Policy level: S = state; L = local; C = college.

TABLE 91.2 Policies That May Help Reduce Access to Alcohol among All Students

Policy	Policy description	Policy level	Policy rationale	Research evidence?
RESTRICT WHERE, WHEN, HOW ALCOHOL IS SOLD				
Limitations on number/density of alcohol establishments	Limit the number of alcohol establishments per capita, per geographic area, or in high-risk areas (e.g. around college campuses)	S, L	Fewer alcohol establishments per geographic area = less access	Yes: General population, College students
State-run alcohol retail stores	In some states, certain types of alcohol (e.g. wine) are only sold in state-run stores; if privatized, these types of alcohol are moved from state-run to privately owned stores	S	State-run stores allow for better control over number of alcohol establishments in an area, reduced hours of sales, and limited advertising = less access	Yes: General population
Restrictions on days of alcohol sales	Retail alcohol sales banned on specific days (e.g. Sundays)	S, L	Reduce number of days alcohol can be sold = less access	Yes: General population
Restrictions on hours of alcohol sales	Retail alcohol sales banned during specified hours of day	S, L	Fewer hours for alcohol sales = less access	Yes: General population
RBS training requirements	Managers and servers of alcohol establishments are trained how to prevent patrons from becoming overly intoxicated (e.g. cutoff service to intoxicated, slow alcohol service, promote alcohol-free drinks/food)	S, L, C	Managers/servers slow service of alcohol or cut off service = less access	Yes: General population
Dram shop liability laws	Individuals are able to sue alcohol serving establishments for injuries sustained after illegal alcohol sales	S	Fewer sales to intoxicated individuals if threat of lawsuit exists = less access	Yes: General population
Alcohol license cost increases	The cost of obtaining an alcohol license for retail establishments can be increased	S, L	Higher price of alcohol licenses may decrease number of alcohol establishments and increase price of alcohol = less physical and financial access	None
INCREASE ALCOHOL PRICE				
Alcohol tax increases	Tax applied on alcoholic beverages at retail level	F, S	Increased taxes on alcohol will lead to higher prices = less financial access	Yes: General population, College students
Restrictions on happy hours/price promotions	Promotions that greatly reduce the price of alcohol at the retail level are prohibited or restricted	S, L, C	Eliminating price promotions for alcohol reduces incentive to drink = less use	Yes: General population, College students
Limitations on free alcohol	Availability of free alcohol at campus events is restricted or prohibited	C	Less free alcohol available = less use	None

(Continued)

TABLE 91.2 Policies That May Help Reduce Access to Alcohol among All Students—cont'd

Policy	Policy description	Policy level	Policy rationale	Research evidence?
REDUCE ACCESS AT CAMPUS EVENTS				
Prohibition of alcohol sales/use in high-risk areas	Alcohol sales or use are prohibited in areas where rates of alcohol use and problems are high (e.g. areas where tailgating events occur, at sporting events)	S, L, C	Eliminating or restricting alcohol at these places and events = less access	Limited: College students
Prohibition of beer kegs	Beer kegs are not allowed on campus or for nonretail use	S, L, C	Prohibiting primary supply of large quantities of inexpensive alcohol = less access	Limited: College students
Prohibition of self-service of alcohol	Alcohol can only be served by trained servers	C	Trained servers can control the number of drinks per person and cutoff intoxicated individuals = less access	Limited: College students
Requirement of low-alcohol content drinks	Alcohol with the lowest concentration of alcohol per volume must be offered	C	Lower alcohol content = less intoxication	Limited: College students
Requirement of alcohol-free drinks and food	Offering of alcohol-free drinks and food required at campus events (e.g. at least 50% of beverages must be alcohol free)	C	Attendees may consume more alcohol-free drinks and food = less alcohol use and less intoxication	None

Note: Policy level: F = federal; S = state; L = local; C = college.

TABLE 91.3 Other Policies Used to Address College Student Drinking

Policy	Policy description	Policy level	Policy rationale	Research evidence?
Prohibition of alcohol sponsorship and advertising	Colleges ban advertising for alcoholic beverages and/or alcohol establishments that serve alcoholic beverages in student newspapers, on campus billboards and other university-controlled media	C	Decreasing advertising and promotion for alcohol = less alcohol use	Yes: General population, College students
Amnesty policies	Underage students in need of medical attention and/or individuals/student organizations who call for help are exempt from Judicial Affairs citation – terms of exemption vary by school and are usually limited to instances occurring on University property	C	Eliminate barrier to helping behavior = more students receiving medical attention = fewer alcohol-related harms and deaths	Limited: College students
Requirement of Friday morning classes	Colleges mandate a minimum number of classes scheduled on Friday mornings	C	Mandating Friday morning classes may decrease heavy drinking on Thursday nights	Limited: College students
Requirement of alcohol-free alternatives	Colleges offer and fund social events and venues that do not serve alcohol and are open during times students commonly drink alcohol	C	Provides social alternatives to drinking for students = less access, less alcohol use	Limited: College students
Alcohol-free campuses and residence halls	Colleges prohibit alcohol on campus or alcohol is prohibited in designated residence halls	C	Fewer locations allowing alcohol consumption = less alcohol use	Yes: College students

Note: Policy level: C = college.

require alcohol retailers to place a unique identifier on a keg and collect the purchaser's name and address. This enables police to identify and hold responsible the person who bought the keg if the keg is found to be a source of alcohol for underage youth. As of January 1, 2011, 31 states have keg registration laws in the United States, although the strength of these laws may vary by state. One study showed that strict state-level keg registration laws are associated with lower alcohol consumption and drinking driving among teens.

Another set of policies that may help prevent social provision of alcohol at parties are social host laws. Social host laws may specify criminal penalties for individuals who host underage drinking parties on their property and/or provide alcohol to underage youth. Alternatively, social host laws may also provide for civil liability, which enables individuals who are injured by an underage drinker to sue a host of an underage drinking party and/or provider to recover damages for those injuries. Finally, social host laws can also provide a mechanism for local communities to recover enforcement costs resulting from law enforcement agencies responding to problems related to underage drinking parties. As of January 1, 2011, 27 states have some form of a state social host law. Research studies suggest that state-level social host laws are associated with fewer drinking and driving-related fatalities among youth and young adults.

Underage individuals may also obtain alcohol by asking people going into liquor establishments to purchase alcohol for them. This is often times referred to as "shoulder tapping." To address this type of social provision, police can conduct shoulder tapping campaigns where underage people, under the supervision of law enforcement, approach an adult outside a store that sells alcohol and asks the adult to purchase alcohol for them. If the adult purchases alcohol, the adult is given a warning or fine or is arrested. One study found that younger males are more likely to agree to purchase alcohol for underage individuals during a shoulder tap than other adults going into alcohol establishments; this suggests that shoulder tap enforcement campaigns may be most effective if they target younger male populations rather than the general adult population. Shoulder tapping to obtain alcohol may be a method used more often by younger age groups than college students.

Reduce Commercial Access to Alcohol

Several research studies show that alcohol establishments, including bars, restaurants, and retail stores, have a fairly high likelihood of selling alcohol to underage patrons. Although many colleges do not allow the sale of alcohol on campus, some colleges have bars

on campus and/or allow the sale of alcohol in stadiums and auditoriums. Many community alcohol establishments often surround college campuses and underage college students often know which bars and stores are most likely to sell to or serve underage patrons.

To help reduce illegal sales to underage students, alcohol servers, managers, and owners of retail establishments selling alcohol, whether on or near campus, can be required to attend training on how to responsibly serve alcohol. Owner and manager training should cover how to develop, communicate, and enforce policies around selling alcohol responsibly. Training of alcohol servers/sellers should focus on how to check age identification and how to refuse alcohol service to those who are underage. Establishments that have monitoring systems to observe their servers to ensure alcohol sales laws are being followed are less likely to sell alcohol to underage individuals. In addition, establishments and communities can restrict the age of those who deliver or serve alcohol. Several research studies have found that younger servers are more likely to sell alcohol to an underage person. Research suggests that responsible beverage service (RBS) training programs by themselves may not be sufficient to prevent underage alcohol sales but may be necessary to build support for more effective enforcement interventions.

One effective enforcement strategy is compliance checks where an underage person attempts to purchase alcohol under the supervision of a law enforcement agent; if alcohol is sold, the server and/or the owner may face penalties. Several studies have shown that compliance checks are effective in reducing the likelihood of sales to underage patrons – but it is important to conduct compliance checks at all establishments and to conduct the checks several times per year to maintain a reduction in likelihood of alcohol sales to underage individuals. Based on the likely effectiveness in reducing sales to underage individuals, the Centers for Disease Control and Prevention (CDC) Community Guide recommends use of compliance checks. The structure and type of penalties for selling to underage individuals are also important to consider.

One type of risky, unmonitored sale that may particularly increase the likelihood of alcohol being sold to an underage person is the home delivery of alcohol. Over half the states in the United States allow home delivery of alcohol and one study showed that 7% of 18–20 year olds reported drinking alcohol that had been delivered to the home from a retail establishment. Alcohol can also be ordered via the Internet. To prevent delivery to underage people, communities can ban or restrict home deliveries of alcohol. Law enforcement officers can also conduct compliance checks where an underage person orders alcohol to be delivered to home.

In addition to focusing on changing merchants' behaviors, campuses and communities may reduce illegal sales to underage students by implementing policies aimed at reducing the use of fake age identification (ID). Several studies have examined the prevalence of fake ID use among college students, with estimates ranging from 13 to 46%. Use of fake IDs appears to increase from freshman to sophomore year and be more prevalent among members of fraternities and sororities. Communities and states can apply strong and certain penalties to those caught using fake age identification and issue drivers' licenses or other identification cards that are difficult to duplicate (e.g. use of holograms), and that clearly identify an underage person (e.g. use of different colors for underage).

POLICIES TO REDUCE ACCESS TO ALCOHOL: ALL STUDENTS

Many policies have been identified that may help reduce access to alcohol among all students (Table 91.2). These policies may affect how easily college students can obtain alcohol as well as the cost of alcohol. Research on the need for and effectiveness of many of these policies have grown significantly; however, some of the suggested policies have no or limited research focusing on them.

Restrict Where, When, and How Alcohol Is Sold

A variety of policies can be used to place restrictions on alcohol sales to decrease the availability of alcohol among all students on campus. Research shows, in general, that increasing availability of alcohol will lead to increased alcohol use and related problems.

Policies can be implemented at the state or community level to restrict the number of or density of alcohol establishments per population size or geographic area. Many studies have found that a higher density or number of alcohol establishments is related to higher rates of alcohol-related problems, including violence, other crime, sexually transmitted diseases, and other health problems in the general population. Research also suggests that a higher density of alcohol establishments around college campuses may increase rates of heavy alcohol use and alcohol-related problems among college students, both among students on campus as well as in the surrounding community. A higher density of alcohol establishments around campuses is associated with more vandalism, noise, and disturbances among neighborhoods surrounding campuses. Based on a systematic review of the research literature, the CDC

Community Guide recommends limiting the density of alcohol establishments to prevent excessive alcohol use and related problems.

The majority of US states allow alcohol to be sold in stores run by private individuals or corporations that are licensed to sell alcohol. Eighteen states as of 2011, however, restrict the sale of some types of alcohol (e.g. liquor and wine) to state-owned stores; these are considered state monopolies. In the 1970s and 1980s, many states privatized their state monopolies, allowing privately owned stores to sell the previously restricted types of alcohol. Studies show that privatization of these state monopolies may lead to an increase in alcohol sales (a proxy for alcohol consumption) in those states. Availability of alcohol may increase following privatization in state monopolies because of a higher number of alcohol establishments, longer hours of alcohol sales, and more advertising at the privately owned stores versus publicly owned stores. Some studies have shown only short-term increases in alcohol sales following privatization, however, other studies suggest that these increases in alcohol sales may be sustained for longer periods of time. No studies have specifically assessed effects of privatization on college students. Preventing privatization of state monopolies may be important for the following reasons: (1) research shows an increase in alcohol sales following privatization of state monopolies, (2) we currently do not know the long-term effects of privatization on alcohol-related problems among the general population or on subgroups such as college students, and (3) once privatization occurs, it is unlikely that states would be able to return to a state monopoly system.

Regardless of the number of alcohol establishments in a community or around a campus, communities or states can enact other restrictions to limit the availability of alcohol. For example, communities and states can restrict the number of days alcohol can be sold. Following the revocation of prohibition, many states banned alcohol sales on Sundays; however, since that time some of these states have overturned their Sunday sales bans (as of January 1, 2011, 14 states still have Sunday bans on alcohol sales). Studies show that increasing the number of days alcohol is sold may result in an increase in alcohol-related problems such as traffic crashes among the general population. Researchers have not looked at the effects of changes in days of alcohol sales on college student behavior. Based on a systematic review of the research literature, the CDC Community Guide recommends maintaining current restrictions on days of alcohol sales. Similar to privatization, once prohibitions on days of alcohol sales are lifted, it may be difficult or impossible for those bans to be re-imposed.

Communities and states can also restrict hours of alcohol sales. Effects of changes in hours of sales may

depend on the scope of the change. If communities increase the hours of alcohol sales by an hour or two, they may not see an increase in alcohol-related problems – rather they may just see a shift when these problems occur. However, an expansion of hours of alcohol sales beyond 1-2 hours appears to increase access to alcohol enough that alcohol-related problems actually increase in the general population. Again based on a systematic review of the research literature, the CDC Community Guide recommends maintaining limits on hours of alcohol sales.

Availability of alcohol can also be controlled by servers at alcohol establishments and other alcohol venues. Similar to preventing alcohol sales to underage patrons, states, communities, and colleges may require RBS training for servers and managers of alcohol establishments to prevent patrons from becoming highly intoxicated. Alcohol servers can be trained to slow service of alcohol, promote alcohol-free beverages and food, and cutoff service to patrons who are already intoxicated. To encourage responsible alcohol servers, managers need to be trained and incentivized to create an establishment environment that sets expectations for responsible alcohol service (e.g. by setting and implementing establishment policies, backing up and rewarding servers' responsible serving behavior). Managers can also set establishment policies that directly affect alcohol use – for example, policies to only serve standard size drinks (e.g. 12 oz.) rather than oversized drinks (e.g. 24 oz.) or pitchers of alcohol. The need for RBS training is clearly indicated by studies showing that alcohol servers at the majority of alcohol establishments, community festivals, and professional stadiums will serve alcohol to customers who are obviously intoxicated. Research on the effectiveness of RBS programs and policies is mixed. Some of the more intensive training programs may reduce the intoxication levels of customers; however, many programs have only changed the knowledge, attitudes, and mild interventions (e.g. offering food) of alcohol servers. Research has shown that not all RBS training programs are equal, and that the best training programs include a focus on policy development for managers and skill-building techniques for alcohol servers. Research has also shown that state RBS laws vary greatly, with stronger laws specifying the required program content (e.g. ensuring skill-building components), having penalties for lack of compliance with the policy, and being supported by active monitoring. Researchers have found that traffic crash deaths decreased following Oregon's enactment of a RBS law, and that Oregon has one of the strongest RBS laws in the United States.

Responsible serving policies may also be encouraged through dram shop liability laws that enable individuals to sue alcohol establishments for injuries sustained after

illegal alcohol sales. Research has shown that dram shop liability laws are associated with decreased traffic crashes and fatalities and incidence of drunk driving. Owners and managers of alcohol establishments may be more motivated to reinforce RBS policies and practices in their establishments when the perceived threat of a lawsuit is relatively high.

Increase the Price of Alcohol

Many studies have shown that higher alcohol prices are associated with lower rates of alcohol use and some alcohol-related problems, such as violence, traffic crashes, and liver cirrhosis mortality. All types of drinkers, including heavy alcohol users and youth, appear to be affected by the price of alcohol; however, the effect of alcohol price will vary by type of alcohol and the category of the drinker. College students exposed to higher alcohol prices are less likely to consume alcohol. Furthermore, among college students, higher beer prices are associated with students less likely to get in trouble with police or college authorities, cause damage to property, have an argument, be in a fight, take advantage of someone sexually or be taken advantage of sexually.

Price of alcohol can be influenced through policy change. One of the recommended policy changes to increase price of alcohol is to raise taxes on alcohol. Taxes are typically set at the state or federal levels and vary by type of alcohol. Since taxes are typically not adjusted for inflation, the effect of taxes erodes over time – resulting in the real price of alcohol also decreasing over time. Research shows that as taxes are increased, alcohol use and alcohol-related problems decrease. Youth and young adults such as college students may be particularly sensitive to changes in taxes. Based on the current research, CDC's Community Guide Task Force recommends increasing the unit price of alcohol by raising taxes.

Price of alcohol may also be influenced by policies restricting happy hours or other price promotions (e.g. two drinks for the price of one, ladies' night) in licensed establishments. Researchers found that happy hours are associated with more alcohol use among light and heavy drinkers in the general population. Drink promotions are common in alcohol establishments around college campuses, with many offering drink promotions at least some days of the week. These drink promotions are associated with heavier alcohol use on college campuses. Research shows that restrictions on happy hours are related to less drinking among college students. Although most of the policy changes affecting price of alcohol are likely to occur at the local, state, or federal levels, college campuses can also implement price-related policies. If campuses have alcohol establishments

on campus, campuses can restrict or ban price promotions.

Reduce Access at Campus Events and Parties

Many students drink heavily at certain types of campus events (e.g. tailgating and sporting events) and parties, where alcohol often flows heavily. Policies can be used to restrict the flow of alcohol at events and places where alcohol consumption and related problems are high. For example, campuses can ban alcohol use in parking lots to ensure that tailgating events on their campuses are alcohol free. Campuses can also ban alcohol sales at sporting events. One study showed that a ban of beer sales at football games at the University of Colorado at Boulder may have reduced rates of game-day arrests for assaults, ejections from the stadium, and student referrals to student affairs.

Policies also can be implemented to reduce the flow of alcohol at parties held on and off campus; however, only a few of these policy recommendations have related research. Beer kegs may provide large amounts of inexpensive alcohol to students attending parties. Beer kegs are banned on the majority of college campuses in the United States and studies suggest that these bans, in combination with other policies, may decrease alcohol-related problems. One study found that allowing the self-service of alcohol at parties may lead to more drinking among college students. Another study found that serving students low alcohol content beer may lead to lower blood alcohol content levels than serving regular alcohol content beer, even though the students consumed the same number of drinks. Although these studies suggest that policies banning beer kegs, requiring the availability of low alcohol content drinks, and banning self-service of alcohol may lead to decreased consumption and related problems, further research is needed to evaluate these policies, as well as other policies listed in Table 91.2, that were identified to reduce the flow of alcohol at parties.

OTHER PROMISING POLICIES FOR ADDRESSING COLLEGE STUDENT DRINKING

College administrators have not limited themselves to policies that reduce access to alcohol. A variety of other approaches are used, and the research base for these emerging efforts is starting to build. These efforts include advertising restrictions, amnesty policies, encouraging faculty to offer classes on Friday morning, providing social activities for students that do not involve alcohol, and banning alcohol from the entire campus or parts of the campus. The following section

reviews these efforts, their rationale, describes the state of the evidence base, and highlights some key considerations for complying with the intent of each effort. Results are also summarized in Table 91.3.

One promising area for reducing student drinking is restricting exposure to advertising. Research studies using cross-sectional designs have shown a strong positive association between marketing/promotion of alcoholic beverages and student drinking levels. However, no research has examined whether changes in marketing and promoting alcohol or policies designed to restrict alcohol advertising have been associated with changes in college student drinking patterns. Colleges may be able to exert some control over student exposure to advertising by adopting policies to ban advertising of alcoholic beverages in various forms of media on campus. These can include student newspapers, radio and television stations, sport stadiums, athletic programs, and campus billboards. Additional research is needed to examine whether such policies can reduce exposure to advertising and lead to lower levels of drinking by students.

Colleges are increasingly adopting or considering policies to provide amnesty from punishment for students who act to get appropriate medical attention for students who have consumed too much alcohol. Amnesty is usually offered to both the victim and helper and some universities also include a provision covering student organizations such as fraternities. Most amnesty policies only apply to the university's judicial affairs process and do not provide amnesty from other legal consequences in the community. The rationale behind amnesty policies is to ensure that students are not deterred from seeking medical assistance out of concern about being punished. Amnesty policies are based on the assumptions that students (1) can correctly identify the warning symptoms of alcohol poisoning; (2) can understand the risk associated with the symptoms; (3) are sober enough to judge the risk; (4) are afraid to seek help because of a fear of getting in trouble, either for themselves or their peers; and (5) are more likely to call for help if an amnesty policy exists. Medical amnesty policies are relatively new and have not yet been well evaluated enough to fully understand potential positive or negative effects. A consideration when implementing medical amnesty policies is that alcohol tends to acutely affect judgment and cognitive skills and as a result students may underestimate emergency situations. Another consideration is that, other factors being equal, heavy drinking students tend to show less concern for alcohol poisoning symptoms and have lower recognition of symptoms of alcohol poisoning than nonheavy drinking students. Finally, some research also suggests that students are less likely to intervene in a party

environment due to a diffusion of responsibility and/or misinterpretation of an emergency situation. While additional research is needed to determine whether medical amnesty policies are effective in reducing harms to students, they may promote increased calls for medical care.

One aspect of college life that has received greater attention in recent years related to student drinking behavior is class scheduling. Heavy drinking among students on Thursday nights appears to be common, and speculation about the reasons for this has focused on the relative lack of classes scheduled on Friday mornings. Some course instructors may prefer to avoid scheduling class on Friday to leave time available for other academic pursuits. Bars and restaurants influence week-night drinking by incenting students with drink specials and promotions. Some descriptive research has been done in this area, but few studies exist. The available research suggests that students who do not schedule a class on Friday morning are more likely to drink heavily on Thursday night. It is possible that students who tend to drink heavily are less likely to schedule their classes on Friday, perhaps to make an additional night available for drinking. As a result of the increased attention on the role of class schedules in student drinking behavior, some colleges have begun to institute policies that increase the offering of classes on Friday morning. Additional research is needed to determine whether these policies reduce student drinking behavior on Thursday nights.

Providing social events and venues that do not involve alcohol are popular efforts to combat heavy drinking among students and considerable college and student resources and activity funds are committed to establishing these efforts. However, there has been very little research to determine whether alcohol-free alternative activities reduce student drinking or attract simply students who do not otherwise drink alcohol. Two important concerns about the effectiveness of these efforts are the relative costs involved and the limited reach in terms of both the number of students who might attend a given event and the number of times such events might be held. Nevertheless, more research is needed to determine whether these popular efforts are effective.

Colleges have established policies that ban alcohol from the entire campus or parts of the campus. Students that attend a college with a ban on alcohol are more likely to abstain from alcohol, less likely to binge drink, and less likely to experience the secondhand effects of drinking by other students than peers attending colleges without a ban. At colleges that allow alcohol on campus, students who live in substance-free residences (i.e. a ban on alcohol and tobacco) are less likely to use alcohol and experience secondhand effects from other students'

drinking. More research is needed to determine whether instituting these policies can reduce student drinking and related harms.

IMPORTANCE OF USING MULTIPLE POLICY STRATEGIES TO TARGET COLLEGE STUDENT DRINKING

Alcohol use is a complex behavior. Changing college student rates and patterns of alcohol use to create substantial and sustained reductions in alcohol-related problems will require a multifaceted intervention. Implementing one program or policy will not be sufficient. The research assessing each of the policies listed in Tables 91.1–91.3 is important to consider in developing more comprehensive interventions. Research can help identify which policies are most likely to help change college student alcohol use and determine ways to increase their effectiveness. Policies can then be combined to decrease access to alcohol in multiple ways, increasing the likelihood of greater shifts in alcohol use and related problems. Policies that reduce access can also be complemented by other campus and community policies that help discourage heavy alcohol use by college students.

Several studies have shown that combining alcohol policies and related enforcement efforts can reduce alcohol use and related problems among underage individuals. One study showed that reducing access to alcohol from multiple sources in a community, both social and commercial, can effectively decrease alcohol use and related problems among 18- to 20-year olds. Multiple state-level policies may also help reduce underage alcohol use. Another study found that states with four or more of laws targeting underage drinking have lower rates of underage alcohol use than states with fewer such laws.

Several recent studies have also assessed effects of combined policies and enforcement efforts to reduce heavy alcohol use and related problems among all college students. The combination of strategies varies across studies. Multiple campus policy strategies have been used to address specific problems (e.g. reducing problems related to homecoming events) as well as all college student drinking in general. Sometimes multiple campus policy strategies have also been combined with policy strategies implemented in the surrounding community to address high rates of alcohol use among college students and related problems occurring on and off campus. Although the studies evaluating these combined strategies have some limitations (e.g. small sample size), taken together these studies indicate that use of multiple policy and enforcement strategies can effectively reduce heavy alcohol use and related

problems among college students on campus and in surrounding neighborhoods.

CONCLUSION

Many policies have been identified that can be implemented on college campuses, in surrounding communities and states, or at the federal level to reduce college student drinking and related problems. Although research studies suggest that combining many of these policies may be an effective approach for addressing college student drinking, more research is needed to determine whether there are ideal combinations of policies to create sustained reductions in high-risk drinking and related problems among college students.

The NIAAA released its recommendations for strategies to address college student drinking in 2002. A national study in 2010 examined whether colleges were implementing these recommendations and found that administrators at a substantial minority were not even aware of the NIAAA recommendations. Although about half of the colleges offered recommended intervention programs for students at high risk for alcohol problems, very few college communities had worked on implementing other recommended strategies such as compliance checks to monitor illegal alcohol sales, mandatory RBS training for alcohol servers, restrictions on the density of alcohol establishments, or increasing the price of alcohol. In contrast, nearly all colleges used educational programs to address student drinking, despite clear findings by the task force that these efforts by themselves were ineffective. These findings suggest that more can be done to address college student drinking and provide a possible explanation for why rates of alcohol use among college students remain problematic.

INTRODUCTION

Underage Drinking

Although the rate of alcohol use has declined somewhat since 1999, underage drinking is still very prevalent in the United States. Over one-fourth of youth aged 12–20 report using alcohol in the past month and almost one-fifth report binge drinking (drinking five or more drinks in one sitting at least once in the past 2 weeks). In 2008, alcohol use initiation, defined as having first used alcohol in the past year, was reported by 4.5 million youth and adults, with almost 85% (3.8 million) of these 4.5 million new alcohol initiates younger than the legal drinking age of 21-years-old at the time of initiation.

By the time adolescents reach age 18, almost 75% will have tried alcohol in their lifetime and almost half will have used alcohol in the past month. Rates of alcohol use vary by ethnicity with Hispanic youth using the most alcohol at the beginning of adolescence and White youth using the most alcohol at the end of

adolescence. Boys begin using alcohol earlier than girls, however, girls quickly catch up and even surpass the boys by 8th grade. By 12th grade, however, alcohol use rates among boys and girls are similar. While alcohol use is more common among older adolescents, use of alcohol is still prevalent among those as young as 13 years. National data suggest that 23.8% of 9th graders report drinking more than a few sips of alcohol before the age of 13 and 3.4% of 12–13-year-olds currently use alcohol. By the ages of 14–15, the percentage of youth who are currently using alcohol almost quadruples to 13.1%.

Alcohol use in early adolescence (by age 12) has been found to be associated with subsequent use of alcohol and problem behaviors in later adolescence including drinking and driving, alcohol-related violence, injuries, as well as increased risk for using other drugs. Youth who drink before age 15 are estimated to be four times more likely to develop alcohol dependence than those who begin drinking after age 18. With each year, the

onset of alcohol use is delayed, the odds of alcohol dependence decrease by 14%, and the odds of abuse decrease by 8%. Research has shown that early users of alcohol, specifically those who use alcohol by the start of 6th grade, are significantly different on nearly all socio-environmental, behavioral, and personal risk factors examined. Early users of alcohol are especially more likely to engage in delinquent and violent behaviors and to have lower self-efficacy, positive outcome expectations, and expectancies concerning alcohol use, greater access to alcohol, higher normative estimates of alcohol use, and a greater number of friends who report using alcohol than nonusers of alcohol in 6th grade. This suggests that it is important to understand and address most factors that put youth at risk for alcohol use early, before youth begin using alcohol. Advertising, specifically, alcohol advertising is one such factor.

Advertising and Youth

Marketing has been in existence for over a century, most often with the purpose of fostering consumer acceptance for the product being promoted, as well as encouraging voluntary purchases of the product. Initial efforts to advertise to children began in the 1930s, with companies placing advertisements for their products during radio show broadcasts. However, it was not until the 1950s, with the advent of television, that children truly began to attract the attention of marketers. Children were, perhaps for the first time, seen by industry professionals as being capable of purchasing products on their own. As McNeal illustrates, the focus on children as consumers has evolved from the perspective of a marketer over time, in that “the ‘50s provided children in large numbers, the ‘60s gave them increased incomes to spend, the ‘70s developed and produced many new products and services for children to want and buy, and the ‘80s gave children the legitimacy, or equality of sorts with adult consumers” (p. 6) all of which led to the commercialization of childhood that began during the 1980s.

Given the newfound legitimacy of children, the 1980s were characterized by an explosion of child-oriented media and advertising. Additionally, changes in the purchasing power of youth, in combination with an increasing number of techniques and outlets to promote products, have resulted in a highly commercialized society where youth are the major targets of marketers. Although the products advertised to children and adolescents have remained relatively constant in recent years, the power of youth to purchase products on their own has increased considerably over time. Recent estimates suggest that personal spending increases with age; for example, individuals between 8 and 12 years of age are

thought to spend \$19.1 billion annually, whereas older youth between the ages of 12 and 17 are thought to spend closer to \$112.5 billion annually. Moreover, it is thought that youth influence more than \$500 billion worth of family spending per year. Thus, when targeting youth, marketers are also making inroads to the spending of their families.

Persuasive advertising techniques, for example animated characters and branded logos, are commonly used in advertisements, and are often used as a means of attracting the attention of youth and engaging them in what is being offered. Moreover, the use of persuasive advertising techniques tends to provide visual cues which represent the attributes of the brand (i.e. fun, excitement), and are often used in an attempt to build awareness, generate product recognition, establish loyalty, and create perceived product value. Although the understanding of the persuasive intent and bias of advertising, mistrust of advertiser motives, and knowledge of advertising tactics all increase with age, youth still may not be able to evaluate messages appropriately given that their ability to access and retrieve such knowledge may not occur until mid-adolescence.

Branding, the process of using a name or symbol to identify or differentiate a product from items within the same product category, is a technique that is often used to create brand equity. Branding helps to create product recognition and helps to communicate product attributes to potential consumers. Because the goal of marketers is to create lifelong customers, establishing brand awareness at an early age is particularly important given that product awareness is thought to lead to stronger brand loyalty, particularly as children grow older. Children are highly aware of brand names and logos beginning at an early age. For example, in a study designed to examine the development of brand awareness among young children, researchers found that children as young as 2 years of age are able to recognize a number of different brand logos for products.

In fact, some of the more well-known techniques used in tobacco advertising included the use of a branded, animated character. Prior to the elimination of cartoon characters in cigarette advertisements in the United States, Joe Camel was perhaps the most prominent one of all, and his popularity was high among both children and adolescents. For example, in one study, slightly more than 90% of 6-year-old children were able to recognize the Joe Camel cartoon as being associated with cigarettes. Among older adolescents, close to 94% of youth were able to identify the Camel cigarette brand name, as opposed to only 58% of adults. Moreover, the use of Joe Camel also helped to increase Camel’s sales among the adolescent market, as their market share moved from 0.5% of youth to 32.8% of youth at the height of

his use. Alcohol products also advertised using animal characters and among 4th and 9th graders, 75 and 87% respectively, recognized the animal character used in a Budweiser advertisement, while 33% of 4th graders and 75% of 9th graders were able to name the brand that the character was used to advertise.

In addition to persuasive advertising techniques, marketers often rely on the emotions of consumers in order to influence them. Emotional marketing, specifically the messages that advertisers use to evoke positive reactions and feelings from consumers, are particularly prominent in alcohol marketing. Given that items within similar product categories are for the most part comparable, alcohol advertising tends to rely heavily on emotional forms of advertising as a way of influencing consumer choice. The effects of emotional advertising may be particularly effective among youth given that they may not possess the cognitive abilities that are necessary to actively process advertising messages. Many psychological models propose that emotional advertising alone may increase the effectiveness of persuasion as well.

Psychological models, for example those that propose that unconscious processes influence consumers, are also hypothesized to persuade youth through such things as brand inference and affect. For example, branded items are often used to create beliefs about the attributes and benefits of products, thus creating and establishing associations with the product and an individual's personal motivations. For youth, fun and excitement are particularly salient motivations that marketers recognize and target. Research suggests that associations that are formed based on inference may actually be stronger than associations that are formed from more direct methods of communication that identify product benefits.

Youth Susceptibility to Advertising

A child's developmental stage is thought to be particularly important in the type of response a child has to a particular product being marketed. A review by Pechmann and colleagues suggests that in contrast to adults, the cognitive development of children and adolescents is characterized by shifts in one's basic cognitive abilities over time. While the adolescent brain does not grow in size after about 6 years of age, it does go through tremendous structural and functional reorganization. This brain plasticity, or changes in the brain systems and structures, may result in certain vulnerabilities as these systems and structures are highly susceptible to negative environmental input. These neurobiological changes are also associated with adolescents' increased likelihood of impulsivity and self-consciousness as compared to adults. As

such, adolescents may be particularly attracted to products deemed as risky (i.e. alcohol products), as well as those who provide immediate gratification and may influence social status. Additionally, due to increased plasticity of the adolescent brain, the use of these products may be especially harmful and increase the risk of future addiction.

As a result, youth may be particularly susceptible to the influence of advertising, especially given its ability to expose some of the common vulnerabilities of youth. For instance, adolescents are more likely to experience heightened self-consciousness and social anxiety during this time of their lives, which Solomon suggests may make them particularly receptive to image advertising, as well as advertisements, which include high-status brands. Given that many youth desire to appear older and more mature, advertisements that focus on achieving social status may also be particularly influential. In fact, adolescents have been found to prefer advertisements with desirable lifestyle images, lowering their ratings of advertisements, brands, and products when lifestyle images were removed from beer and cigarettes advertisements.

Additionally, advertisements, which depict risky behavior, are also thought to be influential among youth, especially given their tendency to experience high negative affect. Because this heightened negative arousal contributes to the propensity of adolescents to engage in risky and impulsive behavior, advertisements using this particular type of theme may be especially effective. Moreover, the choices that adolescents make tend to be driven by reward rather than risk, in part because youth expect to experience less harm as a result of engaging in risky behavior than would adults. As a result, adolescents may be tempted to use heavily advertised popular brands of alcohol, particularly because these brands may fulfill their need for immediate gratification and thrill seeking.

Media Exposure

Media use, including, television, music, computers, video games, print, and movies, has increased among youth as of late. Between 1999 and 2004, total media use among youth in the United States held steady at almost 6½ h day, however, by 2009, youth were consuming slightly more than 7½ h day. Youth spend most time watching television (4½ h), followed by time spent on music/audio (2½ h), computers (1½ h), video games (1¼ h), print (slightly more than ½ h), and movies (slightly less than ½ h). However, given that many youth multitask, overall media exposure has increased dramatically, from 7½ h in 1999 to 8½ h in 2004 to 10¾ h in 2009. Additionally, exposure to advertising is perhaps even greater than what some studies suggest, particularly

given that youth are exposed to advertising in many other forms, for example, billboards, inside or outside of stores, and at community events. In addition to these more traditional forms of media, many new forms have become increasingly popular among youth including social media, smart phones, and tablets. Given that exposure to these forms of media is not always assessed, true exposure rates are likely to be higher.

Alcohol Advertising

Alcohol advertising includes the advertising of products via a number of different media including television, movies, radio, magazines, in-stores, outdoors, and new media (e.g. Internet, video games). Alcohol advertising also includes the use of alcohol-branded merchandise, or items with an alcohol brand name (e.g. T-shirts, hats, key chains). Alcohol advertising, like other forms of advertising, seeks to develop new customer bases as well as maintain current ones. Because heavy drinking tends to peak in later adolescence and early adulthood, advertising to this demographic is important for alcohol brands to develop market shares within these cohorts.

Television and Movies

The Center on Alcohol Marketing and Youth (CAMY) found that alcohol advertising on television in the United States has increased over the past decade. From 2001 to 2009, exposure among youth aged 12–20 years increased by 71%. This increase in exposure among youth was greater than the increase among adults (21 and over). During this time, alcohol manufacturers spent more than \$8.2 billion on 2 664 919 alcohol product television advertisements. Over this same time period, alcohol advertising on cable television increased by 252.7%, while advertising on broadcast network television decreased by only 2.0%. On cable network, the only product to decrease in advertising exposure was wine (–40.6%), while distilled spirits, beer and ale, and alcopops (flavored malt beverages) all increased in exposure (+3078%, +183.3%, and +143.6%, respectively).

In a study using Nielson data, national data obtained from representative households in order to determine viewership of television programming, researchers determined that almost all of the alcohol advertisements appeared in time slots which had 30% or fewer underage adolescent viewers (95% of all time slots). However, each percentage point increase in adolescent viewership (particularly among female adolescents) resulted in an increase of beer, spirits, and alcopop advertisements (7, 15, and 22%, respectively) suggesting that adolescent viewers were exposed to more alcohol advertising than would be expected if the aim of the

advertisement placement was to target adults of legal drinking age.

Dal and colleagues analyzed the content of the top 100 major motion pictures for each year between 1998 and 2002 and found that over 80% of movies showed alcohol use, with a specific alcohol brand appearing in over half of all movies. Even in G/PG rated movies, alcohol use was shown in more than half and almost 20% contained at least one alcohol brand. On an average, movies exposed US adolescents (aged 10–14) to 5.6 h of alcohol use and nearly 250 alcohol-branded moments.

Magazines and Radio

Youth are also exposed to alcohol advertising in magazines and radio. While exposure in magazines is not as prevalent when compared to television, CAMY reports alcohol companies spent \$2.7 billion for 29 026 product advertisements from 2001 to 2008. Unlike television advertising, wine advertisements in magazines increased by 62.7% over the period from 2001 to 2008. Similarly, beer and ale, as well as alcopop advertising, also increased (157.6 and 39.3%, respectively). The only alcohol product to decrease in magazine advertising was spirits, with a 34.4% decrease. In a study of 118 magazines published between 2002 and 2006, youth readership (under age 21) increased so did the likelihood of exposure to alcohol advertising (from 1.5 to 4.6 times greater likelihood of exposure). Radio advertising of alcohol products has declined, with alcohol industry spending for radio advertising in the 25 markets for which data are available decreased from 2001 to 2006 from \$138.2 million to \$86.2 million, respectively. Despite these declines, youth are still exposed to alcohol advertising through this medium.

In-Store Advertising

In the United States, sample of stores that sold alcohol (3961 stores) almost all (94%) contained alcohol advertisements, half of which were within 3½ ft of the floor, a level previously documented to be in the straight eye-line of children. Convenience stores and smaller markets, along with liquor stores, tend to have the most alcohol advertising. Having a greater quantity of alcohol advertising in these locations is problematic because youth typically visit convenience stores and tend to stay longer than adults, thus increasing exposure.

Outdoor Advertising

Outdoor advertising of alcohol products includes billboards, signage on buildings such as product names and price information as well as other advertising on any outdoor structure. Youth exposure to outdoor advertising is common, with studies in Chicago and Boston

documenting increased exposure. In Chicago, students were exposed to approximately 15 outdoor alcohol advertisements, on average, around middle schools. In Boston, alcohol advertising was prevalent on public transit train systems with an average of approximately two alcohol advertisements in each of the train cars sampled. Given that nearly 10 000 youth use the transit system in Boston each day, youth exposure to alcohol advertising is tremendous.

New Media

Given that youth are heavy consumers of media, marketers have expanded to newer mediums such as the Internet, cell phones, and video games to target youth. While spending for these newer mediums is increasing, new media provides an outlet for advertising and promotion that does not require much expense and allows for very high levels of exposure. One form of new media, which may be particularly problematic among youth, is online digital marketing, especially given that advertising on this form of media is not as well understood. Many alcohol brands have their own Facebook® pages and Twitter® accounts. For example, 776 731 people “like” the Budweiser® Facebook® page, an Anheiser Busch® brand, which means that close to 800 000 people receive messages from Budweiser in their Facebook® feed. Depending on how often these companies post messages or how often other friends post about alcohol products, the rate of exposure from this type of advertising could well surpass that on other forms of advertising. What is also important to note about these Facebook® and Twitter® messages is that they are not subject to the same scrutiny as those in the mainstream media. While Facebook® does require youth to be a minimum age of 13 in order to have an account, there is no minimum age on Twitter, so youth of any age could receive these advertising messages.

Targeting of Alcohol Advertising

Despite making up less than half of the total population, Hispanic and African-American youth aged 12–20 are disproportionately exposed to more alcohol advertising in all media including magazines, radio, television, and outdoor advertising. Outdoor advertising of addictive products, such as alcohol and tobacco products, is also more prevalent in African-American and Hispanic neighborhoods as compared with non-Hispanic white neighborhoods. A study of alcohol and tobacco billboards and freestanding outdoor signs in the city of Chicago, for example, found these advertisements were targeted at poor neighborhoods. On an average, there were 11.8 alcohol billboards in the Hispanic majority neighborhoods as compared to 0.7 in the White majority neighborhoods. The researchers estimated that a child

walking to school in a predominantly African-American or Hispanic neighborhood was three times more likely to see an alcohol or tobacco advertisement than a child walking to school in a predominantly White neighborhood. Around middle schools in Chicago, youth attending schools with 20% or more Hispanic students were exposed to 6.5 times more alcohol advertising than students attending schools with less than 20% Hispanic students. Additionally, schools with 20% or more Hispanic students were also surrounded by more beer advertising and alcohol advertisements on bars and liquor stores.

Alcohol Advertising and Underage Drinking

Messages and Themes

Messages in alcohol advertising are particularly appealing to youth and influential in developing their intentions to drink. Exposure to alcohol advertisements lead youth to perceive that those who drink alcohol have more fun, are good looking and happy, likely as a result of the images portrayed in many alcohol advertisements. Studies have found that alcohol advertisements that are particularly appealing to youth advertise distinct themes such as sexual connotations, camaraderie, conformity, recreation, and friendship. Attractiveness cues of models in alcohol advertisements have also been found to portray sex appeal, femininity, friendliness, and sophisticated/high fashion. All of these themes and cues may be particularly appealing to youth given their stage of development and desire to fit in and engage in activities that make them appear older and more mature.

Alcohol advertising has also been found to influence positive expectancies about alcohol use, which in turn influence intention to use alcohol for under-aged youth (15–20). In a study of 5th through 12th graders, 56% reported that alcohol advertising encouraged them to drink. This encouragement to drink reported by youth likely occurs through the use of images and storylines which depict positive outcomes resulting from alcohol use, perhaps because youth are particularly motivated by benefits during adolescence. Exposure to alcohol advertising also leads children to have higher brand recall and hold more positive beliefs about the social and ritual uses of beer. Alcohol advertisements also shape knowledge, attitudes, and perceptions about alcohol use, which in turn are predictive of positive expectancies and intentions to drink.

In addition, it has been suggested that there has been an increase in the value that youth culture attaches to brand labels and symbols and that the marketing of brands has become an integral part of the everyday social lives of young people. Youth see marketing as part of the entertainment, sporting, and cultural environment that

surrounds them, thereby allowing them to link brands for alcohol to normative events in society, and reinforcing the perception that alcohol use is a frequent, everyday occurrence. Through social media, youth are also exposed to messages which promote alcohol use through status updates by friends and other fan pages on Facebook®, Twitter® feeds, and other media sites. Advertising research has shown that over time, repetitive exposure to advertising can lead to low-involvement learning, or learning that occurs when a person is a passive participant. Therefore, even if adolescents do not agree with, like, or are skeptical of advertisements, they still form associations between alcohol use and important values, goals, and lifestyles.

Exposure to Alcohol Advertising and Underage Drinking

In a review of longitudinal studies which document the impact of alcohol advertising and media exposure on adolescent alcohol use, Anderson and colleagues found that across 13 studies findings provide consistent evidence that exposure to alcohol advertising and media is significantly associated with alcohol-use initiation, as well as escalation among those who already use alcohol. In another review of seven longitudinal cohort studies, Smith and Foxcroft also found that increased exposure to alcohol advertising was associated with increased risk of underage drinking.

Several forms of advertising have been linked to underage alcohol use and alcohol-use initiation. In a US national longitudinal study, which examined self-reported exposure to alcohol advertising on television, radio, magazines, and billboards, youth who reported greater exposure had higher levels of alcohol consumption. Specifically, for each additional advertisement that youth saw, the number of drinks consumed increased by 1%. In another study of exposure to alcohol advertising on television, both self-reported exposure to alcohol advertisements as well as type of programming watched were obtained. Using the measure of the type of program watched, 7th graders who watched more television shows were more likely to engage in beer drinking, wine or hard liquor drinking, or have episodes of drinking three or more drinks in a row in 8th grade, while those who watched more sports programs were more likely to engage in beer drinking. For self-reported exposure to alcohol advertising, greater exposure predicted increased beer consumption. Greater exposure to any media (including television, music video and videotapes, computer and video game use), not specifically alcohol advertisements, also predicted alcohol-use initiation among 14–15-year-olds. For every 1-h increase in music video exposure, the odds of drinking initiation risk increased by 31% while the same amount of television exposure increased the odds by 9%. Exposure to

alcohol advertising in movies has also been found to predict alcohol-use initiation among 10–14-year-olds.

Exposure to alcohol advertising in stores has been associated with increased risk of alcohol use among youth in several studies. For example, middle school youth who frequently visited convenience stores, liquor stores, or small grocery stores were more likely to have ever used alcohol. In a sample of 7th graders who did not drink alcohol, exposure to in-store beer advertisements significantly predicted initiation of drinking in 9th grade. Additionally, greater exposure to objectively measured outdoor alcohol advertising, including billboards, other freestanding alcohol signage, and alcohol signage on buildings, predicted increased alcohol use intentions among middle school youth. Among youth who had not used alcohol at baseline, greater exposure to outdoor advertising also predicted increased alcohol use intentions. Interestingly, while overall signage predicted intentions, even those signs which included only brand name or product information predicted increased alcohol intentions, suggesting that even exposure to advertisements which may not be particularly appealing to youth also have an effect on alcohol use.

Alcohol-Branded Merchandise and Underage Drinking

While alcohol advertising on media channels such as television, print, radio, and outdoor media is prevalent and increases the risk of underage drinking, the expenditures of these forms of advertising may account for only one half of the company's advertising budget. Another form of promotion is merchandising, which would include things such as packaging, direct mailing, point-of-sale materials, and branded promotional merchandise or alcohol-branded merchandise.

The influence of alcohol-branded merchandise, or merchandise such as hats, shirts, or water bottles with the name and/or logo of alcohol brands, has been associated with youth alcohol use in several studies. In a nationally representative sample of United States youth aged 10–14, ownership of alcohol-branded merchandise was common, with rates ranging from 11–20%. The most common forms of alcohol-branded merchandise were clothing such as t-shirts, jackets, and headwear (88%) and over 80% of the branded merchandise was for beer brands. Most commonly, adolescents received their alcohol-branded merchandise from friends and family, however, almost one-quarter purchased these items on their own. Youth with higher levels of sensation-seeking and rebelliousness were more likely to own alcohol-branded merchandise and youth who were involved in extracurricular activities were also more likely to own alcohol-branded merchandise. African-American and Hispanic youth were less likely to own alcohol-branded merchandise than White

youth. Alcohol-branded merchandise ownership was significantly related to an increased likelihood of becoming susceptible to alcohol (less likely to refuse peer offers of alcohol, increased intentions to use alcohol, and increased positive expectancies of alcohol use). In addition to indirectly predicting alcohol-use initiation through alcohol susceptibility, owning alcohol-branded merchandise also directly predicted the initiation of alcohol use, as well as binge drinking among those who were nondrinkers at baseline.

In another large cohort study, the Growing Up Today Study, youth aged 9–14 who owned or were willing to own alcohol-branded merchandise were more likely to initiate alcohol use at the 1-year follow-up. Among girls, owning alcohol-branded merchandise was associated with binge drinking. Similarly, students in California middle schools who owned at least one alcohol promotion item were found to be three times more likely to have ever tried drinking and 1.5 times more likely to be current drinkers than those who did not own any alcohol promotion items. In another study of northern New England adolescents, youth who own alcohol-branded merchandise were significantly more likely to have initiated alcohol use 1–2 years later as compared to youth who did not own this type of merchandise. Each of these studies, while not nationally representative, provides evidence that regardless of region of the United States, alcohol-branded merchandise does influence underage alcohol use.

CONCLUSIONS

Underage drinking is prevalent in the United States, and associated with subsequent use of alcohol and other problem behaviors in later adolescence including drinking and driving, alcohol-related violence, injuries, as well as increased risk for using other drugs. As a result of their developmental stage, youth may be particularly susceptible to the influence of advertising, especially given its ability to expose some of the common vulnerabilities of youth. Alcohol advertising, although intended for individuals of legal drinking age, uses persuasive techniques and images that are particularly attractive to youth. As a result, alcohol advertising gains youth attention and engages them in what is being offered. Several longitudinal studies have found that exposure to alcohol advertising and alcohol-branded merchandise both predict underage alcohol use as well as initiation of

alcohol use among nondrinkers. Because early alcohol use is associated with alcohol dependence in later life, understanding the effects of exposure to alcohol advertising, as well as reducing exposure, is crucial.

<i>Studies of Drinking</i>	928		

Alcohol use by youth and young adults is very common and has been associated with a variety of serious societal problems. For example, three-fourths of 12th graders in the United States have consumed alcohol during their lifetimes, with 45% having done so in the last month and 22% having consumed at least five drinks in a single occasion. The Surgeon General's office estimates that 5000 US residents under the age of 21 die each year from injuries due to underage drinking including 1900 related to motor vehicle crashes and 1600 due to homicides. These high levels of alcohol use and problems have led to an array of policies designed to discourage youth drinking including education campaigns, minimum legal drinking age laws, enhanced regulation of driving after drinking, and higher beverage taxes or prices. The impacts of taxes

and prices on adult drinking, young adult drinking, and underage drinking have been evaluated by hundreds of studies over more than 60 years. Although the results of these studies generally indicate that greater taxes and prices are related to less drinking and fewer alcohol-related problems, there is also a fair amount of disagreement within the empirical literature.

Tax- and price-based measures have both advantages and disadvantages relative to other alcohol-control policy options. On the positive side, alcohol tax policies cost relatively little to administer, unlike drunk driving or underage purchase laws that involve considerable expense to enforce and prosecute. Higher beverage taxes can simultaneously reduce the costs that problem drinkers impose on other citizens (such as victims of

drunk driving) and help defray the governmental costs of alcohol-related law enforcement and treatment programs. The major disadvantage of alcohol taxes is that they are not as closely tied to problem drinking as other alcohol-control policies. Whereas underage-sales laws only limit access for a group whose drinking is considered particularly risky and drunk driving laws only affect those who combine alcohol and vehicle use, higher beverage taxes indiscriminately discourage both low-risk and high-risk drinking behaviors. This lack of focus on problem drinking causes beverage taxes to be more controversial than some other alcohol-control policies, and makes it important for empirical research to demonstrate that tax policies reduce the types of alcohol use that are most problematic to society. This level of controversy also encourages political partisans to emphasize studies that either support or discount the harm-reduction potential of tax or price policies, making it important to understand how these policies work and how their effectiveness can best be evaluated.

This chapter provides a general introduction to the effectiveness of tax and price policies for reducing drinking and related problems, particularly among youth and young adults. It is organized as follows: The first section explains how these policies work in theory. The second section explains the ways in which the policies are typically evaluated, stressing the strengths and weaknesses of different methodological approaches. The third section briefly reviews the broader literature estimating price and tax effects on drinking and other related problems among all ages. The fourth section looks more closely at tax and price effects on youth drinking and problems, explaining how variation in findings across studies are often explainable based on their methodological differences. The final section summarizes the strengths and weaknesses of these various parts of the literature and offers conclusions about their usefulness in formulating alcohol-control policy.

HOW TAX AND PRICE POLICIES WORK

The top panel of Fig. 93.1 presents a simplified conceptual model for using taxes or prices to control drinking and related problems.

Taxes to Prices

Although some governments set alcohol prices directly via retail monopolies, others allow market forces to determine beverage prices. These governments use tax policy to influence prices, and the plus sign above the first causal arrow in Fig. 93.1 suggests that tax increases induce alcohol sellers to raise beverage

Conceptual Model:

Typical Empirical Models:

FIGURE 93.1 Conceptual and empirical models of tax or price effects.

prices. Confirming prior research, a 2005 analysis by Donald Kenkel found that a major alcohol tax increase consistently led to even larger price increases across various beverages and outlet types (i.e. the tax increase was more than 100% passed through to customers).

Prices to Drinking

The minus sign above the middle causal arrow represents a negative relationship between alcohol prices and drinking. This reflects the “law of demand” at the core of economics: when a product’s price increases, people will generally choose to buy less of it. Although this assumption is quite sensible among of-age drinkers who typically purchase the beverages they consume, it is somewhat more controversial for underage individuals who are legally prohibited from buying alcohol. Although these individuals sometimes make retail purchases despite being underage, their access more often comes indirectly through social networks, availability in their families’ homes, or purchases by adults on their behalf. The underage drinker may not pay the full cost of their alcohol in such instances, which weakens the logical case for price effects. However, even when young drinkers do not pay for the beverages they consume, someone is paying the retail price, and these purchasers have an incentive to buy less when prices are high. Also, research indicates that youth drinking norms are positively related to adult drinking behaviors in their communities, and these adult behaviors will be affected by prices.

Drinking to Problems

The plus sign over the last causal arrow in Fig. 93.1 reflects the fact that increased drinking is typically associated with increased risks for various problems such as motor vehicle crashes, accidental injuries, assaults (as victim or perpetrator), homicides, suicides, and chronic ailments such as liver disease and some cancers.

HOW THESE POLICIES ARE EVALUATED

Any one empirical study is very unlikely to investigate all of the causal relationships shown in the conceptual model. Instead, such studies tend to relate either taxes or prices to either drinking or problems. These two choices lead to the four typical analysis models shown in the lower panel of Fig. 93.1. Model 1 directly investigates a consumer's purchase decision: faced with a given price level for alcohol, how much does an individual buy? Model 2 directly relates tax rates to drinking while ignoring the intervening effect of prices. Model 3 directly associates prices with some measure of alcohol-related problems such as traffic crashes, disregarding the intermediating impact of drinking. Finally, model 4 relates tax rates directly to an alcohol problem indicator, ignoring the intermediate roles of both prices and drinking. Each of these four typical models can be analyzed using either individual-level or aggregate-level data. An individual-level example for model 1 might relate college-specific price indicators to student-specific survey reports of heavy drinking. An aggregate-level example using model 4 might relate state-specific beer tax rates to state-level automobile fatality rates among youth and adults.

Each of these modeling alternatives involves advantages and disadvantages, both in terms of policy-relevance and the reliability of statistical results. An understanding of these issues is helpful for understanding why the existing empirical literature is less than unanimous in its findings regarding the effectiveness of tax and price policies.

Prices versus Taxes

One attraction of using prices rather than tax rates is that taxes may be a small and varying portion of each beverage's price. For example, wine prices may rise considerably due to poor harvests in grape-growing regions, and tax rates will not be able to explain any resulting decline in wine consumption. Another advantage of using price to predict drinking levels is the product-demand relationship that can be defined in a directly comparable way across the full array of goods and services. Economists typically express this relationship as "price elasticity," defined as the percent change in a product's consumption resulting from a 1% increase in its price. Because the price and purchase changes are both measured as proportions, price elasticities can be directly compared across product categories regardless of the units used for currency or quantity purchased. For example, Craig Gallet's 2007 literature review was able to compare the median-study's elasticity for beer (-0.36 , suggesting a 0.36% drop in purchases from a 1% price increase) to those for wine and spirits

(-0.68 and -0.70 , respectively) and conclude that beer demand was roughly half as responsive to price changes as was demand for spirits or wine. Elasticities calculated using taxes rather than prices will vary with each product's tax-to-price ratio, preventing direct comparisons across different consumer goods.

On the other hand, prices also have some disadvantages relative to taxes. Unlike prices, taxes are directly under the control of policymakers, so results from a tax-based model will be more relevant for policy analysis purposes. Also, any given consumer faces a wide range of possible drink prices depending on his or her choice of beverage, brand quality, container size, and purchase location. Empirical studies generally employ a single price index for each beverage type, often based on a single brand. For example, many US studies have used alcohol prices from the Council for Community and Economic Research's Cost of Living Index (C2ER COLI), formerly published by the American Chamber of Commerce Researchers Association (ACCRA). For several decades, this data system has surveyed local retail prices for one specific brand and container size each for beer, wine, and spirits. The chosen price index may not be particularly relevant for those drinking other brands, and research by Douglas Young and Agnieszka Bielinska-Kwapisz has demonstrated how this imprecision can bias estimated price effects toward zero. This is much less of an issue for models using beverage taxes, where a single rate typically applies over a broad class of beverages.

Drinking versus Problems

Studies also measure drinking in many different ways, including participation (any drinking), frequency of any drinking (e.g. occasions per month), participation in or frequency of "binge" drinking (e.g. occasions with 4+ drinks for females, 5+ for males), average drinks per occasion, or total volume consumed over a given time period. Some of these measures of drinking may be more important from a policy standpoint than are others. As discussed above, alcohol policy should ideally reduce problematic drinking with minimal disruption of low-risk (or even health-improving) alcohol use. Knowing that a price increase would reduce total alcohol consumption by 1% does not clearly imply a reduction in problem drinking. On the other hand, drinking by underage individuals is often considered problematic in and of itself, so youth drinking measures might be more meaningful from a policy perspective. Similarly, survey reports of heavy or binge drinking are typically assumed to be inherently more problematic than other consumption measures. Studies may also investigate a range of specific alcohol-involved problems such as impaired driving,

violence, accidental injuries, or chronic conditions such as liver cirrhosis.

Individual versus Aggregate-Level Data

Studies can also be differentiated by whether they investigate person-level or aggregated drinking problems. Aggregated drinking indicators are generally limited to measures of alcohol sales within a tax jurisdiction, such as barrels of beer sold in a given state and year. A major advantage of aggregated sales data is that the information is automatically and reliably recorded in the process of collecting alcohol taxes, whereas survey self-reports of drinking behaviors will likely be less accurate due to memory lapses or underreporting bias. For example, a recent US analysis by David Nelson and colleagues finds that average per capita self-reported beverage consumption in the Behavioral Risk Factor Survey tends to be roughly one-third as high as per-capita taxable alcohol sales. This finding suggests either that survey respondents greatly understate their drinking or that the heaviest drinkers often refuse to participate in the surveys. Another advantage of taxable-sales data is that they tend to be consistently collected over long time spans, increasing the statistical power to measure price effects with reasonable precision. One disadvantage of taxable-sales data is that certain types of drinking will not be counted (illegal production) or will be counted as consumption in a different jurisdiction (as when individuals cross state or national borders to purchase in a neighboring low-tax jurisdiction but transport the beverages back to their high-tax area). Another limitation of tax-based aggregate drinking measures is that there is no way to differentiate by the types of drinking (e.g. frequency of binge drinking) or groups of drinkers (e.g. youth versus adult), and it may be impossible to differentiate on-premise from off-premise sales (e.g. consuming at a bar versus at home). These specific types of drinking may be differentially related to alcohol problems, and can generally be distinguished only with individual-level surveys.

Analyses of alcohol-related problems can also be performed at the aggregate or individual level. Governments frequently collect jurisdiction-level data on traffic crashes, hospital admissions or fatalities by diagnostic code, arrests for various offenses, and other indicators such as educational performance that may be related to drinking. Unlike for aggregated beverage-sales data, many of these problem rates can be differentiated by age group, such as counts of traffic fatalities among drivers aged 18–20. Although survey data allow more flexibility in terms of specific problems (e.g. arguing with a spouse), aggregate data sources

tend to be more reliable and complete for the limited problems for which they are available.

Aggregate-level studies of drinking or related problems require tax or price data of corresponding geographic areas. For example, state-specific cirrhosis death rates could be compared to state alcohol tax rates. In contrast, individual-level drinking or problems can be related to either aggregated or individual-level price data. Use of aggregated tax/price data has the advantage that is more independent of a person's drinking choice; for example, a student at a college in a high-tax state will likely have to pay more for alcohol regardless of which beverage brand he or she chooses to consume. Self-reported price data, on the other hand, may be heavily influenced by the product chosen (e.g. cheap or expensive brand, large or small container) and drinking location (e.g. at a party versus a bar). This "choose your price" aspect of individual reports can have advantages or disadvantages over aggregate-level price indices. If a hypothetical individual decides to attend a college party without knowing whether there will be a charge for alcohol, then the fact that the chosen party provides free drinks could be said to have an exogenous impact on how much the student drinks on that occasion. Frank Chaloupka has argued that college studies that examine only local retail prices will understate estimated price elasticities by ignoring the effect of such no-cost drinking. Conversely, an individual who intends to drink heavily on a given occasion may be more likely to choose a bar with low prices and to buy the cheapest brand. Such a study would tend to overestimate the price effect on drinking problems because part of the causation is actually going from heavy intended drinking to beverage cheapness.

EMPIRICAL EVIDENCE OF TAX AND PRICE EFFECTS ACROSS ALL AGES

Studies of Drinking

Combining results from 112 separate empirical papers, a 2009 literature review by Alexander Wagenaar and colleagues provides strong general support for the hypothesis that prices and taxes are negatively related to all-age drinking. They found that these studies were over 30 times more likely to report a statistically significant negative impact on drinking than to find a significant positive effect (although analyses with unexpected results may be less likely to appear in the published literature). Ten reviewed studies specifically estimated price or tax effects on various measures of heavy alcohol use, with seven finding a significant negative effect and only one reporting a significant positive relationship. Some authors have hypothesized that heavy alcohol

consumers should be less responsive to price changes than are lighter drinkers due to the addictive nature of alcohol, while other authors expect heavy drinkers to be more affected by prices due to alcohol being a larger part of their household budget. Empirical studies have reached no clear consensus over which group is more price-responsive, however.

Studies of Problems

Wagenaar and colleagues' 2010 literature review provides a similar summary across 50 separate studies relating prices or taxes to mortality and morbidity from various causes. Their meta-analysis procedure calculated average price/tax effect sizes within each of eight problem categories: alcohol-related disease, violence, suicide, traffic, risky sex or sexually transmitted disease, tobacco or drug use, crime or misbehavior, and nonalcohol-specific injuries. All eight of these averaged effects were negative, and all were significantly different from zero except for suicide (which was nearly significant with a p -value of 0.084). Although their meta-analysis combined studies of problems across all age groups, the review also itemized 40 estimates relating prices or taxes to youth-specific problems; 65% of these reported significant effects in the hypothesized negative direction, whereas none found a significant positive relationship.

EMPIRICAL EVIDENCE OF TAX AND PRICE EFFECTS AMONG YOUTH AND YOUNG ADULTS

The literature reviews and meta-analyses discussed above provide strong general support for the hypothesis that price and tax policies can reduce drinking and problems, both in the general population and young age groups. Despite this general agreement in the literature, however, there is a substantial amount of variation in results across studies. This section summarizes the strength and consistency of evidence from various sections of the literature describing youth and young adults.

College Drinking

Survey-based analyses of college drinking typically find the expected negative relationship with prices, but the results vary somewhat depending on how relevant the tax or price measure is to a given school's drinking experience. For example, a 1996 study by Frank Chaloupka and Henry Wechsler relates the city-level C2ER COLI beer-price index to student drinking in Harvard's College Alcohol Study (CAS) and found significant

negative price effects for underage female students but not males or of-age females. A 2005 CAS analysis by these authors and Jenny Williams found more consistently significant price effects by replacing the noncollege-specific C2ER COLI index with a measure of typical prices paid by survey respondents at each particular school, including "all you can drink" fees. A 2009 analysis by Ryan O'Mara and colleagues went even further in the direction of price relevance, finding that individual respondents' blood alcohol levels upon leaving a college bar district had a strong negative association with the amount that they had paid per unit alcohol on that particular day. The less-significant C2ER COLI-based results suggest that broad tax or price indices may not adequately reflect the alcohol costs faced by individual college students. At the other extreme, using prices specific to a single drinking occasion makes the direction of causation somewhat suspect, as individuals who plan to consume heavily may choose cheap brands and low-cost drinking venues.

Other Youth Drinking

Noncollege studies have used a variety of survey data sets to assess whether higher taxes or prices are associated with reductions in youth and young adult drinking. The majority of studies in this literature have confirmed the hypothesized negative relationship. However, a number of studies published since the late 1990s have found far less consistent results using more conservative statistical specifications. This methodological division arises because there is more than one logical explanation for the observation that people drink more where taxes or prices are low. The standard economic demand hypothesis assumes that high taxes and prices in a given area induce local residents to drink less. An alternative explanation suggests that some regional populations will have particularly strong anti-drinking sentiments, and these attitudes could lead to both high local beverage taxes and low levels of drinking, even if taxes or prices themselves do not influence alcohol use. Basic empirical models have generally found that jurisdictions with high taxes tend to have lower per capita drinking, but this evidence is consistent with either hypothesis above. Other statistical models test whether jurisdictions with rising (falling) taxes tend to reduce (increase) their alcohol consumption relative to other places with unchanged taxes, and this sort of study provides a more-direct test of the hypothesis that taxes influence drinking behavior. An influential 1999 paper by Thomas Dee used both types of models to analyze self-reported drinking data from 16 years of the Monitoring the Future (MTF) survey; simpler specifications confirmed earlier findings that youth consumption moves inversely with beer taxes, but models

concentrating on tax changes found inconsistent results. Frank Chaloupka has argued that the latter results are not convincing evidence against the standard demand hypothesis, noting that the rarity of tax changes over the period studied implies low statistical power to identify a significant tax effect. This argument is supported by Christopher Carpenter and colleagues' 2007 analysis that used a longer 28-year sample of MTF data to find significant negative tax effects on youth drinking even using the more conservative specifications. Studies of youth drinking based on other US survey data sets (National Longitudinal Study of Youth, National Survey of Drug Use and Health) have produced a similar pattern of results, with significant negative price or tax effects in simple models but mixed results using the more conservative methods.

Youth Motor Vehicle Crashes

A large number of studies have investigated the relationship between alcohol taxes or prices and youth traffic crashes. Most of these studies have focused on aggregate-level fatal crash statistics for US states, available from the Fatal Accident Reporting System (FARS). This source provides consistently collected data for all states over several decades, with detailed reports collected for all vehicles in every crash involving a fatality. Several different state-level studies using FARS data over various time spans have found that higher prices or taxes are significantly related to lower traffic fatality rates, with the effect usually being stronger among youths than for adults. Unlike in youth drinking studies, these significant negative tax or price effects generally remained even in analyses using more conservative statistical specifications designed to avoid biases from states with antialcohol sentiments enacting higher tax rates. However, a 2001 study by Thomas Dee and William Evans found a similar negative beer tax effect on youth crash fatalities regardless of whether they occurred during the day or night, despite the fact that the daytime crashes were rarely found to have involved drinking. This fact, along with somewhat implausibly large tax elasticities, made the authors question whether these results are really due to the effects of drinking. An individual level 1997 study by Frank Chaloupka and Adit Laixuthai found a significant negative relationship between beer taxes and nonfatal youth crashes as reported in the MTF surveys.

Other Youth Problems

A series of studies by Sara Markowitz and Michael Grossman have related higher alcohol prices to reductions in several problems on college campuses including suicidal thoughts and actions (significant for males but

not females), sexual assault, property damage, and trouble with police. They have also found significant price or tax impacts for youth birth control use and sexually transmitted diseases, the latter of which was confirmed for males only in a 2000 paper by Harrell Chesson and colleagues. A 2003 analysis by Bisakha Sen found that higher beer taxes were associated with fewer teen pregnancies and abortions. Although these results suggest the breadth of problems that could be affected by alcohol price or tax policies, it is hard to judge the robustness of each individual finding in their absence and other analyses investigating that particular outcome measure.

SUMMARY AND CONCLUSIONS

The great majority of empirical studies are consistent with the hypothesis that higher beverage taxes or prices lead to reductions in drinking and related problems. Yet this literature is far from unanimous regarding the size or, to a lesser extent, the direction of these effects. In part because they are not well targeted toward problem drinking, alcohol taxes tend to be controversial, and inconsistent empirical results regarding their harm-reduction effectiveness reduce the political will to raise tax rates. This helps to explain why alcohol taxes in the United States have failed to keep pace with inflation during the past 50 years, with the result that real beverage prices have declined considerably.

There are many possible reasons for the lack of agreement across these empirical studies. All statistical analyses involve some imprecision in their estimates, and this explains some of the variations. Certain measurement issues can further compromise the ability of models to provide accurate estimates of price and tax impacts. For example, single-brand price indices fail to reflect the wide array of product choices that consumers typically choose from, and it has been demonstrated that inaccurate price measures bias elasticity estimates toward zero. The use of single brand, city-level price indexes may be especially poor at capturing the prices spent on alcohol in college drinking studies, helping to explain their inconsistent effect estimates relative to price measures that account for free alcohol or all-you-can-drink fees. Unreliable self-reported drinking on surveys would also result in poorly estimated price or tax effects, and this could help to explain the less-than-consistent results in the literature for youth drinking.

There are also several reasons that tax and price effects may truly vary depending on the situation. For example, a tax increase that applies only to spirits might cause many consumers to switch to wine or beer without any substantial impact on total drinking, whereas an equivalent tax hike across all beverages could lead to a considerably larger drop in overall consumption. The

local impact of a tax increase may also depend on whether consumers can easily substitute locally bought beverages with purchases in neighboring jurisdictions that have not changed their tax rates. Raising taxes that are defined as a percentage of wholesale value will tend to increase prices particularly for high-quality brands, perhaps inducing some drinkers to switch to cheaper brands rather than reduce their total drinking. Raising taxes that are defined as a flat rate per unit of ethanol would most affect the prices of the lowest-cost forms of alcohol, and consumers of these products will have less ability to maintain consumption by switching to cheaper brands. Research by Gruenewald and colleagues based on Swedish price data suggests that equivalent changes in average prices may have far different effects on total alcohol consumption depending on how they are distributed across the brand-quality spectrum. A new study by Tim Stockwell and colleagues further supports this idea, finding that Canadian beverage sales are more sensitive to changes in the cheapest beverages' prices than to the average price across a broad beverage category.

The effect of a given increase in taxes might also vary with the current share of taxes in the full price of drinking. Consider the effect of a proposed 10% rise in beverage taxes. If taxes currently represent 5% of the retail price, the 10% tax hike would only raise that price by about 0.5%. If the current tax share is 50%, however, the same proportional tax hike would raise retail prices by roughly 5%, implying a far larger expected reduction in drinking. The full price of drinking also includes the time spent on obtaining beverages as well as other possible costs related to alcohol use such as penalties for drunk driving. A given proportional change in the monetary price of a beverage would represent a smaller portion of the full price in places with stronger alcohol policies other than taxes, possibly leading to smaller estimates of the price elasticity of drinking. As a result, price sensitivity of drinking may vary considerably across geographic areas or time periods. For example, some authors have noted that US studies using more-recent data tend to find smaller price effects on motor vehicle crashes, which might reflect increased penalties for drunk driving or perhaps other changes in society. A disproportionate share of tax and price studies have been conducted in the United States because of its greater variation in state tax policies but reasonably uniform drinking culture, which lets states with unchanged tax rates function like control cases in judging the effects of other states' tax changes. Although this makes the United States a convenient laboratory for testing tax effects, it does not imply that other countries will experience similar effects of tax or price changes.

In conclusion, the empirical literature provides ample evidence of the potential effectiveness of tax and price

policy for reducing youth drinking and related harms. Some portions of the literature are less conclusive than others. For example, youth drinking studies are typically based on self-reported drinking which may be seriously under-reported, and this may help explain why price effects estimates vary considerably across studies. However, weaknesses in some sections of the literature are compensated somewhat by stronger findings in other areas. Thus, even if price effects are somewhat difficult to measure for youth drinking, there are more-conclusive results for all-age drinking based on aggregate sales data, and traffic fatality studies suggest that youths may be more responsive to tax and price policy than are adults. The literature also provides limited evidence regarding the types of tax or price policies that should be most effective, and also suggest how well they might be expected to work in different social and legal environments. Such research can help individual communities formulate their optimal blend of alcohol-control policies.

INTRODUCTION

Adolescence is the period of increased susceptibility for cigarette smoking uptake and progression. In the United States, approximately 90% of adults who smoke daily begin smoking before the age of 18. Accordingly, efforts to reduce smoking prevalence must include tobacco control policies aimed at preventing smoking uptake and promoting cessation among youth. Rates

of youth smoking in the United States remain unacceptably high. Every day, almost 4000 youth (aged 12–17 years), smoke their first cigarette and about 1000 become daily smokers. In 2009, 19.5% of high school students (grades 9–12) had smoked at least one cigarette in the past month. Furthermore, previously observed declines in youth smoking have stalled; smoking prevalence among youth has remained virtually unchanged since 2003.

Youth smoking behavior is influenced by a variety of intra-individual and contextual factors, including genetic/biological factors, parent/peer influences, and broader environmental influences (i.e. community characteristics, media, policy). Policies are a set of rules that guide the present and future behaviors of individuals and organizations to achieve a specific goal. Youth-centered policy approaches work at the environmental level, by altering the legal, economic, social, and physical contexts that shape tobacco-use behavior. When implemented as part of a comprehensive tobacco control program (e.g. programs involving a range of coordinated and coexisting tobacco control strategies) these policy tools can work independently and synergistically to drive down youth smoking rates.

This chapter provides a broad overview of tobacco control policies that are intended to and/or have an effect on reducing youth cigarette smoking in the United States. For the purpose of this review, we consider four broad policy approaches: youth tobacco access restrictions, smokefree laws, economic approaches, and restrictions on tobacco marketing and promotion. Within each of these broad categories, we review the evidence for specific policies. The contribution of each policy tool is discussed as it relates to the reduction of youth smoking rates. Additionally, because policies can influence youth smoking behavior at multiple points along the smoking trajectory, we consider the action of these policy tools across the tobacco use continuum, from experimentation to cessation.

Youth smoking is a global problem, and a growing number of countries are implementing and enforcing tobacco control policies that influence youth. According to international data, an estimated one in seven teenagers smoke cigarettes, and almost one-quarter of those have smoked their first cigarette before age 10. The youth tobacco problem is especially pronounced in economically developing nations. It is estimated that worldwide more than 80% of youth who smoke live in low- and middle-income countries. While the focus of this chapter is on the United States, examples of global policy approaches are included throughout.

No examination of the tobacco control landscape as it pertains to youth would be complete without a look at the challenges that lie ahead. The tobacco industry is nimble; as policy tools evolve over time, so too do industry tactics designed to circumvent these policies. For example, in the face of an increasingly regulated cigarette market, tobacco companies are actively investigating alternative tobacco products that have the potential to attract young people (e.g. smokeless tobacco, little cigars, hookah). Though cigarettes are the focus of this chapter, many of the policy approaches discussed could be potentially applied to other forms of tobacco.

Youth Policy: US Perspective

A variety of tobacco control policies have been enacted over the last two decades that aim to prevent smoking initiation and reduce consumption among adolescents. Early efforts to reduce youth smoking employed key reports, litigation, and legislation passed at the local, state and federal levels. A 1994 publication by the Institute of Medicine, "Growing up Tobacco Free: Preventing Nicotine Addiction in Children and Youths," was one of the first high-profile reports to focus on youth tobacco use. The report discussed initiatives throughout the world to limit access, control/ban tobacco sales to minors, and reduce tobacco advertising, and examined price sensitivity among youth. Another prominent 1994 publication was "Preventing Tobacco Use Among Young People: A Report of the Surgeon General," which was the first Surgeon General's report to focus entirely on the problem of youth smoking.

The largest civil litigation settlement in US history was the 1998 Master Settlement Agreement (MSA) between the four major US cigarette manufacturers and 46 US states (Florida, Mississippi, Texas, and Minnesota settled separately with the manufacturers around the same time). The main purpose of the MSA was to seek reimbursement for healthcare costs incurred by the states over the decades when the tobacco companies were denying the causal relationship between smoking and disease and the addictive nature of tobacco. A secondary objective was to reduce underage tobacco use through prohibiting tobacco companies from directly or indirectly targeting youth through marketing (enforced by state attorneys general). Funds from the MSA created the American Legacy Foundation that is devoted to "building a world where young people reject tobacco and anyone can quit." Furthermore, the settlement compelled tobacco companies to release millions of internal tobacco industry documents, which revealed long-standing practices of targeting underage users and potential users. The availability of these documents would bolster future litigation efforts to hold tobacco companies accountable for their actions. The MSA represented an important step toward ending some of the tobacco industry's most egregious-youth-marketing practices and helped to set the stage for future policy efforts. However, the MSA was fairly limited in its regulatory authority, leaving many avenues for continued efforts by the tobacco industry to recruit youth smokers.

In addition to the advances achieved through the states' litigation, the 1990s also saw the first serious efforts to pass youth-focused tobacco control legislation. The Synar Amendment, passed in 1992, requires states to enact and enforce laws prohibiting the sale and distribution of tobacco products to individuals less than

18 years of age. In 1996, under US Food and Drug Administration (FDA) Commissioner David Kessler, the FDA issued a groundbreaking rule to restrict the sale, distribution, and advertisement of tobacco products, arguing that smoking is “a pediatric disease,” as the vast majority of smokers smoke their first cigarette before 18 years of age. The tobacco industry challenged these efforts in the courts. Ultimately, the only provisions of that rule that went into effect were a series of youth access restrictions. Though the 1996 final rule was struck down by the US Supreme Court, it laid the groundwork for a 13-year effort that would ultimately result in the passage of even stronger Federal legislation in 2009, which incorporates provisions of the 1996 rule.

2009 United States Family Smoking Prevention and Tobacco Control Act (Tobacco Control Act)

On June 22, 2009, US President Obama signed the legislation granting the FDA broad regulatory authority over the manufacture, distribution, and marketing of tobacco products to protect public health. One of the main objectives of this legislation is to reduce youth tobacco use. The US Congressional Budget Office estimated that the new law would reduce youth smoking by 11% over 10 years. The FDA Center for Tobacco Products (FDA-CTP) was created to oversee the implementation of the Tobacco Control Act. A priority emphasis of the FDA-CTP is to prevent and reduce tobacco use among young people through provisions that target this population. The different components of the law will be implemented over many years. A ban on the manufacture and distribution of flavored cigarettes (with the exception of menthol) went into effect on September 22, 2009. On June 22, 2010, the FDA issued a final rule containing a broad set of federal requirements restricting the sale, distribution, and marketing of tobacco products to make them less accessible and less attractive to kids. This rule builds on the youth access and marketing restrictions that were introduced in the 1990s through the MSA and the 1996 final rule. [Table 94.1](#) shows the provisions contained in the final rule.

The FDA has many other regulatory authorities that, when implemented, could help reduce youth smoking rates. For example, the Tobacco Control Act directs the FDA to require larger text warning labels on smokeless tobacco and larger graphic warning labels on cigarette packages and advertisements, which will help reduce tobacco rates and prevent smoking initiation among youth. Larger smokeless tobacco text warnings went into effect from June 2010, and the FDA issued a final rule in June 2011 mandating graphic health warnings on 50% of the front and back of all cigarette packs. However, the tobacco industry has since sued the US government, alleging that the mandated graphic warning labels on cigarette packages and advertising

TABLE 94.1 FDA Final Rule Restricting the Sale and Distribution and Marketing of Cigarettes and Smokeless Tobacco (Title 21 CFR Part 1140) (June 22, 2010)

Sale and Distribution

- Prohibits the sale of cigarettes or smokeless tobacco to people younger than 18
- Prohibits the sale of cigarette packages with less than 20 cigarettes
- Prohibits the sale of cigarettes and smokeless tobacco in vending machines, self-service displays, or other impersonal modes of sales, except in very limited situations
- Prohibits distribution of free samples of cigarettes and restricts distribution of free samples of smokeless tobacco

Marketing (Labeling, Advertising, and Promotion)

- Prohibits tobacco brand name sponsorship of any athletic, musical, or other social or cultural events, or any team or entry in those events
- Prohibits gifts or other items in exchange for buying cigarettes or smokeless tobacco products
- Requires that audio advertisements use only words with no music or sound effects
- Prohibits the sale or distribution of items, such as hats and t-shirts, with cigarette and smokeless tobacco brands or logos

<http://www.fda.gov/TobaccoProducts/ProtectingKidsfromTobacco/RegsRestrictingSale/ucm205020.htm>.

unconstitutionally infringe on the companies' First Amendment rights. On November 7, 2011, a Federal Judge issued a preliminary injunction staying the FDA from implementing and enforcing its rule. On August 24, 2012 the US Court of Appeals for the D.C. Circuit voted 2–1 against the US FDA graphic warning labels. The case is currently working its way through the courts. The legislation also allows the FDA to set standards for tobacco products appropriate for public health such as reducing nicotine levels (but not to zero), and reducing or eliminating harmful tobacco constituents and components including smoke constituents. Any product standards set by FDA would likely influence youth tobacco use given FDA's mandate to consider the risk and benefits to the population as a whole, including users and nonusers of tobacco products when setting a product standard. A Tobacco Products Scientific Advisory Committee has been established to provide advice, information, and recommendations to the Commissioner of Food and Drugs on health and issues relating to tobacco products.

Youth Policy: International Perspective

The World Health Organization (WHO) reports that important contributing factors increasing the risk of youth smoking include tobacco industry advertising and promotion, easy access to tobacco products, and

low prices. A variety of global policy efforts have been undertaken with the goal of influencing these factors. The most significant of these was the WHO's Framework Convention on Tobacco Control (FCTC), which introduced a legal instrument to enable global cooperation around a variety of tobacco control concerns.

Adopted by the World Health Assembly on May 21, 2003 and entered into force on February 27, 2005, the WHO FCTC is the first international public health treaty promulgated by the WHO. This convention is one of the most widely embraced, with 174 parties having ratified the treaty as of June 2011. The main provisions of the FCTC aim to reduce population-level tobacco consumption and protect youth from the tobacco epidemic. Demand reduction provisions include price and tax measures and nonprice measures to reduce demand for tobacco including protection from secondhand smoke exposure; regulation of the contents of tobacco products; regulation of product disclosures, packaging, and labeling; education, communication, training, and public awareness; restrictions on tobacco advertising, promotion, and sponsorship; and tobacco cessation measures. Core supply reduction provisions include addressing the illicit trade of tobacco products, reducing sales to and by minors, and providing support for economically viable alternative activities.

RESTRICTIONS ON SALES AND DISTRIBUTION

Easy access to tobacco products is an important environmental risk factor for tobacco use among youth. Reducing youth access to tobacco products has been advocated as one strategy to address the problem of youth tobacco use. There are a variety of approaches that can be used to reduce youth access, including regulation of tobacco retailing and sales, as well as civil penalties for youth consumers who purchase or possess tobacco products (PUP laws).

Sales to Minors Laws

It is now unlawful for tobacco retailers to sell tobacco products to minors in all 50 US states. In 1992, the Synar amendment was enacted by the US Congress requiring all states to adopt laws prohibiting the sale of tobacco to any individual under the age of 18. In 2009, the Tobacco Control Act strengthened this standard by setting forth a sweeping set of federal provisions designed to limit young people's access to tobacco products. The Tobacco Control Act prohibits tobacco sales to those under 18, requires photo identification checks for over-the-counter sales to anyone appearing under

27 years of age, and imposes substantial penalties for vendors who violate these provisions. Importantly, this new federal standard does not preempt states or localities from enacting laws relating to access to tobacco products that are more stringent than the access provisions set forth in the Tobacco Control Act. As of March 1, 2010, four states (Alabama, Alaska, New Jersey, and Utah) had established 19 years of age as the minimum legal age for purchasing tobacco products.

Limiting the supply of tobacco to minors can influence youth smoking behavior by deterring smoking uptake, reducing smoking consumption, curtailing the social exchange of cigarettes among youth, and strengthening antismoking social norms. However, controlled intervention studies have suggested that a very high level of retailer compliance, coupled with community involvement, may be necessary before youth access laws can effectively decrease youth smoking rates. This is because despite existing laws, some tobacco retailers persist in selling tobacco products to youth and a large proportion of adolescents are still able to obtain tobacco from commercial and social sources.

Theoretically, illegal tobacco sales can be reduced through active enforcement of tobacco-sales laws whereby merchants' compliance with the law is tested and consequences for noncompliance are administered. Until recently, the primary Federal enforcement oversight mechanism was the Synar Amendment, which requires states to meet annual targets for reducing youth access to tobacco. States measure their compliance by conducting annual, random, unannounced inspections of tobacco retail outlets. The current federal standard requires states to document that no more than 20% of their tobacco retailers are selling tobacco products to minors, or face the loss of millions of dollars of federal aid. All states successfully met this target in 2010. However, the Synar compliance checks have been criticized for underestimating the actual rate of underage tobacco sales and for allowing too high a proportion of noncompliant retailers. Under the Tobacco Control Act, a separate and complementary mechanism for enforcement oversight was introduced that allows FDA to contract with states to conduct compliance check inspections of retailers and take enforcement action when appropriate.

Active enforcement of tobacco sales laws has been shown to change retailer behavior, but whether this extends to reducing young people's access to tobacco or their tobacco-use behaviors is less clear. A number of studies have failed to demonstrate an influence of active enforcement of sales to minor laws on youth smoking behavior. However, experts have argued that rather than this being evidence that such laws are ineffective, these studies are simply evidence that the current compliance standards are not stringent enough to meaningfully curtail the supply of tobacco to youth

and thereby produce the expected reductions in consumption. It remains to be seen whether the new FDA enforcement provisions, along with State and Jurisdictional Synar efforts, will succeed in further reducing underage tobacco sales to youth and youth prevalence.

Sales to minors' laws represent an important tool for combating youth smoking. Unfortunately, the ability of these laws to influence youth demand for tobacco is largely dependent on consistent and stringent enforcement, which has historically been lacking. There is some evidence indicating a stronger effect of these laws on younger adolescents versus older teens. Aggressive approaches to measure retailer compliance with youth access laws and consistent enforcement of penalties are needed if such laws are to influence youths' ability to purchase and use tobacco.

Purchase, Use, and Possession Laws

Enactment and enforcement of laws prohibiting the possession, use, and/or purchase (PUP) of tobacco by minors represents another approach to restrict youth tobacco access. Currently, 45 states have laws that penalize youth for PUP of tobacco. Penalties for youth found in violation of PUP laws include civil fines, loss of driver's license, and/or diversion to tobacco prevention/educational programs, depending on the state. However, controversy exists regarding the appropriateness of continuing to direct tobacco control resources toward enforcing these laws. Although many community members and law enforcement officials endorse the use of PUP laws as a method for decreasing smoking in public places by youth, some anti-tobacco advocates are opposed to this public health policy tool arguing that the laws are conceptually flawed, difficult to enforce, and punish youth rather than the retailers who violate the law and tobacco companies who market these products to youth.

Compared to other youth policy approaches, relatively little is known about the effect of PUP laws on youth smoking behavior. Several studies from school-based samples have suggested that PUP laws may have a deterrence effect and reduce the prevalence of youth smoking, when enforced strictly with a meaningful penalty. But in the United States, PUP laws are rarely enforced. Community-level interventions have successfully increased enforcement of PUP laws within their target communities, suggesting that communities can improve their implementation of PUP laws when provided with targeted assistance.

PUP laws, when enforced strictly, may have the secondary effect of decreasing the visibility of youth smoking in public. This reduced visibility may decrease the effects of smoking behavior modeled by peers and minimize the perception of teenage smoking as normal

and acceptable behavior within the community. To the extent that PUP laws are successful in reducing smoking in public places by youth, they can be a tool for reinforcing community norms against smoking.

Internet Sales

Cigarette sales on the Internet first appeared in the late 1990s and this market continues to grow. The Internet poses serious challenges for tobacco control, including unrestricted sales of low-cost cigarettes to minors. In response to the growing problem of Internet cigarette sales, Congress passed the Prevent All Cigarette Trafficking (PACT) Act. Effective June 29, 2010, the PACT Act requires Internet and other mail-order sellers to check the age and ID of customers both at the point-of-sale and at delivery to stop Internet tobacco product sales to underage buyers. In addition, it bans shipment of cigarettes and smokeless tobacco products via the US postal service. Enforcement tools attached to the law enable federal and state officials to intercept deliveries of illegally sold tobacco products before they reach youth consumers.

Retailer Licensing

The availability of tobacco retail outlets near homes and schools may influence youth tobacco use by making cigarettes easier for youth to obtain. Tobacco retailer licensing laws are a tool that can be used by state and local officials to restrict and control the location and density of tobacco retailers. In ecological studies, the density of tobacco retail outlets near schools has been associated with increased experimental smoking and current smoking by youth. The Institute of Medicine has called for states to place limits on the number of tobacco retail outlets for the express purpose of reducing youth access to tobacco. Despite its potential, few communities have utilized this policy tool and little evidence on the effects of these laws exists. However, tobacco control advocates are encouraged by evidence for similar state and local policies limiting alcohol outlet density, which have been shown to reduce underage alcohol use.

International Perspective

There is substantial international variation in the extent to which youth access policies protect young people from tobacco. Age restrictions on the purchase of tobacco products vary around the world, with most high-income countries having a minimum age policy of 18 or 19 years old. Youth access policies are less common in low- and middle-income countries, such that few legal barriers exist to prevent minors from

purchasing tobacco products. Where youth access policies do exist, there is even greater variation in their enforcement. Even among high-income countries, only a handful of nations enforce youth access laws to the extent necessary to ensure their success. In low-income countries, the necessary infrastructure and resources for implementing and enforcing these restrictions is often lacking entirely.

Summary

When enforced consistently, public policies that aim to restrict young people's access to tobacco may effectively reduce youth demand for cigarettes. However, as currently implemented, these policy tools have generally not succeeded in meaningfully reducing youth access to tobacco, in the United States or internationally. A large proportion of adolescents are still able to obtain tobacco from commercial and social sources. Aggressive enforcement of youth tobacco access laws would likely strengthen the ability of these policies to influence youth's willingness and ability to use tobacco.

SMOKEFREE LAWS

Tobacco control policies that restrict smoking in workplaces and enclosed public places (e.g. restaurants and bars) are primarily intended to protect nonsmokers from exposure to secondhand smoke. However, they also represent an important policy tool for reducing smoking prevalence among youth.

Public Bans

Policy efforts to restrict smoking in public places occur at the state and local level. All 50 states and the District of Columbia restrict or prohibit smoking in certain places, but there is wide variation in the extent of coverage and the stringency of these restrictions leading to variation in youth exposure to smoking restrictions. The most stringent type of restriction is a comprehensive law requiring all public places (i.e. all non-hospitality workplaces, restaurants, and bars) to be 100% smokefree. As of 2011, comprehensive smokefree laws protect approximately 48% of the US population. Many other states and municipalities have enacted partial smokefree laws that limit smoking in at least one of these settings.

In addition to reducing nonsmoker's exposure to secondhand smoke, smokefree laws have also been shown to reduce the prevalence of cigarette smoking among adults. Less is known about the impact of smokefree laws on youth smoking behavior. However, a

growing body of evidence suggests that smoking bans in public places significantly decrease overall youth smoking prevalence. Smokefree laws seem to have their greatest influence on youth cigarette consumption. States and communities with comprehensive smokefree laws consistently have a lower proportion of youth who report daily smoking. Studies have estimated that comprehensive smokefree laws may reduce per capita cigarette consumption among youth by as much as half.

Smokefree laws not only influence consumption but also appear to reduce progression from experimental use to established smoking. There is less evidence to suggest that smokefree laws are effective in deterring smoking initiation, however some studies have found evidence that they are. Teens employed in workplaces with a comprehensive smokefree policy were 32% less likely to ever smoke, compared to teens in workplaces with less restrictive policies. Furthermore, ecological studies have shown that states with more stringent smokefree laws have a lower proportion of ever-smoking youth. The precise mechanisms by which smokefree laws reduce youth smoking are largely unknown, although there are likely a number of contributing factors; smokefree laws reduce opportunities to smoke, raise awareness of the hazards of exposure to tobacco smoke, and contribute to a cultural norm in which smoking is socially unacceptable.

Home Bans

Voluntary bans on smoking at home, even when parents smoke, significantly reduce youth smoking behavior. Home smoking bans are becoming increasingly common in the United States. In 2003, the latest year for which nationally representative data were available, approximately 74% of US households had a complete home smoking ban (i.e. no smoking allowed anywhere inside the home). A growing proportion of youth are also being protected by smokefree policies in multiunit housing complexes. Home smoking bans are more common in households with higher income and education levels. Moreover, emerging evidence suggests that voluntary bans are more likely to be adopted in localities with comprehensive public smokefree laws. Regarding reducing youth smoking, household smoking bans appear to be at least as influential as smokefree laws. Young people living in households with strong rules against smoking in the home are less likely to report smoking themselves, even when one or both parents are smokers. They are also significantly less likely to progress from experimental smoking to established smoking. It is believed that household smoking bans work to reduce youth initiation and smoking uptake by modeling positive behavior and creating a strong norm about the unacceptability of smoking.

Other Smoking Bans

Policies that ban smoking in and around schools are another common type of smokefree policy. The Pro-Children's Act of 1994 requires all schools and daycare facilities receiving federal funding to prohibit indoor smoking. However, school smoking bans are often poorly complied with. Comprehensive smokefree school policies have been found to significantly lower rates of student smoking, but only if the bans are strongly enforced. Increasingly, private vehicles are becoming a focus for smokefree policies. Several states and territories have taken steps to prohibit smoking in privately owned vehicles while children are present. These efforts have brought significant attention to the risks of secondhand smoke exposure in vehicles. However, the impact of such policies on youth smoking rates has not yet been evaluated.

International Perspective

The vast majority of countries restrict smoking in public places to some degree, but there is considerable variation in the comprehensiveness of these smokefree laws worldwide. The United States lags behind many other high-income countries in terms of national smokefree protections. Worldwide, a growing number of countries have passed national comprehensive smoking bans (e.g. Ireland, Italy, Finland, Norway, New Zealand, Hong Kong), and more are poised to do so. In high-income countries smokefree laws tend to be largely self-enforcing, but typically have fairly comprehensive restrictions covering work-sites and sometimes restaurants and bars. In this regard, they successfully reduce nonsmokers exposure to secondhand smoke, reduce the visibility of smoking in public places, and contribute to establishing smokefree norms. In contrast, low- and middle-income countries are still in the early stages of developing such policies. Low- and middle-income countries are less likely to have smokefree laws; if they do, they are often largely ignored. As a result, smokefree laws are currently less able to influence smoking behavior among youth living in low- and middle-income countries.

Summary

Taken together, the evidence suggests that implementing stringent smoking prohibitions, both in public places and at home, is an essential component of a comprehensive tobacco control strategy to reduce youth tobacco use. School nonsmoking policies can significantly lower rates of student smoking, but only if they are strongly enforced.

ECONOMIC APPROACHES

Keeping the price of tobacco products high is viewed as a key component of comprehensive tobacco control strategies. Cost is a major public policy tool that influences both adult and youth smoking behavior. The influence of price on population-level tobacco use is often described in terms of "price elasticity," which refers to the overall change in aggregate cigarette consumption that is expected to occur in response to a price increase. Changes in aggregate cigarette consumption following a price increase are produced by a combination of factors. These include individuals who do not start smoking (who might have otherwise), smokers who quit, and smokers who cut back on their smoking. Thus, price can influence both smoking prevalence (the number of people who smoke) and consumption (the amount that is smoked).

A strong dose-response relationship exists between cigarette price and cigarette consumption, for both youth and adults. It has been estimated that a 10% increase in the price of cigarettes would result in a 4% reduction in overall cigarette consumption in the short-term, and 8% in the long-term, due to compounding effects over time. Among adolescents, this relationship is even more pronounced. A 10% increase in price is estimated to reduce the number of youth who smoke by 7%. Youth may be influenced by cigarette price both directly (reductions in purchasing) and indirectly (changing smoking norms). Economists contend that adolescents are particularly "price sensitive" (i.e. their purchasing behavior is strongly influenced by cost). One reason for greater price sensitivity is that adolescent smokers have a smaller proportion of disposable income compared to adult smokers, making cost increase more difficult to absorb. In addition, many adolescents who smoke are still experimenting with smoking and have not yet become addicted. Thus, they may be less motivated to continue purchasing cigarettes in the face of rising prices. Evidence has shown that more addicted smokers are less responsive to price than their less addicted counterparts.

The smoking uptake continuum may be interrupted through price policies. Cigarette price influences smoking initiation and escalation of smoking behavior among adolescents. Among youth, it is estimated that a 10% increase in the price of cigarette would reduce the probability of smoking initiation by about 3%, of daily smoking by nearly 9%, and of heavy daily smoking by over 10%. Youth who experiment with smoking, or smoke infrequently and at low levels, may get their cigarettes from social sources, including friends, rather than purchasing cigarettes themselves. Thus, experimenters may not be as responsive to higher cigarette prices

compared to youth who have moved to more regular smoking behavior. In contrast, price can be expected to have a larger influence as cigarette consumption increases and is associated with reduced probability that youth will become daily, addicted smokers. This is an important and a key strategy for tobacco control because preventing youth from becoming heavy smokers will reduce the public health burden of tobacco. In addition to preventing escalation, price has also been associated with cessation behaviors. Evidence suggests that a 10% increase in the price of cigarettes would increase the probability of smoking cessation by about 12% for young males and 19% for young females.

Sociodemographic differences have been noted regarding the influence of price on youth and young adults. For instance, differences have been found by ethnicity, socioeconomic status, and education level. It is important to consider that the price of tobacco products may affect subpopulations differently.

Increasing Cigarette Prices

Excise Taxes

There are many ways in which public policy can influence the price of tobacco. Excise taxes are the most common route of increasing price within the United States and are considered to be the most effective government intervention for increasing the price of cigarettes. Excise taxes are additional prices put on the sales of goods or services. These prices are typically based on the quantity of the good that is sold. Tobacco excise taxes are set at both the federal and state level. The Federal Excise Tax on cigarettes was established in 1864. Effective from April 1, 2009, the federal cigarette excise tax increased to \$1.01 per pack from 39 cents per pack. States and many localities also impose excise taxes on tobacco; in 2011 the average combined state-local excise tax rate was \$1.46 per pack; New York City's, at \$5.85 per pack, was the highest.

Minimum Price Laws

Originally designed to ensure fair competition among tobacco retailers, states initiated cigarette minimum price laws in the 1940s. These laws require a minimum percentage markup added to the wholesale/retail price of tobacco products. Minimum price laws can counteract the discounting practices of tobacco companies, and thus represent a potentially important policy tool for keeping tobacco prices high. Unfortunately, minimum price laws are underutilized; they do not exist in every state, and many states have very weak laws. In 2009, the Centers for Disease Control and Prevention (CDC) reported that 25 states had statutory minimum wholesale price markups for cigarettes ranging from

2.0 to 6.5%; however, these markups are likely too low to meaningfully raise prices. Policy efforts to strengthen minimum price laws may help reduce youth smoking prevalence.

Tobacco Industry Efforts to Lower Price

The tobacco industry has recognized the influence that price can have on discouraging teenage smoking and has manipulated price in order to counteract the effects of tax hikes and other economic regulations. Tobacco companies use retail loyalty programs and aggressive promotional pricing strategies such as coupons, multipack specials, and other special discounts to lower the price for consumers. Industry has targeted younger smokers with these price-related promotions, because they are known to be more price-sensitive than adults. When tobacco companies lower tobacco product prices, more people, especially young and new users, tend to purchase cigarettes. Industry efforts to reduce the price of tobacco are often more heavily concentrated in low-income and minority areas, evidence that tobacco companies are selectively targeting the most vulnerable populations.

Much of the literature to date has focused specifically on cigarette excise taxes. However, other products, such as smokeless tobacco and little cigars, can be expected to show price elasticity similar to cigarettes. Use of other tobacco products may also be influenced by any price differential with cigarettes. In recent years, with the release of novel smokeless tobacco products, experts have noted these products are less expensive and frequency of their use among youth is rising. For example, it has been estimated that smokeless tobacco use among males between 16 and 24 years of age would rise by approximately 12% if a state excise tax rate on cigarettes rose by 10%, due in part to the differential excise tax rates. Recent epidemiological trends also show a rise in the use of little cigars (e.g. Black and Mild) among youth, especially black females. Price differential between products plays an important role in tobacco use.

International Perspective

Among industrialized countries, the United States has one of the lowest tax rates on cigarettes. The World Bank recommends setting tobacco taxes between two-thirds to four-fifths of the retail price of cigarettes. Countries receiving the highest percentage of tobacco tax include China, Greece, Nepal, Brazil, and Argentina. The influence of price increases on reducing consumption is stronger in low- and middle-income countries, where an increase in tobacco taxes by 10% is estimated to decrease tobacco consumption by about 8%. Few low-

and middle-income countries achieve this level of taxation, but can significantly increase their tax levels. Youth, minorities, and low-income smokers are two to three times more likely to quit or cut back on their smoking than other smokers in response to price increases.

Summary

A large body of evidence documents that higher prices are effective in reducing youth smoking rates. However, the tobacco industry engages in systematic efforts to drive prices down. As a result, policy tools that keep the price of tobacco high are a critical component of youth tobacco control efforts. There is little evidence on how the price of other types of tobacco products influences their use by youth, however, these products tend to cost less than cigarettes and therefore may have particular appeal for youth.

MARKETING AND PROMOTION

The tobacco industry systematically and aggressively targets youth through advertising and promotion. In a landmark court case, the US Department of Justice successfully prosecuted several major tobacco companies for engaging in a conspiracy to defraud the public about the dangers of smoking, including the practice of purposely targeting youth in their marketing campaigns. The final decision, issued by US District Judge Gladys Kessler in 2006, held that the United States' major tobacco companies had engaged in fraud and violated the Racketeer Influenced and Corrupt Organizations Act statute by falsely denying that they advertised, marketed, and promoted cigarettes to youth. The Federal Trade Commission reports that in 2008 the largest cigarette companies in the United States spent \$9.94 billion on advertising and promotion. The majority of this money (approximately 72%) was spent on price discounts to retailers or wholesalers to reduce the price of cigarettes. Advertising and promotion has been shown to causally influence the decisions of young people to begin and continue smoking. The 2008 National Cancer Institute monograph, "The Role of the Media in Promoting and Reducing Tobacco Use," concluded "the evidence base indicates a causal relationship between tobacco advertising and increased levels of tobacco initiation and continued consumption." Not surprisingly, youth smokers prefer the most heavily advertised brands – Marlboro, Camel, and Newport.

Youth are exposed to pro-cigarette messages through both direct and indirect advertising. Direct advertisements, those that are explicitly meant to market a specific product to consumers, include print (e.g. magazine), point-of-sale (POS) displays, mail, coupons and

promotions, distribution of specialty items (e.g. hats with logos), and sponsorship of sporting events and public entertainment (e.g. placement of brand logos in bars and nightclubs). Indirect advertising refers to marketing a product that is not explicit. An example of indirect advertising includes depictions of smoking in the movies. The Internet is a unique medium for tobacco advertising, as it includes both direct advertisements (e.g. paid advertisements, tobacco industry webpages) and indirect advertisements (e.g. promotion through YouTube videos and social media).

A comprehensive ban on direct and indirect forms of tobacco advertising, promotion, and sponsorship can be expected to have the largest impact on smoking rates. Partial bans (e.g. limiting only some advertising, promotion, or sponsorship options) or voluntary agreements have little or no effect on tobacco consumption. It is estimated that comprehensive bans, those banning tobacco advertising in five or more mediums (television, radio, print, outdoor, point-of-sale, movies, and sponsorship), would result in an overall 7.4% reduction in cigarette use and a 5.4% reduction in tobacco use.

Point-of-Sale Advertising

Point-of-sale (POS) advertising refers to advertising at the place where a product is sold and tobacco companies spend a significant amount of money every year to market products in convenience stores, grocery stores, and pharmacies. The retail environment provides important opportunities for the tobacco industry to communicate with current, former, and potential smokers providing cues to promote smoking consumption, discourage quitting, and encourage smoking uptake. Retail POS advertising is the dominant channel for tobacco advertising in the United States in 2011. Spending on POS promotional materials accounted for \$163.7 million of the tobacco industry's \$9.94 billion marketing budget in 2008. Weekly or more exposure to retail tobacco marketing is associated with a 50% increase in the odds that adolescents will smoke. Tobacco companies provide more advertising and shelf space for cigarettes in stores where adolescents shop frequently. National marketing data have shown that 75% of adolescents shop in a convenience store at least once a week and 63.7% of adolescents report seeing cigarettes advertisements all or most of the time when they visit convenience stores, supermarkets, and gas stations. Teens may be more likely than adults to be influenced by advertising and promotion in convenience stores and other retail outlets and exposure to POS advertising is associated with initiation of cigarette smoking. There is a patchwork of state laws with regards to the display of tobacco products, however, the tobacco industry has been known to place advertisements and displays at children's eye-level

and within children's reach. There are numerous provisions in the Tobacco Control Act that aim to regulate the POS environment and the act is expected to dramatically change how tobacco products are sold and marketed in stores. "Power Wall" displays (prominent display of a particular brand), interior and exterior advertising, and other POS advertisements build brand recognition and loyalty, attract youths' attention, and undermine smokers' motivations to quit.

Depictions of Smoking in the Movies

The 2008 NCI monograph, "The role of the media in promoting and reducing tobacco use," concluded that exposure to depictions of smoking in the movies is causally related to youth smoking initiation. Product placement in movies and television is an indirect advertising form that glamorizes smoking, making it more appealing to youth. Under the MSA, tobacco companies are prohibited from paying for brand placement in movies, however, there is no mechanism to ensure that payoffs are not occurring. Three of the Motion Picture Association of America's six member studios currently have voluntary policies, adopted between 2004 and 2009 that limit or restrict depictions of smoking in movies. For these studios, depictions of tobacco in youth-related films declined 95.8% between 2005 and 2010. For the three member studios with no policies, the decline was only 41.7%, over the same period.

Several studies have shown a dose-response relationship between exposure to smoking in movies and smoking uptake among youth. Currently, efforts are underway to encourage the movie industry to assign an R-rating (for more mature audiences) to movies that depict smoking. The movie industry is also being encouraged to show antismoking messages (Public Service Announcements) before films that include smoking. Limiting smoking to R-rated movies would substantially limit youth exposure to smoking in movies, since youth-rated movies are seen by three times as many teens as R-rated movies. Reducing or eliminating depictions of smoking in the movies is an important avenue for tobacco control policy, especially because many movies have global reach.

Counteradvertising and Anti-tobacco Media Campaigns

Counteradvertising and anti-tobacco media campaigns can help to educate the public and change social norms. However, the financial resources available to the public health community are dwarfed by those available to the tobacco industry. The MSA created a nonprofit organization, the American Legacy Foundation, which has developed some of the most effective youth-focused

anti-tobacco media campaigns to date. Antismoking messages that have large impact on reducing cigarette consumption and denormalizing smoking among youth are those that are aggressive, focus on industry manipulation to recruit young smokers, and focus on the adverse health effects of secondhand smoke exposure. Campaigns that show individuals are not acting autonomously or of their own free will also appear to be very effective in deterring smoking. Pursuant to its new regulatory authority over tobacco, the FDA-CTP will be involved in public education efforts to provide youth and adults with accurate information about tobacco ingredients and the consequences of tobacco use.

Cigarette Warning Labels

The Federal Cigarette Labeling and Advertising Act, enacted in 1965 and amended in 1969, required cigarette packages and print advertisements to contain a textual health warning. In 1984 this act was amended to require that one of four warning labels appear on cigarette packages and advertising. The warning labels have remained unchanged since that time and there is no evidence to suggest that these warning labels had a meaningful impact on youth tobacco use. As required by the Tobacco Control Act, FDA has now mandated nine graphic health warnings to cover 50% of the front and back of cigarette packages and 20% of advertisements. This policy tool is currently the target of litigation by the tobacco industry.

A large body of scientific evidence indicates that graphic warning labels increase public knowledge about the health risks of using tobacco and help to reduce their consumption. Nonsmokers, particularly adolescents, are likely to be influenced by the new graphic warning labels. Evidence from population-based surveys and empirical studies indicates that large graphic warnings on cigarette packages increase adolescents' attention to and cognitive processing of the warning, increase thoughts of quitting and forgoing of cigarettes, and lower intentions to smoke. Additionally, graphic warning labels have been shown to reduce the social appeal of smoking among adolescents.

Other Tobacco Industry Activities

The tobacco industry engages in other activities to promote youth tobacco use and provide an impression of responsibility by building positive public perceptions. These include corporate sponsorship (e.g. sporting and entertainment events), social responsibility efforts (e.g. donations), and public relations advertising (e.g. youth antismoking campaigns) in order to be perceived as ethical and good corporate citizens. Tobacco companies have engaged and sponsored youth antismoking campaigns. The campaigns have been used to conduct

extensive market research on adolescents' attitudes toward smoking. Tobacco companies' youth-targeted smoking prevention advertising campaigns (e.g. "Think. Don't Smoke") have been shown to lower youth's perceived harm of smoking, increase smoking approval, increase intentions to smoke in the future, and increase the likelihood of having smoked in the last 30 days. Other industry sponsored campaigns have focused on such topics as how much money is spent on smoking and placing responsibility on parents, youth, and retailers: these may undermine or compete with more effective campaigns sponsored by government agencies or nongovernment organizations.

International Perspective

In light of the overwhelming evidence that advertising influences youth smoking behavior, the FTC requires parties to implement and enforce a comprehensive ban on all tobacco advertising, promotion, sponsorship, and corporate social responsibility efforts (or to apply restrictions where a ban is not possible). Currently, 18 countries have total bans on tobacco advertising. In other countries (e.g. Canada and New Zealand) advertising bans are part of comprehensive tobacco control efforts, including tax increases and pictorial warning labels. Large declines in tobacco use after implementation were noted in both these countries; however, it is unclear whether smoking declines were mostly attributable to the advertising ban or the comprehensive strategies.

Summary

The tobacco industry engages in aggressive direct and indirect marketing, advertising, and promotion of their products and has challenged FDA's efforts to regulate in these areas. Future efforts must be made to understand how the tobacco industry responds as FDA works to implement the provisions of the Tobacco Control Act that influence tobacco marketing and promotion.

CONCLUSIONS

Effective tobacco control policies are essential in reducing the burden of tobacco use on public health and have important ramifications for adolescent tobacco use. Tobacco control policies do not work in isolation, but rather may influence each other or work synergistically to influence tobacco use. These policies, in different strengths and combinations, have been implemented both in the United States and abroad, resulting in significant reductions in youth smoking rates. Policies may also target different stages along the smoking continuum, from experimentation to cessation, among

youth. Some policy tools, such as large graphic warning labels, advertising bans, and youth access laws, appear to exert their strongest influence on youth smoking initiation. Other tools, such as smokefree laws and tobacco excise taxes, appear to be most effective at reducing consumption and interrupting adolescents' progression along the smoking trajectory. Though initiation is the classic target for youth smoking prevention efforts, disrupting the transition from experimentation to regular (or daily) smoking is equally important.

In the ongoing public health effort to protect youth from tobacco, the passage of the Tobacco Control Act represents a key milestone, and the culmination of decades of policy progress. This historic legislation ushered in a new era of tobacco control in the United States, one that promises to have particular significance for youth. Under the new authority granted by the Tobacco Control Act, the FDA-CTP has a number of new tools at its disposal with the potential to dramatically change the policy environment in which youth initiate and continue to use tobacco products (e.g. flavoring bans, youth access laws, sales and marketing restrictions, graphic warning labels, etc.). Going forward, it will be important to understand how these new policy tools influence patterns of youth tobacco use over time. It will also be important to monitor how the tobacco industry responds to FDA-CTP tobacco regulation.

International efforts for the implementation of effective tobacco control policies are diverse and face distinct obstacles. The WHO FCTC is a landmark policy instrument that contains many provisions aimed at protecting youth from tobacco; however, implementation and enforcement of these provisions currently varies widely across participating parties. It is essential that tobacco policies including youth access laws, smokefree laws, price increases, and restricted advertising are quantified in order to assess the effectiveness of such policies across various populations.

Tobacco control policies targeting youth are important, but tobacco control interventions that reduce consumption and encourage cessation among adults are also imperative. These policies have the effect of reducing youth exposure to tobacco and to tobacco role models. One of the best means of discouraging adolescents from smoking is to reduce tobacco consumption at the population level. Numerous strategies are needed in order to end the global pediatric epidemic of tobacco use. The broad influence, relatively low cost, and notable effectiveness of well-implemented comprehensive tobacco control policies makes these one of the most important components of tobacco control efforts. Such policies, when implemented and enforced, are an effective means of deterring youth smoking and serve to protect future generations from the dangers of tobacco-related disease and death.

Glossary

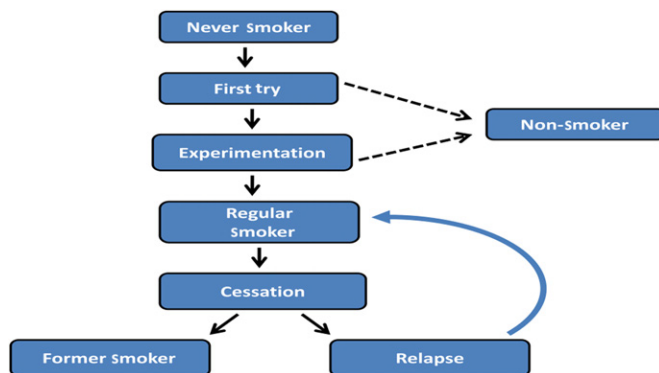

Cigarette smoking the act of drawing in or inhaling smoke of burning tobacco in a cigarette and exhaling it.

Consumption the overall amount of cigarettes consumed among smokers.

Low- and middle-income countries the World Bank's main criterion for classifying economies is gross national income (GNI) per capita. These categories are based on the Bank's operational lending categories. Also referred to as economically developing countries.

Youth smoking rates refers to both the prevalence and the incidence of youth cigarette use. *Prevalence Rate* refers to the total number of existing smokers (e.g. current smoking) in a given population at a particular point of time. *Incidence Rate* refers to the number of new cases of smoking (e.g. initiation) over a given period of time.

Smoking continuum smoking behavior ranges and moves between seven stages. These include never smoker, trying cigarettes or initiation (has had even a puff of a cigarette), experimentation (has had more than a puff of a cigarette, but fewer than 100 cigarettes in lifetime), non-smoker (has tried or experimented, but does not progress to regular smoking), regular smoker (reports smoking at least 100 cigarettes in lifetime and has smoked in the last 30 days), relapse (quits smoking, but reverts back to regular smoking), and former smokers (those who report quitting smoking). The diagram below depicts the smoking continuum.

Tobacco Products Any products containing, made, or derived from tobacco that is intended for human consumption, whether chewed, smoked, absorbed, dissolved, inhaled, snorted, sniffed, or ingested by any other means, or any component, part, or accessory of a tobacco product, including, but not limited to, cigarettes; cigars; little cigars; cheroots; stogies; periques; granulated, plug cut, crimp cut, ready rubbed, and other smoking tobacco; snuff; snuff flour; cavendish; plug and twist tobacco; fine-cut and other chewing tobacco; shorts; refuse scraps, clippings, cuttings and sweepings of tobacco, and other kinds and forms of tobacco. Tobacco products excludes any tobacco product that has been approved by the U.S. Food and Drug Administration for sale as a tobacco cessation product, as a tobacco dependence product, or for other medical purposes, and is being marketed and sold solely for such an approved purpose. (adopted from the Tobacco Modernization and Compliance! Act of 2010, Minn Stat Section 297F.01, subdivision 19).

Youth typically a person between the ages of about 12 and 19. Also known as teen or adolescent.

MINIMUM LEGAL DRINKING AGE

When consumed in moderation, alcohol has been shown to have modest health benefits for some people aged 40 years or older. However, alcohol is an addictive intoxicant and, when abused, can cause numerous public health problems, not only for the drinker but also for the people around the drinker and in society at large. The harmful use of alcohol is the third leading risk factor for premature deaths and disabilities around the world and responsible for an estimated 3.8% of worldwide deaths. Approximately 2 500 000 people die

annually of alcohol-related causes around the world, including 320 000 young people aged 15–29 years. Alcohol abuse is associated with unintentional and intentional injuries, including traffic crashes, assaults, homicides, and suicides, especially with young people. Harmful alcohol use is also associated with several infectious diseases, including HIV/AIDS, tuberculosis, and pneumonia. The degree of risk for the harmful effects of alcohol varies with age, gender, and some biological factors, as well as the setting and the context in which the drinking occurs. Some vulnerable at-risk groups, such as young people, are especially susceptible

to the toxic, psychoactive, and addictive properties of ethanol (alcohol) (*see* Impulsivity, Disinhibition, and Risk Taking in Addiction, Adolescent Substance Use: Symptoms and Course, Addiction and the Human Adolescent Brain, Epidemiology of Adolescent and Young Adult Alcohol, Tobacco, and Drug Use and Misuse in the United States). For these reasons, most countries around the world attempt to control the production, marketing, distribution, and sales of alcohol, at least to some extent.

The harmful use of alcohol is influenced by the general level of alcohol consumption in the population, various drinking patterns, local contexts, and alcohol policies and laws. Populations particularly at risk from harmful alcohol use include children; adolescents; pregnant, breastfeeding, and child-bearing women; and indigenous or other minority low-socioeconomic groups (*see* Behavioral Economic Factors in Addictive Processes, Prenatal Exposure to Alcohol and Illicit Substances, Minority Groups and Addictions). Most countries around the world have established laws concerning the earliest age at which individuals can legally purchase, possess, and/or consume alcoholic beverages. The main reason for MLDA is to protect young people from the harms caused by alcohol and to protect the public from the potential consequences of youthful drinking.

DRINKING AGES AROUND THE WORLD

There are a variety of sources for MLDAs around the world. The International Center for Alcohol Policies (ICAP), a not-for-profit organization supported by major producers of beverage alcohol, appears to have the most comprehensive and most up-to-date list (<http://www.icap.org/Table/MinimumAgeLimitsWorldwide>). ICAP has collected information on the MLDA in 119 countries. Seventy-nine countries have established an MLDA of 18 years old. Eleven countries have an MLDA of 16 years old; one country, 17 years old (Cyprus); two countries, 19 years old; and three countries, 20 years old. Only eight countries on the ICAP list use 21 years old as the MLDA, including the United States. Twelve countries have no MLDA, and alcohol is illegal in two countries. In India, the MLDA ranges from 18 to 25, depending upon the state.

In some countries, the MLDA is different depending upon the beverage type (beer, wine, or spirits). In other countries, the minimum purchasing age is different than the drinking (consumption) age, and in still others, the MLDA is different for on-premise sales (e.g. bars, pubs, and restaurants) compared to off-premise sales (e.g. liquor stores, supermarkets, petrol stations).

The general public assumes that MLDA laws are embodied in a single law, but in actuality, most MLDA

laws have multiple provisions. Some MLDA law provisions target outlets that sell alcohol to underage individuals and persons who provide alcohol to the underage individuals. Other provisions target underage persons who purchase or attempt to purchase, possess, or consume alcohol.

HARMFUL USE OF ALCOHOL

The World Health Organization (WHO), a specialized agency of the United Nations that acts as a coordinating authority on international public health, issued a report in March 2010 documenting strategies that can reduce the harmful use and effects of alcohol. Among other strategies, the WHO report describes evidence demonstrating the importance of a legal framework for reducing, or at least controlling, the availability of alcohol. The implementation and enforcement of laws that set a minimum age for the purchase or the consumption of alcohol or both show clear reductions in alcohol-related harm to youth according to the WHO report. Other strategies described in that report include reducing the hours of sale of alcohol, controlling the marketing and advertising of alcohol, increasing the price of alcohol via taxation, and enforcing existing alcohol legislation.

The policy options and interventions available for national action have been categorized by the WHO into 10 target areas:

1. Leadership, awareness, and commitment
2. Health services' response
3. Community action
4. Drink-driving policies and countermeasures
5. Availability of alcohol
6. Marketing of alcoholic beverages
7. Pricing (taxation) policies
8. Reducing the negative consequences of drinking and alcohol intoxication
9. Reducing the public health impact of illicit alcohol and informally produced alcohol
10. Monitoring and surveillance

MLDA laws are an important component of these policies.

HISTORY OF MINIMUM DRINKING AGE LAWS IN THE UNITED STATES

With the exception of one or two countries, MLDA laws have been established for decades and have not changed at all in most countries around the world. The United States is one of those exceptions. Much is known about the history of MLDA laws in the United States and their effectiveness. MLDA laws were

established in the United States after the repeal of Prohibition in 1933. Most states set the MLDA at age 21 during that time. When the voting age was lowered from 21 to 18 in 1971, many states lowered their drinking age to 18 or 19. Several scientists found significant increases in alcohol-related crashes involving youth aged 18–20 in states that lowered their drinking age. As a result, some states returned to an MLDA of 21. Later, other researchers supported the earlier findings that raising the drinking age was associated with decreased traffic crashes and crash fatalities (*see The Impact of Drink Driving Laws, The Effects of Substances on Driving*). Consequently, the US Congress adopted the National Uniform Drinking Age 21 Act, which provided a substantial financial incentive for states to adopt an MLDA of 21, and the US President Reagan signed the bill into law in 1984. Since 1988, the MLDA has applied to age 21 for both the purchase and possession of alcohol in all 50 states and the District of Columbia. Between 1982 and 1998, the population-adjusted rate involving 16- to 20-year-old drinking drivers in fatal crashes in the United States decreased by 59%. MLDA-21 laws have been independently associated with about half of this decline. According to the US Department of Transportation, MLDA laws save approximately 800–900 lives a year in traffic fatalities alone. Other researchers found a 13% decline in alcohol use by youth aged 20 and younger associated with the older drinking age of 21.

Despite the federal incentive and the state laws raising the drinking age to 21, underage drinking is still prevalent in the United States. Underage drinking causes an estimated 5000 deaths and 2.6 million injuries and other harm annually. The cost to US society of the harm associated with underage drinking is approximately \$62 billion each year. To strengthen drinking age laws and reduce the injuries and deaths associated with youthful drinking, many US states have also enacted other legislation to address the availability of alcohol to youth, the use of fake identification by youth to purchase alcohol, and the minimum server/seller age to make it more difficult for youth to obtain alcohol from retail sources. States are also adopting social host laws that target the hosts of parties who allow underage drinking and that focus on preventing the illegal provision of alcohol to youth. Other expanded laws in the United States focus on preventing or deterring youth from drinking and driving; for example, the zero-tolerance law makes it an offense for drivers aged 20 and younger to operate a vehicle with any amount of alcohol in their systems (blood alcohol concentration (BAC) > .00). Some provisions of recent graduated driver licensing (GDL) laws in the United States have night restrictions on driving by youth to reduce the risk of drinking and driving, most of which occurs at night. So-called “use and lose”

laws that authorize the suspension of the driver’s license for underage alcohol violations (i.e. purchase, possession, or consumption of alcohol) aim to provide meaningful sanctions for youth who violate the MLDA laws. At least 14 expanded laws strengthen the two core MLDA-21 laws (prohibiting possession and purchase) and increase the alcohol prevention efforts targeting US youth. However, states vary substantially in the comprehensiveness of such legislation. For example, although it is illegal in all states and the District of Columbia for underage youth to *possess* alcohol in public, it is still legal in 20 states for youth to *consume* alcohol in public. Not all states have GDL laws, and some states’ GDL laws do not restrict unsupervised driving at night when alcohol is most likely to be a factor. No state has all 16 law components or regulations that have been documented. Of the 16 underage drinking laws that states could adopt, only Utah has adopted as many as 15 of the components, and Kentucky has only 7 of the 16 components. Laws that provide for a driver’s license sanction (suspension or revocation) if a youth is cited for underage drinking have been shown to be effective, yet only 37 states have such “use and lose” laws. Although it is illegal in all US states and the District of Columbia for an underage youth to use a fake identification, it is illegal in only half the states (25) to transfer or produce fake identifications. Thus, the current US effort to control the drinking of alcohol by youth aged 20 and younger involves a variable package of legislative policies, and the level and intensity of enforcement of these policies at the national, state, and local levels is relatively unknown.

Despite the current variability in underage drinking laws and their enforcement across the US states, the two core laws (purchase and possession) have shown significant effects in reducing underage drinking consequences. These laws potentially can be even more effective if all the US states were to adopt all 16 components and if the exceptions to the laws were limited.

EVIDENCE IN SUPPORT OF THE EFFECTIVENESS OF MLDA-21 IN THE UNITED STATES

When the MLDA-21 restriction was initiated across all US states, driver alcohol involvement in fatal traffic crashes declined more significantly among the 16- to 20-year-old population than among drivers aged 21 and older. Although drinking drivers aged 21 and older involved in fatal crashes declined 33% from 1982 to 2004 (Fig. 95.1), drinking drivers aged 20 and younger involved in fatal crashes declined 62% during that period (Fig. 95.2). Tougher legislation, better enforcement, and greater public awareness of the drink-driving problem contributed to the overall decline in drinking-

FIGURE 95.2 Drivers under age 21 involved in fatal crashes, 1982–2004. Adapted from Johnston, L. D., O’Malley, P. M., Bachman, J. G., and Schulenberg, J. E. (2007). *College students and adults ages 19–45. In Monitoring the Future: National Survey Results on Drug Use, 1975–2005 (Vol. II)*. Bethesda, MD: National Institute on Drug Abuse.

driver fatalities, but the MLDA-21 law had an additional effect on drivers aged 20 and younger.

Since adoption of the National Uniform Drinking Age Act, numerous studies have confirmed the association between raising the MLDA to 21 and reducing underage alcohol consumption, youthful traffic fatalities, and other harms. Six types of fatal injuries – car crashes, suicides, homicides, falls, drowning, and alcohol poisoning – decreased for 15- to 24-year-olds following implementation of the MLDA-21 law.

In the United States, the laws making it illegal for youth to possess or purchase alcohol if they are younger than age 21 have reduced the rate of underage drinking drivers in fatal crashes by 16%. That analysis controlled or accounted for numerous other factors – other drunk-driving laws, alcohol consumption, the economy, the culture of the state,

and vehicle miles driven in the state – that could have affected underage drinking and driving. Even when accounting for all those factors, the core laws raising the minimum drinking age to 21 still resulted in a substantial reduction in youth traffic fatalities. This reduction has remained at a low level for many years, indicating that the MLDA-21 laws have maintained their initial impact.

REDUCTIONS IN HOMICIDES AND SUICIDES ASSOCIATED WITH MLDA-21 LAWS

The effects of minimum drinking age laws on alcohol consumption indicate that, as the legal age is lowered, drinking increases. Conversely, as the legal drinking

*Number of days in which youth under aged 21 drank alcohol in the last 30 days.

FIGURE 95.3 30-Day alcohol use and minimum drinking age. Source: O'Malley and Wagenaar (1991).

age is raised, it reduces the consumption of alcohol (see Fig. 95.3).

MLDA-21 laws are associated with reductions in homicides, suicides, and unintentional injuries by 18- to 20-year-olds. Alcohol use interacts with conditions such as depression and stress that contribute to suicide, the third leading cause of death among people aged 14–25. In one study, 37% of eighth grade females who drank heavily reported attempting suicide compared with 11% who did not drink. Individuals younger than aged 21 commit 45% of rapes, 44% of robberies, and 37% of other assaults. Further, an estimated 50% of violent crimes involving all ages is alcohol-related. Researchers have found that as the legal drinking age was lowered in the United States, social problems increased, but as the legal age was raised, alcohol-related problems decreased.

CONSEQUENCES OF ALCOHOL MISUSE AMONG ADOLESCENTS

Alcohol affects adolescents differently than adults, and the higher MLDAs protect them from some of the harmful effects of alcohol. An adolescent (generally considered to be ages 13–19) may look like an adult physically and may even appear more physically fit, but the adolescent's body and brain are still developing. It actually takes less alcohol for adolescents to be intoxicated than it does for adults in their 20s. A normal adult's liver can safely process an estimated 50 alcohol calories per hour (one ounce of 40% alcohol). However, an adolescent's liver can only process half of that amount. To ingest only 25 alcohol calories per hour, an adolescent could drink no more than one-fourth of a "light" beer in 1 hour. Although adolescence is often characterized by increased independence and a desire

for knowledge and exploration, it is also a time when brain changes can result in high-risk behaviors, addiction vulnerability, and mental illness, as different parts of the brain mature at different rates. There is mounting evidence that repeated exposure to alcohol during adolescence leads to long-lasting deficits in cognitive abilities, including learning and memory in humans. In one study of adolescents recruited from treatment programs (aged 13–19), researchers observed that teens who returned to drinking after the treatment program suffered further declines in cognitive abilities, particularly in tests of attention, over the next 4 years. New evidence also indicates that the brain is not fully developed until about age 25, providing further justification for higher drinking ages (see *The Role of Brain Development in Drug Effect and Drug Response and Alcohol Neuroimaging in Humans*).

EARLY ONSET OF DRINKING

In general, the lower the MLDA, the earlier youth begin drinking alcohol. Early onset of drinking by youth has also been shown to significantly increase the risk of future alcohol-related problems (e.g. alcohol dependence as well as getting into fights, experiencing traffic crashes, and other unintentional injuries after drinking), controlling for a variety of personal demographic characteristics as well as a history of smoking and drug use and a family history of alcoholism. Further, early drinking onset has been linked to suicide attempts. In addition, the consequences appear to be more severe for those who start drinking at a younger age. Youth who start drinking before age 15, compared to those who wait until they are age 21, are 12 times more likely to be unintentionally injured while under the influence

of alcohol, 7 times more likely to be in a motor-vehicle crash after drinking, and 10 times more likely to be in a physical fight after drinking. After analytically controlling for history of alcohol dependence, frequency of heavy drinking, years of drinking, age, gender, race/ethnicity, history of cigarette smoking, and illicit drug use, those who start drinking at age 18 are nearly twice as likely to be unintentionally injured, to be in motor-vehicle crashes, and to be in physical fights while under the influence of alcohol compared to those who start drinking alcohol at age 21.

MLDA-18 VERSUS MLDA-21

In most countries, the MLDA is 18. Youth who start drinking at age 18 have twice the odds of drinking to intoxication than youth who start drinking at age 21. Youth who start drinking at age 18 has a 33–52% greater chance of being injured while under the influence of alcohol in their lifetime compared to youth who start drinking at age 21. Fifteen percent of youth who start drinking at age 18 become alcohol dependent at some point in their lives compared to only 9% of youth who wait until age 21 before drinking. Youth who started drinking at age 18 have a 2.4-fold increase in risk of being involved in a motor-vehicle crash because of drinking too much in the past year compared to youth who started drinking at age 21. Youth who started drinking at age 18 have a 50–60% greater chance of being in a physical fight while drinking or after drinking compared to youth who started drinking at age 21.

When the drinking age is 21, those younger than 21 drink less and continue to drink less through their early 20s. The lower rates of drinking before age 21 are not compensated for by a higher rate of drinking after reaching 21, as some have conjectured. In fact, the opposite is true. Early legal access (at age 18) is associated with higher rates of drinking later in life. A full 40% of those who start drinking before the age of 15 meet the criteria for alcohol dependence at some point in their lives. This is four times greater than those who begin drinking at age 21. Twenty-eight percent who start drinking at age 17 and 15% who start drinking at age 18 develop a dependence on alcohol. Youth who start drinking at age 18 are 1.4 times more likely to become alcohol dependent than those who start at age 21 or older, even after controlling for age, gender, race/ethnicity, education, marital status, family history of alcoholism, childhood depression, anti-social behavior, and history of smoking and drug use. No evidence exists to indicate that young people will learn to drink responsibly simply because they can consume alcohol legally at a younger age. Countries with lower drinking ages suffer from alcohol-related problems similar to or greater than those in the United States.

Another country recently changed its drinking age: New Zealand lowered their MLDA from 20 to 18. After the drinking age was lowered to 18, there was a significant increase in traffic crashes among youth affected by the law change. Comparing 4 years before and after New Zealand lowered the MLDA to 18, the rate of traffic crashes and injuries to 18- and 19-year-old males increased 12% and increased 14% for males aged 15–17. For females, the effect was even greater – rates increased 51% for 18- and 19-year-olds and 24% for 15- to 17-year-olds. There was also a “trickle down” effect, as youth even younger than the MLDA increased their alcohol consumption. It is estimated that 400 serious injuries and 12 deaths could be prevented each year among 15- to 19-year-olds if New Zealand were to raise the MLDA back to age 20. The outcomes in New Zealand are similar to the evidence in the United States after the drinking ages were lowered in the 1970s.

LOWER DRINKING AGES IN EUROPE

It is often asserted that alcohol is more integrated into European culture (especially in southern Europe) and that its young people learn to drink moderately at earlier ages within the context of the family. Consequently, it is said that young Europeans learn to drink more responsibly than do young people in the United States. This may be so in a handful of countries, but in reality, a greater percentage of 15- and 16-year-olds in most European countries reported being intoxicated in the past year than in the United States (see Fig. 95.4). Evidence also indicates that some European youth have higher rates of alcohol-related problems because of their heavy drinking.

BINGE DRINKING BY YOUTH

The MLDA is associated with rates of binge drinking by youth. Binge drinking by youth in the United States declined after drinking ages were raised to age 21 nationwide and has been stable at levels lower than the early 1980s. Binge drinking (i.e. reaching a BAC $\geq .08$; typically having five or more drinks for males and four or more drinks for females at a drinking session) is a major problem at many colleges. Binge drinking among US college students has been fairly steady for the past 10 years. Between 1997 and 2006, the proportion of college students reporting binge drinking ranged from a high of 41.7% in 2004 to a low of 38.5% in 2003. The percentage of college students who reported being drunk in the past 30 days shows similar fluctuations and results between 1991 and 2006, with several ups and downs during that period (see

FIGURE 95.4 Prevalence of intoxication in the past year (2007) by adolescents aged 15–16: United States and Europe. Adapted from Johnston, L. D., O'Malley, P. M., Bachman, J. G., and Schulenberg, J. E. (2008b). *Survey Results on Drug Use. In Monitoring the Future (Vol. 1)*. Bethesda, MD: National Institute on Drug Abuse.

FIGURE 95.5 Percentage of college students who reported being drunk in the past 30 days in the United States. Adapted from National Center for Statistics and Analysis. (2005). *Traffic safety facts: 2005 data - young drivers (No. DOT HS 810 630)*. Washington, DC: National Highway Traffic Safety Administration.

Fig. 95.5). Overall, the proportion of 19- and 20-year-olds (college and no college) reporting binge drinking has fluctuated from a low of 31.7% in 1995 to a high of 37.0% in 1991 (see Fig. 95.6). The proportion of 12th graders reporting binge drinking in the last 2 weeks actually declined recently, ranging from 29.8% in 1991 to a high of 31.5% in 1998 to a low of 25.9% in 2007. Thus, though the MLDA-21 in the United States has not eliminated harmful drinking by those aged 20 and younger, it has reduced the problem and sustained

a much lower rate than when the MLDA was lower (see Binge Drinking and Binge Drinking and Withdrawal: Neural Mechanisms in Humans).

COLLEGE BINGE DRINKING

The tradition of drinking and especially excessive drinking on and around college campuses is prevalent in the United States (Fig. 95.5) and in many other

FIGURE 95.6 Percentage of 19- and 20-year-olds binge drinking (5+ drinks in past 2 weeks) in the United States. Adapted from O'Malley, P. M., and Wagenaar, A. C. (1991). *Effects of minimum drinking age laws on alcohol use, related behaviors and traffic crash involvement among American youth: 1976–1987*. *Journal of Studies on Alcohol*, 52(5), 478–491.

industrialized nations. This occurs despite efforts to curtail the behavior and the MLDA in those countries. The negative consequences of alcohol consumption by college students include academic problems, assaults, rapes, and deaths from unintentional and intentional injuries and alcohol poisonings. In the United States, 83% of college students report drinking and 41% report binge drinking (five or more drinks on an occasion) in the past 2 weeks. This heavy episodic, high-risk, or binge drinking is a particularly dangerous pattern of alcohol consumption.

The prevalence of alcohol dependence is highest among US youth, aged 18–24 years, whether they are in college, military, or workforce. College students may start out with lower rates of binge drinking compared to their noncollege peers, but they quickly catch up. Addressing harmful college student drinking is complicated because half or more students on a typical US campus are younger than the MLDA of 21. College officials face serious questions about how to and whether to enforce MLDA-21 on their campuses. They must balance safety, liability, and law enforcement with the colleges' historic role as havens for experimentation, personal freedom, self-expression, and individual responsibility. Beyond the harm to college drinkers themselves, 67% of all property damage, 64% of violent behavior, 42% of physical injury, 37% of emotional difficulty, 38% of poor academic performance, and 28% of all dropouts could be attributed to alcohol abuse in US colleges.

A variety of individual, campus, community, and environmental measures can work in conjunction with

enforcement of the MLDA-21 law to reduce college students' binge drinking. The effectiveness of countermeasures depends upon the culture and context of a particular college campus. In general, strategies that involve multiple aspects of campus life that include the surrounding community and that are sustained over time have a greater chance for success. Some US colleges are pursuing a range of policies and practices aimed at discouraging underage drinking and reducing its appeal:

- Aggressively enforcing the MLDA-21 law in residence halls and throughout the campus
- Offering substance-free housing and/or age-segregated housing
- Restricting or prohibiting alcohol at social activities on campus
- Prohibiting alcohol advertising on campus
- Providing alcohol-free late-night attractive social options, especially for students aged 20 and younger
- Providing information to parents and students of alcohol policies and penalties for violations

Countries with more stringent alcohol control policies tend to have lower adult and college binge-drinking rates.

ENFORCEMENT OF MLDA LAWS

Despite the establishment of MLDA laws in most countries, they are not strictly enforced. The US Centers for Disease Control (CDC) and Prevention, a United States federal agency under the Department of Health

and Human Services that works to protect public health and safety by providing information to enhance health decisions, conducted a systematic review of the evidence on enhanced enforcement of laws prohibiting sales to minors. Enhanced programs to enforce MLDA laws include, for example, retailer compliance checks, or “sting operations,” conducted or coordinated with local law enforcement or alcohol beverage control agencies with violators receiving legal or administrative sanctions (e.g. fines, store closings). These compliance checks typically involve sending a youth (called a minor decoy who looked younger than age 21) into an alcohol establishment to purchase alcohol. If proof of age was asked, the youth did not produce it. If the alcohol was sold to the youth without the proof of age, this was considered not in “compliance” with the law.

Enhanced enforcement of MLDA laws reduce or limit underage purchases of alcohol. Enhanced enforcement programs are effective in reducing retail sales of alcohol to minors. As an example, the median decrease in sales to minor decoys after an enforcement program was implemented was 42% with interquartile intervals of –57% to –17%. Enhanced enforcement programs have been found to be effective in on-premises (e.g. bars and restaurants) and off-premises (e.g. liquor stores, grocery stores) establishments, as well as among different ethnic and socioeconomic groups and in both urban and rural areas. There is little evidence, however, that these changes in retailer behavior actually affect underage drinking. Many experts believe that if MLDA laws were seriously enforced, both the laws aimed at the underage and the providers, the effects of these laws will be substantially enhanced.

SUMMARY

Most countries around the world have adopted MLDA laws for the purchase and/or possession of alcohol as a protective policy for youth. Scientific evidence indicates that the lower the drinking age, the earlier the youth begin to drink and the greater the prevalence of alcohol harm. The raising of the drinking age appears to decrease alcohol consumption for youth and is associated with declines in deaths and injuries caused by the harmful use of alcohol (at least in the United States). MLDA laws are an important component of any effort to control the production, marketing, distribution, and sale of alcoholic beverages.

OVERVIEW

Alcohol problems have been shown to be prevalent among college students, with approximately 56% of students meeting DSM-IV criteria for alcohol abuse or dependence. Although substantial alcohol problems exist in this population, alcohol consumption is not uniformly excessive and there is substantial individual variation. The current chapter explores social, cultural, environmental, biological, and personality factors contributing to this variability. Topics covered include family and parental influences, genetic mechanisms, personality variables, alcohol expectancies, drinking motives, and drinking norms.

FAMILY HISTORY AND GENETIC INFLUENCES ON ALCOHOL-USE DISORDERS

Family, twin, and adoption studies have shown that a family history of alcohol-use disorders is a consistent risk factor for the development of alcohol problems. Although a strong association between family history and alcohol-use disorders has been found in the general population, research on college students has revealed mixed findings. A number of studies assessing large samples of college students have demonstrated that children of alcoholics (COAs) reported higher rates of alcohol-use disorders and alcohol problems compared

to nonCOAs. However, other studies have shown no differences in the level of alcohol consumption between the two groups. These findings indicate that COAs may experience more negative consequences from alcohol than nonCOAs at the same level of alcohol consumption. However, these results may be a function of sampling bias such that college samples of COAs may only include more functional and successful COAs who are drinking at lower levels. It is also possible that COAs are more familiar with alcohol problems due to their family history and thus are more likely to acknowledge their behaviors as problematic, thereby accounting for the higher reports of alcohol-use disorders in COAs. The current findings indicate that having a family history of alcohol-use disorders may be a significant risk factor for the development of alcohol problems, and that both genetic and environmental factors influence the intergenerational transference of alcohol-use disorders.

Research suggests that the genetic etiology of alcohol-use disorders does not involve simple Mendelian dominant or recessive genetic processes, but more complex processes involving multiple genes that reflect multiple characteristics. Further, genetic processes only account for about 50% of the risk for alcohol-use disorders. Thus, cultural and environmental factors, such as parental influence, family environment, and family history of psychopathology, have been shown to be associated with the development of problematic drinking. Moreover, studies have shown that many COAs do not develop alcohol-use disorders whereas many nonCOAs do. This indicates that other mechanisms – besides genetic inheritance – play important roles in the development of alcohol-use disorders.

Genetic Influence

Genetic Factors Predicting Alcohol-Use Disorders

Twin and adoption studies have been used to disentangle the impact of genes versus environment. Twin studies comparing monozygotic twins (one-egg twins who share 100% of genetic material) and dizygotic twins (two-egg twins who share 50% of genetic material) have consistently shown that dizygotic twins of alcoholics have approximately the same alcohol risk as full-siblings whereas monozygotic twins have significantly higher risk. Further, studies of half-siblings of alcoholic parents raised in the same household revealed that half-siblings have a lower risk for alcohol-use disorders than full-siblings. This indicates that despite shared family environment, siblings who are more genetically similar to their alcoholic parents are more at risk for alcohol-use disorders. Adoption studies have also attested to genetic etiology. Children of alcoholics who were adopted into another family have been shown to exhibit similar drinking patterns as

their biological parents and full-siblings. Overall, these studies indicate that genetics play an important role in the intergenerational transference of alcohol-use disorders, with heritability estimates between 50 and 60%.

Although there are strong gender differences in the prevalence of alcohol-use disorders, research indicates that a gender-linked mechanism is unlikely to be a major contributor toward these disorders. This is because the risk for alcohol problems has been shown to be high in both sons and daughters of alcoholics. Consequently, the higher risk for alcohol-use disorders found in men as compared to women appears to reflect cultural rather than genetic mechanisms.

Genes Involved in the Level of Response to Alcohol

The level of response (LR) to alcohol is a genetically influenced characteristic that has been associated with increased risk for alcohol-use disorders. Individuals with a low LR will consume more alcohol than individuals with a high LR to achieve the same physiological effects. Thus, compared to high LR individuals, low LR individuals are more likely to consume larger amounts of alcohol per occasion, associate with heavy-drinking peers, have positive alcohol expectancies, and develop higher tolerance for alcohol, which puts them at increased risk for alcohol-use disorders. The heritability of LR is between 40% and 60%.

The gamma-aminobutyric acid (GABA) gene cluster on chromosome 5, particularly GABRA6 and GABRA1, has been associated with LR to alcohol. GABA receptors are sensitive to alcohol, and their activation can result in sedation, motor impairment, and other responses to alcohol. Polymorphisms in the GABRA6 and GABRA1 genes are associated with a lower LR due to the receptors having less sensitivity to alcohol and to a more rapid development of tolerance as the receptors adapt during a drinking session. The lower LR produced by these mutations increases risk for heavy drinking and alcohol-use disorders. Research has shown that populations that are at risk for alcohol problems, such as COAs, Native Americans, and Koreans, have lower LR than other populations.

Genes Involved in Alcohol Metabolism

Genes involved in alcohol metabolism have also been associated with alcohol-use disorders. When alcohol is consumed, the enzyme alcohol dehydrogenase (ADH) converts ethanol into an active metabolite called acetaldehyde. Acetaldehyde is then oxidized by the mitochondrial enzyme aldehyde dehydrogenase (ALDH2) into acetate, which eventually metabolizes into carbon dioxide and water. About 40–50% of Asian individuals have mutation of the ALDH2 gene (ALDH2*2). This mutation encodes an enzyme that is functionally inactive and is therefore unable to metabolize acetaldehyde.

This results in an accumulation of this toxic substrate, which can lead to physiological responses such as flushing, headache, nausea, tachycardia, and hypotension. Individuals who have two ALDH2*2 alleles (approximately 10% of Asians) accumulate high levels of acetaldehyde in the blood when drinking moderate amounts, which produces intense LR to alcohol that can be aversive. Individuals who have only one ALDH2*2 allele (30–40% of Asians) also demonstrate more intense LR to alcohol than individuals without this variant; however, their response may not be more aversive. It is hypothesized that the high sensitivity to alcohol decreases the amount of alcohol consumption thereby protecting these individuals from alcohol-use disorders. A substantial number of studies have supported this hypothesis showing that those who have the ALDH2*2 mutation reported greater sensitivity to alcohol, lower rates of alcohol use, and fewer drinking consequences.

Similar, but less consistent data has been shown for genetic variations regarding ADH. Two polymorphisms, the ADH1B*2 and the ADH1C*1, have been shown to produce enzymes capable of faster metabolism of alcohol, resulting in a slight increase in acetaldehyde levels and an enhanced LR to alcohol. These genetic mutations have been shown to be protective against alcohol-use disorders in Asian, African American, and Jewish populations.

Parental Influence

Parental drinking has been shown to be an important environmental factor that directly and indirectly increases children's risk for alcohol problems. Research has found that observation of parental drinking habits, drinking refusal self-efficacy, and beliefs about alcohol's effects influence children's perceptions of alcohol and their subsequent drinking behavior. Further, parents' alcohol abuse has been shown to adversely affect global family interactions and the psychological well-being of the children. A number of studies have demonstrated that COAs are at an increased risk for alcohol abuse, either directly by using alcohol as a means to cope with the negative family environment or indirectly by their association with substance using peers due to low parental monitoring. A family history of psychopathology has also been associated with college students' alcohol use. Psychopathology has been found to adversely influence family environment and interaction, which may lead to alcohol use by both parents and children as a coping mechanism.

It should be noted that some studies have found a negative relationship between parents' alcohol use and children's alcohol use. A study assessing Russian family alcohol use found that fathers' alcohol-related violence was associated with lower drinking levels in

children. This effect was termed the "aversive transmission" effect in which children of alcoholics moderate their own drinking due to their perceptions of their parents' problematic drinking behavior. In general, it appears that parental influence and family environment operate as partial mechanisms for the intergenerational transfer of alcohol problems. However, more research is needed to examine the relative significance of the direct and indirect effects of parental influence and family environment on the development of problematic drinking.

DRINKING MOTIVES

Drinking motives refer to the psychological function that drinking alcohol fulfills, or more plainly, reasons to drink. Motives are understood, both theoretically and empirically, to be potent determinants of drinking and alcohol-related problems. In fact, some theorists consider motives to be the final common psychological pathway that is most proximal to drinking and alcohol-related problems. That is, motives can be construed as the mediating mechanisms linking more distal determinants – such as family history, genetic influences, personality factors, alcohol expectancies, etc. – to drinking.

The most widely used model of drinking motives is based on the "motivational model of alcohol use," and posits that there are two motivational dimensions at play: valence (positive versus negative reinforcement motives) and source (internal versus external reinforcement motives). These two dimensions intersect to generate four specific types of drinking motives: coping (negative, internal), conformity (negative, external), enhancement (positive, internal), and social (positive, external) motives. Among college students, drinking motives have been found to be established predictors of heavy drinking and alcohol-related problems.

Also known as "drinking-to-cope," avoidance drinking, or self-medication, coping motives entail drinking to avoid experiencing negative affect, primarily anxiety and depression. Coping motives significantly predict drinking frequency and alcohol-related problems as well as increased psychological distress for college students. Of all the drinking motives, only coping motives have been found to be associated with solitary heavy drinking. When distinguishing the types of coping motives, researchers have found that college students with stronger coping motives for depression consumed more alcohol to cope with their depression, and those with stronger coping motives for anxiety consumed more alcohol to cope with their anxious mood. Coping motives have also been found to be differentially related to levels of social anxiety. Among college

students who have high or moderate social anxiety, coping motives are related to greater alcohol use and problems. However, this relationship was not found for those low in social anxiety.

General associations between coping motives and drinking among college students tend to be stronger for women than men. Some researchers speculate that this gender difference may be due to women being diagnosed with depression more so than men, and thus, women may exhibit higher coping motives for drinking to decrease symptoms. Coping motives have also been shown to account for increased drinking in women with higher sensitivity to anxiety. Additionally, college students who endorse coping motives lack other coping skills and thus drink to cope with their aversive internal states, and this pattern continues to be stronger among women than men.

Driven by the desire to attain peer acceptance, conformity motives involve drinking to avoid the experience of social disapproval. Conformity motives are related to alcohol-related problems and drinking during social contexts in which there are pressures to conform. Conformity-motivated heavy college drinkers tend to have greater self-consciousness and greater anxiety, and are more likely to be men. In one recent study, freshman students and students of color had higher scores on the conformity motives than senior students and Caucasian students, respectively. For students of color, this may be due to the pressure and stress surrounding their adjustment to the largely Caucasian environment of many college campuses. Given that this study is unique, follow-up studies replicating this pattern are necessary before making conclusions. Furthermore, future studies that consider cultural constructs, such as acculturation and loss of face, and ethnicity are necessary to further elucidate these patterns.

According to the “motivational model of alcohol use,” coping and conformity motives are understood to influence drinking behavior through negative reinforcement. Research in this area is somewhat mixed. Perhaps counter intuitively, some studies find that students higher in social anxiety consumed less alcohol. This may be due to the fact that these students are in less contact with social environments where alcohol is involved. However, these students experience more negative consequences from alcohol use. Other studies have found that coping and conformity motives mediate the relationship between social anxiety and negative consequences such that students who experience more social anxiety also exhibit more coping and conformity motives, leading to increased drinking and consequences. Regardless of the mixed findings, this research demonstrates the importance of addressing the negative reinforcement motives behind unwanted consequences of drinking.

The remaining two drinking motives, enhancement and social motives, have received relatively less research attention than conformity and coping motives. Enhancement motives involve drinking to increase positive affect. They have been found to predict alcohol-related problems and to be the best predictor of heavy social drinking over other motives. Drinking to achieve social affiliation is known as social motives. Although social motives are related to alcohol consumption (these students tend to socialize more and attend social situations where alcohol is present), social motives are not necessarily related to alcohol-related problems.

Taken together, research findings appear to indicate that coping, conformity, enhancement, and social motives are related to alcohol use and problematic drinking. Further, coping motives have been shown to be particularly hazardous, and drinking motives generally have been shown to play an important role in delineating the effects of personality factors on drinking.

PERSONALITY FACTORS

Within psychology and psychiatry generally and within addictions theory specifically, a long-standing tradition advances the assertion that personality exerts a determinative role in explaining behavior. Personality theorists define personality as an organized set of characteristics possessed by an individual that influences his or her thoughts, feelings, motivations, and behaviors in a systematic fashion across various situations. Personality factors are understood to represent intrinsic and unchanging dispositional tendencies that are biologically based and established early in life. In keeping with the tradition of personality theory, researchers have examined several personality factors thought to influence drinking and drinking-related outcomes among college students.

The Five-Factor Model and Related Constructs

Several decades of research by multiple investigative teams generated an empirically driven multidimensional model of personality thought to encompass the broadest array of personality attributes. The model offers a valuable heuristic frame for discussing the link between personality and college drinking.

The Five-Factor Model (FFM) identifies five distinct dimensions or higher-order factors – neuroticism, extraversion, openness to experience, agreeableness, and conscientious, each of which subsumes a set of specific facets or lower-order factors. For instance, impulsivity, anxiety, and depression are facets of neuroticism; whereas, gregariousness and excitement seeking are

facets of extraversion. While these selected facets would – at a glance – seem intuitively relevant to drinking, researchers have examined all five dimensions and many of the subsidiary facets to evaluate their predictive value and explanatory relevance to college drinking outcomes. Overall, current trends seem to indicate that, while personality factors can be demonstrated to have a direct impact on drinking, these influences are increasingly understood to operate indirectly via drinking motives. That is, personality factors seem to fuel motives to drink and these motives, in turn, fuel drinking and related outcomes.

Neuroticism

Neuroticism refers to a person's tendency to be emotionally labile, susceptible to anxiety, hypersensitive to criticism, self-doubting, and inclined to dwell on the negative. The distinction between direct (personality trait → drinking) versus indirect pathways (personality trait → drinking motive → drinking) is especially striking with neuroticism. In this case, evidence suggests that the two pathways manifest opposite effects. The direct pathway appears protective, thereby lowering drinking risk, whereas the indirect pathway appears to heighten risks. Research examining direct linkages from this broad higher-order conceptualization of neuroticism to drinking variables indicates reduced drinking risks. That is, being high in neuroticism may serve a protective function against drinking and associated negative outcomes. The logic seems to be that more neurotic individuals have a lower likelihood of encountering social factors that might otherwise foster drinking activities. Presumably, their tendencies toward anxiety and negativism may curtail their socializing, thereby limiting opportunities for engaging in alcohol-involved social situations. However, evidence of an indirect pathway suggests that more neurotic individuals are motivated to drink as a way to alleviate their negative affect (particularly anxiety and depression) and that this drinking-to-cope pathway fuels greater drinking and more problematic drinking outcomes. Thus, neuroticism seems to have intriguingly paradoxical effects on drinking and this pattern warrants further study.

Impulsivity and Related Constructs

Recall that the FFM posits that neuroticism subsumes distinct subfactors or facets. Among them, impulsivity has received considerable research attention with respect to drinking, as have other related constructs. Impulsivity is generally defined as the tendency to act based on immediate urges without regard for rules, regulations, and consequences. This tendency toward rash action is considered a complex

construct, with scientists speculating a range of interrelated yet distinct aspects including urgency (a tendency to act rashly), lack of premeditation (inability to anticipate consequences), lack of perseverance or boredom susceptibility (inability to follow through on task completion), lack of inhibitory control (inability to refrain from or delay responding), and excitement or thrill seeking (which is often also considered an aspect of extraversion and refers to one's attraction to risky events and actions).

Research shows that impulsivity is a clear risk factor for drinking. A recent review of relevant studies indicated that impulsivity increases the likelihood of initiating alcohol use, continuing drinking over the college years, and developing alcohol-use disorders. Impulsivity has also been linked to greater hazardous drinking. Moreover, particular impulsivity subconstructs – for instance, motor impulsivity and boredom susceptibility – have been shown to predict heavy episodic drinking (more than four (women) or five (men) drinks in 2 h). As with neuroticism, the influence of impulsivity on drinking outcomes can be mediated by drinking motives. In one recent study, impulsivity increased alcohol problems via a direct pathway and an indirect pathway via the drinking-to-cope motive. This suggests that impulsive individuals may overly rely on quick, easy ways to cope with distress, such as drinking alcohol. They may also drink in riskier environments, thus increasing the likelihood of alcohol-related problems. It has been noted that impulsivity can have a reciprocal relationship with drinking, such that drinking induces greater impulsivity, which in turn, fuels greater drinking.

Urgency

Two emotion-based personality factors have been identified as related to impulsivity: Positive urgency is the tendency to act rashly when experiencing extremely positive emotion and negative urgency is the tendency to act rashly when experiencing extremely negative emotion. Both these urgency constructs have been shown to be related to college drinking. In an extensive series of cross-sectional surveys, a team of researchers showed that urgency (unspecified) predicted drinking and alcohol-related problems. In subsequent studies, this team showed that positive versus negative urgency exhibited differential predictive value. Positive urgency was positively related with problem drinking and other risky behaviors. In a longitudinal study, these investigators showed that positive urgency predicted increases in the amount of alcohol consumed and negative drinking outcomes. Further, in another longitudinal study, they found that positive urgency predicted drinking quantity at the end of the first year of college. Laboratory studies also showed that positive urgency predicted risk-taking

and beer consumption, but only after a positive mood had been induced.

The association between positive urgency and problem drinking has been shown to be moderated by drinking motives. Positive urgency was associated with problem drinking more strongly for students who scored higher on the enhancement-drinking motive. Thus consistent with the theory, the tendency to act rashly in a positive mood state was related to problem drinking, but only for students who drink for positive internal reasons. This pattern was unique for positive urgency and did not occur with negative urgency. Alcohol expectancies also played a moderating role, such that associations were stronger for students higher in the belief that alcohol makes one social, attractive, or sexually excited. In one of the longitudinal studies mentioned earlier, negative urgency also predicted drinking quantity and the effect was mediated by the drink-to-cope motive. Thus, it appears that urgency – one's tendency to act rashly – is an important element of impulsivity with regard to college drinking. Moreover, the role played by this trait seems specific to the valence of the associated mood states; and, like other personality factors, can exert its effects on drinking outcomes either directly or indirectly via drinking motives.

Extraversion, Excitement Seeking, and Sensation Seeking

Extraversion refers to the tendency to focus on gratification obtained from outside the self. Extroverts are characterized by warmth, positivity, gregariousness, and excitement seeking. Among college students, extraversion has been consistently associated with drinking and with a host of drinking outcomes such as hangover symptoms, risky drinking, and alcohol-related problems. Extraversion is positively related to enhancement motives, and the association between extraversion and alcohol use can be mediated by enhancement motives. Additionally, social motives have also been found to mediate the relation between extraversion and alcohol use.

The FFM posits that extraversion subsumes distinct subfactors. Among them, excitement seeking has received research attention with respect to college drinking, as have other related constructs. Sensation seeking, a personality construct identified with both excitement seeking and impulsivity, has also received considerable attention. Sensation seeking has been defined by the need for “varied, novel, and complex sensations and experience and the willingness to take physical and social risks for the sake of such experience.” These more specific components of extraversion tend to be more strongly related to college drinking than the broader construct.

Conscientiousness

Conscientiousness refers to tendencies that adhere to socially prescribed norms and rules regarding impulse control, to be orderly, to be achievement striving and goal-directed, and to be deliberative about planning ahead. As such, being high in conscientiousness is largely antithetical to drinking excessively and manifesting derivative problems. Accordingly, research shows that students low in conscientiousness are most likely to exhibit drinking, excessive drinking, and drinking-related negative consequences. In one study looking at the role of drinking motives, conscientiousness was negatively related to both enhancement and coping motives, and the negative association between conscientiousness and alcohol use was partially mediated by both enhancement and coping motives. Furthermore, the influence of conscientiousness has been shown to be mediated by use of protective behavioral strategies. These strategies are defined as “behaviors that individuals can engage in while drinking alcohol in order to limit negative alcohol-related problems” and include strategies such as adhering to a predetermined drink limit, avoiding drinking games, and resisting social pressure to drink more. Students who are high in conscientiousness use more of these protective strategies and as a result exhibit less drinking and alcohol-related problems.

Agreeableness

Agreeableness reflects the individual's tendency to develop and maintain prosocial relationships. Individuals high in this trait are more trustworthy, straightforward, altruistic, compliant, modest, and tender-minded. Conversely, individuals low in agreeableness are less concerned about social approval and less concerned about protecting others and themselves from harm. Research shows that agreeableness tends to be negatively related to excessive drinking and alcohol-related problems, especially alcohol-related aggression. Regarding drinking motives, one study showed that agreeableness was predicted by both positive reinforcement motives (drinking to attain positive outcomes). It has not been determined whether the relationship between agreeableness and drinking is mediated by motives.

Despite a seemingly protective effect, high agreeableness also carries a risk: individuals who are high in this trait are more susceptible to peer-drinking influences. Apparently, in their concern for complying with others and their efforts to meet group expectations, more agreeable individuals tend to drink less around light drinking peers, but drink more around heavy drinking peers. In a laboratory experiment, individuals high in

agreeableness were more likely to match their drinking during a taste-rating task to that of a stranger, compared to individuals low in agreeableness. Thus, the relationship between agreeableness and college drinking is not always straightforward depending on social context.

Openness to Experience

Openness, which includes intellectual curiosity and preference for variety, appears to be the personality trait that is least reliably related to college drinking among the FFM traits. Although, a recent study reported evidence that curiosity relates to drinking outcomes. Two aspects of curiosity had opposite associations with problem drinking. Higher scores on exploration, the desire to seek out novel information and experiences, were negatively related to alcohol-related problems. Higher scores on absorption, the tendency to become deeply involved in such activities, were positively related to alcohol-related problems. This observation that curiosity factors could alternately serve protective and risk functions among college drinkers is intriguing and warrants further study. Also, the links between curiosity and drinking motives will be important to investigate.

PRECOLLEGE DRINKING AND MATURING OUT OF COLLEGE DRINKING

It has become increasingly well established that college drinking patterns do not necessarily typify lifetime drinking patterns. Precollege drinking variables such as age at first intoxication and high school drinking quantity and frequency do tend to foreshadow and predict college-drinking variables. A more delayed debut of drinking and intoxication prior to college and lesser high school consumption are protective against excessive drinking and development of alcohol problems and abuse during college. Conversely, college drinking may not foreshadow later drinking. After college, drinking patterns characterized by excessiveness and alcohol-related problems tend to subside as students transition to more demanding adult statuses such as career employment, marriage, and children, which are largely incompatible with heavy drinking. Further, changes in personality may be an important mechanism in this so-called "maturing out" of college drinking. In longitudinal studies, students who exhibited a pattern of maturing out of college drinking showed decreases in neuroticism and impulsivity and increases in conscientiousness. These findings suggest that individual variation factors seemingly as stable as

personality can operate more dynamically within individuals as a function of significant life transitions.

ALCOHOL EXPECTANCIES

Alcohol expectancies refer to beliefs people hold about the "positive" and "negative" consequences of drinking alcohol. According to Expectancy Theory, high positive and low negative expectations about the effects of drinking alcohol lead to elevated alcohol consumption. Decades of research have consistently demonstrated that positive alcohol expectancies are associated with increased drinking behavior (including number of drinks and binge episodes) among college students in both cross-sectional and longitudinal studies. Domains of positive alcohol expectancies include tension reduction, sexual enhancement, enhanced sociability, and social assertion. Alcohol expectancies have been shown to be better predictors of problem drinking than background demographic variables such as gender, class, ethnicity, marital status, religiosity, and family history of alcohol problems.

A number of factors, such as gender, family history, and anxiety, have been shown to moderate the relationship between positive alcohol expectancies and drinking behavior. Different types of drinkers tend to endorse different types of alcohol expectancies. Problem drinkers, individuals who abuse alcohol, are more likely to expect tension reduction whereas social drinkers expect social enhancement from alcohol. Further, heavier drinkers expect more positive effects than lighter drinkers. When examining different types of drinkers over the course of the freshmen college year, those who consistently consume low levels of alcohol endorsed lower alcohol expectancies than all other groups of freshman drinkers.

Anxiety among college students is another factor that has been proposed to moderate the relationship between alcohol expectancies and problematic drinking. Among college student populations, beliefs regarding increased sociability and assertiveness from drinking were positively correlated with alcohol use. College student problem drinkers had greater expectancies for improvements in social behavior than nonproblem drinkers. Alcohol expectancies of social anxiety reduction predicted quantity of alcohol consumed per occasion but not frequency of consumption in the past month, such that alcohol consumed per occasion was increased but not the overall frequency in consumption. Furthermore, socially anxious college students with low self-efficacy for avoiding heavy drinking in social situations and high positive expectancies for social facilitation reported more alcohol consumption

than other socially anxious college students. These findings demonstrate that college student problem drinking may vary depending on alcohol expectancies surrounding sociability.

Negative alcohol expectancies, which can include cognitive and behavioral impairment, depressant effects, risk and aggression, and negative self-perception, are also meaningful when examining college student alcohol use. However, the relationship between negative alcohol expectancies and drinking is less straightforward than positive expectancies and drinking. More recently, the categorization of alcohol expectancies as “positive” or “negative” has been debated, as well as the inclusion of individual valuation of alcohol expectancies (the extent to which an individual desires these outcomes when drinking). It may be that the negative expectancies individuals report are not necessarily desired, but can influence drinking and drinking-related consequences regardless of their individual valuation. Theoretically, college students endorsing negative alcohol expectancies will drink at lower levels. However, the evidence is mixed.

The relationship between negative alcohol expectancies and drinking varies depending on the type of expectancy. Expectations of depressive symptoms such as feeling sad or sleepy has not been found to be associated with alcohol consumption among college students, but has been found to be associated with alcohol problems. This suggests that students who report these expectancies tend to experience more consequences, but do not similarly report that these expectancies lead them to consume more alcohol. Alcohol expectancies of greater physiological impairment (e.g. becoming dizzy and getting a headache) have been found to be a significant predictor for elevated alcohol use and alcohol problems. Perhaps negative alcohol expectancies are related to alcohol-related problems such that individuals who report these expectancies experience consequences related to these expectancies more frequently. Among female college athletes, favorable valuations of negative expectancies were associated with heavy drinking. When controlling for age, athletic membership and peer use, more negative expectancies and favorable valuations of negative and positive expectancies were predictive of increased hazardous alcohol use. Valuations of alcohol expectancies accounted for additional variance of hazardous alcohol use beyond that of expectancies. It appears that the level that individuals desire expectancy is just as meaningful as the expectancy itself. Additionally, college problem drinkers had greater expectancies of improvements in cognitive and motor abilities than nonproblem drinkers, demonstrating that expectancies are not necessarily universal across college students. Indeed, negative alcohol expectancies seem to have a complicated

relationship with alcohol use and alcohol-related problems among college students.

Researchers theorize that alcohol expectancies are developed within college students’ social/cultural surroundings. Given the cultural foundation of alcohol expectancies, one would venture to guess cultural differences in alcohol expectancies. Evidence suggests ethnic differences among college students in the endorsement of alcohol expectancies. Asian Americans have been found to increase their positive alcohol expectancies over the course of 3 years of college. In Australia, Asian college students expected cognitive enhancement and negative consequences from alcohol more so than their Caucasian counterparts. African-American women reported less positive alcohol expectancies than other groups of women. Among Mexican American college students, those who endorsed expectancies of physical and social pleasure and increased social assertiveness were more likely to engage in frequent heavy drinking. Longitudinal studies show that gay men increase their alcohol use at greater rates than heterosexual men during the transition into college from high school, and this relationship was mediated by positive alcohol expectancies. It is clear that the relationship between alcohol expectancies and alcohol use may differ depending on the population. However, alcohol expectancy research incorporating cultural factors is limited and thus, overall conclusions cannot yet be made.

Does addressing alcohol expectancies reduce drinking on college campuses? Overall, evidence suggests that interventions aimed at challenging alcohol expectancies are effective in decreasing alcohol use, including heavy episodic drinking, in college students. Research has shown that single-session interventions that challenge alcohol expectancies among college students can lead to significant decreases in alcohol consumptions at a 1-month follow-up, when compared to controls. However, there are some studies that suggest challenging alcohol expectancies alone may not be as effective as other interventions. For example, compared to brief motivational interventions, interventions that challenge alcohol expectancies have been shown to produce similar decreases in heavy episodic drinking and alcohol use overall, however, brief motivational interventions additionally produced decreases in alcohol problems. It has also been found that readiness to change is associated with stronger effects on challenging alcohol expectancies and more reduction in alcohol use.

DRINKING NORMS

Research has repeatedly shown the influence that peers can have on predicting alcohol use during college. Therefore, it follows logically that students’ perceptions

about how frequently other students are drinking should also impact their use of alcohol. A large amount of research has been dedicated to examining the role that these drinking norms can play in alcohol use, and has repeatedly suggested that the perceptions students hold about the alcohol use of their peers can be an independent risk factor for drinking. Research on the impact of these perceptions on alcohol use during college has defined two different categories of perceptions. These two categories include injunctive norms, or perceptions that students hold about others' approval of alcohol use, and descriptive norms, or the estimated rate of drinking that students make about their peer groups. Both descriptive and injunctive norms have been linked to alcohol use and the approval of alcohol use.

It has been suggested that students have limited knowledge about how other students think and act. Therefore, the development of inaccurate, descriptive norms about alcohol use among college students may stem in part from readily available images and information about heavy college drinking in the media and from peers. Additionally, these descriptive norms may be further developed and perpetuated by students' desire to see themselves or their own alcohol use in a favorable way. Injunctive norms may also be informed by public behavior and attitudes exhibited by students in the media regarding alcohol use. Furthermore, students tend to report their own attitudes toward drinking as being more conservative than the attitudes of their peers. This phenomenon is referred to as pluralistic ignorance and can result in a student's inaccurate perceptions about the attitudes toward drinking on campus.

In general, students have been found to overestimate the frequency and quantity of how much other students drink. Similarly, it has also been found that students tend to overestimate the drinking approval rates of their classmates. Even when students hold moderate views about their own drinking behavior, this overestimation persists. Additionally, students have been found to not only overestimate how much their peers drink in relation to their own alcohol use but they also overestimate the rates of student drinking when these rates are measured independently. Furthermore, students tend to estimate higher amount of negative consequences from drinking for other students than for themselves.

Inaccurate drinking norms have been frequently associated with heavier drinking rates among college students. This link has been the most strongly identified for descriptive norms. This may be because injunctive norms can vary depending on the population that the student is being asked about, thereby making injunctive norms more difficult to study. Injunctive norms have been found to be the most strongly linked to heavier drinking rates when the perception of approval is from

proximal referents such as friends and family. There has also been some evidence to support that students who express higher drinking norms, both descriptive and injunctive, experience more alcohol-related problems. However, injunctive norms surrounding perceived approval from parents and close friends have been found to most strongly predict alcohol-related problems. Therefore, it seems that there may be a complex relationship between how descriptive and injunctive norms influence a student's drinking behavior.

Students may also have unique perceptions about the drinking behavior of different groups, and this may influence their personal alcohol use depending on their affiliation with these groups. It has been suggested that a higher identification with same-sex students is associated with a stronger relationship between drinking norms for this group and the student's personal drinking. This same relationship has also been found with students having stronger identification to same-race and same-Greek-affiliation students. However, research has indicated that overall, male students express higher drinking norms than female students, in addition to consuming more alcohol on average than female students. Males may be more susceptible to peer influence, and this could have an indirect impact on distortions in injunctive norms or increases in the perceived acceptance of alcohol use.

Studies have further suggested that there may be differences in the relationship between drinking norms and alcohol use for ethnic minorities. The limited research in this area has indicated that certain ethnic groups, such as Asian Pacific Islanders and African-Americans, may express less exaggerated drinking norms than Caucasians. Further, some studies have shown that even when drinking norms are similar between ethnic minority women and Caucasian women, these norms appear to be less associated with drinking behavior for ethnic minority women than for Caucasian women. Furthermore, Caucasian women have been found to drink more similarly to Caucasian men regardless of drinking norms. This suggests that culture may serve as a protective factor against heavy alcohol use for some ethnic groups despite drinking norm misperceptions. It is important for future research to more closely examine how this may be operating for different ethnic minority groups, as well as how social norms may impact alcohol use for these groups.

Intervention programs have frequently targeted drinking norms in order to address problematic drinking on college campuses. Research has consistently found that correcting inaccurate descriptive norms decreases drinking for college students. Addressing injunctive norms has produced more conflicting results in terms of its impact on reducing alcohol use. This may be because injunctive norms are harder to address

and vary depending on which group attitude is the most salient for a student. Despite these complexities, numerous studies have shown that providing accurate data on drinking rates to college students reduce heavy drinking. Addressing drinking norms has become a key component for intervention programs that target alcohol use during college.

SUMMARY

“Danger: College life ahead!” This is not the typical farewell tiding or welcome greeting heard when starting college. College is a time of growth spurts in independence, autonomy, scholastics, social maturation, sexual exploration, and personal growth. However, warnings about dangers in college life are not misplaced because of the high prevalence of alcohol use, alcohol abuse, alcohol dependence, and alcohol-related problems. In the absence of uniformity in college drinking patterns, an understanding of the determinants of individual variation in alcohol variables is important for discerning, navigating, and potentially mitigating the risks associated with college drinking. We reviewed the roles played by family and parental influences, genetic mechanisms, personality variables, alcohol expectancies, drinking motives, and drinking norms in shaping individual variation in college drinking. All these factors can influence drinking and often exert their influence interactively. Notably, static factors such as genetic makeup, stable factors such as personality, and dynamic factors such as alcohol expectancies have been shown to have effects on drinking outcomes that are mediated or moderated by motives. The nexus posed by these interactions potentially provide important junctures for prevention and therapeutic interventions. Also, the tendency for students to mature out of excessive drinking after college suggests that modifications in structure role responsibilities in college could foster protective effects.

List of Abbreviations

COA children of alcoholics
LR level of response

Glossary

Alcohol dehydrogenase (ADH) enzyme that converts ethanol into an active metabolite called acetaldehyde; the first step in the metabolism of alcohol by the liver.
ADH1B*2 and ADH1C*1 mutation of the ADH gene; this mutation produces enzymes capable of faster metabolism of alcohol, resulting in a slight increase in acetaldehyde levels and an enhanced level of response to alcohol.
Alcohol expectancies beliefs regarding the positive and negative consequences of drinking alcohol.

Aldehyde dehydrogenase (ALDH2) mitochondrial enzyme that oxidizes acetaldehyde into acetate, which eventually metabolizes into carbon dioxide and water; the second step in the metabolism of alcohol by the liver.

ALDH2*2 mutation of the ALDH2 gene; this mutation encodes an enzyme that is functionally inactive and is therefore unable to metabolize acetaldehyde. This results in physiological responses such as flushing, headache, nausea, tachycardia, and hypotension.

Agreeableness tendency to develop and maintain prosocial relationships characterized by trustworthiness, altruism, compliance, modesty, and tender-mindedness.

Conformity motive drinking to avoid the experience of social disapproval.

Coping motive or drinking-to-cope motive drinking alcohol to cope with distress; drinking to avoid experiencing negative affect.

Conscientiousness a tendency to adhere to socially prescribed norms and rules regarding impulse control, to be orderly, to be achievement striving and goal-directed, and to be deliberative about planning ahead.

Descriptive norms estimated rate of drinking that students make about their peer groups.

Dizygotic twins two-egg twins who share 50% of their genes; nonidentical twins.

Drinking motive the psychological function that drinking alcohol fulfills; reasons to drink.

Enhancement motive drinking alcohol to increase positive affect.

Extraversion the tendency to focus on gratification obtained from outside the self; characterized by warmth, positivity, gregariousness, and excitement seeking.

Five-Factor Model (FFM) multidimensional model of personality that identifies five distinct higher-order personality attributes: neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness.

Gamma-aminobutyric acid (GABA) gene cluster on chromosome 5 that has been associated with level of response to alcohol. GABA receptors are sensitive to alcohol, and their activation can result in sedation and motor impairment.

Heavy episodic drinking consuming four or more drinks for women or five or more drinks for men in a 2-h period.

Impulsivity a facet of neuroticism; the tendency to act based on immediate urges without regard for rules, regulations, and consequences.

Injunctive norms perceptions that students hold about others' approval of alcohol.

Level of response to alcohol the degree to which an individual experience the physiological effects of alcohol after consumption.

Monozygotic twins one-egg twins who share 100% of their genes; identical twins.

Negative alcohol expectancies beliefs that alcohol consumption will lead to cognitive and behavioral impairment, depressant effects, risk-taking and aggression, and negative self-perception.

Neuroticism a person's tendency to be emotionally labile, susceptible to anxiety, hypersensitive to criticism, self-doubting, and inclined to dwell on the negative.

Openness to experience tendency for intellectual curiosity and preference for variety.

Positive alcohol expectancies beliefs that alcohol consumption will lead to tension reduction, sexual enhancement, enhanced sociability, and social assertion.

Social motive drinking to achieve social affiliation.

Urgency emotion-based personality factor related to impulsivity; a tendency to act rashly; positive urgency is the tendency to act rashly when experiencing extremely positive emotion and negative urgency is the tendency to act rashly when experiencing extremely negative emotion.

Preface

Principles of Addiction is one of three volumes encompassing the 2500 page series.

Comprehensive addictive behaviors and disorders: In both print and online formats, this series provides the most comprehensive compilation of current knowledge on addictive behaviors and disorders to date. In short, it is the definitive reference work on addictions.

The significance of this series stems from the fact that addictive behaviors and disorders represent major personal, social, and public health problems throughout the world. While research on addictions has grown exponentially over the past 20 years, the primary literature in this field is widely dispersed. For researchers and clinicians, staying abreast of this vast and expanding knowledge is a challenging, if not impossible, task. Researchers specializing in one addiction subspecialty (e.g. clinical research, neuroscience, health services, public policy, treatment, pharmacology, genetics) are unable to keep apprised of the big picture. In addition, research findings on one type of addiction (e.g. alcohol dependence, excessive gambling, methamphetamine dependence) may have relevance to other types (e.g. cocaine or opiate dependence) but such findings are not readily available to all addiction scientists since they are dispersed among so many specialty journals, books and web sites. Until now, there has been no all-encompassing resource that could serve as the “go-to” compendium for information on any and all addictions.

Comprehensive addictive behaviors and disorders fills this void by providing a unique and valuable storehouse of interdisciplinary scientific information for researchers, clinicians, and policy makers that comprehensively summarizes state-of-the-art knowledge. The terms “behavior” as well as “disorder” are used purposefully in the title since the work includes both excessive use (what is often called “at risk” or “harmful” use) as well as true physiological dependence. In addition, there is lack of evidence and some controversy over the issue of whether or not some behavioral excesses (e.g. texting or video gaming) can be classified as true addictions. Finally a number of the more basic, translational chapters cover addictive brain or behavioral processes rather than focusing on “disorders” per se.

Conceptually, the three volumes that make up this series, *Principles of Addiction*, *Biological Research on Addiction*, and *Interventions for Addictions*, cover an extensive

range of topics including, but not limited to, the nature of addiction, cravings, comorbidities, types of addictions, behavioral biology, neuroscience, neuroimaging, genetics, neuropharmacology, psychosocial treatments, addiction medications, application of addiction science to practice, public policy, and prevention. With the growing emphasis on translational research, the goal has been to integrate diverse findings into a meaningful conceptualization of all aspects of use and abuse.

The audience for the series includes advanced undergraduates, graduates and postdoctoral students, professors, researchers, clinicians and policy makers. The series can also serve as a valuable aid to instructors and students in the hundreds of university-level addiction degree programs throughout the world. As an encyclopedic series, the mass media as well as the general public will find this work to be a comprehensive source of evidence-based, scientific information on addictions. This is especially important since the field of addiction is continually plagued by anecdotal and misleading information found both in print and online.

SCOPE AND FORMAT

The development and compilation of this series has been a truly collaborative effort. Nine internationally recognized addiction experts have served on the editorial board for this project. The board is composed of Peter Miller, PhD, Medical University of South Carolina; Mary Larimer, PhD, University of Washington; Kyle Kampman, MD, University of Pennsylvania School of Medicine; David Kavanagh, PhD, Queensland University of Technology; Samuel Ball, PhD., Yale University School of Medicine; Phillipe DeWitte, MD, Université Catholique de Louvain (Belgium); Marsha Bates, PhD, Rutgers University; Nancy Petry, PhD, University of Connecticut Health Center; and Arthur Blume, PhD, Washington State University. The board members were chosen to provide a wide range of interdisciplinary expertise.

The board members were responsible for selecting and inviting authors for chapters in their specialty areas and to provide editorial guidance. Chapters are authored by reputable, well-recognized authorities in the addictions field. Authors were selected for their

expertise and experience, with particular emphasis placed on selecting an international group with diverse philosophies and research backgrounds.

Each chapter is approximately 6500 words in length. Chapters consist of approximately 10 printed pages each, ranging from 5 to 15 pages depending on the topic. Many chapters include tables and figures to better illustrate data. Authors were asked to summarize current knowledge in their areas without providing references within the text. Thus, the work reads like an encyclopedia, providing the reader with an overview of the state-of-the-art rather than an in-depth research report. A further reading and web site list are provided at the end of each chapter for those who require research references and more detailed information. In addition, an outline, glossary, list of keywords, and list of cross-references are provided for each chapter.

The hope is that this compendium will provide a universal platform for a more science-based approach to the study, prevention and treatment of addictions. The ultimate goal is to improve the lives of addicted individuals and their families throughout the world through a more comprehensive and detailed understanding of the addictive process.

VOLUME 3: INTERVENTIONS FOR ADDICTIONS

This third volume, *Intervention for Addictions*, provides chapters on psychosocial treatments, pharmacological treatments, provision of health care to addicted individuals, prevention, and public policy issues. Basically, this volume contains the practical application of the information in Volumes 1 and 2.

Historically, because of the lack of scientific studies at the time, treatment of addiction was based almost exclusively on personal familiarity (especially by counselors who were recovering addicts) and clinical experience. While this was standard care at the time such intuitive treatment has become increasingly unacceptable. The current emphasis on cost-effectiveness and accountability has led to a shift toward science-based treatments, i.e. treatments for which there is significant research evidence of effectiveness. Chapters in this volume describe each of these treatments, together with details of their use and evidence of their efficacy.

Chapters focus on both psychosocial treatments as well as pharmacological ones. Psychosocial chapters cover a wide range of treatment methods, ranging from traditional ones such as self-help/12-step programs to newer, innovative treatments such as contingency management. Chapters include a variety

of treatments from simple, time-efficient ones such as brief feedback (used primarily with nondependent heavy drinkers or binge drinkers) to more involved treatments including cognitive behavior therapy and multidimensional family therapy. The list of chapters on psychosocial treatments is extensive and includes not only widely used methods but also such specialized treatments as internet-based therapies, faith-based methods, criminal justice interventions, and mindfulness treatments. More challenging treatments such as those involving addicted individuals with psychiatric comorbidities are also included.

More recently, pharmacological treatments have been combined with psychosocial methods in an attempt to improve therapeutic efficacy. The explosion of neurobiological research on addictions (as provided in Volume 2) has led to the development and evaluation of new compounds that have shown great promise with some substances of abuse. For example, naltrexone, acamprostate, and topiramate have been used successfully to decrease cravings and relapse in individuals with alcohol dependence. Nicotine replacement preparations as well as sustained-release bupropion and varenicline are available for the treatment of tobacco use and, more recently, buprenorphine has dramatically improved the treatment of opiate abuse. Chapters on pharmacotherapies for each of the major substances of abuse as well as for behavioral addictions are included in this volume.

Another important issue that is addressed in this volume is the time gap between the development of both psychosocial and pharmacological treatments and their use in everyday practice by clinicians. Many are examining the barriers to practical implementation and, based on this information, are developing strategies to overcome them.

In addition to science-based treatments and their routine use in clinical practice, public policy and prevention are also important issues. Countries throughout the world, often with the help of the World Health Organization (WHO), are trying to prevent or slow the progress of addictions by focusing on legislative action, price controls, and limitations on advertising. In Europe, ALICE RAP, Addictions and Lifestyles in Contemporary Europe – Reframing Addictions Project, is an innovative and dynamic transdisciplinary European Union project that aims to help policy makers rethink and reshape current and future approaches to the human and economic costs of addictions and lifestyles in Europe. Receiving input from over 126 researchers (many of whom are authors of chapters in this volume) and 73 major research institutions representing 31 countries, this project will analyze a wide range of multidisciplinary

factors related to addiction to improve its prevention and treatment. This project is truly a prototype for advancing public policy interventions aimed at addictive behaviors and disorders.

Overall, this volume provides a detailed picture of the myriad of science-based interventions available for the treatment of addiction. With the expanding growth of

neurobiological research, newer and more effective pharmacological treatments should be available on the near horizon. Public policy interventions are increasingly being based on the scientific literature rather than political ideologies, leading to more effective prevention interventions throughout the world.

Peter M. Miller

Editors: Biographies

Peter Miller

Peter M. Miller, PhD, is a professor of psychiatry and behavioral sciences in the Center for Drug and Alcohol Programs at the Medical University of South Carolina. He also holds a faculty appointment in the College of Dental Medicine. He is a clinical psychologist and is board certified by the American Board of Professional Psychology. He specializes in research on alcohol and substance abuse screening and intervention in medical and dental settings, with particular reference to alcohol-sensitive diseases such as hypertension and oral cancer. He has published over 100 scientific articles, has authored 11 books and has served as editor on major addictions textbooks and reference works. He is editor in chief of two international research journals, *Addictive Behaviors* and *Eating Behaviors*, and serves on several editorial boards. He is past president of the International Society of Addiction Journal Editors (ISAJE).

Samuel Ball

Samuel A. Ball, PhD, is a professor and assistant chair for education and career development in the Department of Psychiatry at Yale University School of Medicine. He also serves as research director for the NIDA-funded Psychotherapy Development Research Center, NIH-funded BIRCWH Women's Health and Addictive Behaviors program, and The APT Foundation in New Haven, CT. His research focuses on the assessment and treatment implications of personality dimensions, personality disorders, and multidimensional subtypes in substance abuse.

Arthur Blume

Arthur W. Blume is a professor of psychology at Washington State University. Before joining the faculty at Washington State University, Dr Blume was on the faculty at the University of North Carolina at Charlotte and before that at the University of Texas at El Paso. He currently serves as a section editor for this volume, and as an associate editor of the journals *Addictive Behaviors* and *Cultural Diversity and Ethnic Minority Psychology*. From 2007 to 2009, he was an American Indian representative on the National Committee on Ethnic Minority Affairs of the American Psychological Association in the United States. His program of research has focused on addictive behaviors among high-risk populations, especially those from ethnic minority groups in the United States. His extramurally funded research and

publications reflect his keen interests in ethnic minority health and well-being.

David Kavanagh

David Kavanagh, PhD, is a research capacity-building professor in the Institute and Health & Biomedical Innovation and School of Psychology & Counselling at Queensland University of Technology, and has adjunct posts at the University of Queensland and Griffith University. He was educated at Sydney and Stanford Universities and led a community mental health service before becoming an academic. He has researched and written widely on addiction, comorbidity and dissemination of evidence-based treatments and is currently researching the elicitation and maintenance of functional motivation. He has been on the editorial boards of several journals, including *Addiction* and *Addictive Behaviors*, and has served on several state and national expert committees on comorbidity and addiction.

Kyle Kampman

A board-certified psychiatrist specializing in addiction psychiatry, Dr Kyle M. Kampman, MD, received his medical degree from Tulane University School of Medicine. He completed his residency in psychiatry and fellowship in addiction psychiatry at the University of Pennsylvania. Currently, he is a medical director of the Charles O'Brien Center for the Treatment of Addictions, professor of psychiatry, and medical director of the Treatment Research Center at the University of Pennsylvania in Philadelphia. His research interests include pharmacotherapy for cocaine dependence and the cocaine withdrawal syndrome. He is an associate editor of *Drug and Alcohol Dependence*. He serves on the editorial board of the *Journal of Addiction Medicine* and is an active member of the American Society of Addiction Medicine, College on Problems of Drug Dependence, and the Pennsylvania Society of Addiction Medicine. His contributions to the field have been acknowledged by the Scott Mackler Award for Excellence in Substance Abuse Teaching presented by the University of Pennsylvania School of Medicine and the Caron Foundation's Medical Professional-Physician Award.

Marsha E. Bates

Marsha E. Bates, PhD (Rutgers – the State University of New Jersey), is a research professor of psychology at the Center of Alcohol Studies (CAS) at Rutgers

University and an associate professor of psychiatry at UMDNJ/Robert Wood Johnson Medical School. She directs the Cognitive Neuroscience Laboratory that promotes translation between basic human experimental and clinical science. Her current multiinstitution research project is a component of the NIAAA Mechanism of Behavior Change Interdisciplinary Research Consortium (MIRC) which seeks to build novel approaches to alcohol-related problems via mechanism-based strategies. Dr Bates is vice-chair of the Rutgers Institutional Review Board for the Protection of Human Subjects involved in research. She is a member of the Behavioral and Social Advisory Council of ABMRF/The Foundation for Alcohol Research and vice-chair of the Board of Trustees of Alcohol Research Documentation, Inc. She is an editorial board member of the *Journal of Studies on Alcohol and Drugs* and a past associate editor of *Psychology of Addictive Behaviors* and *Alcoholism: Clinical and Experimental Research*. She is a fellow of the American Psychological Association (APA), previously served as president of APA Division 50 (Society of Addiction Psychologists), and received their 2011 Distinguished Scientific Contribution Award. Address: Center of Alcohol Studies, Rutgers – the State University of New Jersey, 607 Allison Road, Piscataway, NJ 08854, USA; E-mail: mebates@rutgers.edu.

Mary Larimer

Mary E. Larimer is a professor of psychiatry and behavioral sciences, an adjunct professor of psychology, associate director of the Addictive Behaviors Research Center, and director of the Center for the Study of Health and Risk Behaviors at the University of Washington. She received her PhD in clinical psychology from the University of Washington and has been a member of the faculty since 1995. Dr Larimer's research and clinical interests include (1) prevention and treatment of alcohol and drug problems among adolescents and young adults (with a particular focus on college drinking prevention), (2) cross-cultural research regarding prediction of initiation of drinking and trajectories of alcohol and substance use during emerging adulthood, (3) comorbidity of substance use with depression,

suicide, trauma, PTSD, disordered eating, and gambling problems, (4) evaluation of housing and treatment programs for chronically homeless and incarcerated individuals, and (5) dissemination of evidence-based prevention and treatment approaches into clinical-, school-, and work-site settings. She has published more than 100 articles and book chapters on these topics.

Nancy M. Petry

Nancy Petry is a professor of medicine at the University of Connecticut Health Center, and she earned her PhD in psychology from Harvard University. She developed the prize reinforcement system that has been widely disseminated in the context of treating substance use disorders and is now being applied to address other conditions including overweight/obesity, exercise, medication adherence, and diabetes. She also conducts research related to pathological gambling and its treatment.

Philippe De Witte

Professor De Witte heads the Laboratory of Behavioural Biology at the Université Catholique de Louvain. In 1987, he received a Fulbright grant to complete a specialization in brain research at the NIH. He has also worked as invited professor in Washington State University and the University of Colorado.

He is the editor in chief of *Alcohol and Alcoholism* and on the editorial advisory board of a number of leading journals. He was president of the European Society for Biomedical Research on Alcoholism (ESBRA) for two terms from 1993 to 2001 and was the president of the International Society for Biomedical Research on Alcoholism (ISBRA, 1998–2002). He joined the ERAB Advisory Board in 2003 and became chairman on 1 January 2007.

His research interests include pharmacology and neurobiology of addiction including therapeutics and treatments. He is a member of a number of professional bodies including ESBRA, ISBRA, RSA, The Belgian College of Neuropsychopharmacology and Biological Psychiatry (BCNBP) and the Société française d'Alcoologie (SFA) and has published over 200 articles in scientific journals, twice as many abstracts and book chapters.
