DEFINITION

Opinions vary regarding what exactly constitutes a brief intervention – many terms and definitions have been developed over the years, such as brief advice, feedback interventions, feedback evaluations, brief intervention, and minimal intervention. For the purpose of this entry, a brief feedback-focused intervention (BFI)

will be defined as an interaction addressing an addictive behavior lasting typically from 15 min to an hour in duration. The number of sessions can range from one to six, with the potential for follow-up contacts used to monitor the individual's progress. BFIs have been used therapeutically with a wide range of problem behaviors (e.g. alcohol and other drug use), with a typical goal of identifying a real or possible problem and motivating

the individual to take steps to change the behavior. These BFIs are delivered by trained interventionists, who provide the recipient personalized information regarding his or her substance use. The source of this feedback is typically an assessment of the behavior of interest. The complexity of this assessment varies as some assess only basic information (e.g. quantity and frequency of drinking), while others may also include problems and beliefs the individual may have related to their addictive behavior. Other BFIs may include laboratory analysis of blood or urine to evaluate the individual's health (e.g. liver damage).

BFIs can be confused with minimal interventions due to their shared emphasis on limited contact with the individual. Minimal interventions are defined as consisting of one contact with the individual, resulting in a therapeutic effect, which can be as short as 5 min. These treatments are usually based on self-help principles, and in some minimal interventions there is no face-to-face contact with a therapist: bibliotherapy (the use of books or written materials to address a behavioral or emotional problem) is an example. Minimal interventions have also been called "simple" or "brief" advice because it prescribes a certain change, yet does not specify a specific way to achieve this objective. In contrast, BFIs provide specific information regarding the behavior of interest as well as recommendations and strategies for change.

THE DEVELOPMENT OF BRIEF FEEDBACK-FOCUSED INTERVENTIONS

Over the past 30 years, BFIs have emerged as a promising option for reducing addictive behaviors. For example, such interventions have been used in the treatment of heroin addiction, helping individuals quit smoking, promoting cardiovascular health. Brief interventions have been used extensively in the treatment of alcohol abuse, with clients ranging from adolescent to elderly.

Since 1980, the World Health Organization (WHO) has been developing and implementing BFIs for individuals experiencing problems with alcohol. These efforts began with the recognition that there was not an efficient way to identify individuals who were experiencing a problem with alcohol. Therefore, Phase I of the WHO Collaborative Project in Identification and Treatment of Persons with Harmful Alcohol Consumption began in 1982, and led to the development of the Alcohol Use Disorders Identification Test (AUDIT). The AUDIT was developed to identify individuals who could benefit from a BFI in primary care settings. Phase II consisted of implementing a randomized

clinical trial implementing screening and BFI in primary health care settings, and Phase III focused on identifying the barriers to the widespread adoption of the BFI by general practitioners. Phase IV, currently underway, is to develop and implement strategies that would successfully implement the BFI in primary care settings in 13 countries around the world.

The Drinker's Check-Up (DCU) represents one of the first applications of administering BFIs in the general population. Advertisements were placed in newspapers and on a college campus that described the check-up as follows: "The check-up is not part of any treatment program, and it is not intended for alcoholics. Rather, it is an informal health service. Participants will not be labeled or diagnosed, and consultation is completely confidential. Objective personal feedback of results will be provided. It is up to the participant to determine what, if anything, to do about the feedback received." Individuals who responded to the advertisements were given the DCU, which consisted of a 2-h assessment followed by a 1-h feedback session. The assessment component consisted of measures that evaluated the quantity and frequency of alcohol consumption, blood tests designed to detect alcohol-related liver damage, and neuropsychological tests that were sensitive to drinking-related impairment. At a later date, the results of these tests were then provided to the individual in an empathetic, nonjudgmental way. Then, the participant was asked to discuss his or her feelings about the assessment results. Finally, the interviewer discussed possible change options with the participant.

The feedback interview in the DCU was done in the style known as motivational interviewing (MI). Such an interview approach is defined as a counseling style that is both client centered and directive and seeks to explore and resolve the client's ambivalence about engaging in a particular behavior. This exploration and resolution of ambivalence is done by the individual and not the interviewer, fostering a greater awareness of his or her problems with alcohol and the need to change. The interviewer's role is to listen and provide the necessary information and advice regarding the changes the client feels is needed. Above all, the interviewer takes care to avoid confrontation, a style that has been observed to result in client resistance and even increase in drinking.

ROLE IN OVERALL TREATMENT

In the context of the continuum of prevention developed by the Institute of Medicine in 2004, BFIs are typically used as a selective and indicated prevention strategy. Selective prevention targets individuals who are at risk for developing the problem behavior

(e.g. substance use). Indicated prevention efforts are appropriate for those who are already experiencing harm from the target behavior (e.g. individuals who are experiencing alcohol-related problems). In contrast, universal prevention efforts are provided to the entire population, and tend to be more didactic in nature and may not include the personalized feedback provided in BFIs. Furthermore, BFIs are not intended as a stand-alone treatment for individuals exhibiting alcohol dependence. Although these individuals may significantly change their alcohol use following a BFI, often the desired outcome is engagement in more intensive treatment.

GOALS OF BFIs

The nature of the outcome goal may play a role in the success of brief interventions. Recent BFIs, such as those conducted with college students, tend not to present abstinence as the only acceptable option. Rather, they reflect an approach more oriented toward raising the awareness of students about their drinking habits and the potential risks associated with it. This approach, identified as harm reduction, has become the focus of the majority of BFIs regardless of the target population (adults, college students, adolescents). This flexibility has been spurred by research indicating that a mandatory goal of abstinence may not be very productive for several reasons. First, the majority of individuals may not view themselves as problem drinkers, and may view abstinence as too drastic a response to their drinking, where instead, moderation of their drinking may be more appealing. Second, the limited contact the interventionist has with the BFI recipient may make it more productive to view abstinence as an ideal outcome but not as a necessary result of brief interventions. Third, long-term follow-ups of traditional alcohol treatment programs indicate that a goal of abstinence following an intervention may not be realistic. Research with adult drinkers indicates that about a third of the participants remained abstinent after 1 year; 4 years after treatment, less than 10% have remained abstinent.

For these reasons, many BFIs often adopt a harm reduction approach. Any movement of an individual on this continuum that reduces the amount of alcohol one consumes (and concordantly reduces the risk of negative consequences as a result of their drinking) is seen as a desirable result. This approach has been used with a number of addictive behaviors ranging from alcohol and drug use to gambling and has influenced several college drinking reduction efforts. An intervention approach that promotes moderate and responsible drinking may be received more positively by the

individual, and may in fact help to reduce the more problematic consequences of the targeted behavior.

A harm reduction approach is not without controversy, however, especially if the behavior is risky even in moderation (e.g. IV drug use) or illegal (e.g. underage drinking and smoking). In these situations, there is an ethical trade-off between encouraging a reduction in a risky behavior as opposed to focusing on an abstinence-only goal, which in turn may result in reactance or dismissal from the recipient.

PROPOSED ACTIVE INGREDIENTS OF BFIs

FRAMES

In a seminal article published in 1993, Miller and Sanchez reviewed the literature and developed an acronym to capture six important components of BFIs. These six elements can be remembered by the acronym FRAMES. First, Feedback is given to the client concerning his or her current addictive behavior. This can include such components as comparing individual use with national averages, problems resulting from use, and the harmful effects the behavior has on physical and emotional well being. This information alone can often motivate the client to realize the severity of his or her behavior, resulting in a desire for change. Second, an emphasis is placed on the client's Responsibility for bringing about such changes. The client is told that he or she alone is the one that can bring about desired changes. Third, clear Advice given to the client about how specifically to change one's current behavior can be influential and helpful. This advice may also consist of seeking further, more involved treatment. Fourth, providing a Menu of options for the client to follow is also helpful, instead of prescribing a predetermined or uniform change strategy. This provision of a range of options to decrease one's drinking lets the individual decide which approach is the most realistic. This decision, made by the individual and not the counselor, tends to enhance a commitment to change by one's self-selected method. Fifth, Empathy from the person conveying the information is vital to the process. It helps reduce the suspicion that the counselor may be judgmental, or have a hidden agenda to coerce the client into a form of treatment against his or her will. Confrontational attitudes (e.g. "you have a problem and you are going to listen to me") can often lead to resistance and even increased drinking. The goal of using an empathetic approach is to maintain the client's receptivity to the feedback and avoid defensiveness. A nonconfrontational, empathetic approach is especially important as many individuals are not likely to accept labels such as

alcoholic or problem drinker. Sixth, when a sense of Self-efficacy can be fostered, the client will be much more likely to change his or her behavior. Self-efficacy has been described as a person's belief in one's own ability to succeed in obtaining a certain goal or task. With a sense of self-efficacy, an individual can develop a sense of optimism and hope to change their addictive behavior.

The use of personalized graphic feedback summaries during the brief motivational intervention helps illustrate an individual's drinking behaviors and associated risks as reported in previously collected self-report data. Participants may complete a comprehensive battery of instruments examining the addictive behavior and other risk factors. A personalized feedback form is then created using the participant's most current information related to a summary of behavior, comparison to population drinking norms, risk factors (e.g. family history), cognitive factors (e.g. beliefs about the behavior's effects), and consequences associated with the addictive behavior. The personalized feedback offers an outline and structure for client discussions about current and past behavior. It is believed that providing participants with results from survey data in a graphic form contributes to increased comprehension and retention of material.

MI

Many BFIs are delivered using MI. MI is a therapeutic style of communication that is directive and client centered that facilitates behavior change through the exploration and resolution of ambivalence regarding a specific behavior (e.g. alcohol use). MI has also been described as an approach that combines both style (e.g. empathy) and technique (e.g. reflective listening). Specifically, the interviewer helps the individual explore and resolve ambivalence about reducing one's alcohol use. The interviewer creates an atmosphere of collaboration during the session: the individual is not told what to do. Instead, the interviewer adopts the role of a consultant who listens to and gently directs the individual toward a greater understanding of problems and options for change. It is emphasized that the individual alone is responsible for any changes that are made. Above all, the interviewer avoids being confrontational, a style observed to result in client resistance and even increased drinking. Overall, this gently guided self-evaluation of personal drinking fosters a greater awareness of the individual's problems with alcohol and the need to change. It is possible that the style of the interviewer (expressed empathy, collaboration, etc.) and the individual (e.g. disclosure, cooperation, engagement) may also influence changes that occur following an intervention.

Readiness to Change

Many recipients of BFIs are at risk for problems related to their addictive behaviors but have not looked for information or help for their problem. Individuals may be unaware that their behavior is not typical, and most likely have not sought formal treatment previously. Therefore, any BFI should be adaptable to differing willingness to recognize a drinking problem, a range of severity of problems experienced as a result of drinking, and variable motivation to change.

It has been difficult to specify exactly what process occurs when an individual seeks to change an addictive behavior. The transtheoretical model of behavior change, initially conceptualized in the early 1980s by James Prochaska and Carlo DiClemente, proposes that the individual progresses through five phases, or stages, of change. The stages of change model posit five phases of the change process. First, an individual is in the *pre-contemplation* stage when he or she is unaware of any potential problems related to his or her addictive behavior, and as a result see no reason to change. If individuals in this stage are told they have a problem, they will often react with surprise instead of evasiveness and anger. In this stage, others may see the individual as having difficulties, and may urge the individual to seek treatment (family members, concerned friends, employers). The next stage is one of *contemplation*, where the individual experiences more ambivalence. A student may know that he/she has a problem, but also feels changing current behavior is too drastic a response. The person can see the advantages and disadvantages of either continuing or cutting down on the addictive behavior, and feels ambivalent regarding the two options. At this point, arguments emphasizing the negative consequences of drinking can often drive the individual to defend the benefits of his/her current addictive behavior.

Eventually, the individual may arrive at the realization that he or she has to reduce the current level of use. This can be brought about by a particular event, personal enlightenment, or the BFI. The individual has entered the *preparation* stage, in which a willingness to cut down on the addictive behavior is present. The motivation is there, and there is likely to be some small changes in the behavior – the individual now just needs to take effective action. The next phase is the *action* stage, when the individual sets about changing the addictive behavior. Once the individual has initiated changes and begins moving toward reducing the addictive behavior, there are two possible paths he or she may take. The first is *maintenance* of the desired changes can occur. Maintenance is defined as continued commitment to sustaining a new behavior, typically lasting between 6 months or more. During this period, individuals

develop a plan for follow-up support, they reinforce internal rewards, and, critical to the continued success of behavior change, they discuss coping with potential relapse. Often during the maintenance stage the integration of family, friends, and other support services is essential to sustained behavior change. The second path after an initial behavior change is a *relapse*. Relapse is identified as resuming old addictive behaviors and can often be the result of a trigger, a lack of motivation to maintain reductions in the addictive behavior, influence by barriers to sustained behavior change, and a lack of strong coping strategies. Once relapse has occurred, the individual may return to the earlier stages (except contemplation).

The benefit of a BFI is that it can provide a flexible mechanism to increase an individual's readiness to change, regardless of the baseline stage occupied. Using heavy drinking as an example, those that are unconcerned about their heavy drinking could benefit from the BFI through raising personal awareness of alcohol-related problems, altering their perceptions of surrounding alcohol norms, and increasing their knowledge about alcohol's effects on their body and mind. Being exposed to such information, especially when presented in a nonconfrontational manner, may move people farther along the stages of change. As for the individuals who recognize that they drink excessively and are prepared to change their alcohol consumption, the goal of the intervention can be to mobilize them into action. The content of their brief intervention can focus on concrete options that help them attain this goal. Therefore, a major advantage of BFIs are their flexibility in dealing with individuals at different levels of readiness to change. For those individuals who are ready to change, this type of intervention may bring about self-initiated reductions in the addictive behavior and related risks. For individuals who are precontemplative or contemplative, the awareness raising may increase their receptivity to change at a later date.

Assessment Reactivity

The simple act of collecting such information may also bring about a change following a BFI. Very often, control group individuals decrease their drinking after being evaluated. This occurs in research with adults as well as college students. Therefore, assessment does not appear to be a neutral event and its influence on alcohol use is not fully understood. In most brief interventions, the information gathered during assessment is presented to the individual in another session, and care is taken to present such material in an empathetic, nonjudgmental way. The assessment feedback is discussed, and options are formulated to reduce alcohol

consumption or otherwise reduce the risk of harm to the individual.

BEHAVIORS ADDRESSED BY BFIs

BFIs have addressed a wide range of addictive behaviors. Perhaps alcohol use has received the most attention, and there have been many BFIs developed for alcohol use, in the adult (e.g. drinker's check-up) and adolescent population. These interventions traditionally use personalized feedback, however, the information provided varies widely (e.g. basic quantity-frequency of the behavior, consequences experienced laboratory results of liver functioning). These interventions have been associated with significant reductions in both alcohol use and alcohol-related problems.

Smoking

BFIs have also been developed for smoking, with feedback topics including costs of smoking, results of carbon dioxide levels in the lungs, and other physical markers related to cigarette use (e.g. genetic susceptibility to cancer). Perceptions about cigarette use (expectancies about use, aspects of smoking that are particularly troubling or enjoyable, motivation to quit) have also been provided in BFIs with smokers.

Gambling

Gambling has been addressed using BFIs with personalized feedback including frequency and time spent gambling, money lost and won while gambling, types of gambling activity, and costs of gambling behaviors (legal, relationships with others). Recent research suggests that these interventions can significantly reduce gambling behaviors and consequences.

Sexual Risk

BFIs have addressed sexual risk behaviors in the context of addictive behaviors and as a multi-risk approach (combined alcohol and sexual risk behaviors) to intervention. Topics of personalized feedback have included frequency and type of protected and unprotected sex, consequences of sexual behaviors, perceptions of sexual risk, expectancies regarding sexual behaviors, and the use of drugs and alcohol while engaging in risky sex. These interventions have been associated with reduction in the occurrence of risky sex and an increase in protective behaviors. To date, however, multi-risk BFIs have had limited success in reducing concurrent risky behaviors.

Other Behaviors

BFIs have been implemented with marijuana use, caffeine use, smokeless tobacco, indoor tanning, and a variety of other addictive behaviors. However, these approaches have been studied much less than BFIs for alcohol use, and their efficacy has yet to be determined.

FEEDBACK CONTENT

Occurrence of Target Behavior

The BFI most often contains a description of the behavior the BFI is targeting. For example, in a BFI addressing alcohol use, the individual's typical and quantity of drinking would be provided (e.g. you reported that in the past month you typically consume alcohol 5 days per week, consuming 3–5 drinks per occasion). A number of other aspects of the behavior may be reported such as peak episodes of consumption, percent days abstinent or using over a certain time frame, or types of alcohol typically consumed.

Personal Problems Associated with Target Behavior

BFIs can also include a section detailing problems related to the target behavior. This section typically consists of two types of problems – problems the individual has already experienced as a result of his/her use (e.g. fights, hangovers), and/or problems that he/she is at risk of experiencing if they continue to use substances (e.g. cancer, death).

Norms

Norms can be conceptualized as a perception of the behaviors and values that are deemed acceptable by members of a group. Two types of norms have been commonly assessed in the addictive behavior research literature: descriptive and injunctive norms. Descriptive norms refer to the perception of other's quantity and frequency of the addictive behavior (the norms of "is") – these are largely based on observations of the addictive behavior. Injunctive norms refer to the perceived approval of the addictive behavior (the norm of "ought"). These norms represent the perceived moral rules of the peer group. Injunctive norms assist an individual to determine what is acceptable and unacceptable social behavior. Both descriptive and injunctive norms have been linked to addictive behaviors, perhaps most extensively to alcohol use in the college setting. Descriptive and injunctive norms have therefore been incorporated most commonly in brief

motivational interventions (BMI) with this population. It is hypothesized that when personal alcohol consumption levels, and their approval of drinking, are revealed to be higher than relevant norms, a decrease in alcohol use may be triggered as the individual attempts to conform to the actual, more conservative norm. Indeed, changes in estimates of drinking norms mediated reductions in alcohol use following a BMI.

Alcohol-Related Expectancies

Alcohol expectancies are beliefs about the cognitive, affective, or behavioral effects of alcohol use and can be both positive (e.g. "drinking allows me to relax around others") and negative (e.g. "when I drink, I often say things I regret later"). Expectancies appear to have both etiological and maintaining influences on alcohol use, especially positive expectancies and social/physical pleasure expectancies. Dose-related expectancies have been addressed in "expectancy challenge" interventions with college students. For instance, a person who believes that he/she has to consume four to five beers in an hour to become fully relaxed and sociable is provided information on how certain amounts of alcohol affect one's mood and judgment and how lower blood alcohol levels have corresponding positive effects on mood. In this way, expectancy challenges may prompt one to consume less alcohol without sacrificing the desired and expected positive effects of drinking. Expectancies appear linked to subsequent reduction in alcohol use following expectancy challenges with college students, although they have not yet been formally demonstrated to mediate drinking reductions following a BMI. It is possible that students with fewer positive alcohol expectancies may be more responsive to an intervention addressing their drinking.

Strategies to Reduce Risk

BFIs can often include specific strategies to reduce risk, often linked to the behaviors and consequences the recipient has endorsed. These are often identified as "protective behaviors." For example, if drinking and driving have been endorsed, a provided strategy may be "Always designate a sober driver at the beginning of the evening." Other feedback can endorse specific skills, such as alternating alcoholic drinks with nonalcoholic drinks (alcohol use), staying away from casinos, and not carrying a credit card or checkbook (gambling).

Other Feedback

BFIs have a wide range of topics. For example, over 60 types of feedback have been presented in BFIs

addressing college student drinking, such as estimated blood alcohol levels, personal motives for drinking, caloric intake, and the financial costs of drinking. Many of these feedback components have been used to address other addictive behaviors (e.g. financial costs of smoking), as well as ones specific to the addictive behavior (e.g. gambling losses). Undoubtedly, more feedback components will be developed through advancements in our understanding of addictive behaviors.

MODALITIES

Individual

The most common form of BFIs is still one-on-one, in person. In this context, the individual is provided personalized feedback and discusses it with a professional. The content and depth of discussion of these BFIs vary widely.

Group

While group therapy has a long history, group BFIs have a more recent development. Specifically, group BFIs provide the entire group of individuals with information regarding the addictive behavior of interest. Within BFIs delivered to college students surrounding alcohol use, group-based BFIs have been shown to reduce drinking behaviors with students mandated to treatment following a campus alcohol violation. To date, group-based BFIs success has been limited to this specific population; however, similar approaches for other addictive behaviors (gambling, smoking cessation) and other populations (adults, adolescents) are currently being explored. One promising approach that has been implemented is the real-time presentation of normative feedback. Specifically, members of the Greek system used personal digital assistants (PDAs) to provide estimates of their own drinking, that of their peers in the room, and of the typical student on campus. The students type in their estimates on the PDA and then the results of this survey are displayed immediately to the group. As a result, the students were able to see the accuracy of the estimates they had made seconds before regarding the drinking behaviors and approval of drinking of the individuals in the room with them. Reductions of both normative perceptions and alcohol use have been observed following this BFI in members of the Greek system. However, this innovative approach has yet to be implemented in other populations.

Mailed

In the early days of BFIs, personalized feedback forms were mailed to individuals via standard mail and the content of the feedback was discussed via telephone. However, given the advances in the Internet and concerns regarding confidentiality (e.g. someone else opening the mail), email and the use of encrypted files (which can only be opened by the intended recipient) have become much more common. Usually, these interventions have contact numbers to call to discuss the provided information or to engage in formal treatment for the behavior addressed.

Internet

In the past 10 years, there has been a considerable increase in websites that can generate personalized feedback regarding a variety of behaviors, ranging from alcohol use, marijuana use, to eating habits. These websites simply require the individual to provide personal information about their current drinking and/or other drug use behaviors. Once information is entered, a personalized web-based feedback is immediately generated offering concrete information use patterns, risk profiles, and consequences of current use. The information presented is similar to what is created for one-on-one, in person BFIs, however, no face-to-face meeting occurs and the individual views the information independently. Early research suggests this approach has some benefits with high-risk drinking populations (e.g. first-year college students).

Peer-Based Intervention Approaches

Peer-based intervention and education programs have been found to be effective in creating behavior change in college students for a variety of behaviors (e.g. safe sex, alcohol and drug use). It is possible that students relate better to peers than to older adults, peer-delivered programs have a stronger influence on students' attitudes and behavior, and using upper class students to implement substance abuse programs may be effective for first-year students. More recently, a trend toward incorporating peer counseling into alcohol interventions has led to new applications for motivational feedback approaches. A number of studies have examined the use of peer-based techniques to effectively impact drinking behaviors and consequences. Only skills-based group approaches, an education approach based on norms information, and an individually based motivational intervention have been efficacious in reducing alcohol use and consequences. Peer-led BFIs have also been found to be efficacious for enhancing drinking behavior changes. This intervention includes

a one-on-one discussion about personal drinking behaviors, accurate normative drinking information with comparisons to perceived normative beliefs, negative consequences, and information on drinking reduction techniques.

POPULATIONS

Adolescents

A range of BFIs for adolescent populations have been tested to reduce and eliminate harmful behaviors associated with substance use. Specifically, in person BFIs, family-based BFIs, and parent-based BFIs. Each approach works toward the goal of reducing harms associated with substance use.

College Students

As a reaction to high levels of alcohol use and associated negative consequences among college students, various BFIs aimed at reducing harm and high-risk drinking behaviors have been developed. Specifically, BFIs with peers and professional counselors, personal feedback (mailed or computerized) on drinking behaviors, group-based education and/or motivation feedback classes, and expectancy challenge based interventions have all been evaluated in recent years.

Noncollege Adults

Community samples, including those recruited from hospital emergency departments, in- and out-patient psychiatric hospitals, and general community members have also been the target population for a range of BFIs. These have been delivered in person, via telephone, and web-based with general success in reducing harmful behaviors.

SUMMARY

BFIs have been implemented in a wide range of settings due to their ability to address a wide variety of behaviors. Research supports their efficacy, although further work is needed to better understand exactly how individual behavior change is facilitated. Furthermore, the different types of feedback that can be provided in the context of a BFI has increased exponentially as a result of ongoing dissemination efforts addressing different behaviors and populations. Advances in research have also led to innovative feedback topics such as genetic susceptibility to alcoholism and smoking, as well as more sophisticated presentation delivery

methods (e.g. via web or video). In sum, the combination of empirical support, improved understanding of how BFIs can bring about change in recipients, increased dissemination efforts, and ongoing innovation regarding the content and presentation of feedback topics have ensured a central role of BFIs in future prevention and intervention efforts addressing addictive behaviors.

List of Abbreviations

AUDIT	Alcohol Use Disorders Identification Test
BMI	brief motivational interventions
DCU	Drinker's Check-Up
PDA	personal digital assistant
WHO	World Health Organization

Glossary

- Brief feedback-focused Interventions (BFI)** an interaction addressing an addictive behavior lasting typically from 15 min to an hour in duration.
- Feedback** verbal or written information regarding the addictive behavior that is provided and discussed during a BFI.
- Motivational interviewing (MI)** a counseling style that is both client centered and directive and seeks to explore and resolve the client's ambivalence about engaging in a particular behavior.
- Norms** a perception of the prevalence of addictive behaviors (descriptive norms) and approval of these behaviors (injunctive norms) by members of a group.
- Transtheoretical model** a theoretical conceptualization of the process the individual undergoes when attempting to reduce or cease an addictive behavior (stages of change).

INTRODUCTION

Enhancement of an individual's motivation to change is an important component of interventions for addictive behaviors. People who believe they have alcohol or drug use problems and commit to changing them are more likely to engage in treatment and have improved outcomes. Motivational enhancement approaches for substance-use disorders have become increasingly popular during the past two decades. Foremost among them is motivational interviewing (MI) developed by William Miller and Stephen Rollnick. This chapter describes what MI is and is not, its basic principles and techniques, empirical support, applications to areas likely to co-occur with addictions, how to learn MI, dissemination of the approach, and future research directions.

WHAT IS MOTIVATIONAL INTERVIEWING?

Miller and Rollnick have defined MI as a person-centered counseling method for eliciting and strengthening personal motivation for change. The approach is grounded in humanistic psychology, especially the work of Carl Rogers, in that it employs a very empathic, nonjudgmental style of interacting with peoples and presumes that the potential for change lies within everyone. MI is distinct from nondirective approaches, however, in that practitioners intentionally attend to and selectively reinforce people's motives that support change. Over the course of the interview, practitioners help people identify these change-oriented motives, elaborate upon them, and resolve ambivalence about change. If successful, people become more likely to

commit to changing their behaviors and initiating a change plan.

The process of enhancing motivation in MI can be thought of as having two different phases. The first phase involves building motivation for change. In this phase, practitioners work with people to understand and resolve their resistance to change and develop their sense of the importance and perceived ability to change. When people show signs of readiness to change (e.g. reasons for change are prominent, they ask for advice or direction, they state their intention to change), practitioners shift to the second phase of motivational enhancement in which they work toward strengthening commitment to change, most often through the development of a change plan (described below). This process activates or mobilizes people's motivations in that individuals identify how they will try to change and begin to enact these steps to reduce or stop their addictive behaviors.

Skilled practitioners try to match their use of MI strategies to the individual's level of motivation. For example, practitioners move more quickly to change planning with people who are already motivated to change. Extensive exploration of their motives for change might frustrate people who want to move forward. In contrast, attempting to develop change plans with people who are not yet committed to change will likely increase resistance in that this strategy would put people in a position in which they might assert in words or in actions how they are not yet ready. This latter interaction illustrates how motives to change (called "change talk") and motives to stay the same (called "sustain talk") can be thought of as opposite sides of the same coin, meaning that if practitioners give insufficient attention to addressing important issues that impede change, people are likely to raise these issues again during the interview. Concomitantly, practitioners expect people who initially argue against change to have some intrinsic motivation for change within them. It is the responsibility of the practitioners to look for opportunities to draw it out.

MI is best construed as a style of communication that informs the way in which practitioners interact with others throughout the change process. In this regard, MI often is discussed within the context of the stages of change model by James Prochaska and Carlo DiClemente. The stage of change model posits that behavior change occurs sequentially across recurring stages. The earlier stages include precontemplation (people are unaware or do not believe there is a problem or need to change it), contemplation (people are ambivalent about recognizing a problem and shy away from changing it), and preparation (people are ready to work toward behavior change in the near future and develop a plan for change). The later stages include

action (people consistently make specific changes) and maintenance (people work to maintain and sustain long-lasting change). Tailoring treatment strategies to achieve stage-related tasks is a hallmark of this model (e.g. conducting a cost-benefit analysis for someone contemplating change).

MI naturally fits into the stage of change model in that it can be used to help move people from one stage to another, especially in the early stages. Person-centered counseling skills may build rapport and engage people who are less motivated to change. Eliciting additional change talk might lead ambivalent individuals to conclude it is relatively worth it for them to change rather than to keep drinking or using drugs. Working with people to identify steps they are able to take might help them feel more prepared to initiate a change plan. In later stages, MI strategies are useful for attending to wavering motivation as people take action or try to maintain changes in stressful situations. Finally, the stages of change model illustrates how MI integrates well with other treatment approaches that are more action-oriented. For example, MI might be used to engage people in treatment that then teaches them relapse prevention skills. The combining of MI with more action-oriented treatments, such as cognitive behavioral therapy, is becoming more prevalent.

MI emerged out of early efforts to establish brief interventions for alcohol problems. These interventions shared a harm reduction approach in that they aimed to help people move toward reduced drinking to lower risks rather than to automatically advocate for total abstinence as the only acceptable goal. Common components of these brief interventions, as represented in a FRAMES acronym, were Feedback, emphasis on personal Responsibility, Advice, a Menu of options, an Empathic counseling style, and support for Self-efficacy. With FRAMES as a guidepost, William Miller and his colleagues developed the "drinker's checkup" in which people received feedback about their drinking relative to population or clinical norms and then explored what it might suggest about their drinking and motivation for reducing or stopping it. Early studies found the drinker's checkup to be quite effective. Given this success, MI with personalized assessment feedback then became adapted into a more structured and manualized format and termed motivational enhancement therapy (MET). The efficacy of MET, compared to cognitive behavior therapy and 12-step facilitation, for alcohol-dependent adults, subsequently was tested in a large-scale, multi-site study conducted in the United States called Project MATCH. MET was found to be as effective as the other treatments overall, though it achieved these effects using fewer treatment sessions.

Finally, as implied in the above discussion, MI is behaviorally specific and has direction. This means

that practitioners need to be clear about what it is that they are trying to motivate people for. Motivation for change in one area does not guarantee motivation for change in another (e.g. a person may commit to cocaine abstinence, but not agree to reduce or stop drinking or smoking marijuana or to enter an addiction treatment program). Each behavior may require a separate motivational enhancement process. MI also requires that practitioners take a stance about the preferred direction for change. For addictive behaviors, this decision is relatively clear in that most people would agree that it is ethically sound to enhance motivation for the reduction or cessation of substances that are potentially harmful or hazardous. However, some behavioral issues do not have a clear change direction. For example, decisions about organ donation or pregnancy termination likely would require a nondirective approach in which practitioners suspend their own values or goals and assume a position of “equipose” (i.e. indifference or no clear attachment to a position or recommendation). In these situations, a person-centered counseling approach, devoid of evocation, would allow people to explore their ambivalence without intentional practitioner influence.

WHAT IS NOT MOTIVATIONAL INTERVIEWING?

For clarification purposes, it is helpful to consider what MI is not. Most antithetical to MI is a disease concept model of addiction in which individuals are seen as denying or rationalizing their addictive behaviors and needing to “hit bottom” before they will change. The use of direct confrontation, surrendering and accepting one’s powerlessness and loss of control in the face of addiction, and emphasis on total abstinence as the only acceptable goal are hallmarks of this approach and quite inconsistent with MI. Less obvious are several common misconceptions about MI. As noted above, MI is not based on the stages of change model, though it is complementary to it. Stages of change is more of a comprehensive way of thinking about how people change, whereas MI is a clinical method that helps people prepare for change. Likewise, MI is not cognitive behavioral therapy. The latter approach supplies people with education and coping skill development and encourages the repeated practice of these skills to better manage their problems. MI is fundamentally humanistic, not behavioral, in origin in that it elicits the people’s motivations for change rather than putting in place what is missing (knowledge and skills). MI also is not a way of manipulating others or making them change when they do not want to. Behavior change in MI is born out of a person’s intrinsic motivations. Practitioners can only call forth motivations that already

exist within people, not impose upon them other people’s concerns or wishes when individuals do not see these issues as in their best interests. Finally, MI does not require that practitioners conduct a decisional balance or provide personalized feedback. These are techniques that often are helpful for eliciting change talk, but they are not essential to the conduct of MI, and they often are used in other treatment approaches. In this regard, MI is not a series of techniques, but rather a way of being with people in which principles organize the practice, as Miller and Rollnick put it, like music to words of a song.

PRINCIPLES

Four key principles, embodied in the REDS (rolling with resistance, express empathy, develop discrepancy, support self-efficacy) acronym, compose the manner in which practitioners interact with people when using MI.

Roll with Resistance

Resistance in MI traditionally has referred to people’s statements about what sustains their problematic behaviors. These expressions may be about the reasons for the behaviors (“Drinking relaxes me”) or the difficulties of trying to change them (“I can’t resist the urge to smoke”). Resistance informs practitioners about dilemmas faced by individuals, thereby providing opportunities for addressing obstacles to change. Practitioners avoid adopting a confrontational, authoritative, warning, or threatening tone (all inconsistent with MI), which might cause others to become even less engaged in treatment.

Express Empathy

Practitioners attempt to accurately understand people’s dilemmas without judgment or criticism. Being able to listen carefully to what people mean and reflect this back to them is a critical skill. People are more likely to explore their motivations for change and speak candidly when they feel comfortable with and understood by their practitioners.

Develop Discrepancy

Motivation for change often depends on the existence of a discrepancy between an individual’s current behavior and important values or goals. For example, a teacher who prides herself in being a positive role model for her students might stop smoking marijuana if she believes this behavior is discrepant with what she would want her students to know about her. In

MI, practitioners reflect these discrepancies and explore how behavior change might help people feel they are acting in accordance with their preferred self-perceptions and aims.

Support Self-Efficacy

People typically become more motivated when they believe they can change their behavior. When people lack confidence, they often shy away from change. Practitioners look for opportunities to support people's self-efficacy by helping them recognize their personal strengths and available resources. Likewise, they pay attention to people's past successful change efforts, which might inform how these individuals approach their current dilemmas.

By embracing these principles, practitioners adopt a style of interaction, that is, (1) collaborative by demonstrating respect for people's ideas and goals and seeing others as equal partners in the therapeutic process, (2) evocative by intentionally searching for the people's motives that favor change, and (3) supportive of people's autonomy and capacity to make decisions and initiate change. These three components embody the spirit of how practitioners interact with others (formally referred to MI spirit in this approach).

TECHNIQUES

While MI is more of a style or spirit of being with others based on the above principles rather than a mere application of techniques, MI incorporates several techniques that operationalize how practitioners use MI. These techniques include fundamental strategies, sometimes called microskills (open questions, affirmations, reflections, and summaries), and direct methods for evoking change talk. Practitioners attend to the balance of statements made by people that support or thwart behavior change (i.e. change versus sustain talk) to gauge individuals' level of motivation and adjust their use of MI techniques accordingly. Practitioners' capacities to recognize and elicit change talk and reduce sustain talk through the use of these techniques, with the aim of strengthening people's commitment to change, are seen as necessary elements in MI.

Fundamental Strategies

Open questions, affirmations, reflections, and summaries (OARS) are the mainstay of all MI sessions. In particular, MI relies heavily on the skilled use of reflective listening in which practitioners restate or paraphrase their understanding of what people have said to express empathy, as well as to bring attention to

ambivalence, highlight change talk, and explore and lessen resistance. Reflections are coined "simple" in MI when practitioners essentially repeat what others have said and "complex" when practitioners have articulated new meaning implied by the original statements. Complex reflections demonstrate a deeper understanding of people's experiences. For example, a person concerned about her HIV status says, "I've played around a bit in the past several months, but last year when I had a HIV test, I was negative." A practitioner could use a simple reflection to encourage more discussion about her risk behavior ("You've played around a bit"). A complex reflection would capture her implied concern and show more empathy ("You're a little worried that you have put yourself at risk for HIV").

Open questions encourage people to talk more and may be used to strategically draw out motivations for change (e.g. "What would be good about not smoking?"). They stand in contrast to closed questions, in which, practitioners seek specific information (e.g. demographics, history, symptoms), often with questions that can be answered with a "yes" or a "no" response. For example, a practitioner might ask, "Has your depression worsened with your crystal meth use?" A person's positive response would support not using crystal methamphetamine; however, he or she would not have fully elaborated on the negative effects of depression resulting from drug use, which an open question might have elicited (e.g. How has using crystal meth negatively impacted your depression?). Affirmations (i.e. acknowledgment of a person's strengths, attitudes, and efforts that promote behavior change) build collaboration between practitioners and others and promote self-efficacy. Sometimes, this entails reframing a behavior in a manner that helps people see it in a more positive light (e.g. "You were quite determined to get high, and now you are trying to use that same determination to stop using cocaine").

Summaries provide opportunities for practitioners to demonstrate fuller understanding of other people's experiences and help them consider the bigger picture of their motivations for change. Summaries also allow practitioners to collect multiple change talk statements as a strategy to enhance motivation, link discrepant statements that capture ambivalence, and shift focus to other behavioral areas (e.g. move from discussing drinking to prescription opiate use). The following is an example of a collection summary of change talk: "You're concerned that you have been taking more pain meds than you are prescribed, and you've noticed you need more pills to get the same effect. You feel badly about going to a doctor other than your primary care physician to get percocet when you ran out. Most importantly, you almost fell asleep at the wheel last week with your kid in the car, and you think that this literally is

your wake-up call to do something about this problem before something terrible happens to you and others.”

Direct Methods

Direct methods for evoking change talk hinge on the capacity of practitioners to recognize how people talk about change. Practitioners' selection of direct methods for motivational enhancement depends on the type and strength of change talk provided by people as the interview unfolds. Hence, an individual's statements continuously signal the practitioner about how to conduct the interview.

Change talk is embodied in the acronym DARN-CAT (desire, ability, reasons, need, commitment, activation, taking steps). DARN (desire, ability, reasons, need) is sometimes referred to as preparatory language in that these statements represent the building of motivation that prepares people to make a commitment to change (consistent with the first phase of motivational enhancement). Desire statements indicate a clear wish for change (“I don't want my liver disease to get worse” or “I want to get my life back”). Ability statements indicate people's beliefs that they can change, given their skills and available resources (“I was able to stop using speed 5 years ago, so maybe I have a chance now”). Reason statements note the benefits of change and the costs of not changing (“I will have more money in my pocket” or “If I don't stop, I will go more in debt”). Need statements underscore how the problem behavior interferes with important areas of an individual's life and how changing the behavior would likely improve matters (“I don't even recognize myself; I can't go on like this anymore”).

CAT (commitment, activation, taking steps) represents statements that suggest people are mobilizing themselves for change (consistent with the second phase of motivational enhancement). Commitment statements convey the stated intention to change (“My quit date will be this Thursday”). Activation statements indicate how people are getting ready to change (“I am going to an AA meeting tonight”). Statements about taking steps to change are the strongest demonstration of commitment in that the people have put their words into action and are reporting these early efforts to the practitioner (“Instead of going out to drink after work, I went to the gym and worked out”).

During the interview, practitioners identify the extent to which people express motivation in each of these areas, use their fundamental skills to support and develop people's change talk and have them elaborate further, and in a goal-oriented fashion, directly attempt to draw out more motivations for change. MI offers multiple techniques for these purposes. For example, people who consistently report obstacles to being able to stop smoking marijuana might be asked about past

periods when they have smoked less marijuana or none at all (appealing to past successes to enhance ability). People who do not express much concern about their current levels of drug use might be asked to look to the future at some time interval (e.g. 1 year from now) and consider where their lives might be headed with continued use (attempting to reveal potential reasons or need to change to enhance the importance of change). Alternatively, a practitioner could ask someone to rate how important it would be to reduce or stop drug use on an 11-point scale, with zero representing “not at all important” and ten representing “extremely important.” Providing this person gives a response higher than zero, the practitioner would follow-up by asking, “Why not lower, like a zero?” to elicit what lends some importance to changing drug use now.

Other Useful Techniques

Addiction treatment typically requires simultaneous attention to several behavioral issues (e.g. multiple substance, HIV risk behaviors, psychiatric, and health concerns), and this reality often is overwhelming to people and their practitioners during any one appointment where time is limited. Practitioners can use a simple agenda setting chart in which they record the pertinent behavior change issues on paper and have people indicate which of them they want to discuss during the interview. These priorities are then dovetailed with any pressing practitioner concerns as a means to organize the conversation.

Education, advice-giving, and direction are commonplace in the addiction treatment, particularly because practitioners often have a natural tendency to try to fix people's problems (referred to as the “righting reflex”). When people have not solicited professional input, however, they may not be receptive to it. Instead, practitioners ask permission to provide information or advice and employ an elicit-provide-elicited (or ask-tell-ask) technique in which practitioners (1) elicit from people what they know about the topic being discussed, (2) provide information as needed, and (3) elicit people's reactions to the shared information. For example, a practitioner may wish to recommend a treatment program to someone. Instead of providing the recommendation in an unsolicited manner, the practitioner would first ask the person what he or she knows about the program and then, with permission, talks about it and concludes by getting the person's reaction. This technique promotes collaboration and reduces the chance that people experience their practitioners as lecturing or telling them what to do.

Use of a decisional balance activity (i.e. exploring the costs and benefits of changing and not changing) is common in MI. This activity provides a structured method for understanding the basis of a person's

ambivalence in that the benefits of change (“I’ll have more money if I get a job”) and the costs of not changing (“If I don’t seek employment, I will feel like I have given up on myself”) provide reasons to change, whereas the benefits of not changing (I don’t have to present myself in an interview”) and the costs of changing (“I don’t have transportation”) provide reasons to remain the same. By strategically eliciting more reasons for change and, to the extent possible, resolving reasons to remain the same (e.g. practice interviewing, resolving transportation issues), a practitioner might help the person tip the balance toward change.

Another important skill is how to gauge patients’ readiness to change and to transition from the first to second phase of motivational enhancement. Practitioners typically recapitulate what others have said, especially those statements that suggest how they are now ready to change. Following this summary, practitioners then pose a key question to solidify commitment to change (“What’s your next step?” or “From what you’ve told me, how do you want to proceed?”). Miller and Rollnick have used the analogy of a person as a skier standing at the summit (assisted up the mountain by the practitioner). The key question provides a supportive nudge that helps the person go down the mountain.

Change planning is an overall strategy practitioners use to negotiate a plan with people about how they will change their behavior. Critical to this process is maintaining a person-centered stance in which the plan is derived by the individual, with the assistance of the practitioner, rather than the practitioner becoming prescriptive at this point. Practitioners ask people to set their targeted behavior change goal (“I am going to stop using heroin”), describe steps they will take to change (“I want to try buprenorphine”, “I need your help to get PTSD counseling”), identify who might support them and how (“I am going to stay with my parents”), anticipate obstacles (“I have to change my cell phone number to keep people from calling me”), and reaffirm their commitment to the plan. If during the process of mobilizing their commitment people become uncertain again (the cold-feet phenomenon), the practitioner reflects this ambivalence rather than trying to press through it and provides another opportunity to revisit the plan in the current session or at another time. Being in a hurry to complete the plan when people are not ready is a common trap into which practitioners fall.

HANDLING RESISTANCE

Changing addictive behaviors is difficult for several reasons. People may like the effects of drinking or using drugs. They may be involved with others who use substances. People may feel unable to manage their

urges to drink, smoke, or get high. They may not see their lives improving in the absence of alcohol or drug use. Moreover, they may have obstacles (transportation, financial, child care, safety concerns) that impede their treatment involvement. These issues may sustain people’s addictive behaviors, and practitioners must attend to them in an MI consistent manner, rather than with confrontation or warning, when people raise them.

Some strategies for handling resistance include (1) simply reflecting the resistance to buy time or better understand the issue (“You don’t believe you have any problems even though others do” in response to a person who says, “I don’t care what everyone else thinks; I don’t have any problems”); (2) amplified reflections to determine the degree of commitment to a resistant statement (“Your wife has no basis for concern about your drinking” in response to a person who complains how his wife needs to stop bothering him about his drinking); and (3) double-sided reflections to pair the resistant statement with other things said that favor change, thereby introducing some ambivalence back into the conversation (“You feel like dropping out of the program, and you worry that you won’t be able to remain drug free without it”). These strategies are delivered with an attitude of genuine interest, not sarcasm or manipulation, and of seeing resistance as a natural part of the change process.

It is also useful to make a distinction between sustain talk and more contemporary notions of resistance in MI. Sustain talk is the stated motive to not change behavior. Resistance is the interpersonal style in which people interact with practitioners that conveys tension or trouble in the relationship (e.g. arguing, interrupting, negating, dismissing, ignoring). Often sustain talk and resistance occur together. However, this is not necessarily the case and could lead to missed opportunities for motivational enhancement. For example, a person who says he is willing to drink less might become quiet when a practitioner warns him about the hazards of drinking any amount of alcohol. The person initially provided change talk, but his interpersonal style is now marked by resistance. The practitioner might mistakenly assume the person is unmotivated for change even though the person has indicated a desire to reduce his quantity or frequency of drinking. A more empathic practitioner stance that supported and reinforced change talk, rather than a cautionary one, would have been preferable (e.g. “How come you think drinking less would be better for you?”).

EMPIRICAL SUPPORT

Several reviews of the large body of MI research have come to some conclusions about how well MI works across a wide range of problem areas

(e.g. alcohol, tobacco, illicit drugs, gambling, diet/exercise, treatment adherence/engagement). The most recent review was conducted by Brad Lundahl and his colleagues. It included 119 studies that isolated the unique effect of MI on treatment outcomes. They showed that across problem areas MI exerted small yet clinically significant effects, consistent with effects produced by other behavior change interventions but in less time. MI also significantly increased people's treatment engagement. The effects were durable, lasting up to 1 year. Specific to substance use problems, the evidence suggested that compared to other well-established addiction treatments, MI was as effective for treating problematic drinking, marijuana dependence, and other drugs (e.g. cocaine and heroin) and less effective for promoting tobacco cessation. MI used in its basic form seemed to work best as a pretreatment intervention to prepare people for more intensive treatment, whereas MET (manualized MI with personalized feedback) worked best as a stand-alone treatment.

Studies examining how MI works have supported the underlying theory of MI. Miller and Rose provide a helpful summary of this literature. In brief, these studies have shown that practitioners who adhere to MI are more likely to elicit change talk in others, whereas those who are MI nonadherent experience corresponding increases in resistant statements. Studies vary in the degree to which the presence of commitment language, or the strength of it, is uniquely predictive or whether the mere accumulation of change talk across categories per se is most essential. Nonetheless, people with increased in-session change talk have improved treatment outcomes (e.g. drinking, drug use, gambling) over the subsequent follow-up periods of up to 1 year. Terri Moyers and her colleagues have documented how MI consistent interventions cause increased change talk in others which in turn mediates outcome. These findings underscore the importance of practitioners selectively eliciting and reinforcing change talk when conducting MI.

OTHER APPLICATIONS

The empirical base of MI and the ubiquitous nature of motivational issues as part of most behavior change efforts have created substantial interest and broad application of MI into many areas other than addictions. Of particular interest to the addiction field is the integration of MI into the treatment of psychological (e.g. depression, anxiety, or psychosis) and health-related behavior problems (e.g. diet, exercise, or risky behavior), both areas of high comorbidity for people with substance use disorders. Extensive reviews of this literature and

demonstrations of these kinds of clinical applications are now available. Moreover, given that many offenders are adjudicated on drug-related crimes, the corrections field has become increasingly interested in applying MI to rehabilitate offenders. Many parole and probation officers and other correction professionals are now learning how to use MI to interact with offenders at all stages of legal supervision. Empirical evidence for the use of MI for these new applications awaits controlled clinical research.

LEARNING MOTIVATIONAL INTERVIEWING

A variety of training resources exist to learn MI. These resources include textbooks, treatment manuals, training videotapes, a supervision toolkit, and an international training group called the Motivational Interviewing Network of Trainers.

Literature on how to train practitioners in MI is emerging. The most popular approach has been the use of several day workshops. Research on the effectiveness of MI workshops (expert facilitated didactics and skill-building activities delivered in a group format) shows practitioners consistently improve their attitudes, knowledge, and confidence in MI, but immediate skill gains resulting from the training diminish within a few months.

Clinical supervision that includes direct observation of practitioners' sessions (via audio recordings), use of treatment integrity rating-based performance feedback, and individualized coaching has been shown to be more effective in improving practitioners' MI skills when it is used at least monthly for 3–4 months following workshop training. Several practitioner performance rating scales are now available that can be used to reliably supervise MI practice in this manner. This approach to supervision is particularly important given that practitioners typically evaluate their performance more positively than when the same sessions are reviewed by their supervisors or independent judges. Moreover, in the absence of supervision in MI, practitioners may be more prone to initiate informal discussions (i.e. chat) about matters that are unrelated to their patients' treatment. Careful training and supervision in MI may help practitioners better adhere to the approach.

Even with supervision, practitioners will vary in their capacity to learn MI and their performance may vacillate under different clinical circumstances posed by the people they treat or by the settings in which they work. For example, Miller has speculated that a minimum level of pretraining empathic abilities might be necessary for practitioners to learn MI. Screening

practitioners for their capacity to demonstrate empathy might be useful when making judgments about who to train or hire if the intention is to have these practitioners use MI.

Characteristics of people may also affect the proficiency with which practitioners use MI. For example, people who are most resistant to change likely make the application of MI more difficult. The organizational context of treatment programs (e.g. institutional resources, staff attributes and stability, and organizational climate and philosophical consistency with MI) also may affect the extent to which practitioners learn MI. One study by John Baer and colleagues found that practitioners showed the greatest gains in MI skills when they worked within programs they felt were more open to change and less supportive of practitioners functioning completely independently within the agency. Organizational factors likely can help or hinder practitioners' efforts to learn and use MI.

Finally, learning MI may require that practitioners sequentially build their skills in different stages. Miller and Moyers proposed eight stages for learning MI. First, practitioners need to develop openness to the spirit of MI such that they grasp the overriding philosophy of the approach (stage 1). Next, they must master the patient-centered counseling skills embodied in the OARS (stage 2), the foundation from which they then learn how to recognize and reinforce change talk (stage 3). Practitioners then learn strategies for evoking change talk (stage 4), rolling with resistance (stage 5), and developing a change plan (stage 6). Training in consolidating and strengthening commitment comes next (stage 7). If MI is to be used with other treatment approaches, learning how to switch between the methods or integrate MI into other practices is the last stage (stage 8). Practitioners may vary in the sequence and degree to which they learn the skills embedded within each stage. Nonetheless, the stages of learning MI imply a training progression that might be used to organize the design of training programs. Moreover, they suggest that MI involves a complex set of skills that practitioners must use flexibly and adaptively in response to what people say within sessions.

DISSEMINATION OF MOTIVATIONAL INTERVIEWING

MI has become very popular in the United States and internationally. Single State Authorities throughout the United States and their equivalent bodies in other countries frequently recommend MI as an empirically supported clinical approach they want practitioners to learn. The MI textbook has been translated into at least 22 languages, and there are now MI trainers in

over 40 different countries. It may be that the person-centeredness of the approach and, hence, sensitivity to diverse cultural perspectives that make MI broadly attractive worldwide. Moreover, the number of publications about MI has increased exponentially in the past two decades as well as funded research grants examining applications of MI to a variety of clinical problems and populations.

FUTURE RESEARCH DIRECTIONS

Many questions remain about MI that could be addressed in future research. Given the widespread application of MI, establishing how well MI works with nonaddictive problem behaviors, populations, and varying age groups remains an open question. In particular, the internationalization of MI suggests more study is needed about the efficacy of MI with diverse ethnic and cultural groups. The efficacy using MI in modalities other than individual treatment (e.g. group, family, or couples) also has not been established. The relative contributions of the fundamental or person-centered strategies and those used for selectively eliciting and reinforcing change talk to MI's effectiveness remain unclear, including the role of personalized feedback as used in MET. In addition, more work is needed to identify effective strategies for training practitioners in MI, sustaining adequate practitioner performance over time, and linking these training efforts to improved patient outcomes. Finally, innovations in the delivery of MI might make the approach more feasible and acceptable for use in busy clinical settings where it is increasingly being applied. The degree to which MI can be programmed for computer or web-based applications needs to be established.

CONCLUSIONS

MI is a recognized empirically supported treatment for addictive behaviors. It has a clear set of principles and techniques that guide implementation and substantial training resources to prepare practitioners to conduct MI proficiently. The popularity of MI is likely to grow and the field will be challenged to study if and how it works within its new applications and to ensure that practitioners implement it with integrity if it is to improve treatment outcomes.

Glossary

- Affirmations** acknowledgment of a person's strengths, attitudes, and efforts that promote change.
- Change planning** a formal strategy used in motivational interviewing in which practitioners help people who have expressed an intention to change develop a plan for how to achieve it.
- Change talk** a category of language in motivational interviewing in which a person expresses his or her motives for change (e.g. "If I keep using cocaine, it will destroy my marriage").
- Closed questions** questions that call for a "yes" or "no" response or that seek specific information or details (e.g. "Have you had more than four drinks on any one occasion in the past 3 months?").
- Commitment language** the way people speak about their commitment to change (e.g. expressed intentions to change, plans and steps taken toward change).
- Complex reflection** a reflection in which a practitioner paraphrases what someone has said in a manner that adds meaning to it, often based on implications within the person's spoken words (e.g. "You sound frustrated by your predicament").
- DARN-CAT** an acronym used in motivational interviewing that describes different categories of change talk (desire, ability, reasons, need, commitment, activation, taking steps).
- Decisional balance** an approach used to help people consider the costs and benefits of making changes versus not changing something.
- Developing discrepancy** a strategy used in motivational interviewing in which a practitioner has someone consider the way in which his or her current behavior conflicts with important values or goals (e.g. drinking with parenting) and how behavior change (e.g. not drinking) might resolve the discordance.
- Direct methods** strategies used in motivational interviewing for identifying and reinforcing people's motives for positive behavior change.
- EPE** an acronym used in motivational interviewing that stands for elicit, provide, elicit, which is a technique for collaboratively sharing information or giving advice.
- Equipoise** a stance in which someone is indifferent or has no clear attachment to a position or recommendation for another person.
- Evocation** the general practitioner stance in motivational interviewing that presumes all people have motivations for change and that underpins the direct methods of this approach for drawing out these motivations.
- Key question** a question used in motivational interviewing when someone has shown signs of readiness to change and is poised to make a commitment to change (e.g. What do you think you want to do at this point?).
- Microskills** fundamental or basic strategies used in motivational interview (open questions, affirmations, reflections, and summaries) that underpin the person-centered aspect of the approach.
- MINT** an acronym for an international training group called the Motivational Interviewing Network of Trainers.
- MI spirit** the style in which practitioners interact with people when they are using motivational interviewing, incorporating the elements of collaboration, evocation, and supporting autonomy.
- Motivational enhancement therapy** a manualized version of motivational interviewing, which includes a personalized feedback intervention that was developed for a large-scale, multi-site study conducted in the United States called Project MATCH.
- Motivational interviewing (MI)** a person-centered counseling method developed by William Miller and Stephen Rollnick that aims to elicit and strengthen personal motivation for change.
- OARS** an acronym used in motivational interviewing to describe fundamental or basic strategies of the approach (open questions, affirmations, reflections, and summaries).
- Open questions** questions or requests that invite discussion, exploration, or elaboration about a topic and are phrased in a manner that cannot be answered with a "yes" or "no" response (e.g. "What do you think about that?" "Tell me more about that").
- Personalized feedback** a strategy in which a practitioner gives someone information from an assessment about his or her behavior relative to norms (e.g. describes how much the person is drinking compared to peers) or other important factors (e.g. "Your boss said you can keep your job if you do something about your drinking") to cause the person to consider changing.
- Person-centered counseling** a nondirective humanistic psychotherapeutic approach based largely on the work of Carl Rogers.
- Preparatory language** the way people speak about what motivates them to change, often involving statements about their desire, ability, reasons, and need for change, often as a prelude to making a commitment to change.
- Project MATCH** a large-scale, multi-site study conducted in the United States in which the efficacy of motivational interviewing, cognitive behavior therapy, and 12-step facilitation for alcohol-dependent adults was compared.
- REDS** an acronym used in motivational interviewing that details the basic principles of the approach (rolling with resistance, express empathy, develop discrepancy, support self-efficacy).
- Reflection** a statement about what a person said to indicate one's understanding about what that person meant.
- Resistance** the interpersonal style in which a person interacts with someone in a manner that indicates tension or trouble in the relationship (e.g. arguing, interrupting, negating, dismissing, ignoring).
- Righting reflex** the natural tendency of others to try to fix people's problems when they are told about them.
- Simple reflection** a reflection in which a practitioner repeats or rephrases what someone has said without adding any meaning to it.
- Solicited advice** advice that is given only when someone has specifically sought or requested it or granted permission for it to be shared.
- Stages of change** a transtheoretical model of behavior change developed by James Prochaska and Carlo DiClemente that posits that behavior change occurs sequentially across recurring stages (precontemplation, contemplation, preparation, action, and maintenance).
- Summaries** a technique used in motivational interviewing to reflect back to people multiple things that they had said for the purpose of: (1) collecting ideas to convey the bigger picture or to reinforce a person's motives for change; (2) linking statements to fully capture both sides of a person's ambivalence; or (3) capturing a common understanding of what has been said before transitioning to another topic.
- Sustain talk** a category of language used in motivational interviewing in which a person expresses his or her motives to not change one's behavior (e.g. "I like the way drinking makes me feel").
- Unsolicited advice** advice that is given to someone when they have not requested it or granted permission for it to be shared.

History and Theoretical Underpinnings	23	Summary	27
Defining Elements of CBT	25		
Empirical Support for CBT	26		

INTRODUCTION

Cognitive behavioral treatments are among the most well-defined and rigorously studied psychotherapeutic interventions for substance use disorders. While this entry will focus primarily on cognitive-behavioral therapy (CBT) for addictive behaviors, it should be noted that CBT shares several features with other empirically supported behavioral approaches. First, it is applicable across a broad range of addictive behaviors. That is, well-controlled trials have supported its efficacy across alcohol-, nicotine-, cocaine-, marijuana-, stimulant-, and opioid-dependent populations and also extended to other forms of addiction such as gambling, eating, and internet disorders (although this entry will focus primarily on applications to substance use disorders). Second, CBT was developed from well-founded theoretical traditions with established theories and principles of human behavior. Hence, CBT has also been shown to be effective with a wide range of other disorders and problems, including those that frequently co-occur with addictive disorders, such as depression and anxiety disorders as well as behavioral health issues such as insomnia and eating disorders. Third, CBT is highly flexible and can be implemented in a wide range of clinical modalities and settings, and delivered in a wide range of formats (individual, group,

computer assisted). CBT can also be integrated with a range of other empirically supported therapies described elsewhere in this volume, including motivational interviewing (MI), contingency management, and structured family approaches. Moreover, it is compatible with a variety of pharmacotherapies and, in many cases, can foster compliance and enhance the effects of pharmacotherapies for specific substance use disorders including methadone, buprenorphine, and naltrexone (for opioid addicted individuals), naltrexone and disulfiram (for alcohol-dependent individuals), and nicotine replacement therapies (for nicotine-dependent populations). Finally, CBT is highly focused and relatively brief/short-term, emphasizing rapid, targeted change in substance use and related problems. Thus, CBT is highly compatible in the evolving health care environment, where substance use problems may be identified and treated in a range of nontraditional settings (schools, correctional settings, primary care, etc.).

HISTORY AND THEORETICAL UNDERPINNINGS

Cognitive behavioral treatments have their roots in classical behavioral theory and the pioneering work of Pavlov, Watson, Skinner, and Bandura. Pavlov's work

on classical conditioning demonstrated that a previously neutral stimulus could elicit a conditioned response after being paired repeatedly with an unconditioned stimulus. Furthermore, repeated exposure to the conditioned stimulus without the unconditioned stimulus would eventually lead to extinction of the conditioned response. These classical conditioning concepts play an important role in CBT, and particularly in interventions directed at reducing some forms of craving for drugs. For instance, the clinician attempts to help the patient understand and recognize conditioned craving, identify his/her own idiosyncratic array of conditioned cues for craving, avoid exposure to those cues, and cope effectively with craving when it does occur without using drugs so that conditioned craving is reduced and eliminated over time.

Skinner's work on operant conditioning demonstrated that behaviors that are positively reinforced are likely to be exhibited more frequently. Behavior therapies assume that addictive behaviors are learned through their association with the positively reinforcing properties of abused substances as well as their secondary association with other environmental stimuli. CBT attempts to disrupt this learned association between drug-related cues or stimuli and drug craving or use by understanding and changing these behavior patterns. Operant conditioning concepts are used several ways in CBT. First, through a detailed examination of the antecedents and consequences of substance use, the clinician attempts to develop an understanding of the reasons the patient may be more likely to use in a given situation and to understand the role that the substance plays in their life. This "functional analysis" of substance use is thus used to identify the high risk situations in which the patient is likely to use drugs or alcohol and thus to provide the basis for learning more effective coping behaviors in those situations. Second, the clinician attempts to help the patient develop meaningful alternate reinforcers to substance use; that is, other activities and involvements (relationships, work, hobbies) that serve as viable alternatives to the addictive behavior. Finally, a detailed examination of the consequences, both long- and short-term, of the substance use, is used as a strategy to build or reinforce the patient's resolve to reduce or eliminate the addictive behavior.

CBT conceives substance use disorders as complex, multi-determined issues, with a number of influences playing a role in the development or perpetuation of the disorder. These may include family history and genetic factors; the presence of comorbid psychopathology; personality traits such as sensation seeking or impulsivity; and a host of environmental factors, including drug availability and lack of countervailing influences and rewards. Though CBT for substance use

primarily emphasizes the reinforcing properties of drugs and alcohol as central to the acquisition and maintenance of addictive behaviors, these etiological influences are seen as heightening risk or vulnerability to the development of substance use problems. For example, some individuals may find drugs and alcohol unusually highly rewarding secondary to genetic vulnerability, comorbid depression, a high need for sensation seeking, and modeling of family and friends who use substances or environments devoid of alternative reinforcers.

Cognitive behavioral treatments also reflect the pioneering work of Ellis and Beck that emphasizes the importance of the person's thoughts and feelings as determinants of behavior. CBT evolved in part from dissatisfaction with the extreme positions of radical behaviorism (e.g. emphasis on overt behaviors) and classical psychoanalysis (emphasis on unconscious conflicts or representations). CBT emphasizes how the individual perceives and interprets life events as important determinants of behavior. A person's conscious thoughts, feelings, and expectancies mediate an individual's response to the environment. Thus, a central strategy is to help individuals become aware of maladaptive cognitions and change them.

Just as CBT assumes that many individuals essentially "learn" to become substance users over time, through complex interplays of modeling, classical conditioning, or operant conditioning, each of these principles is invoked in CBT to help the individual stop using drugs and alcohol. For example, modeling is used to help the patient learn new behaviors (e.g. how to refuse an offer of alcohol, how to break off or limit a relationship with a drug-using associate) by having the patient participate in role plays with the clinician during the treatment. That is, the patient learns to respond in new, unfamiliar ways by first watching the clinician model those new strategies and then practicing those strategies within the supportive context of treatment.

Learning serves as an important metaphor for treatment process. CBT clinicians tell patients that a goal of the treatment is to help them "unlearn" old, ineffective behaviors and "learn" new ones. Patients, particularly those who are demoralized by their failure to change their substance use, or for whom the consequences of addiction have been severe, are frequently surprised to think about substance use as a type of skill, as something they have learned to do over time: In effect they have learned a complex set of skills that enabled them to acquire the money needed to buy drugs and alcohol (which often led to another set of licit or illicit skills), avoid detection, and so on. Patients who can reframe their self-appraisals in terms of being "skilled" in this way can often see that they also have the capacity to

learn a new set of skills, this time, though, skills that will help them remain abstinent.

DEFINING ELEMENTS OF CBT

CBT has two critical components and defining features: First, a thorough functional analysis of the role the addictive disorder plays in the individual's life. For each instance of substance use the patient experiences during treatment, the clinician and patient will identify the patient's thoughts, feelings, and circumstances before the substance use, as well as the patient's thoughts, feelings, and circumstances after the episode of substance use. Early in treatment, the functional analysis plays a critical role in helping the patient and clinician assess the determinants, or high risk situations, that are likely to lead to substance use, as well as shed light on some of the reasons the individual may be using drugs. The second critical component of CBT is skills training. In CBT, this consists of a highly individualized training program that helps individuals with addictive behaviors modify old habits and behaviors and learn and implement more effective ones.

Specific techniques vary widely with the type of cognitive-behavioral treatment used, and there are a variety of manuals, protocols, and training programs available which describe the techniques associated with each approach. As described earlier, the two key defining features of CBT for illegal drug use are (1) functional analysis of drug use, that is, understanding drug use with respect to its antecedents and consequences and (2) skills training. CBT approaches include a range of skills to foster or maintain abstinence. These typically include strategies for (1) understanding the patterns that maintain substance use and developing strategies for changing these patterns. This often involves self-monitoring of thoughts and behaviors that takes place before, during, and after high-risk situations or episodes of substance use, (2) fostering the resolution to stop substance use through exploring positive and negative consequences of continued use (also known as the decisional balance technique), (3) understanding craving, craving cues, and the development of skills for coping with craving when it occurs. These include a variety of affect regulation strategies (distraction, talking through a craving, "urge surfing" and so on), (4) recognizing and challenging the cognitions that accompany and maintain patterns of substance use, (5) increasing awareness of the consequences of even small decisions (e.g. which route to take home from work), and the identification of "seemingly irrelevant" decisions which can culminate in high-risk situations, (6) development of problem-solving skills, and practicing application of those skills to substance-related and more general

problems (e.g. managing the various social and legal problems associated with drug and alcohol use) (7) planning for emergencies and unexpected problems and situations that can lead to high-risk situations. (8) developing skills for assertively refusing offers of drugs, and reducing exposure to drugs and drug-related cues.

These basic skills are useful in their application to helping patients control their substance use, but it is essential that clinicians also point out how these same skills can be applied to a range of other problems. For example, functional analysis can be used to understand the determinants of a wide range of behavior patterns, skills used to cope with craving can easily be applied to other aspects of affect tolerance, the principles used in the sessions on seemingly irrelevant decisions can easily be adapted to understand a wide range of behavior chains, and drug/alcohol refusal skills can easily be transferred to more effective and assertive responding in a number of situations. It is essential that when clinicians teach coping skills, they emphasize and demonstrate that the skills can be applied immediately to control substance use, but also can be used as general strategies that can be useful across a wide range of situations and problems the patient may encounter in the future.

CBT is typically highly structured. That is, it is generally brief (12–24 weeks) and organized closely around well-specified treatment goals. An articulated agenda exists for each session and the clinical discussion remains focused around issues directly related to substance use. Progress toward treatment goals is monitored closely and frequently, with frequent monitoring of drug use through urine toxicology screens, and the clinician takes an active stance throughout treatment. In broad spectrum cognitive-behavioral approaches, sessions often are organized roughly in thirds (the 20/20/20 rule), with the first third of the session devoted to the assessment of the patient's substance use, general functioning in the past week, and report of current concerns and problems; the second third is more didactic and devoted to skills training and practice; and the final third allows time for clinician and patient to plan for the week ahead and discuss how new skills will be implemented. The therapeutic relationship is seen as principally collaborative. Thus, the role of the clinician is one of consultant, educator, and guide who can lead the patient through a functional analysis of his/her substance use, aid in identifying and prioritizing target behaviors, and consult in selecting and implementing strategies to foster the desired behavior changes.

The early sessions in CBT focus on gathering history, building a therapeutic relationship, introducing the CBT model, and teaching some of the more fundamental skills to achieve abstinence (e.g. functional analysis for

identifying triggers, coping with craving, building motivation). As the patient progresses, later sessions build on these basic skills by addressing more complex topics, such as problem solving and cognitive reframing.

While structured and didactic, CBT is also a highly individualized and flexible treatment. The clinician carefully matches the content, timing, and nature of presentation of the material to the individual patient. The clinician attempts to provide skills training that are highly tailored to the individual's strengths, weaknesses, and current level of functioning. For instance, the clinician does not belabor topics such as breaking ties with drug suppliers with a patient who's highly motivated and has been abstinent for several weeks. Similarly, the clinician does not race through material in an attempt to "cover" all of it in a few weeks; for some patients, it may take several weeks to master a basic skill. Along these lines, clinicians should also be careful to use language that is compatible with the patient's level of understanding, making frequent attempts to check with patients to be sure they understand a concept and are comfortable with a specific skill. For example, while some can readily understand the concept of conditioned craving, others may require further explanation through use of concrete examples and more familiar language. Therefore, clinicians should be always be aware of patients' comprehension of the material, and should feel free to repeat session material as many times and in as many different ways as needed.

In CBT, clinicians encourage patients to practice new skills; as such practice is a central, essential, component of treatment. The degree to which the treatment is a "skills training" versus merely a "skills exposure" approach has to do with the degree to which there is opportunity to practice and implement coping skills, making extra-session practice and homework all the more important. It is critical that patients have opportunity to "try out" new skills within the supportive context of treatment. Through first-hand experience, patients can learn what new approaches work or don't work for them, where they have difficulty or problems, and so on. There are many opportunities for practice within CBT, both within sessions and outside of them. Within each session, there are opportunities for patients to rehearse and review ideas, raise concerns, and get feedback from the clinician.

EMPIRICAL SUPPORT FOR CBT

Among existing treatments for addictive behaviors, CBT has been among the most-studied and has garnered a high level of empirical support. It is notable that CBT has been included in most of the multisite clinical trials that have shaped the field of treatment of addictive

behavior; including Project MATCH (a 9-site trial comparing manualized CBT, MI, and 12-step facilitation for alcohol use disorders), the Cocaine Collaborative Study (a randomized trial evaluating cognitive therapy versus drug counseling versus interpersonal therapy among abstinent cocaine users), and the Marijuana Treatment Project (a three-site randomized trial comparing a nine session MI-CBT combination to three sessions of MI to a delayed treatment control condition among marijuana-using adults). Multiple meta-analyses have pointed to its efficacy across a range of addictive behaviors (including alcohol, illicit drug, and behavioral addictions), its compatibility and efficacy when combined with available pharmacotherapies, and particularly its durability. That is, several studies have pointed to continuing improvement in the targeted addictive behavior after the end of CBT treatment.

The converging evidence suggesting that CBT is a particularly durable approach has led to increased focus on unique or distinctive aspects of CBT that might account for its durability. Encouraging clients to implement and practice skills outside of sessions via homework assignments is one possible mechanism for this effect. Homework encourages practice of skills outside of sessions and possibly generalization of skills to other problems, and emphasis on extra-session practice assignments is a critical defining feature of CBT (see Table 3.1). Thus, homework and skill acquisition/implementation are two likely "active ingredients" of CBT.

NOVEL METHODS OF DELIVERY AND DISSEMINATION

Although many clinicians are familiar with aspects of CBT, efforts to successfully implement it in community settings have been mixed. CBT is a comparatively complex and demanding approach, for both clinicians and patients, and thus may be more infrequently or "weakly" implemented than would be ideal. Thus, implementation and training efforts have tended to emphasize that one does not learn CBT optimally from reading a manual or attending a single workshop; rather, extensive practice, supervision, and feedback are needed for most clinicians to implement CBT effectively. Because training and supervision of individual clinicians are costly and time-consuming, there is a dearth of well-trained CBT clinicians and dissemination efforts have begun to focus on novel methods of CBT delivery.

The last decade has been characterized by exponential growth in the development of technology-based interventions for psychiatric disorders, and in particular the creation of computer-delivered versions of CBT. Given the structure and didactic nature of CBT, it

TABLE 3.1 Defining Elements of CBT

Essential interventions in CBT	<ul style="list-style-type: none"> • Conducting functional analyses of substance use • Providing individualized skills training in strategies such as recognizing and coping with craving; monitoring, challenging, and changing thoughts about substance use; problem-solving skills; planning for emergencies; recognizing seemingly irrelevant decisions; and refusal skills. • Examination of the patient's cognitive processes related to substance use and related issues • Identification and debriefing of past and future high-risk situations • Encouragement and review of extra-session implementation of skills via homework • Practice of skills within session
Recommended interventions	<ul style="list-style-type: none"> • Discussing, reviewing, reformulating the patient's goals for treatment • Monitoring substance use and craving • Monitoring general functioning • Exploring positive and negative consequences of substance use • Exploring the relationship between affect states and substance use • Providing feedback on urinalysis results • Setting a clear agenda for the session • Making process comments as indicated • Discussing the advantages of an abstinence goal and exploration of the patient's ambivalence • Meeting resistance with exploration and a problem-solving approach • Supporting patient efforts to institute behavior change, assessing the level of family support
Acceptable interventions	<ul style="list-style-type: none"> • Involvement in self-help activities (e.g. NA meetings) as a coping skill • Identifying means of self-reinforcement for abstinence • Exploring discrepancies between patient's stated goals and actions • Eliciting concerns about substance use and consequences (e.g. decisional balance)
Proscribed interventions	<ul style="list-style-type: none"> • Extensive self-disclosure by the therapist • Use of a confrontational style or a confrontation-of-denial approach • Requiring the patient attend self-help groups (as in 12-step facilitation) • Use of disease model language or slogans (as in 12-step facilitation) • Extensive exploration of interpersonal aspects of substance use (as in interpersonal or supportive-psychodynamic approaches) • Extensive discussion or interpretation of underlying conflicts or motives (as in supportive-psychodynamic approaches) • Provision of direct reinforcement for abstinence (e.g. vouchers, tokens, as in contingency management approaches)

appears to be one of the more easily transferrable empirically supported treatments into a computerized format, which offers the benefits of standardized delivery and broader access. CBT may be particularly well suited to translation to as direct-to-patients computer-assisted learning model for many reasons. First, the key elements of CBT are didactic, skills based, progressive, and often require repetition and modeling for effective learning – all of which can be facilitated through computer programs. Use of the multimedia format associated with computer-based training (e.g. graphics, audio prompts, cartoons, videotaped vignettes and role plays, self-assessment of progress, prompts, and so on) can facilitate skills building by individuals who have different learning styles. Although computer-assisted means of delivering CBT have great potential to make empirically supported therapies more widely available and to broaden the base of substance abuse treatment, and some of the early data on their effectiveness is very encouraging, substantially more testing and evaluation is needed before they can be widely distributed.

SUMMARY

Cognitive behavioral therapy is a structured, manualized approach to the treatment of addictive behaviors. It is one of the most frequently studied treatments and has among the highest level of empirical support. It is compatible with and effective when integrated with several other empirically supported therapies, including behavioral therapies and medications. One of its defining features is its durability, as effects of CBT tend to persist, and even increase, after the end of treatment.

Glossary

Affect/craving regulation strategies specific strategies that can be helpful in managing strong feelings or powerful cravings. These include mindfulness techniques, “thinking” through the behavior, “urge surfing,” self-talk, and recognition that strong affects and cravings grow, peak, and eventually dissipate over time.

Assertive refusals an important strategy in changing addictive behaviors in situations where the behavior is encouraged by another person. In assertive refusals, the individual says “no” clearly, with good eye contact, assertive body language, and use of “I” statements (e.g. “I don’t want to have a drink, and I’d appreciate it if you wouldn’t ask me again”). Assertive refusals can be distinguished from passive refusals (“Not now”) or aggressive refusals (“Get away, you jerk”) which tend to be much less effective.

Cognitive reframing also called cognitive restructuring, refers to the strategy used in CBT where maladaptive or distorted thoughts are identified and challenged.

Collaborative stance the therapeutic style used by CBT clinicians with the group or individual to foster a positive working relationship with shared development and agreement on the goals and tasks of the treatment.

Conditioned craving craving that occurs as a result of classical conditioning (Pavlovian conditioning). This occurs when certain cues or triggers (e.g. settings such as bars, drug-using friends, casinos) are repeatedly paired with an addictive behavior (drinking alcohol, using drugs, gambling). After multiple repeated pairings, the cue itself can elicit strong conditioned craving for the behavior.

Decisional balance a systematic evaluation of the pros and cons of engaging in a specific addictive behavior versus forgoing it. This is a strategy used in CBT to address ambivalence about the addictive behavior and help the individual temporize their behavior or delay the decision to engage in the behavior.

Functional analysis observing/evaluating behaviors in terms of their antecedents and consequences (i.e. understanding the “function” of a given behavior). When applied to treatment of addictive behavior, this refers to understanding the thoughts, cues, situations, or “triggers” that occur just prior to an episode of substance use/craving, understanding the thoughts, behaviors, and feelings that occur within an episode of substance use, and understanding the changes/behaviors/thoughts that occur after the episode.

High-risk situations situations in which the addictive behavior is highly likely. These are typically situations, settings, or internal states previously paired with the addictive behavior.

Homework homework in CBT refers to practice and evaluation of new skills outside of therapy sessions. These can be formal, as in written assignments, or informal, as in “trying out a new thought.”

Problem-solving skills a systematic process that can be applied to a wide range of addictive behaviors and related problems. Steps in a typically problem-solving process include (1) recognizing a problem exists, (2) defining the problem and if possible breaking the problem down into manageable components, (3) identifying multiple strategies to address the problem (brainstorming), (4) selecting a problem-solving strategy, and (5) implementing and evaluating the effectiveness of the strategy selected.

Seemingly irrelevant decisions decisions that, on first consideration, may seem to be unrelated to the addictive behavior but can lead to a chain of events that result in a high risk situation or relapse. Examples include the “seemingly irrelevant decision” to take a route home from work past a place where the individual previously engaged in the addictive behavior cashing instead of depositing one’s paycheck.

Triggers situations, states, cognitions, or cues previously paired with addictive behavior that can elicit strong craving or desire for the addictive behavior.

<i>Explaining CET to Clients</i>	31	<i>Summary of the Evidence</i>	34
<i>Beverage Exposure</i>	31		

The last few decades saw major advances in the development of effective behavioral treatments for substance use disorders (SUDs), particularly with the recognition that effective pharmacotherapies had not been developed for some SUDs (such as cocaine use disorders) or were limited in effectiveness such as naltrexone for alcohol use disorders (AUD), were limited in who could receive them, and were always more effective when combined with behavioral treatments. Cue exposure treatment (CET) approaches were one of these advances.

THEORETICAL RATIONALE FOR CET

Exposure-based treatments for SUDs were derived from a foundation in classical learning principles and broadened to incorporate coping skills training within the exposure sessions as derived from cognitive social learning theory. These theories indicate that SUDs are

acquired on a foundation of individual biological predisposing factors using the same learning principles by which any other behaviors are learned. The most relevant of these principles for CET is respondent learning, sometimes called classical conditioning or associative learning, in which a response becomes associated to a stimulus that does not inherently elicit (call forth) that response. We call these stimuli "cues." Pleasurable physiologic reactions to drug ingestion become associated with all the sights, sounds, and smells that were associated repeatedly with drug use, including even places, times of day, or days of the week. For cocaine-dependent patients, after snorting cocaine repeatedly, the sight of any white powder, a mirror, a bank card, or a certain neighborhood can elicit increased heart rate and cravings. The types of cues (conditioned stimuli) associated with substance use become complex and broader than the sight and smell of the drug itself and can include emotions, people, environments, and temporal cues. This learning is not considered to occur in a mechanistic

manner but instead is affected by cognitive processes such as encoding, organizing, and retrieving information to mediate between environmental events and behavior.

Cues associated with drug use can pose a risk for relapse through three different mechanisms. First, the conditioned responses learned through respondent conditioning include a variety of physiological and emotional responses, and these can result in an urge (desire, or craving) to use the substance. (The terms “urge” or “desire” will be used instead of “craving” because they represent the full range of desires to use rather than just extreme desire.) Second, when people are reacting to these cues, these learned reactions can interfere with the ability to use coping skills or motivational messages by reducing the amount of cognitive resources available for efforts to stay clean and sober. Third, the learned responses can lead to operant behavior (i.e. substance use) designed to decrease aversive aspects of the reactions and to obtain the pleasurable drug responses associated in the past with these cues.

GENERAL PRINCIPLES OF CET

Associations cannot be unlearned, so CET is not designed to cause unlearning. Instead, CET approaches have focused on two mechanisms of effect: (1) the first is to reduce the strength of these learned associations by repeatedly presenting these cues while preventing the substance use from occurring. These unreinforced exposure trials are designed to make the client react less strongly and automatically to the cues through habituation so as to make them less susceptible to the cues when they later encounter such cues in the environment. Exposure must be in an environment where substance use can be prevented, exposure must be long enough to result in within-session habituation, and a wide variety of different cues need to be used in the CET sessions since many cues are associated with substance abuse. (2) The second is to provide practice in using coping skills while under the influence of these conditioned responses to cues so that reactions to cues will be less likely to disrupt coping efforts when the client is in the natural environment after treatment. For the maximum benefit, coping practice during each exposure needs to occur when urges to use and other reactions are at their peak. Furthermore, while some CET approaches have focused only on the unreinforced exposure aspects, the practice of coping with urges while urges are being elicited makes sense to clients and thereby makes clients more willing to engage in the treatment sessions in addition to providing them with a useful set of coping methods. Therefore, it makes sense to use both the exposure and the coping practice under exposure conditions in CET.

The earliest uses of CET, used for people with AUDs in Britain, involved having clients expose themselves to their favorite alcohol beverage repeatedly while resisting drinking. However, in addition to exposure sessions, sobriety-oriented skills training was usually provided as well, although not integrated into the exposure as described in the above paragraph. The clients were given advice about how to change high-risk situations, they role-played how to handle high-risk situations, and alternative activities were discussed, as described by Blakey and Baker. An approach using only exposure was developed for people with AUDs by Drummond, and for people with opiate or cocaine use disorders by O'Brien and his colleagues. The method developed by Monti, Rohsenow, and their colleagues that is discussed in more detail below includes urge-specific coping skills training integrated into the series of sessions of exposure to a variety of drinking cues. This approach has been supported in several randomized controlled clinical trials.

The nature of the cues to be used in the treatment sessions is important to consider. The sight, smell, and feel of the substance itself are usually used since it is the final common pathway immediately before use. However, other cues can occur earlier in the chain of events that lead to substance use and can trigger drug-seeking so are important to address in the sessions as well. Most of these cues cannot be brought into a treatment room (e.g. drug-dealing neighborhood; getting off work) or are not physical (e.g. anger or loneliness) or cannot be planned (e.g. fight with one's kids, call from an ex-spouse). Therefore, imaginal imagery produced through prompts or scripts are commonly used for more complex situations. While virtual reality methods have been proposed for research purposes and photographs of drinks have been used to elicit reactions in teens, these inherently involve sets of standardized cues rather than personalized cues. Since studies have consistently found individually personalized cues to elicit stronger reactions than standardized cues, these methods are likely to be weaker approaches. Furthermore, such visual methods cannot present nontangible cues such as emotions, conflicts, and times of day. Thus, beverages or simulated drugs with their associated equipment, and imaginal methods to present other cues for drinking, are the recommended ways to present a wide range of cues.

ASSESSMENTS USED IN CET

Drinking Triggers Interview

The primary assessment to use before conducting CET is the Drinking Triggers Interview, used as the foundation for the imaginal imagery used in CET

sessions. The DTI is a structured interview designed to identify the situations most strongly related to urges to drink or relapse for the individual client. A copy of the full measure is available in a treatment guide for therapists by Monti and his colleagues. In the DTI, we asked a client to describe all the situations or events that have been associated with past heavy drinking or relapse. These “triggers” include situations, environments, objects, people, or emotional experiences that lead to drinking episodes or to urges to drink for them. After writing down the key elements of each trigger, we ask the client to rate each one for their confidence that they could handle the situation today without drinking, using a 0–10 scale from “not at all confident” to “completely confident.” Then the client rates each trigger for the urge to drink they would experience if out of the treatment program and confronted with that trigger today, rated from 0 “no urge at all” to 10 “extremely strong urge to drink.” Finally, the client rank orders the situations for the frequency with which they occur. We choose the order to present triggers in CET based on the anticipated strength of the urge, highest urge first, with ties broken by choosing the more frequent one first.

Urge-Specific Coping Skills

The therapist could also obtain a pretreatment assessment of the extent to which the client knows and uses the skills for coping with urges that have been found to be related to less drinking after treatment (evidence is reviewed below). The Urge-Specific Strategies Questionnaire is also available in the treatment guide. First, clients are asked to describe everything they have done to keep themselves from drinking when they have had an urge to drink; this open-ended list can be coded into the types of strategies found effective (e.g. reminding oneself of the positive consequences of staying sober or substituting an alternative activity) or ineffective (e.g. self-punishment or willpower alone). Then the client is given a list of key coping strategies worded in plain language; the client indicates the frequency with which they used each one when having an urge to drink and trying to stay sober. This tool can be used to identify existing strengths and weaknesses to work on in treatment.

CUE EXPOSURE WITH URGE COPING SKILLS FOR AUDS

Overview

The CET method described here is the one that has the most evidence-based support, the one by Monti, Rohsenow, and their colleagues and described in several

of the further readings. Some other versions of CET rely on just exposure to the alcohol beverage alone or exposure with limited drinking followed by resisting further drinking. The method described here follows exposure to the beverage with exposure to a variety of imagined trigger situations, with learning and repeated practice of a specific set of urge coping skills while the urge to drink is at its highest in the CET session. The approach described here involves six to eight 50-min sessions. While most evidence is for individual sessions, it was adapted for small groups as well.

Explaining CET to Clients

The therapist needs to explain why this approach is being done, because it is so unusual. We tell clients that trouble staying sober is often due to the reactions they have to triggers associated with drinking in the past. While many people stop having cravings while in treatment and away from these triggers, many of these triggers are unavoidable (such as conflicts or getting off work) and they may have strong urges to drink when first experiencing their triggers again after treatment, with no one there to help them. Therefore, this treatment is designed to help them learn to resist their drinking triggers while in the safety of the program. One way is by experiencing their drinking triggers until they feel the urge to drink decreasing so they will know through experience that the urges will decrease if they do not drink. The second way is by teaching them some skills for handling urges without drinking and letting them practice using these skills while they are experiencing real urges to drink. This practice will make it so they use these skills more quickly and effectively later on. We warn them not to try any exposure on their own, because if they test themselves and fail, all the treatment will have been wasted. The goal is simply to help them handle the unavoidable triggers more effectively.

Beverage Exposure

Each session begins with exposure to their usual alcoholic beverage, since this is the final common pathway to drinking and usually a strong trigger. The beverage should be their own most commonly consumed beverage, using the same brand they use, prepared the way they usually drink it. The urges are stronger if they pour the drink themselves. We always provide a glass, even though many never use a glass in real life, because it allows the smell to be stronger. Since the time it takes for the urge to decrease always becomes shorter across sessions, we time the exposure so we can give them feedback on this aspect in later sessions. We start a stopwatch when we first bring the beverage

into view, then ask the client to pour and mix the beverage but without filling the glass more than halfway. We ask if the urge would be stronger when holding the can or bottle than the glass. Since most alcoholics never remove their hand from what they drink from, we have them keep their hand on that item throughout. While we have them smell the glass of alcohol at least once; if this results in less urge than looking at and holding it, we do not repeat that. "Focus on whatever aspect of the drink that gives you the greatest urge – the sight, smell, feel of the glass, or your thoughts. Try to experience the greatest urge you can." We redirect their attention if they are trying to avoid the stimulus so as to avoid the urge. We ask them to report their urge level on a 0–10 scale (from none to the strongest urge possible) every few minutes to track the timing of the increase and later the decrease in urge level, and stop the exposure when this level reaches a 2 or less (whatever the client thinks is the lowest the urge could go).

Imaginal Exposure to Trigger Situations

We use the answer sheet from the Drinking Triggers Interview to guide the imagery. We start with the highest ranked trigger but try to cover all the triggers across the different sessions to maximize generalization. We ask the clients to vividly imagine being in the situation without imagining drinking and to focus on the aspects of the situation that give the greatest urges. We ask them to report their urge level every time it changes on the 0–10 scale, and track the time to peak and back to minimum. If the urge level fails to increase or stays high after coping skills have been applied, ask the person to describe their thoughts and images and give corrective feedback (e.g. stay in that same situation without adding new elements, do not imagine drinking). Some clients deliberately block their urges; we stress the importance of allowing themselves to feel the urges to drink while in these treatment sessions.

Integrating Urge Coping Skills Training

Each 50-min session has time for one or two beverage exposures and two to about five imagery exposures. In between exposures, we teach a new coping skill or review one taught in the previous session and tell the clients that they will be asked to imagine using the skill when we tell them to. Only one new skill is taught in each session. When the urge is as high as the client believes it will go, we ask them to imagine still being in the same situation but to imagine using the coping skill to deal with the urge in the situation. Then we terminate the exposure when the urge is a 2 or less and as low as the client believes it will go. We match

most of the strategies with many of the drinking triggers over the sessions and ask them to notice which strategies work best for them in which situations (for example, imagining negative consequences of drinking can increase bad moods and be less effective for negative mood triggers than imagining positive consequences of sobriety or imagining using an alternative activity). After the third or fourth session, rather than prescribing specific coping tools, we ask them to "use any tool or combination of tools to bring the urge down," to encourage generalization, and to practice recalling and implementing strategies on their own. The last session includes a review of all the coping strategies, which worked best for which triggers, and a reminder of the importance of using these in their own environment.

Urge Coping Strategies

We have empirically determined the strategies that are associated with the best drinking outcomes after treatment. Two popular but ineffective strategies we discourage: self-punishment and willpower alone. Other ineffective strategies are listed by Rohsenow. One pair of highly effective strategies not used in CET are escape and avoidance; these are not used because they prevent the exposure aspects of the session. We recommend avoidance and escape as the first methods to use always and to use the other tools we are teaching whenever escape or avoidance is not possible. Clients are told it is important to have as many "tools" in their "toolbox" as possible to stay sober. We write down the tools, and the ways they personalized the tools for themselves, on a written list that we give them to keep. The following coping strategies are taught:

1. *Delay.* During the first beverage exposure, we have clients simply keep looking at the beverage until the urge has gone down to a low level. Most clients expect that their urge would never decrease, but it always does. We then teach them delay ("wait it out") as an active coping strategy, that they can always tell themselves that they can wait out the urge until it goes down, and that it will go down without drinking. We then repeat the beverage exposure while having them practice the active version of this tool and see the difference in time for the urge to decrease.
2. *Negative consequences of drinking.* We ask the client to "think about all the bad things that could happen if you took that drink." This is future oriented since past consequences are associated with self-blame (self-punishment) and may not recur so would be less powerful than imagining what actually would be likely to happen. We have them evaluate the personal importance of each consequence and write up their own personal list of meaningful potential consequences on the "Toolbox" handout.

3. *Positive consequences of staying sober.* We do parallel procedures for positive consequences, focusing on relatively immediate positive consequences they could expect to experience. For feeling sad or lonely or bored, thinking of the positives is less likely to aggravate the trigger situation, as well as providing positive incentives across any situation.
4. *Alternative food or drink.* Have the client imagine eating or drinking something pleasurable and write down his or her preferred substitutes.
5. *Alternative behaviors.* Have the client imagine doing some activity that could distract him/her from the urge, whether it is pleasurable, it involves the satisfaction of accomplishing something, or it is seeking support such as through a sponsor or supportive relative. It needs to be something they could engage in immediately in the trigger situation.

EVIDENCE-BASED EFFECTIVENESS OF CET

CET for Smoking Cessation

Effectiveness has not been demonstrated for the use of CET, even when combined with coping skills training, for smoking cessation. A large randomized clinical trial by Niaura's group showed there was no benefit to adding CET to cognitive-behavioral skills training and nicotine gum. Several small studies with various methods also failed to show beneficial results. An approach to using CET by means of virtual reality did not investigate effects on smoking outside the sessions so its effectiveness is unknown. Therefore, CET for smoking cessation is not recommended for clinical use at this time.

CET for Cocaine or Opiate Dependence

While a study of CET for methadone-maintained clients with opiate dependence by McLellan's group found it to reduce craving, the clients treated with psychotherapy with no CET did equally well in terms of abstinence from drugs at follow-up after the end of treatment. A small study by Dawe and colleagues found no effect for CET on craving, withdrawal, or drug use. O'Brien and colleagues found that CET with recently abstinent clients with cocaine dependence resulted in significant decreases in craving and withdrawal ratings over 15 sessions, with craving near zero by the seventh session, and time to relapse was longer and self-reported drug use lower after CET compared to control groups. However, drop-out rates were high, almost everyone in both CET and comparison treatment did relapse, and there were no differences in drug use at a follow-up after treatment had ended. CET has not been studied

in controlled trials for other drugs of abuse. Therefore, CET is not recommended for clinical use at this time for cocaine or opiate use disorders.

CET for Alcohol Use Disorders

CET's effectiveness has been investigated with or without integrated urge coping skills training; clients in a comprehensive treatment program have better outcomes when they also receive either form of CET. CET is not designed to be a stand-alone treatment.

Several studies used CET based on simple exposure to the sight and smell of clients' usual alcohol beverage without teaching skills to cope with the urges. First, a small study by Drummond's group with 35 alcohol-dependent clients who were participating in inpatient treatment programs randomly assigned clients to receive ten 40-min sessions of either relaxation training or CET. Clients who received CET drank significantly less during follow-up after treatment and took longer to relapse to heavy drinking. Second, a study by Sitharthan and colleagues with nondependent problem drinkers who sought to drink moderately, randomly assigned 42 clients to either cognitive-behavioral treatment without cue exposure or to CET that included drinking a moderate amount of alcohol and then holding and smelling another drink without drinking it, with sessions occurring both in the clinic and at home. They were also taught various strategies for limiting their drinking along with self-monitoring their drinking. Compared to the clients in the control treatment, those who received CET drank less often and drank fewer drinks per occasion during the 6 months after treatment. Third, in another study of CET for moderate drinking goals, Heather's group randomly assigned 91 clients with alcohol use disorders to eight 90-min sessions of either CET or behavioral self-control training. The CET involved consuming one drink and then resisting continued drinking in sessions in both the clinic and at home. Clients in both types of treatment reduced their drinking by similar amounts over the 6 months after treatment. Thus, there is some evidence for exposure without urge coping skills training for training moderate drinking in clients with alcohol use disorders but only a small study of its effectiveness for abstinence goals.

CET with integrated urge coping skills training has considerable evidence for effectiveness as an adjunct to a comprehensive treatment program for clients with alcohol dependence in a series of studies by Monti, Rohsenow, and their colleagues. The first initial small study of this approach randomly assigned half of the 34 alcohol-dependent clients in an abstinence-oriented inpatient treatment to CET. The CET was six 50-min individual sessions of the combined CET described

above (beverage and imaginal cues, with integrated urge coping training). While clients in both CET and control treatment had equivalently low drinking during the first 3 months after treatment, only clients who received CET continued to show decreased quantity and frequency of drinking during the second 3 months after treatment. About two-thirds of clients with AUDs reacted to alcohol cues with increased urge to drink at the pretreatment assessment, and among these clients, those randomly assigned to CET showed greater reductions in urges to drink, were more likely to use coping skills after treatment, and had more abstinent days 4–6 months after treatment. Thus, the clients with the strongest reactions to beverage cues received the most benefit from CET.

The second larger study used a 2×2 experimental design: 100 clients with AUDs in an intensive day treatment program (“partial hospital”) were randomly assigned to eight individual sessions of the CET (almost the same as in the first study) or a control procedure (relaxation training), and clients in each of these conditions were also randomly assigned to Communication Skills Training (CST: a type of cognitive-behavioral treatment discussed in another chapter) or to an alcohol education control procedure. This type of experimental design allows a statistical analysis of the effects of CET while controlling for the effects of CST. CET resulted in fewer heavy drinking days among clients who relapsed to any drinking during the 12 months after treatment, compared to the clients who received the control training sessions as their addition to the intensive treatment program. Clients received an average of eight CET sessions added to a full day treatment program (i.e. very few people dropped out before completing all the sessions) and this brief addition resulted in improvements in drinking out to at least 12 months.

The third study compared CET (exposure with integrated urge coping skills training for 45 min) combined with CST with the alcohol beverages still displayed (for another 45 min) to a combined control treatment (relaxation and alcohol education) in a 2×2 design that also randomly assigned half the clients in each behavioral treatment to receive a medication (naltrexone) or a placebo pill for 12 weeks. The behavioral treatments were conducted in group format and each lasted 90 min per session for at most six sessions, with clients completing an average of 4.6 sessions. These occurred during the intensive day treatment program that lasted an average of 13 days, and the medication or placebo was started on the day of discharge to the outpatient aftercare program. The CET combined with CST had a lasting effect up to at least 12 months while the medication effects lasted only slightly longer than the 12 weeks of medication. After CET with CST, clients were less likely to relapse and reported fewer heavy drinking days during the subsequent 12 months than

did clients in the intensive treatment program who received the control condition, even though only four to five sessions of the experimental treatment were completed due to the constraints of managed care.

The mechanism of effect of this form of CET seems to be primarily by increasing use of coping skills when having urges to drink. CET resulted in greater self-reports of use of urge-specific coping strategies after treatment and use of these strategies correlated with less frequent drinking. The CET combined with CST also resulted in more frequent use of the urge-specific coping strategies, with a significant relationship between coping strategy use and frequency of drinking and with relapse (Monti et al., 2001). CET did not result in more decrease in salivation or urge to drink in response to the sight and smell of an alcohol beverage in a cue-reactivity assessment compared to the control group, although cue-elicited urge to drink among those who reacted at all pretreatment decreased more after CET than after no additional treatment in one study. Clients who received CET with CST showed less urge in response to the sight and smell of an alcohol beverage in a cue-reactivity assessment after the behavioral treatment than clients in the control condition, but relapse status at 3, 6, and 12 months was largely unrelated to degree of urge in this assessment. Therefore, there is no good support for the mechanism of effect of CET being via effects on reactions to alcohol beverage stimuli but good evidence of its effects resulting from increasing use of certain types of coping skills after treatment.

Summary of the Evidence

The controlled studies of use of CET for clients with AUDs consistently show beneficial effects on outcome. The evidence is most compelling when CET is integrated with urge-specific coping skills training, with lasting effects throughout a 12-month follow-up even when only 4–8 sessions of CET were delivered. The studies based on exposure to alcohol beverage stimuli without integrating practice coping with the urges also showed significant reductions in drinking throughout 6 months after treatment, although one study did not use alcohol-dependent clients and two of the studies focused on practicing drinking moderately rather than practicing abstinence. Therefore, it is less clear how well the CET without coping skills training would work for abstinence in a large study. The evidence on mechanisms of effect suggests that the practice of coping with urges elicited in a safe environment may have been the primary way that clients benefitted from this form of treatment. Given that without such practices, urges to drink can lead to impulsive drinking and disrupts cognitive abilities, including such practices is likely to

provide an advantage over exposure without urge coping skills training, with no disadvantage to this combination.

INTRODUCTION

Contingency management (CM) therapy is primarily a process of systematically using positive reinforcement to promote clinically relevant behaviors. CM has demonstrated efficacy for improving abstinence and other substance use disorder (SUD) treatment outcomes in a diverse range of treatment populations and settings. This technique is based on behavioral principles of

operant conditioning; specifically, that presenting an incentive or reward soon after a specific behavior occurs increases the likelihood that the behavior will reoccur. Grounded in behavioral economics theory, extensive research demonstrates that consumption of drugs and alcohol is sensitive to environmental consequences like the availability of alternative reinforcers, supporting the application of CM to treating SUD. The primary goal of CM is to reinforce behaviors that are compatible

with a drug-free lifestyle so that those behaviors increase in frequency, which might translate into improved long-term outcomes.

There are four central tenets of CM. First, select a specific and clinically relevant, objectively verifiable target behavior (e.g. abstinence verified by a drug-negative urine test). Second, monitor the target behavior frequently to maximize reinforcement opportunities and minimize failing to detect competing behaviors (drug use). Third, deliver a tangible incentive soon after the behavior occurs that is sufficiently valuable to the recipient to drive the desired behaviors, with encouragement and support. Fourth, withhold incentives when the target behavior does not occur. These elements are essential to CM.

Recent meta-analyses suggest that CM is among the most efficacious behavioral therapies for the treatment of SUD. These procedures are generally used to target abstinence directly by reinforcing urine and breath samples that test negative for substances of abuse. As discussed below, CM has demonstrated efficacy for increasing abstinence from alcohol, cocaine, opiates, benzodiazepines, marijuana, and cigarette smoking compared to standard care without CM. CM can also be used to increase other clinically relevant behaviors like counseling attendance, medication adherence, and completion of activities related to treatment goals. Central to the efficacy of CM treatment is the type of reinforcer or incentive used to motivate behavior change.

REINFORCERS

In CM therapy, appropriate incentives are tangible goods and services that are consistent with a drug-free lifestyle. For an incentive or reward to successfully reinforce a goal behavior, it needs to be sufficiently valuable to motivate individuals toward the desired behavior (e.g. abstinence) and away from competing behaviors (e.g. substance use). Practical considerations include the availability of incentives in the treatment environment and associated costs, which affect feasibility, sustainability, and acceptability.

Clinic Privileges

Clinic privileges are tangible, readily available, low- or no-cost commodities that can be used to promote increases in desired behaviors in the context of CM. Before the formalization of CM, privileges and contingencies on behavior were used in various settings for behavior modification purposes but often with a focus on punishment and nonsystematic use of rewards.

Dr Maxine Stitzer and colleagues at Johns Hopkins University largely initiated exploring effects of systematic positive reinforcement for specific therapeutic behaviors in the context of SUD treatment and did so in the context of the methadone maintenance clinic. Potentially powerful incentives readily available in methadone treatment include take-home methadone doses, dose adjustments, access to early dosing windows, and other privileges. Early studies also examined effects of behavior-contingent cash, although noncash incentives are typically used as they are less easily diverted. Researchers observed differential preference for some rewards over others, individual differences in reward preferences, and that differences in sensitivity to CM were attributable at least in part to patients' substance abuse histories. This initial body of research was seminal in shaping the abundance of subsequent research on CM techniques in an array of populations and settings.

Voucher-Based CM

Persistent substance use is a common problem in psychosocial outpatient treatment as it is in methadone treatment. An additional problem is poor treatment retention. Earlier success with CM for cocaine use in methadone patients suggested that CM might be efficacious for improving outcomes in cocaine-dependent psychosocial treatment patients, but a challenge was the relative lack of low or no-cost incentives. Research on effects of CM in this setting required a contrived reinforcement system, and Dr Stephen Higgins at the University of Vermont developed and conducted seminal research on what became voucher-based CM. Vouchers are essentially promissory notes with a monetary equivalent that are redeemable for goods and services consistent with treatment goals (e.g. payment of an electricity bill, groceries, and recreational items). Vouchers occur on a fixed ratio reinforcement schedule, meaning that patients earn a voucher every time a target behavior occurs. When the target is cocaine abstinence, urine samples are tested two to three times weekly on nonconsecutive days (e.g. Monday and Thursday). Vouchers start at \$2.50 for the first negative test and escalate by \$1.25 for each consecutive negative test, with a bonus (e.g. \$10.00 voucher) for every three negative tests in a row. Vouchers reset to \$2.50 with a positive test or unexcused absence, and the highest amount is reinstated with three consecutive negative tests following a reset. Vouchers are stored in a clinic "bank account" until redeemed. In a typical 12-week voucher program for cocaine abstinence, maximal earnings tend to be about \$1000–\$1200, and actual earnings are about half of that on average. Vouchers are redeemed

for goods and services individualized to patients' preferences, and there is more control over what is acquired with vouchers than possible with cash incentives. One limitation is that there is some delay between earning and redeeming vouchers (referred to as the exchange delay), and longer delays are associated with decreased treatment effect size. By contrast, the relatively large reinforcement magnitudes typical of voucher CM are associated with increased effect sizes, although cost may limit feasibility and sustainability, depending on many factors (see Dissemination and Uptake Challenges below).

Prize-Based CM

In response to concerns about the cost of voucher CM, Dr Nancy Petry at the University of Connecticut Health Center developed prize-based CM, a low-magnitude reinforcement system by design relative to voucher CM. In prize CM, patients earn at least one chance for a reward, or "prize," for each target behavior. A standard prize bowl contains 500 cards, with 250 cards containing a supportive statement (e.g. Good job for being abstinent!) and not a prize, 230 small prize cards worth about \$1 (e.g. toiletries, snacks), 19 large prize cards worth about \$20 (e.g. gift certificate, phone cards), and 1 jumbo prize card worth about \$100 (e.g. DVD player, mp3 player). Thus, there is a 50% chance of receiving any prize, and the chance of earning a small, large, and jumbo prize is inversely related to prize magnitude. Draws escalate, reset, and can include bonuses, akin to voucher CM procedures. Prize inventory is kept onsite which minimizes exchange delays and patients are encouraged to redeem earnings immediately but can bank them if working toward a specific item. Maximal earnings for a 12-week prize CM program are typically on the order of about \$400–\$600 in prizes, with actual earnings about half of that on average. Voucher CM and prize CM seem comparably efficacious when reinforcement earnings are relatively equivalent. Prize CM has small exchange delays, prizes are individualized based on patient preferences, goods are purchased in bulk shopping trips, and programmed incentive costs are relatively low. The possibility of large magnitude reinforcement early in treatment may be associated with treatment effects, although that is not clear. One concern about prize CM is that the element of chance may jeopardize individuals in recovery for pathological gambling, and those individuals are therefore typically excluded in research, although there is no evidence of increased gambling with prize CM. A possible limitation of prize CM and low-magnitude reinforcement generally is that the magnitude of treatment effects decreases with decreased reinforcement magnitude.

Housing and Employment

In substance abusers with chronic housing and employment problems, opportunities in these areas can be used to improve treatment outcomes while also addressing patients' limited employment options and lack of stable housing. To that end, Dr Ken Silverman and colleagues established a potentially self-sustaining data entry business, referred to as the Therapeutic Workplace, in conjunction with a methadone maintenance program. Access to job training and employment is made contingent on drug-negative urinalysis and treatment attendance. Aspects of employment settings that make them particularly suited to CM interventions include ongoing long-term opportunity for monitoring with ready access to monetary consequences for substance use. Other efforts have also examined abstinence-contingent employment/work training as well as contingent access to housing. Overall, the cost of establishing and maintaining such programs is relatively high, but may be justified by the benefits of achieving some progress on chronic problems in these populations.

Cash

Cash incentives avoid some of the costs associated with maintaining goods-based programs. A disadvantage is the clinical safety concern that cash could be used to purchase drugs and alcohol, although frequent monitoring and reinforcement of abstinence may decrease the likelihood of that happening. Surveys indicate that cash is generally preferred over goods or privileges, suggesting that it might be possible to retain efficacy at a lower cost in situations in which provision of cash proves to be safe.

Onsite Retail

With onsite retail-based CM, commodities are pre-purchased and stored onsite. Exchange delays are minimized, shopping can be done in bulk which requires fewer resources than shopping on a per patient basis, and some tailoring to accommodate patient preferences is possible.

Refunds

A patient-sided approach for providing reinforcers is to have patients make a deposit using their own funds and then reacquire portions of the deposit by meeting goals like testing negative on urinalysis. Deposit contracting transfers the cost of incentives from the service provider to the service user, but limits participation to those willing and able to make deposits.

ISSUES CENTRAL TO CM

Key elements of CM that affect treatment efficacy include the behavior targeted for change; the monitoring and reinforcement schedule; reinforcement immediacy, magnitude, and exposure; and the contingent nature of reinforcement.

Target Behaviors

The target or goal behavior is the behavior identified for change via reinforcement contingencies. Objective verification of the target behavior is required, with the form of objective evidence agreed upon beforehand. Verbal reports are more subject to interpretation and influenced by external factors, and are not adequate. The most common target behavior is abstinence verified by drug-negative urinalysis or breath test, and sample validity checks are available if needed, including temperature and creatine tests. Other types of target behaviors include treatment attendance, as verified by direct observation or clinical chart review, and completion of treatment goal-related activities like attending a doctor appointment or developing a resume, verified by receipt. Behavioral targets should be achievable and might already occur at a low level in the intended population. Else, manageable steps toward a larger goal can be reinforced. There is little need to reinforce behaviors that already occur frequently, and behaviors that are too difficult to accomplish will result in little or no exposure to reinforcement and improved outcomes will be unlikely.

Monitoring and Reinforcement Schedule

The monitoring schedule should maximize opportunities to detect the target behavior, and in the case of abstinence, minimize carryover effects of any substance use from one test to another. Monitoring might mimic the natural occurrence of the behavior (e.g. every therapy session). “Reinforcement schedule” refers to the rules used to present reinforcers following a behavior. Examples include the provision of reinforcement with certainty for every occurrence of a goal behavior as in voucher CM, or when the probability of reinforcement is less than certain, as with prize CM. Reinforcement schedules with specific characteristics designed to promote sustained abstinence are typically used in effective CM programs. Specifically, reinforcement escalates with consecutive target behaviors. Reinforcement is reset to a low level when the target behavior does not occur, and it is reinstated to a previously high level after the behavior occurs a set number

of times after reset. Further, bonuses are often available for sets of target behaviors.

Reinforcement Magnitude

Another factor that can affect the efficacy of CM therapy is reinforcement magnitude. Incentive magnitude needs to be sufficiently large to compete with drug use and related undesirable behaviors. What constitutes sufficient depends on factors that can affect the subjective value of reinforcers including reinforcer immediacy, response cost, and patient characteristics like severity of dependence. Higher reinforcer magnitudes can increase response rates, although it is important to monitor for “ceiling effects,” in which there is little or no room for improvement because the target behavior already occurs frequently or for other reasons. Importantly, CM programs that have relatively low-magnitude reinforcement but that adhere to the behavioral principles discussed in this chapter can be efficacious.

Reinforcement Immediacy

Relatively immediate reinforcement can produce better outcomes than delayed reinforcement. This may be explained by a phenomenon from the field of behavioral economics referred to as delay discounting, which refers to the decrease in the subjective value of a reinforcer as time until it is available increases. Delays between earning and receiving rewards (the “exchange delay”) can weaken the strength of the reinforcement; hence, the goal generally is to keep reinforcers relatively readily available to facilitate redemption and minimize delays to reinforcement.

Reinforcement Exposure

For CM to be effective, exposure to reinforcement is required. Conditions that prevent or limit exposure will negatively affect outcomes, as in the case of when a target behavior is particularly difficult, resulting in few patients meeting criterion. One option in such cases may be to shape behavior, a process by which incremental steps toward the desired behavior are reinforced. For example, given that 2–3 days of cocaine abstinence is required to test negative on urinalysis, a daily cocaine user will be less likely than an infrequent user to achieve this goal on day 1 of a contingent reinforcement protocol or even at all. In that case, abstinence can be shaped by making reinforcement contingent on increasing percentage reductions in cocaine metabolites (e.g. 25% reduction on day 1, 50% reduction on day 2, etc.), until a negative test is achieved. A disadvantage of such quantitative

testing is that it is more expensive and less readily available than the semiquantitative onsite urine dipstick tests used widely, and sending samples out for quantitative testing imposes delays, which can decrease treatment effects. Increasing exposure to reinforcement can also be accomplished through priming, a process of delivering incentives independent of abstinence or another target behavior and at a time before the goal behavior is possible or likely. For example, for a patient unlikely to test negative on day 1 of a protocol, submission of the urine sample itself independent of urinalysis results might be reinforced, to ensure exposure to incentives and encourage engagement. Another option might be to adjust reinforcement density, which refers to the magnitude of reinforcement over time. For example, a typical prize CM program has a 50% chance of drawing a prize each time that abstinence occurs, but there might be conditions in which a modified version with guaranteed reinforcement could be beneficial, like during the early stages of recovery.

Contingent Reinforcement

Finally, the contingent nature of reinforcement is essential to the efficacy of CM. Contingent reinforcement reliably produces increased abstinence and other goal behaviors compared to noncontingent, or the absence of, reinforcement.

EFFICACY

Methadone Maintenance

Methadone maintenance is efficacious for reducing heroin use and related high-risk behaviors. However, a relatively common problem that jeopardizes treatment outcomes for many patients is persistent substance use during treatment. Detection of ongoing substance use often results in punitive measures like premature detoxification and treatment discharge, which is associated with increased likelihood of high-risk behaviors like drug use, needle sharing, and other criminal activity and is therefore counterproductive. Medication compliance can also be problematic. For example, in the case of disulfiram (Antabuse) therapy for alcohol abuse, the medication causes highly aversive effects if alcohol is consumed, and many patients avoid those effects by simply not taking the medication. Further, while patients go to the clinic daily to receive their methadone medication, some patients nevertheless do not attend counseling as prescribed.

Early studies on CM in methadone patients investigated effects of contingent methadone take-home doses, dose adjustments, and cash to improve

abstinence, medication compliance, and treatment attendance. These were relatively small-scale studies, but results generally supported improvements with contingent incentives. For example, one study examined effects of abstinence-contingent methadone take-home doses and other privileges on benzodiazepine use and found that contingent reinforcement increased rates of drug-negative urine samples. Other studies found similar effects of contingent incentives on unsanctioned opioid use and cocaine use in polysubstance abusing patients, as well as increased adherence to disulfiram therapy and naltrexone therapy. Importantly, a few early studies compared the effects of not only the availability of methadone dose adjustments up with drug-negative tests, but also effects of contingent dose adjustments down with drug-positive tests, in polysubstance abusers. While both contingencies increased abstinence rates, dose-adjustments down lead to increased rates of treatment dropout, which is associated with significant adverse consequences like increased drug use and related criminal activity and risky behavior. That observation largely led to the emphasis on positive incentives in all subsequent research on CM techniques. More recently, research has established the efficacy of both voucher CM and prize CM for improving during treatment abstinence and treatment attendance in cocaine-dependent methadone patients, as well as increased abstinence during periods of methadone dose tapering or detoxification with CM. Effects of CM extend beyond abstinence and treatment attendance to decreases in risky behaviors like needle sharing. Moreover, voucher CM has been used to improve abstinence in women who are pregnant, postpartum, or with children, a particularly vulnerable population. Other findings related to CM in methadone patients can be found in specific sections below.

Psychosocial Treatment

In psychosocial treatment, continued substance use can precipitate high rates of early treatment dropout, with negative effects on outcomes. The absence of an approved pharmacotherapy for cocaine dependence makes treating the disorder particularly challenging. In seminal research, Dr Stephen Higgins and colleagues examined effects of voucher CM for improving outcomes in psychosocial treatment patients. In that research, CM was explored as an adjunct to community reinforcement approach therapy, an intensive behavioral therapy that involves extensive outreach to garner social sources of reinforcement supportive of a drug-free lifestyle. Results indicated about a doubling in retention and abstinence rates with CM compared to

standard treatment. Subsequent research supported the importance of the contingent nature of reinforcement and isolated treatment effects to the CM component. Findings of improved abstinence and retention in psychosocial treatment patients with both voucher-based and prize-based CM, and in conjunction with intensive as well as less intensive counseling, have been replicated and extended. Abstinence-contingent incentives have also been used to prevent relapse in cocaine treatment patients immediately following release from residential treatment. Other findings of benefits with CM in psychosocial treatment settings are found in specific sections below.

As discussed further below, one challenge concerns the sustainability of CM treatment effects, which often dissipate after behavioral contingencies and reinforcement end. However, a reliable predictor of abstinence long-term is the longest duration of sustained abstinence (LDA) achieved during treatment, and CM increases LDA. This association between CM and LDA has been reported in psychosocial and methadone treatment patients, with voucher and prize CM, and under a variety of conditions.

While efficacious, it is also important to recognize that, as with treatments generally, CM does not improve outcomes for all patients. CM procedures that adhere to the principles and elements discussed in this chapter are associated with medium to large treatment effect sizes, but not all patients respond, and individuals differ on magnitude of response. One known factor that affects treatment response is addiction severity. Patients who have a negative versus positive urinalysis on admission, a proxy for addiction severity, seem to be more likely to respond to CM than those who test drug-positive. Marijuana-dependent and cocaine-dependent patients who have a positive urinalysis early in treatment are less likely to achieve significant periods of sustained abstinence during treatment. Upward adjustments to reinforcement magnitude or other modifications may be needed to improve outcomes in patients expected to be low- or no-responders to CM treatment (see Issues Central to CM below).

Other Substance Use

The research literature on CM for improving abstinence from marijuana, cigarette smoking, methamphetamines, and alcohol is relatively small but generally supports increased abstinence with CM.

Nicotine

Even with recommended pharmacological and behavioral treatments for smoking, many people do not quit, and relapse rates are high. CM in combination with

pharmaco and/or behavioral therapy may improve smoking outcomes. Research in the general population of smokers consists of laboratory studies and relatively small trials but results generally support feasibility and at least short-term efficacy. CM for smoking in a few specific populations has received more attention. The adverse consequences of smoking unique to pregnant and postpartum women are well-documented, and pharmacotherapy remains contraindicated, increasing the need for effective behavioral treatments. CM can increase short- and long-term smoking abstinence in this population, possibly with beneficial effects on birth outcomes. In people with other SUD, the prevalence of smoking is several times higher than in the general population, and smoking-related morbidity and mortality are disproportionately high. CM can reduce smoking and increase LDA from smoking in methadone and potentially other substance abuse treatment patients, but research is needed on combining CM with pharmacotherapy when appropriate or other methods to improve response rates and long-term benefits. Importantly, concerns that SUD treatment outcomes might be jeopardized if smoking is addressed have not borne out. CM for smoking in adolescents, young adults, and people with schizophrenia has also received some attention, with promising results.

Challenges of addressing smoking in the context of CM include technological limitations surrounding detection of the biologic indicators of smoking – expired carbon monoxide, a combustion byproduct, and cotinine, a major metabolite of nicotine. Issues with carbon monoxide include the possibility of environment exposure; an elimination rate of about 3–8 h, requiring multiple tests daily to detect all smoking; and the ability to avoid detection by adjusting smoking around scheduled tests. In response to the latter two, researchers have examined remotely monitoring and administering CM for smoking abstinence via webcam, e-mail, and the Internet. Results support feasibility, and there is increased interest in Internet-, computer-, and mobile technology-based interventions generally, for smoking and otherwise. Regarding cotinine, it can take about 4 days of abstinence to test negative for smoking, complicating reinforcement of abstinence.

Marijuana

There are a few well-controlled trials on CM in persons seeking treatment for a primary marijuana SUD, with results suggesting beneficial effects of combining CM with motivational enhancement therapy and cognitive behavioral therapy. It has been suggested that adolescent marijuana users might particularly benefit from CM. Adolescents do not typically initiate treatment themselves, likely due in part to having not

yet experienced the serious adverse consequences of chronic use that can motivate older individuals to treatment. In this context of low motivation, the concrete rewards with CM might be one way to incentivize change. Initial research in this population indicates increases in LDA from marijuana during treatment with CM compared to that without it. Another population of specific interest is people with schizophrenia, in whom marijuana use is highly prevalent, with feasibility studies suggesting that CM might be beneficial in this population.

Monitoring marijuana abstinence in the context of CM has challenges. In chronic heavy users, it can take 3 weeks of abstinence to test negative. A 2-week notice prior to contingencies or a baseline period without reinforcement consequences on urine tests can be used in the interim. Another option may be to reinforce percentage reductions in metabolite levels during initial weeks (and after lapses), although approximately daily testing may be necessary for reliable results and testing equipment is expensive. Moreover, factors that can change the rate of cannabinoid release from fat cells, like exercise, can obscure results.

Methamphetamines

As with cocaine dependence, there are no approved pharmacotherapies for methamphetamine dependence, underscoring the need for effective behavioral treatments. CM can improve abstinence and LDA in methamphetamine treatment patients, particularly when reinforcement magnitude is relatively high. The literature on effects of CM in methamphetamine abusers outside of traditional drug abuse treatment settings is mixed. Issues that challenge use of CM techniques for methamphetamine problems include that use tends to occur more periodically, and methamphetamine has a longer elimination rate, than with cocaine, with implications for urinalysis testing.

Alcohol

There are efficacious behavioral treatments for alcohol problems but there is much room for improvement, and adherence with pharmacotherapy regimens (e.g. disulfiram, naltrexone) is generally low because of aversive direct or side effects of medications. CM can increase adherence to alcohol treatment medications. Currently, CM that directly targets alcohol abstinence is difficult due to by issues similar to those discussed above in relation to detecting smoking (quick elimination rate, ability to adjust use around scheduled sessions). Advances in technology like continuous alcohol monitoring devices and potentially Internet-based or other mobile procedures provide a potential means to overcome monitoring issues.

Non-Abstinence Behavioral Targets

Goal-Related Activities

A comprehensive treatment plan not only not only supports abstinence, but also supports steps toward goals in other problem areas, such as family and social functioning and employment. A needs assessment can be conducted with patients to identify goal areas, and activities related to those goals identified for completion and reinforcement, with the difficulty of activities adjusted depending on psychosocial functioning. Few studies have compared CM for abstinence and CM for activities, with mixed results. There is demonstrated efficacy for CM when abstinence and activities are independently reinforced.

Employment

As introduced above, the Therapeutic Workplace intervention is an intensive integrated approach to treating chronic unemployment in persons with long histories of SUD who are unsuccessful in standard treatment. The Workplace involves regular urinalysis monitoring with access to job skills training and subsequently employment, both contingent on negative drug tests and workplace attendance. Positive or missed urine tests result in pay reductions, which can be earned back by submitting negative drug tests and attending work. Initial research in pregnant and postpartum women demonstrated increased cocaine and opioid negative drug tests and LDA in CM compared to usual care patients, with improvements in abstinence evident at year 3. Subsequent studies in methadone maintained cocaine users and injection drug users suggest that exposure to reinforcement early on may be critical. Moreover, there is some evidence that similar procedures may be effective in alcohol-dependent homeless persons.

Housing

SUD is prevalent among the homeless, as is serious mental illness. It can contribute to risk of homelessness, and the homeless are at increased risk for illness and psychosocial deficits in myriad domains, with severely limited access to services. Dr Jesse Milby and colleagues developed an integrated approach to SUD treatment and housing for homeless crack cocaine users seeking treatment. Day treatment involves daily individual and group therapy with objective goal setting and random urinalysis, transportation, and a midday meal. Contingent housing involves access to an apartment or group home contingent on drug-negative tests, and drug-positive tests or unexcused absences result in transition to a shelter, with an opportunity to return to housing after a set number of drug-negative tests. Contingent work therapy/employment consists of training and paid experiences, and with positive tests or unexcused absences

resulting in a reset to a lower hourly wage. In clinical trials on contingent housing and employment/training with day treatment or cognitive behavioral therapy in this population, LDA during treatment predicted long-term abstinence regardless of treatment condition as well as long-term housing and employment stability. In another study, prize CM was used to engender increased abstinence in homeless persons with both substance use and psychiatric problems. Perhaps not surprisingly, an integrated and comprehensive approach to treating these chronic issues seems to produce the best outcomes.

Medication Adherence

Several pharmacotherapies exist for SUD (agonists, antagonists, aversive medications, anti-craving medications) and for problems common in SUD populations (e.g. human immunodeficiency virus, comorbid psychiatric conditions). Adherence with agonist medications is generally relatively high because of the reinforcing effects of the medications, but diversion to nonprescription use can occur. Adherence is more problematic when medications produce adverse effects with continued substance use or aversive side effects themselves. The delayed benefits to health with many medications and low motivation to change in general can further undermine medication adherence. Notably, CM can introduce immediate rewarding effects and increase medication adherence.

DISSEMINATION AND UPTAKE CHALLENGES

As discussed in this chapter, there is strong empirical support from well-designed randomized clinical trials demonstrating that CM interventions that adhere to the key principles reviewed above are efficacious, and there is growing interest in translation of CM from research to practice. There have been several relatively large efforts to integrate CM into practice. New York City Health and Hospitals Corporation successfully provided CM services to five SUD treatment facilities. CM workshops were provided to 432 therapists in South Carolina. Virgin Healthcare initiated a multimillion-dollar employee program in which insurers fund prizes for behavior change. The Veteran's Administration called for use of CM nationwide in substance abuse treatment programs in 2011, and as of 2012, it has been successfully implemented in over 60 clinics. In England, efforts to introduce CM into the National Health Care System have been undertaken. Some variables that influence the dissemination and uptake of evidence-based treatments in general as well as those specific to CM are discussed below.

Costs

Cost is a primary concern. Various aspects of CM have associated costs. Training and oversight directly affect treatment fidelity and need to be provided to staff who will be administering CM. There are operating costs, including those incurred by the frequent urinalysis schedule required for effective CM, which exceed standard testing practices. Incentive costs are another concern, and even low-magnitude incentives are a cost that many programs cannot absorb. One way to reduce costs might be automated procedures like that possible via computers. It might also be possible to contain some costs by integrating CM into settings like government programs, workplaces, and the criminal justice system which have large infrastructures already in place and have advantages like long-term relationships and large target audiences. Another option might be to identify appropriate low or no-cost incentives. Soliciting community donations might also be viable, which has been done to sustain CM programs for treating cigarette smoking in pregnant, postpartum, and parenting women, although the extent to which communities are willing to support these programs may or may not generalize to other populations. Deposit contracts are an example of a patient-sided approach to funding incentives, but access is limited to patients willing and able to provide the required funds. In dual diagnosis patients, one possibility may be to make receipt of disability payments contingent on therapeutic behaviors. Options for combinations of patient, provider, and third party subsidizing of costs may offer the flexibility to best accommodate the needs of a wide range of potential service providers and users. In terms of overall costs, the relative cost-effectiveness of CM treatment depends in part on the referent treatment, incremental cost-effectiveness ratios, and threshold values on acceptability curves. There is empirical support for the cost-effectiveness of CM, but larger scale research is required to more fully determine the conditions under which it is so. Ultimately, the research and treatment communities, insurers, political forces, treatment service users, communities at large, and other stakeholders will determine the acceptability of cost-effectiveness and cost-benefit ratios and willingness of society to pay for this evidence-based treatment.

Sustainability of Treatment Effects

One aspect that will affect determinations of cost-effectiveness and cost-benefit is the sustainability of treatment effects. Treatment gains generally drop off after discontinuation of incentives. It may be that some situations warrant a continuing care approach, which is the case in drug abuse treatment more generally and not unlike treatment and treatment response with diabetes, hypertension, and asthma, for which a return

of symptoms and signs precipitates a continuation or reinstatement of care. Another consideration is that the best approach to defining treatment response is subject to debate, with important implications for observed (or lack thereof) treatment effects, long-term or otherwise. Some have explored tapering reinforcement at the end of a treatment episode to possibly increase the durability of benefits. Another approach might be to combine CM with cognitive behavioral therapy or potentially other therapies, as CM increases abstinence during treatment while cognitive behavioral therapy has more substantial benefits long-term. Notably, there is some evidence in the literature of improved long-term outcomes with this combined treatment approach in cocaine-dependent methadone patients and marijuana treatment patients.

Generalizability and Fit

Randomized Clinical Trials

Concerns that the methodology and outcomes of well-controlled randomized clinical trials may not generalize to “real-world” treatment could hamper uptake of CM. Narrow inclusion criteria may produce research samples that appear dissimilar to patients at large. Interventions may appear disconnected from the complicated reality of practice. Further, well-trained research staff have largely administered and managed CM interventions to date, raising doubts about feasibility and effectiveness in non-research settings. Recognizing these issues, some researchers have loosened eligibility criteria to improve generalization. Further, studies have been conducted in which community treatment staff have been successfully trained and then administered CM, with improved outcomes observed with CM versus usual care. One example is a National Institute on Drug Abuse Clinical Trial Network large multisite trial in which cocaine and methamphetamine psychosocial treatment patients were randomly assigned to usual care only or usual care plus prize CM, with reinforcement contingent on testing negative for amphetamine, cocaine, and methamphetamine and alcohol, and bonuses for opioid- and marijuana-negative tests. Treatment retention and abstinence were increased in the CM condition, and CM patients were more likely to achieve specific durations of LDA compared to usual care patients. In an analogous trial in methadone patients, CM patients were twice as likely to submit negative tests and were several-fold more likely to achieve specific durations of LDA compared to usual care patients. Ultimately, an ongoing dialogue about the benefits and limitations of scientific research, along with efforts that demonstrate effectiveness under conditions that promote feasibility and generalizability, is needed.

One versus Multiple Drug Targets

The tendency in research to focus on one drug and the clinical tendency not to may contribute to a perceived lack of fit between research and practice. Research often focuses on a primary SUD that is targeted for reinforcement, and there are no reinforcement consequences on other substance use. Advantages include that having a single drug target is associated with increased treatment effect size relative to studies with multiple drug targets. By contrast, the non-research treatment scenario is largely one of polysubstance abusers and all patients receive treatment for all SUD. Typically, CM is employed against a backdrop of usual care in which all patients are treated for all SUD, but the misalignment between approaches may provoke opposition. If there is concern or evidence that a goal of complete abstinence might be too difficult for some polysubstance abusing patients and results in little or no reinforcement opportunities, one option may be to make reinforcement contingent on abstinence from the primary substance of abuse, with bonuses for abstinence from secondary substances. Improved understanding of these and other conditions under which targeting one or multiple substances is most beneficial may increase acceptability of CM.

Abstinence versus Attendance

Most CM research has focused on abstinence. Although highly clinically relevant, disadvantages in practice include that urinalysis frequency rarely meets ideal monitoring and reinforcement schedule requirements of CM, and the resources necessary to increase testing are unlikely to be available at many programs. Attendance is more easily verifiable via review of daily census records and at little or no additional cost, and reinforcing attendance may sufficiently improve outcomes in some patients. However, there are circumstances in which reinforcing abstinence is more likely to improve outcomes and the costs of doing so especially justified. For example, patients with a positive urinalysis test at treatment admission tend to have worse treatment outcomes than individuals who test negative, and reinforcing abstinence can decrease drug use and increase retention in those patients. Additional research is needed to inform decisions about the pros and cons of targeting abstinence versus attendance under various conditions relevant to practice settings.

Individual versus Group Treatment

Another area of apparent mismatch between research and practice is the typical practice of private meetings with patients to conduct CM in research compared to the preponderance of group therapy in practice. It follows that interventions that can be administered in

group may be more easily integrated into usual care. Research on prize CM delivered in a group setting indicates feasibility and efficacy of reinforcing attendance as well as reinforcing both attendance and abstinence (with precautions to protect patients' confidentiality) in this setting, when CM is administered by research staff and when conducted by community therapists.

Therapeutic Process

There is some concern that the focus on external reinforcers with CM might interfere with internal motivation to change. Comprehensive treatment plans address a multitude of issues underlying addiction and recovery, and all patients benefit from those services, some of which may improve motivation or not. How CM interacts with motivation is an empirical question, and the few studies that have addressed motivation with CM have mixed results. Related, there is some evidence that CM delivered in group therapy may be associated with improved therapeutic alliance and group cohesion. It will be important for future research to examine relations between CM, therapeutic process variables, and treatment outcomes.

SUMMARY

CM is the systematic application of behavioral principles of positive reinforcement to the treatment of SUDs. CM interventions that adhere to specific key principles have demonstrated efficacy for improving outcomes in a wide range of substance abuse treatment populations and settings, and CM is among the most efficacious evidence-based treatments for substance abuse. Some areas for further research include identifying conditions and methods that can lead to increased treatment response and sustained treatment benefits long-term, in substance abuse patients generally as well as in specific populations; useful combinations of CM and other effective treatments for SUDs; and, methods to facilitate translation of CM techniques from research to practice.

Glossary

- Agonist** a chemical substance that can produce the same reaction or activity when it binds to a receptor on a cell as some endogenous substance that typically binds to the receptor.
- Antagonist** a chemical substance that tends to nullify the action of another substance by, for example, blocking binding of that substance to a cell receptor, but without producing a response itself.
- Buprenorphine** a semisynthetic narcotic analgesic that is administered sublingually to treat opioid dependence.
- Effect size** a standardized measure of the strength of an effect of an independent variable on a dependent variable. It represents the change (measured in standard deviations) in an average person's outcome (the dependent variable) if given the treatment (the independent variable).
- Longest duration of abstinence** The greatest period of time (usually in weeks) during which all breath and urine samples collected test negative for all substances targeted, ostensibly when samples are collected and tested sufficiently frequently and at adequate intervals to detect substance use if it occurs.
- Opioid** a substance that possesses some properties characteristic of opiates but unlike opiates not themselves contained in the resin of the opium poppy. Examples include heroin, oxycodone, and methadone.
- Priming** refers to an increased sensitivity to certain stimuli (reinforcement, in the sense used in this chapter) due to prior experience.
- Reinforcement** in behavioral science, the presentation of a stimulus following a response that increases the frequency of subsequent responses.
- Shaping** a process through which successive approximations of a desired behavior are reinforced to increase the likelihood of the desired behavior in the future.

COMMUNITY REINFORCEMENT APPROACH: CRA

Overview

The Community Reinforcement Approach (CRA) is a behavioral treatment for individuals with substance use disorders that was introduced by George Hunt and Nate Azrin approximately 40 years ago. As the name implies, it is based on the belief that one's "community" (i.e., family, romantic partners, friends,

coworkers, teammates, congregations) plays a significant role in reinforcing (rewarding/supporting) recovery. Thus it is not unusual for a critical member of the client's family community (i.e. a partner) to accompany the client to several therapy sessions. Overall, the goal of CRA is to help clients develop a clean and sober lifestyle that is more rewarding than a lifestyle filled with substance use. CRA accomplishes this through the use of behavioral procedures based on reinforcement principles that steer clear of confrontation. Given that CRA is

a behavioral and not a cognitive-behavioral treatment, it does not focus on cognitions. Importantly, CRA has been used successfully to treat individuals with varying degrees and types of substance use problems and across different treatment settings (inpatient, outpatient, day treatment). The first half of this chapter provides an overview of the treatment for the substance-abusing individual (CRA), whereas the second half reviews the treatment for the loved ones of treatment-refusing alcohol or illicit drug users (Community Reinforcement and Family Training; CRAFT).

CRA PROCEDURES

CRA Functional Analyses

CRA's Functional Analysis for Substance Use is a semi-structured interview that outlines triggers and consequences (both positive and negative) of substance-using behavior, thereby providing a framework for a conversation about the context within which the use occurs. This wealth of information is a map that guides the selection of other CRA procedures in subsequent sessions. Specifically, this functional analysis is important for (1) recognizing and interrupting internal and external triggers to assist in relapse prevention, (2) providing a measurement of quantity and frequency of use that can be contrasted later in therapy, (3) identifying and amplifying the client's reported reasons to change (i.e. long-term negative consequences) in order to activate him/her to begin the change process, and (4) identifying the factors that reinforce the substance use (i.e. short-term positive consequences) so that healthy behaviors offering somewhat similar rewards can be found. Identifying the most rewarding aspects of using substances appears to be one of the most powerful parts of the functional analysis exercise. Clients always are pleasantly surprised that a therapist is interested in discussing this topic, and they readily outline their perceived alcohol/drug-associated rewards (e.g. mellows them out, makes social activities more fun, addresses their boredom). This information is critical as far as helping clients build and maintain a healthy new lifestyle that addresses their particular needs in the process. The CRA Functional Analysis for *Pro-Social* Behavior is used to highlight enjoyable activities and eliminate barriers so that these behaviors may be selected over substance use more often.

Sobriety Sampling

Sobriety Sampling is a "gentle" approach to abstinence; an alternative to the traditional message that an individual can never drink/use again for the rest of his/her life. CRA recognizes that the notion of long-term

abstinence may seem overwhelming at treatment onset and consequently could lead to dropout. So instead, CRA therapists first discuss the advantages of a "trial period" of sobriety, such as the opportunity to gain family support and test new coping strategies. Once a client agrees to sample sobriety, the negotiation begins. Regardless of whether the client settles on 3 or 30 days, the next appointment should occur prior to the end of the contracted period of sobriety so that additional trial periods of abstinence can be linked.

Agreeing to a time-limited period of abstinence is only the beginning, since a plan for accomplishing this goal must be established. The triggers that were outlined in the CRA functional analysis for substance use are examined and strategies for addressing them are devised. For example, if a client had reported previously that he/she often dealt with his/her frustration (internal trigger) by getting high, the sobriety sampling plan would include both a strategy for minimizing the client's frustration at high-risk times, and for coping with frustration, once it appeared, in some manner besides getting high. In subsequent sessions, the therapist would highlight the positive consequences experienced by the client as a result of being clean/sober and would introduce problem-solving if abstinence had been threatened.

The Treatment Plan: Happiness Scale and Goals of Counseling

The Happiness Scale is a versatile tool that assesses the client's perceived happiness in 10 life areas (e.g., social life, job/school) on a 10-point scale ranging from 1 (completely unhappy) to 10 (completely happy). It is administered at the onset of therapy, and then periodically throughout to monitor progress. Clients are informed that the Happiness Scale highlights potential avenues for increasing healthy rewards in their life.

The Goals of Counseling mirrors the Happiness Scale's categories and is used to list clients' goals and strategies. Clients are trained to word their goals in terms that are brief, specific, positive (what the client *wants* as opposed to what the client *does not want* anymore), under the client's control, and realistic. Furthermore, CRA stresses the importance of successive approximations toward goals. For example, if a client rated money management a "6" on the Happiness Scale, the clinician might ask, "What could you do over the next week to increase that rating to a 7?" Such a question invites clients to identify specific tasks that could incrementally increase their happiness.

Communication Skills

Being able to communicate effectively is a critical part of a rewarding lifestyle. CRA therapists explain that

positive communication is not only “contagious,” but it also increases the likelihood that clients will get what they want. Communication skills are taught by describing the components of effective communication while supplying examples, by practicing the skills in role-plays, and by having the client apply the skills to real-world situations for homework. CRA’s positive communication components are: be brief, refer to specific behaviors, use positive wording, state your feelings, give an understanding statement, take partial responsibility, and offer to help.

As an example, assume that a female client was upset because her husband was unwilling to accompany her to new nondrinking social activities. Below are attempts by the client to phrase her request for her husband to attend a movie with her:

Attempt #1: “How am I supposed to find new sober things to do if you won’t ever try any of them with me? What’s so awful about going to a movie with me?”

Attempt #2 (after therapist feedback): “I know you’d rather stay home on Friday nights because you’re really tired from a hectic week of work [*understanding statement*], but I really need to get out of the house. Can’t we go to a movie?”

Attempt #3 (after further therapist feedback): “I know you’d rather stay home on Friday nights because you’re really tired from a hectic week [*understanding statement*], but Friday nights are really stressful if I don’t have something fun planned [*feelings statement*]. What if I ordered a pizza so we could have a quick dinner on Friday, and then we could head out the door to a movie without any hassle [*offer to help*]?”

Problem-Solving Skills

It is imperative for clients to learn how to solve problems, even complex or emotionally charged ones, so they can focus on meeting their goals. CRA’s problem-solving procedure is adapted from D’Zurilla and Goldfried. To illustrate both the problem-solving procedure and a reasonable time for introducing it in a therapy session, assume that a 35-year-old male client made a goal to incorporate more clean/sober social activities into his week. He decided to play basketball at least weekly with his nonusing buddies, but a dilemma arose when his wife said she did not want him to go as he was heading out the door. The problem became apparent to the therapist when the homework assignment was reviewed at the start of the next session. The therapist asked, “Phil, how did the basketball assignment go this week?” Phil replied, “Not so good. My wife got upset as I was leaving on Wednesday to play, so I didn’t go. She said she was afraid that I was going to get high;

that I might run into my former using buddies. I got mad at her and left, but I just went for a quick walk.” The therapist responded, “Well, it sounds like you’re using some of your skills for handling your anger, so that part is good. But what do you think about your goal of playing more basketball with your nonusing friends? Is this something you’d still like to do?” Phil answered, “Yes, but I don’t know how it’s going to happen without creating a war at home.” The therapist remarked, “Sounds to me like it’s a problem for which we could use some problem-solving skills. Shall we give it a shot?” The therapist would explain the objective of the procedure and define each of the steps while working on the relevant problem. In the problem-solving “worksheet” below, sample responses are supplied for this case.

1. *Define the problem:* This step distills complex problems into one that is specific and manageable.
 - 1st (vague) definition: “My wife doesn’t trust me anymore”
 - Refined definition: “My wife doesn’t trust me to stay away from my old using friends if I play basketball in the park.”
2. *Generate alternatives (brainstorm):* Brainstorming demands quantity. Suggested alternatives should not be censored, as unrealistic or counterproductive ones will be vetted in subsequent steps.
 - Sample suggestions: have brother go too; call or text wife every 45 min; play at new indoor court; just tell wife that I won’t use; have one of my nonusing friends call her to reassure her.
3. *Eliminate unwanted suggestions:* The client is empowered to eliminate solutions without explanation.
4. *Select a solution:* The client chooses one possible solution from those remaining, and describes how it will be implemented.
 - Play at the new indoor court (ride with Sal; check for open court nights)
5. *Check for obstacles:* Numerous obstacles should be generated, even when the client initially reports that there are none.
 - No courts free
 - One of the friends can’t go
6. *Address each obstacle:* If an obstacle cannot be addressed, another potential solution should be selected instead.
 - No courts free (reserve one in advance)
 - One of the friends can’t go (have a back-up friend lined up)
7. *Evaluate the outcome:* The outcome of the assignment is reviewed at the subsequent session.

The therapist’s job is not to solve their clients’ problems, but to teach them a technique that will help

them solve their own problems. It is often necessary to repeat this procedure with several problems until the client has internalized the steps and can apply them with proficiency and confidence outside of the session. The CRA therapist always links the accomplishments that grow out of the problem-solving exercise (e.g. the wife no longer objecting her husband leaving to play basketball with his nonusing friends) with the client's own goals (i.e. to increase his nonusing social activities).

Drink and Drug Refusal Skills

Clients seeking assistance to change substance abusing patterns often struggle with the ability to refuse substances assertively. This occurs for many reasons, not the least of which is that the clients have no reference point for how to conduct themselves in social situations without using substances. Many clients also do not have appropriate models for assertive behavior and find themselves vacillating between passivity and aggression. To complicate this further, clients frequently overestimate their ability to refuse drugs/alcohol. Statements such as "All I have to do is just make up my mind not to drink" are common and are often said in sessions that precede a relapse. Unfortunately, most clients can become overwhelmed by social cues and external reinforcers to use, even if they are motivated to remain abstinent.

Teaching clients drink/drug refusal skills can be broken down into four parts, starting with reviewing high-risk situations. Frequently these are extrapolated from the functional analysis. Next, a person who can provide support in the high-risk situation is identified. This individual is often a family member or a significant other who is invested in the client's ability to remain substance free. Then options for assertive refusal are reviewed and applied to the high-risk situation. Finally, a series of role-plays follow, often starting with a *reverse* role-play (with the clinician taking on the role of the client). This reversal allows the clinician to effectively model the refusal skills and gives clients a chance to add some authenticity to the conversation, as they may have pressured their own peers to use in the past.

Job-Finding Skills

In order to maximize "community" reinforcement, most individuals not only need a job, but also a satisfying one. In addition to providing the obvious financial rewards, a job can offer access to other reinforcers as well (e.g. pleasant social interactions, increased self confidence). For the many substance-using clients who do not have the skills to find or keep a meaningful job, CRA's job-finding training can be worthwhile. In brief, CRA's successful job acquisition involves the client

and therapist working together to develop a resume, generate job leads, complete applications, practice telephone inquiries and follow-up calls, and rehearse for job interviews.

Azrin firmly believed that finding a job was a full-time job. Consequently the CRA approach to obtaining a job is very structured, comprehensive, and efficient. This deliberate job-finding approach offers a stark contrast to many newly sober individuals' common practice of taking the first job they can find without carefully weighing its pros and cons. So, for example, when generating ideas for the types of job of interest, the CRA therapist asks whether the desired job would place the client in a high-risk environment in terms of substance use. In generating and following up on job leads, clients are taught to be appropriately assertive, but to be prepared to cope with rejection in a healthy manner if they are faced with it. Role-plays are used extensively in preparation for initial telephone inquiries about job openings, as well as for actual job interviews. Importantly, clients are assisted with identifying their strengths so that these can be highlighted on applications and in interviews.

CRA's job maintenance component focuses on checking in with clients regularly, usually through the Happiness Scale, to be sure that the expected job reinforcers are present. Also, time is devoted to addressing possible threats to keeping the job. For example, if a client was fired from past jobs due to arguments with the boss, anger management exercises or problem-solving would be practiced as a precaution. A full description of the job-finding procedures was published in a comprehensive manual by Azrin and Besalel.

Social/Recreational Counseling

It is common for the social lives and friendships of substance-abusing individuals to center around drugs and alcohol. Given that such relationships and activities can be powerful triggers for relapse, CRA places a major emphasis on helping clients develop and nurture a happy and healthy social life. This task is usually quite difficult, since many clients are simply unaware of nonusing options for fun, or they doubt that they will find pleasure in clean/sober activities. CRA has several methods for addressing these issues.

As noted earlier, the functional analysis for pro-social behavior may be used to increase the likelihood of a client selecting a healthy social activity (that is already occurring occasionally) over substance use. For example, assume a client routinely has been going to a bar after work to drink with coworkers. However, approximately twice a month he opts to play racquetball with a friend for a few hours after work instead. The functional analysis for pro-social behavior could be

used to examine the factors that set the stage for the client to choose racquetball over the bar periodically, and the barriers that interfere with him selecting racquetball more often. So imagine the client reports that the main positive consequences of playing racquetball (i.e. decreasing his job-related stress, allowing for fun time with a friend) are very similar to the positive consequences he experiences in the bar. Importantly, racquetball offers additional benefits (e.g. provides a healthy workout, boosts confidence in his athletic skills). This functional analysis would also highlight the barriers to choosing racquetball over drinking after work and would provide an opportunity to address them. For instance, if the client says he feels sore after playing racquetball and needs time to recover before playing again, the CRA therapist could help the client develop a plan for minimizing the soreness. The plan could even include additional enjoyable activities, such as getting a set of weights or setting up some other fitness routine that would improve his level of fitness overall. The details would need to be carefully planned out regarding when this new workout would take place, and the importance of the activity being pleasant enough to compete with drinking would be stressed. Given that one of the positive consequences of drinking at the bar was to socialize, the therapist might suggest that the new fitness regime be scheduled at a gym or at least with a friend. Together the therapist and client would develop an assignment for the week, such as to go to a gym as the guest of a member/friend and sample some weightlifting under the guidance of a trainer. The therapist would inquire at the next session about the amount of pleasure obtained from the assignment and would help modify the plan if the activity did not appear to be sufficiently enjoyable to compete with drinking at the bar.

The problem-solving procedure was illustrated earlier with an example of how to address barriers for participating in a social activity, but it also can be used to generate ideas for novel social activities. Assume a 30-year-old, single client states that she has no idea how she might replace her weekend "partying" with a fun but healthy activity. The problem-solving procedure would first narrow down the problem (e.g. to Saturday nights), and the therapist would help the client brainstorm an array of potential activities (e.g. take an evening dance class, go out to dinner with nonusing friends). Eventually the client would settle upon one new activity to sample in the upcoming week, and obstacles would be addressed. As always, the outcome would be reviewed in the next session.

Taking the first step toward sampling a new activity, particularly when one is clean/sober, can seem monumental to some clients. CRA's systematic encouragement may be warranted in these cases. It entails

helping clients make that first contact during the session, such as a phone call to obtain a recreation facility's hours of operation, or a call to a family member to line up transportation. Role-plays are frequently conducted prior to placing these calls. Importantly, the therapist follows up in the next session to determine whether the client enjoyed the activity, and if any problems arose that needed resolving. For situations in which numerous CRA clients are being seen at one site, a social club has sometimes been established to provide positive social experiences. Clients who have become isolated because of their drinking/drug use are the prime candidates for the social club, because it enables them to practice their social skills in a nonthreatening sober environment, and to experience pleasure from clean/sober activities. Typically these clubs hold their activities during high-risk times, such as weekend nights. The substance-free activities themselves may include having pot-luck dinners, watching rented movies as a group, playing cards, or having local musicians entertain. Not surprisingly, social clubs are most successful when the *clients* play a major role in selecting the weekly activities.

Relationship Therapy

Another potential source of reinforcement that is part of many individuals' "community" is their relationship with a significant other. CRA includes several sessions of behavioral couple therapy for clients with romantic partners. This relationship therapy begins with each partner completing the Relationship Happiness Scale; a couple's version of the Happiness Scale. The Relationship Happiness Scale asks both the client and the partner to rate their happiness with the *other person* in 10 different areas (e.g. household responsibilities, social activities). Each individual selects one category in which he/she would like to see a change in the other person in the upcoming week, and the therapist helps them develop brief, positive, and specific requests. The positive communication skills that have already been taught to the client are reviewed for the partner, and the request for change is made using these skills. Negotiation ensues until an assignment is agreed upon; sometimes problem-solving skills are introduced to facilitate the process. The goals and assignments are documented on the Perfect Relationship form, which is the couple version of the Goals of Counseling.

The Daily Reminder to Be Nice is an exercise to "jump start" pleasant interactions at home in the early stages of therapy. This seven-item form includes items such as: expressing appreciation for something the partner does, and giving a pleasant surprise. Each individual makes a commitment to do at least one of these pleasant acts for the partner daily, and session time is devoted to practicing several of them. The therapist checks on

progress toward increasing these behaviors at the next session and troubleshoots any problems. Subsequent couple sessions are devoted to selecting additional categories from the Relationship Happiness Scale and negotiating goals.

Relapse Prevention

Although CRA procedures overall are designed to prevent relapse, several additional procedures specifically target high-risk situations. The Early Warning System entails identifying a suitable family member or friend who is in a position to recognize the client's early warning signs for relapse, and establishing a plan of action for that individual to help deal with an impending relapse. Assume, for example, that a male client asked his wife to support his decision to abstain while out to dinner with friends. Given that the wife knew her husband started stammering and fidgeting when he was battling over a decision to drink, the plan was for her to announce that she had received a text from the sitter that their child was sick, and so they needed to leave. An Early Warning System is only incorporated into treatment if both the client and the family member/friend agree to the terms, and both individuals demonstrate that they can be supportive of each other in the process.

In the event that a relapse does occur during treatment, a CRA Functional Analysis for Relapse may be used to identify the specific contributing factors. Alternatively, the therapist may outline the behavioral chain of events leading to the relapse and assist the client in realizing that different decisions can be made at various "links" throughout the chain of events in the future so that relapse is thwarted.

Medication Monitoring

The Medication Monitoring component of CRA was introduced initially as a method for ensuring that clinically appropriate individuals took their disulfiram (Antabuse). Disulfiram, a "deterrent" to drinking, causes an acute physical illness that can range from mild to very severe if a person who is taking it drinks alcohol. It is essential to have a physician involved in its prescription and management. Primary candidates for disulfiram as a temporary adjunct to treatment are clients who are having tremendous difficulty achieving even short periods of abstinence, or those who will face very serious consequences if they drink again.

A monitor is a critical aspect of disulfiram treatment. Typically a family member, this monitor attends a therapy session with the drinker so that a daily routine for administering the disulfiram can be established, and positive communication can be practiced as part

of this ritual. For example, a couple may start breakfast each morning with the disulfiram administration. The family member might give the disulfiram to the drinker and say, "I can't tell you how much it means to me that you've made this commitment to being sober. You're doing a wonderful thing for yourself and our family." The drinker would respond with a comment such as, "Thanks for always being here to support me. It's made a big difference in my recovery."

Still, the monitor also serves as part of an Early Warning System, since the client's refusal to take disulfiram for several consecutive days could be a signal that a relapse is imminent. Thus, an agreed-upon plan would already be in place regarding how the monitor should respond in such a situation (e.g. call the therapist). In more recent years, this monitoring system has been used with other medications for clients with comorbid disorders, such as adolescents with attention deficit hyperactivity disorder (ADHD) or adults with bipolar disorder.

CRA SCIENTIFIC SUPPORT

CRA was first tested by Hunt and Azrin on inpatient alcoholics back in the 1970s. Two studies found that inpatients who received CRA improved significantly more than patients who received the hospital's standard treatment; 12-step groups. These improvements were found in the areas of drinking, hospitalization, employment, and time with family. Next CRA was tested in two outpatient studies. The first study discovered abstinence rates that favored the CRA + disulfiram monitoring condition over the two 12-step conditions. A larger outpatient study detected roughly similar findings for the first 6 months after treatment began, but some of the effects were lost in the later follow-ups. CRA's effectiveness also was demonstrated with homeless individuals in a day treatment setting. Overall, meta-analyses and comprehensive reviews routinely have ranked CRA near the top of the list of alcohol treatments.

CRA has been used to effectively treat illicit substance problems as well; primarily cocaine or opioid dependence for adults and marijuana abuse for adolescents. Much of this CRA research with adults has added a voucher component, in which vouchers representing "prizes" are used to reward abstinence in the early stages of treatment (a full review is beyond the scope of this chapter). CRA's demonstrated effectiveness with adolescent marijuana abusers is reviewed in this volume in a chapter devoted to adolescent treatment.

One of the "unknowns" with CRA is *why* it works, and so studies are under way in which that question is being addressed. Additionally, we are attempting to

determine why a subset of individuals does not seem to respond to CRA treatment. A modified CRA program for treating obesity is also in the planning stages.

COMMUNITY REINFORCEMENT AND FAMILY TRAINING: CRAFT

Overview

CRAFT is a scientifically supported treatment designed by Robert Meyers to work through the family members (concerned significant others; CSOs) of treatment-refusing substance abusers (identified patients; IPs) in an effort to get the IPs to seek treatment. CRAFT teaches CSOs to rearrange their own behavior toward the IP so that clean/sober behavior is rewarded and drinking/drug use is experienced by the IP as less pleasant. CRAFT grew out of CRA; the science-based treatment intended for working directly with the substance abusers. Early CRA researchers recognized that the family members of problem drinkers were an underutilized resource, as the family members had access to powerful reinforcers and contingencies in the clients' lives which could serve to influence change.

Another CRAFT goal is to enhance the psychological functioning of CSOs, regardless of whether their IP enters treatment. These family members experience extremely stressful lives, much of which is the result of the IP's ongoing substance use. CSO problems include depression, anxiety, legal issues, parenting problems, emotional and sexual relationship issues, financial instability, and domestic violence.

Until recently, distressed CSOs primarily had Al-Anon and the Johnson Intervention as options. Al-Anon, a 12-step program that advocates "loving detachment," has been shown to enhance the well-being of CSOs but has not been successful in getting resistant substance abusers into treatment. The Johnson Intervention is a "surprise party" during which CSOs confront IPs about their substance use and demand treatment entry. It has high engagement rates when the intervention is fully carried out, but the vast majority of CSOs who begin the Johnson Intervention dropout.

CRAFT PROCEDURES

Enhancement of CSO Motivation

During the first CRAFT session, CSOs are given time to describe the problems created by their IP's substance use and their own associated distress. Next, CRAFT's goals and procedures are outlined, and the expected role of CSOs is highlighted. Finally, in an effort to instill positive expectations for change, an overview of the

scientific support for CRAFT is presented. This includes a summary of CRAFT's success in engaging treatment-refusing IPs into treatment and enhancing CSOs' functioning, and an overview of the types of individuals and relationships who have responded well (e.g., IPs with various drugs of choice; CSO-IP relationships that included spouses, parents, adult children, etc.).

Functional Analysis of IP's Substance-Using Behavior

CRAFT uses a variation of the CRA Functional Analysis of substance using behavior, with the CSOs completing the form for their IPs. Recognizing triggers and consequences is necessary to formulate points of influence CSOs have over their IP's using behavior. Assume, for example, that a sister (CSO) who is completing the functional analysis for her brother (IP) reports in the positive consequences column that the brother likes smoking marijuana after a stressful workday because it helps him relax. The clinician would inquire about other ways that the IP has relaxed after work in the past and would see whether the CSO could play a part in increasing the likelihood that the brother would choose these healthier methods over smoking. At the same time, care would be taken to make sure the CSO understands that although the objective is to influence her brother's behavior, ultimately she cannot control it, nor is she culpable for negative outcomes resulting from his substance use decisions.

Domestic Violence Precautions

CRAFT-trained CSOs are taught to change their behavior toward their IP during times of substance use; behavior changes that are intended to be experienced by IPs as unpleasant. Given the already strong correlation between substance use and domestic violence, it is critical to assess the potential for violence when determining *which* behavior changes on the part of the CSO are safe to introduce. Domestic violence was an exclusionary factor in the original CRAFT studies, and so the therapist also must decide whether it is safe for CSOs to receive CRAFT treatment. If it is deemed reasonable to proceed, a functional analysis of IP aggression may help illustrate the triggers for IP violence and offer insight into its maintenance. Relevant CRA procedures may be woven into CRAFT as well, such as role-plays of positive communication, and problem-solving to develop any necessary prevention or protection plans.

Communication Skills

Communication skills training is a critical component of CRAFT, since the CSO-IP communication style

commonly swings between aggressiveness and silence. The training follows the same procedure as that introduced in CRA, with the exception that the CSO is being taught the skills instead of the substance abusing client. Learning how to communicate in a positive manner lays the foundation for other CRAFT procedures. For instance, positive communication is essential for minimizing IP defensiveness when it is time for CSOs to explain changes in their behavior toward the IP (such as the withdrawal of rewards during substance-using times), or when CSOs are ready to invite the IP to sample treatment.

Assume that a CSO (the wife) rehearses the conversation she hopes to have with the IP (her husband) when they sit down to dinner that evening. With much practice and feedback during the session, the CSO arrives at: "Martin, I know you're unhappy with your job these days and you like to unwind with your friends after work (*understanding statement*) by stopping for a few drinks. And I guess it doesn't help your stress level when I immediately start going down our long list of financial problems as soon as you walk through the door each night (*partial responsibility*), so I could do my best to stop that (*offer to help*). I know if you come straight home you like to eat earlier. I could move dinner up about 20 min (*offer to help*). What do you think?" The CSO would have role-played this conversation repeatedly and decided *when* to approach her husband. Furthermore, she would have discussed how she might react if the IP responded negatively.

Positive Reinforcement for Clean and Sober IP Behavior

CRAFT is built upon the principle of positive reinforcement; namely, people are more likely to repeat a behavior if it is rewarded. CSOs are taught to systematically reward their IP's clean/sober behavior. Since many CSOs mistake positive reinforcement for "enabling," the therapist explains that enabling inadvertently makes it easier for the substance-using behavior to continue, whereas positive reinforcement is paired exclusively with clean/sober behavior. Once the principle is understood, CSOs are assisted in identifying several small, inexpensive rewards which can be introduced *when the IP is clean and sober*. Popular examples include: watching the IP's favorite TV show with him/her, making a special dessert, or giving a compliment or a hug. Details regarding when and how the reward will be delivered are addressed, and the conversation with the IP about why the reward is being delivered is practiced. An example of a polished conversation about a positive reinforcement that a husband (CSO) might prepare for his wife (IP) is: "Honey, how about we go to that antique mall you like so much and do a little window shopping

before dinner? I can see that you haven't been using today, and I love spending time with you when you've stayed away from those medications."

Negative Consequences for Substance-Using Behavior

The counterpart to rewarding nonusing IP behavior is to withdraw rewards when substance use occurs. This "time-out" from positive reinforcement is relatively straight-forward if the reward in question is one of the newly introduced ones. For instance, if a CSO has started to watch one of her partner's (IP's) favorite TV programs on those evenings when he does not smoke marijuana, then she would elect *not* to sit and watch the show with him if he had smoked that day. She would use her positive communication skills to convey this: "It looks like tonight isn't going to be a good night for us to watch TV together, because I can tell that you've been smoking. It has really been fun spending time with you in the evenings when you're not high. Let's try again tomorrow." The therapist helps the CSO identify additional reasonable rewards to withdraw at times of IP substance use as well, while always exploring the potential for a violent IP reaction, and adjusting accordingly.

The second manner in which negative consequences are introduced for drinking or drug use is by allowing the *natural* consequences of substance use to occur. Assume that a mother (CSO) typically cares for her adult child (IP) whenever he/she has a hangover by calling in sick for him/her. In all probability the CSO would be asked to consider letting the son/daughter deal with the consequences of nobody contacting his workplace at the time of his/her next hangover. Certainly, the negative ramifications of changing the CSO's normal behavior in these situations would be discussed at length, since both CSO and IP safety are of paramount importance. In the majority of cases CSOs elect to inform their IP in advance that this change in behavior will take place if drinking or drug use resumes.

Helping CSOs Improve their Own Lives

The Happiness Scale and Goals of Counseling forms are borrowed from CRA to help CSOs target different areas of their lives in which they would like to make changes. Since social isolation is quite common for CSOs, the "social life" category on the Happiness Scale is often a focus for goal-setting. For example, a goal for the CSO might be to reconnect with an old friend, or to take a class through Continuing Education in an effort to sample a new recreational activity. Potential problematic reactions from their IPs are always discussed in advance.

Inviting the IP to Sample Treatment

The procedures described thus far set the stage for treatment engagement to occur (as well as address other goals), but the final piece entails helping CSOs determine how and when to invite the IP to enter treatment. To articulate the request, positive communication skills are put into play again, but motivational “hooks” are added that stress IP-specific incentives. For example, if an IP has been struggling to find a job, the CSO might say, “I know you’ve been trying really hard to find work. The agency that I’m going to for my own therapy has counselors who can help people with a lot of things, including finding jobs. What do you think about giving that a try?” Reluctant IPs might also be encouraged to “sample” treatment for a session or two without making any long-term commitment. Another motivational hook is the idea that IPs can have their own therapist; they do not have to see their CSO’s therapist.

Regarding the ideal time to extend the invitation, CSOs are taught to look for “windows of opportunity;” occasions representing a greater likelihood that the IP will agree to treatment. One common example is when an IP starts asking questions about what happens in the CSO’s own therapy. CSOs are prepped to respond, “Why don’t you come to a session with me and find out? I’d love to introduce you to my therapist.” A somewhat different case is the IP who is unaware of the fact that the CSO is in therapy – and who asks the CSO why he/she has been acting differently toward the IP lately (i.e. the CSO has been using positive communication and rewards). The CSO might respond, “I’ve been in therapy to work on our relationship. We’ve been having our ups and downs, as you know. How would you feel about joining me for a session or two? It would mean a lot to me.”

Although many IPs agree to treatment at this point in the CRAFT program, CSOs must be prepared for the possibility that the IP will still refuse at least temporarily. If this occurs, the CSO is encouraged to continue with the various CRAFT procedures. Given that most IPs *do* agree to attend treatment eventually, it is necessary to have an arrangement for a therapist to be available so that the IP does not get placed on a waiting list. Ideally the therapist should be behavioral or cognitive-behavioral so as to complement the CRAFT approach.

CRAFT SCIENTIFIC SUPPORT

CRAFT was first tested in a small study in the 1980s with the wives (CSOs) of treatment-refusing problem drinkers (IPs). The CSOs who received CRAFT were successful at getting their loved one to enter treatment in 86% of the cases, whereas none of the CSOs who

received the traditional (disease-based) treatment did. In subsequent years, the CRAFT program has been studied largely through the efforts of Meyers and Miller. CRAFT has continued to demonstrate high engagement rates, regardless of the type of relationship between the CSO and the IP (e.g. spouses, romantic partners, siblings, parents and their adult children). Some of the most compelling evidence comes from studies that contrasted CRAFT with the more traditional alcohol interventions. Specifically, the IP treatment engagement rates for CRAFT-trained CSOs (64%) were significantly better than those of CSOs in either one-on-one Al-Anon sessions (13%) or in the confrontational “intervention” (30%). Recently CRAFT was successfully conducted in a community treatment setting with CSOs of alcohol-dependent IPs who had multiple other life problems.

The robust CRAFT findings have been similar for adult studies in which the treatment-refusing individual used illegal drugs. A recent meta-analysis by Roozen and colleagues supports these conclusions. And when CRAFT was applied to an adolescent sample, the parents (CSOs) demonstrated an engagement rate of 71% for their marijuana-abusing teens. One of the newest CRAFT studies was a test of the program in a group format. This format deserves further testing, both due to the cost-effectiveness of group therapy, and the potential benefits of learning from other CSOs in the group.

In addition to the high engagement rates, an important finding of the various CRAFT studies is that the CSOs typically experienced significant improvements in their own psychological functioning irrespective of whether their loved one entered treatment, and also regardless of the treatment they received. Importantly, CRAFT was successful in getting the resistant IP to enter treatment in an average of less than five CSO sessions. Finally, CRAFT has been shown to work equally well across ethnic groups, but since the main ethnic minority representation thus far has been Hispanic individuals, future testing should recruit a higher percent of African American, Asian, and Native American samples. Studies are already planned for testing CRAFT in the obesity and eating disorders area.

CONCLUSION

CRA and CRAFT are science-based treatments that use behavioral principles to facilitate change in alcohol or drug use, by working either directly with the substance abusing individual (CRA) or indirectly through the distraught family member (CRAFT). Both of these treatments have commonly been well received by therapists and clients alike, in all probability due to their highly supportive style and flexible application.

Glossary of Terms

Alcoholics Anonymous this is an international organization that provides a support group for persons trying to overcome alcoholism that is characterized by its 12-step program.

Al-Anon the Al-Anon family groups are a fellowship of relatives and friends of alcoholics who share their experience, strength, and hope, in order to solve their common problems.

Behavior therapy this type of therapy uses basic learning principles to modify maladaptive behavior patterns.

Community Reinforcement Approach (CRA) CRA is an empirically supported behavioral treatment for individuals with substance use disorders that is based on the belief that one's "community" broadly defined plays a critical role in the recovery process. Relying heavily on operant principles, the main goal of CRA is to help clients achieve a clean and sober lifestyle that is more rewarding than a substance using one.

Community Reinforcement and Family Training (CRAFT) this empirically supported modification of CRA is designed to work through a family member or friend of a treatment-refusing drinker or drug user, with the goal of getting the resistant individual to enter treatment.

Concerned Significant Other (CSO) a CSO is a family member or friend of a treatment-refusing substance abuser who seeks treatment himself/herself in an effort to learn the techniques to get the treatment-refusing substance abuser to ultimately enter treatment.

Evidence-based treatment this term refers to mental and behavioral health interventions for which systematic empirical research has provided evidence of statistically significant effectiveness as treatments for specific problems (e.g. substance use disorders).

Functional analysis (FA) the functional analysis is a structured interview that outlines triggers and consequences (positive and negative) of substance-using behavior, thereby providing a framework for a conversation about the context within which the use occurs.

Identified patient (IP) the IP is a treatment-refusing substance user.

Johnson Institute Intervention (JII) an intervention is an orchestrated attempt by a number of people (usually family and friends) to get

someone to seek professional help with an addiction problem. In many cases this involves the family members gathering to confront the substance abuser about the negative impact of his/her behavior on others.

Positive reinforcement positive reinforcement occurs when a behavior is followed by a stimulus that is rewarding, and which then increases the frequency of that behavior.

INTRODUCTION

Alcoholism has historically been viewed and treated as individual conditions or disease processes. However, over the last 35 years, there has been growing recognition about the role of the family in understanding and treating alcoholism. Behavioral couples therapy (BCT) for alcoholism is one approach that has developed out of the recognition that significant others can play a substantial role in alcoholism and the recovery process. A goal of this chapter is to familiarize the reader with the BCT approach to treating alcoholism and to summarize empirical evidence supporting the application of this treatment. We begin by describing the rationale for this approach to treating alcoholism. Next we provide an overview of the major interventions that serve as components to this therapy. We then summarize the empirical findings in support of BCT as an efficacious treatment for individuals with a committed partner who does not have a substance abuse problem and who is willing to actively participate in the patient's alcoholism treatment.

We specifically describe the evidence showing that this treatment is related to reductions in alcohol-related problems, is related to improvements in intimate relationships, is shown to be cost effective, and is related to improvements in children's functioning. We also describe contraindications for the application of BCT, along with challenges that may be faced in implementing this treatment. Finally, we provide suggestions for future research and application of this therapy.

BI DIRECTIONAL ASSOCIATION BETWEEN ALCOHOLISM AND INTIMATE RELATIONSHIPS

A foundational assumption of BCT is that there exists a bi directional relationship between alcoholism and intimate relationships. According to this model, alcoholism not only creates problems for the individual with the condition, but these problems often have rippling effects that damage relationships with significant others

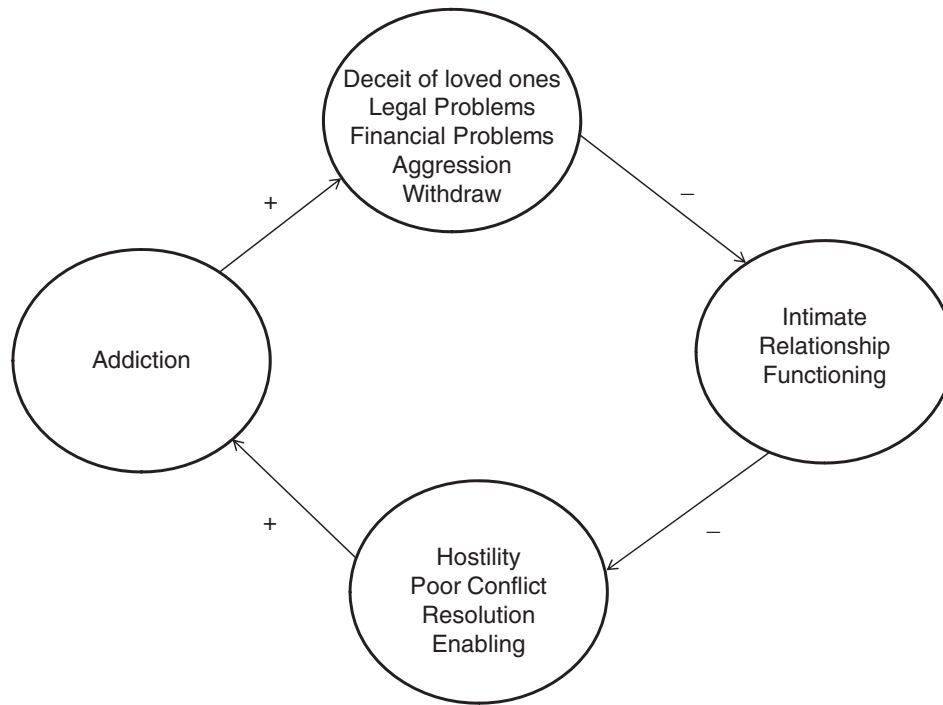

FIGURE 7.1 Bi directional association between addiction and intimate relationships.

(Fig. 7.1). It is unfortunately common for individuals with alcoholism to lie to their loved ones in order to try to cover up their drinking and its negative consequences. This, by itself, can undermine trust within relationships and lead to conflict and loved ones withdrawing support for the alcoholic individual who in turn drinks more in a vicious cycle. In addition, alcoholism contributes to problems, such as job loss or revocation of driving privileges, which impact not only the alcoholic individual but also their loved ones. These problems can be a substantial source of conflict and lead to ongoing resentments between individuals with alcoholism and their family members. Finally, research demonstrates that individuals with alcoholism and their significant others are at substantially elevated risk for experiencing intimate partner violence. Hence, alcoholism can undermine the basic safety and well-being of intimate relationships by contributing to circumstances in which individuals with alcoholism and their significant others resort to aggression toward one another.

In addition to the hypothesis that alcoholism damages intimate relationships, the BCT presumes that intimate relationship functioning can influence the progression or recovery from addictions. Individuals with alcoholism who are in critical and hostile family environments are at greater risk for relapsing to addictive behaviors (see Ketamine). Critical and hostile family systems may lead individuals with addictions to experience negative emotions, and it is common for individuals with addictions to revert to addictive behaviors as a method for

self-soothing difficult and painful emotional experiences. In addition, independent researchers have found that couples where one or both partners exhibit an addiction tend to have poorer conflict management styles versus couples where neither partner exhibits addictions. A lack of conflict management skills may exacerbate relationship distress and undermine the ability to collectively solve problems as they arise. Along with couples' conflict management deficits as an impeding factor to addiction recovery, it is common for significant others to unintentionally reinforce addictive behaviors. These enabling behaviors on the part of significant others can include obtaining alcohol or drugs for the person with the addiction or making excuses or covering up for the consequences of their addiction. These factors may, in turn, increase risk for relapse and reduce chances at recovery among individuals with addictions (see Fig. 7.1).

OVERVIEW OF BCT AND ITS MAJOR COMPONENTS

BCT is typically delivered in 12–20 therapy sessions. Published manuals by Timothy O'Farrell and by Barbara McCrady provide variations of the treatment approach. Typically these sessions are attended on a weekly basis by the couple. As will be described later in this chapter, BCT has undergone extensive empirical scrutiny supporting their application to the treatment of addictions.

BCT fits well into various addiction treatment settings in that it has been researched and employed in both group and single couple formats. In addition, BCT has been delivered and tested as a stand-alone intervention, as well as being delivered together with other individual and group-based addiction therapy. The treatment can be easily integrated into a variety of orientations to addiction treatment, including 12-step and cognitive behavioral addiction programs.

Given the bi directional cycle that occurs between addiction and relationship functioning, BCT provides interventions that target each of these domains. This therapy utilizes behavioral principles to help couples to work together in reducing addictive behaviors and their consequences, while also working to improve their relationship. The therapy has the specific goals of reinforcing behaviors that are consistent with addiction-related goals and helping couples to make positive behavioral changes within their relationship.

Interventions for Achieving Abstinence

The BCT approach has historically involved a primary goal of abstinence from addictive behaviors, since it is assumed that abstinence must first be obtained for the couple to be able to effectively work on relationship issues. The approach taken by Timothy O'Farrell and colleagues includes a behavioral recovery contract to help the couple to work jointly to achieve sobriety for the person with the addiction. A major component of the recovery contract is the daily "trust discussion." A goal of the daily trust discussion is to rebuild trust in the relationship around the issue of sobriety, which is often damaged as a result of attempts to cover up or minimize addictive behaviors and its consequences. In addition, it is often the case that the person with the addiction receives criticism for engaging in addictive behaviors with little positive reinforcement for the occasions during which sobriety is achieved. Therefore, another important goal of the trust discussion is to reinforce the addictive partner's sobriety behavior and the supporting partner's efforts to help in achieving sobriety.

When completing the trust discussion, couples are instructed to choose a specified time and place where they can talk without interruption. Couples are encouraged to try to make this as part of a daily routine; therefore, the trust discussion should be completed, if possible, during approximately the same time each day. The partner with the addiction issue is encouraged to take responsibility for his or her recovery by initiating the trust discussion. In the trust discussion, the patient states his or her intent not to drink or use drugs that day (in the tradition of 1 day at a time), the spouse expresses support for the patient's efforts to stay

abstinent, and the patient thanks the spouse for the encouragement and support. For patients taking a recovery-related medication (e.g. disulfiram, naltrexone), daily medication ingestion witnessed and verbally reinforced by the spouse also takes place during the trust discussion.

In addition to the daily trust discussion, the couple recovery contract includes several additional interventions to help the couple to work toward sobriety. One component is the commitment for both partners to focus on the present and future and not the past. This is meant to assist the couple in breaking away from the cycle of focusing on past addictive behaviors and relationship problems, which can escalate into arguments and negative feelings that contribute to relapse. The recovery contract also often includes commitment to self-help attendance by the person with the addiction (e.g. Alcoholics Anonymous), as well as self-help support for the partner (e.g. Al-Anon). Therefore, the treatment is quite complimentary to supporting self-help approaches to recovery. For individuals with drug addictions, the recovery contract typically includes weekly urine drug screens, with results being shared in the BCT sessions. These are used to help to reinforce sobriety from drugs and to help individuals with drug addictions rebuild trust with their partners.

Another BCT strategy is to check in at the beginning of the session about any engagement in addictive behaviors or thoughts, urges, or cravings to engage in these behaviors and implement strategies for coping with these. This is meant to emphasize the primary focus of the treatment on recovery from the addiction, and prioritize finding ways of stopping these behaviors. One approach that has been adopted by Barbara McCrady and colleagues in building couples skills in this area is to help each partner to engage in a detailed functional analysis of addictive thoughts and behaviors in order to better understand their patterns and ultimately be able to anticipate and better cope with them when they arise. Hence, McCrady and colleagues have integrated into their BCT approach that is often used in addressing addictive behaviors within individually oriented, cognitive behavioral treatment models for addiction.

It is common for partners to unintentionally enable ongoing addictive behaviors. For example, partners may try to assist the person with the addiction by helping to cover up for the consequences of their addictive behaviors or purchasing alcohol or drugs for the person with the addiction. Therefore, BCT seeks to help couples to recognize and stop partner enabling behaviors. This is done by educating couples on the common ways that enabling may occur and identify ways that enabling may be occurring within the couple's relationship. A plan for eliminating these enabling

behaviors is then developed, and therapists follow up throughout treatment to ensure that this plan is being effectively implemented.

Interventions for Improving the Relationship

BCT takes a stepwise approach to providing interventions for improving the relationship. The first set of interventions is meant to help the couple begin to increase the number of positive relationship behaviors. This follows the finding that couples who are dissatisfied with their relationship tend to display a relatively lower ratio of positive relationship behaviors and higher ratio of undesirable relationship behaviors versus those who are satisfied. It is often the cases that couples in which one or both partners have an addiction engage in a high degree of negative behavioral exchanges. This can contribute to these couples becoming dissatisfied with their relationship, thereby making it more difficult for them to work together to eliminate the addictive behaviors. Hence, the initial behavioral interventions are meant to help couples to begin to increase the number of positive exchanges within the relationship. It is thought that by improving the frequency of these relationship behaviors, couples' relationship satisfaction may increase, resulting in increased chances for obtaining and remaining abstinent from addictive behaviors.

One initial way that the treatment seeks to increase positive behavioral exchanges is to have the couple practice a daily ritual of noticing positive relationship behaviors. Addictions often lead couples to begin to notice and focus upon the undesirable behaviors within their relationship, while failing to notice many of the positive behaviors. Therefore, the "catch your partner doing something nice" exercise is meant to help couples to practice refocusing their attention to positive behaviors within the relationship. Once couples obtain practice noticing positive relationship behaviors, partners build upon this skill by sharing on a daily basis the noticed positive behaviors. Couples are taught that actively communicating and reinforcing these behaviors will help to improve relationship functioning and, in turn, improve chances at achieving sobriety.

Other BCT strategies for helping couples to increase positive behavioral exchanges include shared rewarding activities and planned caring days. Among couples with addiction, it is common to greatly decrease or cease activities that are mutually enjoyable and that do not involve engaging in the addictive behavior. Therefore, to address this tendency, shared rewarding activities help the couple to regularly plan and participate together in at least one mutually enjoyable sober activity per week. Some examples include going to the movies together, taking the kids to the park, or going on a walk together. Couples also practice engaging in "caring days" that involve planning

and engaging in a series of special surprises for one another. An example would be surprising one's partner by fixing his or her favorite breakfast, packing his or her lunch for work and including an "I love you" note in the lunch, and surprising him or her with a backrub that evening. The idea behind this intervention is that addictions often lead couples to reduce the frequencies in which they engage in unexpected signs of courtship and caring toward one another. This can also happen, independent of the effects of addiction, with couples naturally reducing the frequency of these behaviors the longer that they are in the relationship. Therefore, by reinvesting behavioral efforts into surprising signs of affection, couples will increase their relationship satisfaction. This increased relationship satisfaction will then serve as a resource for reducing the likelihood of ongoing addiction.

After introducing these basic behavioral strategies for improving positive couple exchanges, BCT helps couples to improve their communication. This is an important intervention for couples with addictions, since couples with addictions are shown to exhibit poorer communication strategies than those who do not have addictions. Poor communication and conflict resolution may decrease the likelihood that partners with addiction remain sober, while increasing the likelihood of engaging in ongoing cycles of addictive behaviors. Therefore, BCT teaches couples effective speaking and listening skills by providing in session instruction, modeling, and practice of these skills. Couples also practice applying these skills outside of the session, so that they learn to use these skills in their day-to-day lives. Once couples achieve basic competency of basic communication skills, they then learn effective advanced communication techniques to facilitate effective problem solving and to work together to identify and change areas that they would like to improve in their relationship.

Along with teaching general communication and problem-solving skills, BCT helps couples to improve their conflict resolution strategies. Unfortunately, partner violence is a common co-occurring issue for couples with addictions. Therefore, couples are taught ways to avoid conflicts escalating into violence. The "time out" intervention is one central component that Timothy O'Farrell and colleagues have built into their treatment. This strategy involves couples implementing a "time out" when arguments escalate to the point that the couple is at risk to engage in verbal or physical aggression. Partners learn to request a time out for a defined period of time. That way, it is clear how long the time out is expected to occur, and it helps the couple to avoid the common mistake of withdrawing and avoiding indefinitely without satisfactorily discussing the issue. During the time out, partners practice

engaging in self-soothing behaviors (e.g. going on a walk) to help them to de-escalate anger and other negative emotions. The couple then reconvenes after the agreed upon period of time to further discuss the issue in a nonthreatening and calmer manner. In addition to the time out method, couples are taught to avoid engaging in arguments when one or both partners are under the influence of alcohol or drugs. This is done because it is highly common for arguments when either partner is under the influence to escalate to violence.

Interventions for Maintaining Treatment Gains and Addressing Relapse

Prior to ending BCT, therapists work with couples to develop a well-defined and mutually agreed upon continuing recovery plan for how they will continue to maintain their treatment gains. The philosophy is that recovery is a continuing process, and just because the couple ends BCT, this does not mean that the recovery process is finished. The continuing recovery plan provides a structured contract for what BCT interventions that the couple will continue to utilize following the end of the therapy. It also helps couples to identify strategies for maintaining sobriety and improvements in their relationship. An important focus during this final stage of treatment is to help couples to personalize their recovery plan so that they are selecting those interventions that they found to be most helpful. This will increase the likelihood that they will continue to engage in dyadic behaviors that were learned and practiced during the therapy.

Couples will often include follow-up visits with their BCT therapist as part of their continuing recovery plan. These visits typically occur every 2 months for a year following the end of the standard weekly therapy, but the schedule can be adjusted to fit the couple's needs. These sessions are used as an opportunity to check-in and ensure that the continuing recovery plan is being effectively sustained and as booster sessions to continue to work on developing dyadic recovery skills. Independent research by Timothy O'Farrell and Barbara McCrady demonstrated benefits of BCT booster sessions. Benefits of BCT booster sessions are especially evident for couples with more severe addiction problems. Hence, it is strongly encouraged for couples with more severe addiction problems to structure in follow-up sessions as part of the continuing recovery plan.

In addition to the interventions aimed at helping couples to maintain treatment gains, BCT therapists work with the couple to develop an action plan in the event that a relapse occurs. A fire evacuation plan is often used in presenting this to the couple by stating that having a relapse action plan is a good idea just like having a fire evacuation plan. Having such a plan

does not guarantee that you are going to experience a relapse (or fire), but it does make it safer and easier to deal with these circumstances if they were to arise. Therefore, BCT helps couples to identify upcoming situations that might increase the risk for relapse and develop a plan of action for addressing these. In addition, the treatment helps couples to identify early warning signs to relapse (e.g. stopping self-help attendance, changes in mood) and a plan for correcting these problems. Finally, BCT therapists help couples to identify sources of support for coping with relapses (e.g. AA sponsors, friends) and strategies for obtaining help from others during these events. Couples are encouraged to contact the BCT therapist if a relapse were to occur, so that the therapist can help the couple to navigate this issue and minimize the relapse.

EMPIRICAL SUPPORT FOR BCT

For those who have committed family members who are willing to be active participants in treatment, evidence supports the superiority of family-based treatment over individually based treatment for alcoholism. Of the couple-based approaches for treating alcoholism, BCT exhibits the strongest empirical support. In randomized clinical trials, the degree of difference favoring family-based over individually based alcoholism treatment is typically in the medium effect size range. In addition to multiple naturalistic studies, there have been at least 10 randomized clinical trials examining the efficacy of BCT. In nearly all of the randomized clinical trials, BCT is compared to another credible, individually focused alcoholism treatment, including individual cognitive behavioral or 12-step-oriented treatment. Hence, among couples in which a committed partner is willing and able to actively participate in treatment, these studies provide information on the relative efficacy of BCT versus other well-established alcoholism treatments. Follow-up periods range from 6 months following treatment in initial studies to 12–24 months following treatment in more recent studies.

Primary Outcomes: Addictive Behaviors and Relationship Adjustment

In comparison to individually focused alcoholism treatment, BCT is shown to produce a higher number of abstinence days, lower days of heavy drinking, and lower negative consequences associated with use. The average effect size favoring BCT is in the medium range. It is noteworthy that studies normally do not show differences between BCT and individually oriented alcoholism treatment when these outcomes are assessed at posttreatment. Hence, individuals with alcohol use

disorders who receive BCT or individually focused treatment appear to gain similar benefits in showing reductions in substance-using behaviors immediately following treatment. However, during the extended follow-up period after treatment ends, studies tend to show BCT outperforming its active therapy comparators with regard to substance use outcomes. Typically, this is due to individuals who receive BCT sustaining their treatment gains better than those who receive individual alcoholism treatment, while those who receive individual treatment have more substantial deterioration with regard to alcohol-using behaviors.

Regarding relationship outcomes, BCT demonstrates an advantage over individual alcoholism treatment, with an effect size that is in the medium range. Couples who receive BCT tend to show fewer days separated, higher relationship satisfaction, higher agreement on important matters, and more positive communication behaviors versus those who receive individual alcoholism treatment. The general pattern of findings demonstrate that in comparison to those who receive individual treatment, couples who receive BCT show better functioning in this domain immediately following treatment and during the 6–24 months following treatment.

Researches on factors that may impact the responses to BCT are increasingly coming into focus. A recent study by Barbara McCrady and colleagues examined the efficacy of BCT among women with alcohol use disorder who had a committed male partner. In addition to the general finding that BCT led to greater reductions in alcohol use versus individual treatment, McCrady and colleagues also examined pretreatment factors that might influence responses to treatment. They found that BCT was especially efficacious for producing abstinence from alcohol among women who exhibited poorer relationship functioning upon entering treatment. Other findings showed that BCT was better than individual therapy in producing sobriety among women who exhibited mental health disorders that were co-occurring with the addiction. These results suggest that BCT may especially be beneficial in producing sobriety among women who have poorer relationship functioning and who exhibit mental health problems in addition to the addiction.

Intimate Partner Violence

Intimate partner violence is a common problem among couples with alcoholism and one that has been assessed in BCT outcome studies. Results from randomized clinical trials suggest that intimate partner violence is more substantially reduced with BCT versus individual alcoholism treatment. In addition, studies have examined the relative degree of partner violence among couples with alcoholism who receive BCT in comparison

to case-matched community couples where neither member exhibits a substance use problem. Results show clear and drastic declines in partner violence following BCT. During the year prior to BCT more than 60% of couples exhibit intimate partner violence, which is nearly five times higher than what is found in demographically similar couples without substance use problems. Following treatment, prevalence decreases to around one quarter to one third reporting partner violence. Further, studies of alcoholic couples who participate in BCT show that those who demonstrate remission of their drinking problems following treatment are similar to nonalcoholic community couples in rates of violence, while those who relapse have violence rates that are higher than community couples. This suggests that the ability of BCT to produce alcoholism remission following treatment may be particularly important in eliminating partner violence behaviors.

Child Functioning

Studies suggest that BCT results in better improvement in child functioning versus individually based alcoholism treatment. Although studies to date have exclusively focused upon heterosexual couples in which the father has an alcohol use disorder, results show better child functioning during the year following treatment for fathers who receive BCT versus those who receive individual treatment. These results are promising in suggesting that the benefits of BCT may generalize to the children of parents with alcoholism.

Cost Effectiveness and Cost–Benefit Outcomes

Several studies have examined the degree to which BCT is cost effective and results in reductions to societal costs. Regarding cost effectiveness, a study by Timothy O'Farrell and colleagues showed that BCT was more cost effective than interactional couples group therapy. In addition, there is clear evidence that BCT produces societal cost benefits in terms of reduction in addiction-related healthcare utilization, reduction in legal system involvement, and reduction in public assistance costs. Estimates indicate that BCT exhibits more than a 5:1 benefit-to-cost ratio. This means that for every dollar spent in providing BCT, there is a \$5 savings in societal costs.

CONTRAINDICATIONS AND CHALLENGES TO USING BCT

BCT is not appropriate for all couples with alcoholism, and it is necessary to consider circumstances

where it is contraindicated. First, when either partner is actively suicidal or homicidal, the treatment is foregone, and the intervention shifts to ensuring safety. Second, if either partner is actively psychotic, BCT is unlikely to be beneficial, since individuals may be unable to fully engage in sessions or follow through in practicing the therapy skills. Third, the treatment cannot be implemented in situations where a restraining order exists between partners. In such cases, partners must wait to begin BCT until the courts remove this order.

BCT is also not appropriate for couples that exhibit a recent history of severe partner violence on days when they have not been using alcohol or drugs. By severe partner violence, we mean behaviors such as using a weapon or striking a partner in a manner that is, likely to result in serious injury. In these cases, the nature of the violence is often consistent with efforts to dominate and control one's partner, a violence pattern that is sometimes referred to as "domestic terrorism." We recommend in these cases a referral to a domestic violence program and working with the victim to ensure personal safety (e.g. referral to a shelter). In our clinical work and research, we have found this type of violence to be relatively rare among couples who present for BCT. Rather, it is common for couples to present with a history of less severe acts of violence (e.g. pushing or slapping) and violence typically occurring on days when one or both partners are using alcohol or drugs. As previously described, studies show that BCT can be beneficial for reducing violence among couples who do not exhibit severe levels of partner violence, which may be a function of reductions in addictive behaviors and improvements in relationship functioning and conflict resolution skills.

A challenge to implementing BCT is when couples are unclear with regard to their commitment to the relationship. We do not recommend pursuing BCT with couples who are unwilling to try to stay in the relationship long enough to attempt the program. This does not mean that they must promise to stay together permanently in order to try the treatment, but rather couples should be able to make a commitment to fully work with one another in trying the treatment and then see how the treatment impacts their situation. With these couples, therapists should consider meeting with couples to explore and establish a minimal level of commitment prior to proceeding with BCT.

Another challenge to implementing BCT involves the scenario in which both partners have an addiction issue. The efficacy of BCT with these couples has yet to be formally studied. However, we have clinically applied the treatment in such circumstances by making the necessary adaptations to focus on both partner's sobriety. For example, in these cases the recovery contract is modified to address each partner's plans for achieving sobriety.

Another challenge to implementing BCT is dealing with couples that become separated, either prior to or during treatment. If a couple is yet to start the treatment, it is good to establish what conditions must be met in order for the couple to reunite, and then work with the couple in addressing this prior to implementing BCT. Similarly, when couples separate during the course of treatment, therapists should discuss with the couple what conditions are necessary for them to get back together and the degree to which it is realistic to be able to continue with BCT under these circumstances.

A final challenge in the implementation of BCT is engaging couples in the treatment. It is sometimes difficult to obtain consent from individuals who are in addiction care to involve their partners due to concerns over what will be discussed or embarrassment. Therapists may also find that partners are holding resentments or are experiencing negative emotions toward the individual with the problem and may, therefore, have some reluctance to engage in treatment. To address these, we typically follow a series of steps that involve normalizing these feelings and asking for small commitments toward involving partners in care (e.g. start with an initial telephone call to the partner in the presence of the patient or ask for an initial joint meeting with both partners to explore various treatments options). In addition to reluctance to engage in therapy due to negative feelings, there is also the practical issue of scheduling couples when at least one of the partners may be working. To address this in our research studies and clinical practice of BCT, we have offered evening and weekend appointment times. Hence, it is ideal for clinics and treatment providers who are seeking to implement BCT to consider offering to patients some scheduling options that are outside of a standard nine to five workday. This will increase the likelihood that couples can realistically engage in the therapy and attend sessions regularly.

FUTURE DIRECTIONS

Although BCT is the most highly researched couple-based treatment for addictions, there is an additional need to expand research and the clinical application of BCT. The majority of studies conducted on BCT have involved heterosexual couples in which the male partner has a primary alcohol addiction. Although randomized clinical trials have supported the efficacy of BCT among heterosexual couples in which the female partner has an alcohol use disorder, the number of these studies is limited. Evidence also exists to suggest that BCT is efficacious for homosexual dyads, but this research requires replication. Finally, there are fewer studies where the primary addiction issue is something

other than alcohol. In fact, we are not aware of any randomized clinical trials examining the efficacy of BCT for the treatment of gambling addiction and know of relatively few examining the efficacy in treating various drug use disorders. Therefore, there is a need for more research on the efficacy of BCT in treating nonalcohol-related addictions.

Although BCT can be adapted to treat couples in which both partners exhibit a current addiction problem, the efficacy of the treatment for this population is yet to be formally researched. By treating both partners together, BCT may be a more efficient and effective method for addressing dually addicted couples in comparison to approaches that treat each partners' addiction on an individual basis. However, dually addicted couples may also be at higher risk for relapsing, since one partner's relapse may result in the other partner relapsing as well. Studies are needed to clarify if BCT produces better outcomes for these couples than competing addiction therapy approaches.

Another area of opportunity exists in the integration of BCT with interventions that address co-occurring mental health disorders. It is quite common for individuals with addictions to also exhibit co-occurring mental health problems, such as mood or anxiety disorders. This can create additional challenges for individuals to achieve sobriety, since negative affect is shown to be a common trigger for relapse. A study by McCrady and colleagues is promising in finding that when compared to individual therapy, BCT produced higher rates of sobriety among women alcoholism and with co-occurring mental health disorders. In addition, studies demonstrate that intimate partner relationships that involve higher degrees of hostility and criticism are risk factors for relapse to alcohol and drugs along with experiencing relapses with other mental health problems, such as depression or anxiety. Together, these findings suggest that treatment that integrates BCT with interventions that also address co-occurring emotional problems may be a promising approach to improving outcomes.

Finally, although BCT has a relatively strong evidence base in treating addiction, dissemination of BCT to clinical practice settings and training opportunities for clinicians in BCT are just beginning. An initial dissemination study by O'Farrell transported BCT to a community clinic in Calgary. Implementation of BCT was considered successful because BCT had better 6-month follow-up outcomes than the clinic's typical individual counseling program in a quasi-experimental evaluation, and because the BCT program in Calgary that began in 1998 continues to the present.

Training in BCT that is available consists mainly of isolated workshops, not a systematic, high quality, sustained training program or organization devoted to

teaching and fostering implementation of BCT. There are also other resources for training in BCT. The 2006 book on BCT by O'Farrell is a comprehensive clinician's guide book to BCT and includes a session-by-session BCT treatment manual. A web-based training course in BCT also is available. A link to this course is given in "Relevant Websites" section.

SUMMARY

BCT is a couple-based treatment for addictions that has been developed and researched over the past 35 years. The treatment conceptualizes addictions and intimate partner relationship functioning as having a bi directional association. According to this model, addictions deteriorate relationship functioning, while poor relationship functioning, in turn, increases engagement in addictive behaviors. Therefore, BCT seeks to reduce addictive behaviors, while simultaneously improving relationship functioning. Randomized controlled trials support the superiority of BCT versus individually oriented treatments for alcoholism for patients who have a nonaffected spouse willing to be engaged in the therapy process. Specifically, BCT is associated with greater sobriety, less addiction-related problems, and better relationship functioning following treatment. In addition, there is evidence that BCT is associated with significant reductions in intimate partner violence and improvements in child functioning. Evidence also shows that BCT has cost-benefit ratio of better than 5:1, suggesting significant societal cost savings for the delivery of this treatment. More studies are needed to understand the treatment's efficacy among those with nonalcohol-related disorders, couples where both partners exhibit addictions, and among nonheterosexual couples.

Glossary

Abstinence refraining entirely from addictive behaviors.

BCT behavioral couples therapy

Conflict management behavioral and communicative style in responding to arguments or disagreements.

Enabling behaviors that promote or unintentionally reinforce the continuation of a family member's addiction.

Functional analysis method of assessing the causal chain of events that leads to a specific behavior.

Intimate partner violence antagonistic verbal or physical behaviors toward a relationship partner.

Relapse returning to a prior pattern of addictive behaviors.

INTRODUCTION

Alcohol dependence is a serious and widespread addictive disorder. Based on results from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC), it is estimated that about 12% of American adults have had an alcohol dependence problem at some time in their life. In 2002 the US Department of Health and Human Services estimated that the cost of alcohol dependence to the US economy was

approximately 185 billion dollars per year. Despite being among the oldest of America's addictions, alcoholism remains one of its most pernicious, with few good treatment options available. The purpose of the present chapter is to provide an introduction to a treatment approach that may help some individuals reduce their dependence on alcohol. The approach is referred to here as Network Support treatment, and it is intended to help alcohol-dependent persons increase the number of nondrinking people in their social network. In the

course of introducing this approach, we will present background information to place Network Support treatment in perspective, and will discuss some of the results from treatment trials with this and similar approaches to alcohol-dependence treatment.

THE PROBLEM OF RELAPSE

Network Support treatment is not intended to get people to stop drinking. Rather it is designed to prevent relapse. Interestingly, the most significant problem related to treatment of alcohol dependence is not getting people to stop drinking. The real problem consists in getting people to stay abstinent once they have stopped. It has been estimated that fully one-third of treated individuals relapse in the first 90 days after completion of treatment. Furthermore, 1–2 years after treatment less than half of the patients who have been treated for alcohol dependence maintain sobriety. Despite increased attention to the problem of relapse in the last two decades, no treatments have been able to effectively counter the relapse phenomenon.

Many factors suggest that the cards are stacked against an alcohol-dependent person remaining abstinent after treatment. One conception of the processes involved in treatment and relapse suggests that individuals are rewarded for staying sober during treatment, but after leaving the treatment setting, the person once again encounters cues for drinking, and the old drinking pattern is reestablished. The evidence that this process occurs is persuasive. Several studies have concluded that drinking is increased when access to alternative rewards, such as nondrinking friends or activities, is constrained. Conversely, when access to alcohol is constrained, consumption is decreased. Even when treatment is conducted on an outpatient basis, the accessibility of alcohol is constrained (more or less voluntarily), thus reducing consumption, and making treatment-relevant activities more likely to be engaged in. When the person finishes treatment, however, access to alcohol is typically less constrained (e.g. the support for limiting alcohol use is gone) and the person often experiences few rewards for sobriety to compete with reinforcement from drinking.

According to this reinforcement model, to be effective against relapse, treatment needs to shift the source of reinforcement from the therapy setting to the person's home environment. That is, the nontreatment home environment must become as reinforcing of abstinence as the therapy setting was. This shifting of reinforcement would entail providing, or teaching the patient to provide for him/herself, alternative reinforcers for abstinence away from the treatment environment that will compete with the reinforcement from alcohol use.

ENCOURAGING PARTICIPATION IN NON-ALCOHOL-RELATED ACTIVITIES

The behavioral view of relapse discussed above pinpoints at least one difficulty with treatment, but also provides a possible answer. Since the rewards that keep people abstinent during treatment are not typically available when treatment is finished, perhaps it is possible to get the patient to develop new sources of reward for abstinence.

Studies by Martin Iguchi with drug abusers, and Nancy Petry with alcoholics, suggested that it may be possible to provide rewards for performance of activities that compete with drinking and that this may be a way to reduce drinking after treatment. In the Petry study, alcohol-dependent veterans presenting for alcoholism treatment at a Veterans' Administration Medical Center received a treatment in which patients earned the opportunity to win prizes by submitting negative breathalyzer samples and by completing steps toward treatment goals.

Treatment goals included developing participation in Alcoholics Anonymous (AA), improving relationships with family, improving health, and extending education. Steps toward these goals were defined in terms of specific behaviors that could be verified. For instance, developing participation in AA might entail attending three meetings per week or contacting an AA sponsor. Improving relationships with family members might include writing letters to loved ones or developing plans to do things together. The authors reported that 84% of these patients stayed in treatment throughout an 8-week period compared to 22% of standard treatment participants. By the end of the treatment period, 69% of those receiving the reward treatment were still abstinent, as compared to only 39% of those receiving the standard treatment alone. This study demonstrated that it was possible to devise a treatment that had the potential to help the patient change his/her own environment and lifestyle and to encourage the adoption of activities that might compete with drinking.

The most ambitious attempt to encourage the participation in nondrinking activities for alcohol-dependence treatment and relapse prevention is the Community Reinforcement Approach (CRA), first proposed in 1973, and since refined. CRA involves providing rewards for sobriety and encouraging the development of activities incompatible with alcohol use, such as participation in recreational and social activities and employment. CRA was intended as an all-encompassing effort to change both the physical and social environment of the patient. To achieve such change in the environment, CRA might include job counseling, assistance with finding housing, medical care, and legal help. Treatment might also incorporate pharmacological as

well as psychosocial interventions, including the prescription of Antabuse or other drugs that can help reduce drinking. Although CRA is frequently cited as one of the most efficacious approaches to treatment, its use is not widespread, possibly because of the time, effort, and expense required to implement such a comprehensive program. Additionally, the complexity of the intervention makes it difficult to determine what features of CRA make it effective. Attention has thus turned to more limited ways of altering the environment so that it provides less encouragement for drinking.

THE SOCIAL NETWORK, AA, AND RELAPSE

Network Support for Drinking

One potent source of reinforcement for drinking is the drinker's social network, that group of people with whom a person spends the most time, or the most important time. The social milieu of an alcoholic serves to support the drinking of those in the network. Although this phenomenon has been recognized for some time, it has been difficult to quantify. General social support, for example, or simply the degree to which people support one another emotionally, has not been a particularly good determinant of how alcohol-dependent people respond to treatment. Two researchers, Richard Longabaugh and Martha Beattie, recognized that a specific kind of support may help to determine whether patients continued to drink or not. They differentiated drinking-specific support from general support and coined the term *network support for drinking*. This network support construct, designating the amount of support an individual receives specifically for drinking, has been found to be a powerful indicator of poor outcomes in patients who go into treatment. Specifically, those who have social networks that are dominated by drinkers and that encourage drinking are much more likely to relapse back to drinking at a faster rate.

It follows that if a social network that reinforces drinking behavior leads to more drinking, then networks that reinforce sobriety should yield greater abstinence from alcohol. Evidence for this proposition has been scarce, and somewhat indirect. For example, researchers Andrew Gordon and Mark Zrull reported that some alcoholic patients who were treated and then contacted a year later reported that the active support (including participation in treatment) of nondrinking friends and coworkers was the most influential factor in their recovery. It seems that the best predictor of relapses was encouragement of drinking by coworkers, some of whom were members of the

patient's social network. As early as 1982, John Mallams conducted a study in which attendance by alcohol-dependent patients at a social group for recovering drinkers was planned. Those who attended the group drank significantly less than those who did not attend, experienced less behavioral impairment, and spent less time in heavy drinking.

The Influence of AA

Perhaps the clearest example of a social network that supports sobriety is AA. In many ways AA is a ready-made sobriety-supporting network, and fulfills several of the conditions of a program that can compete with drinking. AA is conducted in groups, all members of which share the same goal and provide support. AA provides alternative activities to drinking, it constrains access to alcohol, and it rewards sober behavior. Certainly in the United States, AA has been credited with success in reducing alcohol use. It is frequently claimed that AA members achieve abstinence at a higher rate than do professionally treated alcoholics and that AA participants who are more active in the fellowship program do as well or better than less active participants. Studies of AA are difficult to conduct, however, because the members are usually devoted to one of the guiding principles of AA, anonymity, making it difficult to follow particular individuals over time. Those studies that have been conducted have produced results that are consistent with the idea that social support for sobriety can enhance treatment outcome.

From a scientific point of view, the studies that have been conducted of AA are troubling. A well-known difficulty with these studies is that patients who actually attend AA are self-selected. That is, these people go to AA on their own. Thus, it is not possible to know what the true effect of AA is. To put it another way, there is no way of knowing what would have happened to these individuals if they had *not* gone to AA. Perhaps many of those who choose to go to AA are people who would get better with any help, or with none. To get an understanding of the true value of AA, attendance at AA would have to be manipulated. Some people would have to get sent to AA while other people would not, and the choice of who gets AA or not would have to be random. To some extent this was done in Project MATCH, the largest psychotherapy study ever undertaken.

PROJECT MATCH

Project MATCH involved the collaboration of nine different treatment sites and over 1700 alcohol-dependent patients. The purpose of the study was to

determine whether patients could be optimally matched to different kinds of treatments based on certain characteristics. It was believed, for example, that a cognitive-behavioral treatment might be a better match for patients who had psychiatric problems than would a treatment based on the twelve-step principles of AA (i.e. twelve-step facilitation treatment, or TSF). For the most part these matching hypotheses did not hold true.

Project MATCH has provided some of the most detailed information on social networks in alcoholics to date, however, and shown interesting results regarding people whose social networks were heavily populated with drinkers. Analyses of the Project MATCH data set indicated overall that patients whose social networks were supportive of drinking had worse outcomes than those whose social network did not support drinking. A high level of network support for drinking was also related to a decreased likelihood of involvement in AA. It was discovered, however, that among those with high network support for drinking, patients who had been assigned to the TSF treatment had better outcomes than patients assigned to another of the treatments (Motivational Enhancement Therapy or MET).

Further analysis revealed that exposure to TSF resulted in greater involvement in AA, even among those whose social networks were highly supportive of drinking. Thus, AA involvement by patients with high network support for drinking seemed to be at least partly responsible for the matching effect. Patients with both high network support for drinking and high AA involvement had more abstinence than those with network support for drinking who were not involved in AA (across all three treatments). In contrast, for patients whose social network did not support continued drinking, AA involvement had much less effect on outcome. The implication of these findings was that a treatment that encourages a change of social network, from one that is supportive of drinking to one that is supportive of sobriety, might be an effective way to prevent relapse.

THE UNITED KINGDOM ALCOHOL TREATMENT TRIAL SOCIAL BEHAVIOUR AND NETWORK THERAPY STUDY

Another significant large-scale effort to enhance the social network of drinkers was the United Kingdom Alcohol Treatment Trial Social Behaviour and Network Therapy study (UKATT SBNT). Over 700 patients at seven sites in the United Kingdom were assigned to either SBNT or to a three-session MET, a brief treatment intended to mobilize the patient to make changes on his/her own. As used in UKATT, SBNT consisted of

eight sessions conducted over a period of 12 weeks, covering three phases: Phase 1 was concerned with the identification of the social network; Phase 2 (sessions 2–7) focused on expanding or mobilizing the social network; and Phase 3, conducted in the last session, was used to consolidate the work carried out in previous sessions and preparing for the future. Unlike the TSF treatment in Project MATCH, there was very little emphasis placed on making use of AA, which tends to be less popular in Europe than it is in the United States.

At the end of the trial the research team reported that both MET and SBNT yielded significant decreases in drinking and in drinking-related problems at 12 months, but that there were no differences between treatment groups. Despite the measurement of network characteristics, the authors did not report whether SBNT did in fact act on the social network as planned, or whether changes in social network were related to drinking outcomes. It is not clear, therefore, whether UKATT provided support for a social network-based treatment for alcohol-dependent persons or not.

NETWORK SUPPORT TREATMENT

Guiding Philosophy

Like the UKATT SBNT, Network Support treatment was developed as an explicit attempt to change the patient's social network from one that is supportive of drinking to one that is supportive of sobriety. Unlike the SBNT, which hoped to use existing networks of friends and family, it was decided that Network Support would make use of the most extensive preexisting sober social network for drinkers in the United States, namely AA. To do this, Network Support was based on the TSF treatment developed in Project MATCH. Because the aim of TSF was to encourage AA attendance, it was considered a good basis for a treatment that could provide the patient with a new social network of nondrinkers.

Unlike TSF, AA is not the sole focus of Network Support treatment. Nor is the AA philosophy totally embraced in Network Support. Although AA attendance is encouraged, the exact means by which the social network is changed is determined by the individual patient. AA is presented as a tool, one among many, by which patients may develop a sober social network. For most patients, the spiritual aspects of AA are downplayed, and the disease and helplessness aspects are presented and challenged. Indeed, for most patients alcohol dependence is portrayed as something that can be managed. AA meetings are useful, however, and are portrayed in part as refuges: places where nondrinking is the norm. As such AA is a valuable resource.

STRUCTURE OF NETWORK SUPPORT TREATMENT

Overall Structure

Network Support treatment was originally designed to be a test treatment, a treatment used in research. As such it has a rather strict structure. Treatment involves 12 weekly, individual, outpatient sessions with a therapist. Each session lasts 60 min. Patients have up to 16 weeks to complete 12 sessions of treatment. Breathalyzer readings are collected at the beginning of each treatment session, and any patient with a blood alcohol reading above .05 is asked to wait until their blood level declines, or to return at a later date.

Abstinence Goal

Network Support treatment is intended for those who meet criteria for alcohol dependence. Generally these are individuals who have tried, sometimes many times, and failed to control their drinking. Therefore, the goal of Network Support treatment is to maintain abstinence from drinking. Patients are not dropped from treatment for occasional alcohol or other substance use, but if they do report drinking they are encouraged to commit to renewed abstinence during treatment, rather than to try controlled drinking. Patients who do not commit to abstinence are not disqualified from treatment, but the problems of continuing drinking are addressed by the therapist.

Session Structure

Network Support treatment is composed of several topics, one new topic for each weekly session of treatment. To help ensure adequate exposure to topic material, the 60-min session is divided into three phases. The first phase, about 20 min long, is focused on progress and past assignments. This phase involves obtaining a breath sample, reviewing the patient's progress since the last session, and reviewing the between-session practice exercises assigned at the previous session. Review of patient progress includes an assessment of sober days versus drinking days, the presence of any withdrawal symptoms, and praise for adaptive skills used to promote abstinence. The patient's goals are discussed, and the patient's reactions to treatment and abstinence are also assessed.

The second phase of the session, about 30 min long, is devoted to providing the rationale and skill guidelines of the topic for that session. In addition to skills practice between sessions, patients are asked to practice skills during sessions as well. Therapists elicit patient reactions and individualized examples related to topic

material, and the therapist models specific skill components. Role-plays between patient and therapist may also occur during some sessions. The final phase of the session, about 10 min long, includes a summarization of session material, a brief discussion of how the patient might handle upcoming obstacles to sobriety, and the assignment of between-session skills practice for the upcoming week. Typically three between-session assignments are scheduled each week. The concept of between-session assignments (sometimes referred to as "homework") is sometimes unpopular with patients, but extremely important. The work of treatment takes place not in the office with the therapist, but when the patient is in his/her home environment, enacting the behavioral changes discussed.

SESSION TOPICS: CORE TOPICS AND ELECTIVES

Table 8.1 shows the topics covered in Network Support. The topics listed in bold type are core sessions and are intended to be discussed in the order listed by all patients. The remaining topics are electives and may be covered at the discretion of the therapist and patient. The set of topics to be covered is usually determined in the first few sessions, but may be subject to change. In particular, if a patient might benefit from additional conjoint sessions (sessions that include the presence of the patient's spouse or partner), those sessions may substitute for others that were originally planned.

Program Introduction

The program introduction presents the rationale for the program as well as the expectations for treatment. Patients are told specifically about the role of the social network in maintaining drinking, and the value of a new network to reinforce sobriety. The goal of abstinence is presented as the best approach for most people. The patient's confidentiality and its limits are discussed. The patient's drinking and treatment history are also reviewed, particularly his/her experience with AA. The patient is also introduced to the idea of ongoing between-session assignments. The importance of engaging in between-session assignments is stressed in the first session. After these introductory topics are addressed the therapist and patient discuss appropriate between-session assignments that can be reviewed the next week. These assignments may take the form of reading about AA, or attending a meeting, or completing an activities worksheet that may become the basis for developing activities that the patient can engage in with other nondrinking people.

TABLE 8.1 Network Support Session Topics

Core topics	Elective topics
Program introduction	Introduction to assertiveness
Need for support	Increasing pleasant activities
Getting active	Social skills identification
People, places and things	Social skills: Conversations
Termination	HALT
	Sober living
	Genogram
	Conjoint session – Enabling
	Conjoint sessions (multiple sessions possible)

Need for Support

Certainly a key aspect of the AA philosophy is the idea that the alcohol-dependent individual is unable to control his/her drinking, and needs others, a fellowship, to help stay sober. In Network Support this topic material is based on the AA Step 1 idea of acceptance of oneself as unable to control drinking, but is modified slightly. Therapists discuss with patients the value of having a network of people who will support them in their efforts to stay abstinent, whether it is through AA or through other outlets. They also deal with the idea that drinking has become out of their control. The AA notion of “helplessness” is not stressed. Patients are not told that they are helpless in the face of drinking. But the need for assistance from others is stressed, and AA is presented as a tool to foster this assistance.

Getting Active

The third core session of the treatment program is entitled “Getting Active.” The principle aim of this topic is to prepare the patient to get more active in AA. This entails familiarizing the person with some of the behavioral prescriptions embodied in AA slogans. Examples include “One Day at a Time,” which is a key tenet of AA, but also expresses an adaptive way of dealing with the stress of stopping drinking. The AA concept of People, Places, and Things refers to identifying those stimuli in the person’s environment that are cues for craving alcohol and drinking. The AA slogan “Easy Does It” reminds the client to avoid solving too many problems at once, and to “not bite off more than we can chew.” “First Things First” emphasizes the importance of sobriety, making

sobriety the patient’s top priority, and taking steps to promote sobriety. The therapist in this session also encourages the patient to talk things over with supportive family, friends, and AA peers to help set appropriate limits to drinking and other activities that have led to drinking in the past. Included in the session is a discussion of the advantages of AA attendance, encouragement to attend AA meetings, and to find an AA sponsor, a dedicated AA member on whom the patient can rely and contact in case of difficulty with drinking or cravings to drink.

People, Places, and Things

This topic is a key aspect of Network Support treatment. It encapsulates the theory on which Network Support was developed, namely that it is necessary to find ways to avoid or change the people, places, and things that cue and reinforce drinking. The need for the patient to learn to change his/her lifestyle, in particular the social network, to stay sober is stressed. The first step involves a discussion of the person’s existing social network, particularly any drinking buddies or friends with whom the person frequently drinks. Discussion then turns to how the social network can be changed, what obstacles to change exist, and how they can be addressed. Between-session assignments take the form of scheduling attendance at AA meetings, searching for an AA sponsor, and finding nondrinking activities, preferably social activities, outside of treatment.

Increasing Pleasant Activities

Related to the idea of people, places, and things is the idea that pleasant (nondrinking) activities can serve as substitutes for those activities or situations that patients find stressful and that cue drinking. It is often not enough simply to have people eliminate activities that are not good for them. They need to substitute activities (people, places, things) that *are* good for them, in the sense that they are not linked to drinking, and can take the place of drinking activities. Not everyone needs help with this, but many people do. Patients in this session complete a leisure questionnaire designed to evaluate their interests and to provide a basis for discussion of alternative nondrinking activities. The therapist and patient review the questionnaire responses and discuss ways in which the patient might increase the number of such activities, while reducing the number of drinking-related activities. Between-session assignments include attending an AA meeting and scheduling a new nondrinking activity outside of AA.

Social Skills Identification

This is an elective topic, intended to help those who are having difficulty with the idea of changing their social networks, or who particularly reject AA. A key aspect of this topic is the idea that it is more important to add a nondrinking friend to one's network of close associates (i.e. those with whom one spends time at least once per week), than it is to drop drinking friends. A difficulty for some patients is that they have poor social skills, making it difficult for them to meet new people and maintain relationships even if they wanted to do so. Social skills are those behaviors that facilitate interaction and communication with others, making relationships possible. These include communication skills as well as nonverbal behaviors that people use to function in social situations. During this session the patient's social skills are assessed using the Social Functioning Interview, an interview-based survey developed by psychologist Alan Bellack, which also identifies those social situations that might be difficult for the patient to manage, and which might cue drinking. Having identified problematic situations, the therapist can help the patient work on ways to deal with them. Between-session assignments after this session might include listing problematic social situations, working out ways to improve such situations, and practicing social skills discussed in the session, such as introducing oneself to a nondrinking person.

Social Skills: Conversations

Conversational skills are an important subset of more general social skills. Alcohol-dependent people who do not have well-developed conversational skills may drink in part to avoid the discomfort of social situations. Good conversational skills are critical for establishing friendships and other close relationships, as well as for getting along with coworkers in the workplace. Training in conversation skills focuses on increasing the frequency of interactions with others and improving the quality of those interactions. Good conversational skills require the ability to track and spontaneously respond to the other person, both verbally and nonverbally. In this session, patients complete a conversation skills assessment, in which patients rate themselves on their ability in different phases of a conversation, such as starting and maintaining a conversation. The therapist may work with the patient on different conversation skills using role-playing. Between-session assignments may include suggesting that the patient start a conversation with an unfamiliar person in a nondrinking environment, and asking him/her to maintain a conversation (minimum of 5 min) with someone at an AA meeting, or in another nondrinking environment.

Introduction to Assertiveness

Assertiveness refers to expressing oneself in a direct, nonaggressive way, particularly with respect to expressing one's needs or desires. Lack of assertiveness can lead to anxiety and frustration, which in turn may lead to drinking. Assertiveness training is frequently included as a component of more general social skills training. In Network Support treatment, assertiveness is evaluated in terms of how it may play a role in helping the patient meet new people and change the social network. Those who are too passive or too aggressive, for example, may be unable to make new acquaintances or maintain friendships. The session involves an assessment of assertiveness skills, a discussion of appropriate assertive responses in various situations, and role-playing. Between-session assignments may include approaching a potential AA sponsor or practicing assertive skills in a nondrinking social activity outside of AA.

HALT

Another elective session concerns the AA-based acronym HALT, which stands for Hungry, Angry, Lonely, Tired. This is a shorthand term to refer to those situations in which relapse to drinking becomes more likely. Observational data and patient reports bear out the conventional wisdom that abstinent alcohol-dependent persons are more likely to drink if they are feeling vulnerable. This session, more than most of the others, focuses on self-care issues. The therapist discusses with the patient the need to get plenty of rest, and to eat appropriately, as being important to recovery. Other issues addressed include the need for sufficient sleep to be able to be refreshed enough in the day to cope with difficulties that may threaten sobriety. Other issues for discussion include instances of anger or loneliness, either of which may trigger urges to drink. The therapist briefly assesses these conditions, and the therapist and patient discuss potential solutions. Exercise, relaxation, hobbies, and other activities are all discussed as a means of managing mood. It is pointed out that a sober social network can help the patient with these issues. Between-session assignments usually include engaging in some new activity that addresses one of the HALT concerns, preferably in the company of nondrinking peers (e.g. playing basketball with a nondrinking friend; getting lunch with a nondrinker).

Sober Living (Nutrition, Exercise, and Hobbies)

It is sometimes the case that patients have very impoverished social lives. Over time alcohol dependence can "shrink" a person's lifestyle. As alcohol dependence develops, the client loses or abandons old

friends, old hobbies, and interests and activities. Life becomes increasingly centered around obtaining alcohol and maintaining access to alcohol. In early sobriety especially, emptiness and boredom can drive the person back toward drinking. This session content is designed to address this emptiness and boredom. The patient's nutrition, exercise, and hobbies are a specific focus of this session. This session differs from the HALT session in that HALT is focused primarily on finding ways to manage emergencies. This session is about changing significant parts of one's lifestyle. At the conclusion of the session, the patient is asked to commit to one way to improve his/her lifestyle in each of the three areas by the next session.

Genogram

The word genogram refers to a diagram illustrating a person's family members, how they are related, and their medical history. The genogram allows the patient to see hereditary patterns of behavior and medical and psychological factors that run through families. In Network Support treatment, the genogram helps the patient see the presence of alcohol dependence across generations, and can motivate the person to break the cycle of addiction by increasing his/her social support for abstinence. In the session the therapist diagrams two or three generations of the patient's family, starting with the patient's own generation. The patient is asked about drinking in his/her parents, and grandparents, as well as siblings and cousins. The patient is also asked about the possibility that his/her children might be affected by alcohol dependence. Patterns of inheritance are explored, and the patient is confronted with the possible implications of these patterns. At the conclusion of the session, the patient is asked to develop options to deal with facts exposed by the genogram, including finding ways to stay sober.

Conjoint Session – Enabling

An important aspect of Network Support treatment is securing support from those individuals already in the patient's close social network if possible. Typically the most important person in the network is the spouse or partner, if one is available. It is often the case, however, that the spouse or partner, rather than supporting abstinence, "enables" the patient to continue drinking. "Enabling" is the process whereby a close supporter of the patient may try to help the patient, but in reality makes it easier for the person to continue to drink. A common form of enabling is making excuses or lying for the person, for instance by providing to an employer an excuse for missing work. The support person may feel that providing the excuse can save the patient's

job, allowing him/her time to get things in order. Support persons may purchase alcohol for the patient, doing so in the belief that it is safer for the person to drink at home rather than drive to another location to purchase alcohol or to drink. The common effect of all forms of enabling, however, is to shield the patient from the natural consequences of his/her drinking problems.

This session topic is covered if a partner or spouse (supporter) is available and willing to help support the patient through treatment. In the session the supporter and the patient discuss behaviors by the supporter that might serve to enable the patient to drink. The discussion also deals with the possible motivations for the enabling behavior, the supporter's reactions to the patient's drinking, and possible ways for the supporter to cease the enabling. This might include the supporter attending Al-Anon meetings, intended to help the person accept the reality of alcohol dependence in someone close to him/her. Whether with or without the aid of Al-Anon, the emphasis in the session is for the supporter to take care of herself/himself, without regard for the patient; that is, the supporter must allow the patient to make the mistakes and face the consequences associated with heavy drinking. This is a means by which the supporter can become an important element of the patients' social network, reinforcing abstinence rather than drinking.

Additional Conjoint Sessions

Because of the importance of the spouse or partner in supporting abstinence in the patient, additional conjoint sessions may take the place of other elective sessions, depending on the desires and goals of the patient and the partner. Among the additional sessions that might be conducted with the spouse or partner are sessions on supporting and rewarding the patient's abstinence, and on detaching from the patient. Sessions focused on rewarding the patient's abstinence involve teaching the spouse or partner to get in the habit of noticing the improvements the patient is making in his/her drinking, and in other areas as well (e.g. mood, health). Partners are informed that slips may be a part of the recovery process and that together he/she and the patient can learn from them. Criticism should be avoided. The patient and partner are also asked to try to anticipate stressful periods or other circumstances that might test the patient and to plan on ways of dealing with those situations.

A session on partner detaching may be conducted if the spouse or partner has been unable to cope with the patient's treatment efforts, or difficulty with treatment. In such cases it may not be possible for the spouse to help the patient, but it is important that the treatment

not harm the spouse or partner. In these situations the partner is counseled to “detach” from the situation. That is, he/she is encouraged to accept that the patient is dependent on alcohol and cannot necessarily help him/her. As in the session on enabling, the spouse or partner is encouraged to allow the patient to experience the negative consequences of his/her actions. The spouse is counseled to let go of anxiety, anger, and resentment.

Termination

The termination session is a core session of Network Support treatment. It is intended to provide closure to the first phase of a long and intensive process and to prepare the patient to maintain any gains made during the treatment. During this final session, the therapist and patient review the goals that were discussed and the patient’s progress toward those goals. The purpose of the program is reiterated and the patient is urged to continue to make adaptive changes to his/her social network. The topics covered in treatment are summarized and the patient is asked about what topics were most and least useful. Additional treatment referrals are provided if necessary. The therapist ends by congratulating the patient on his/her achievements.

EFFICACY OF NETWORK SUPPORT TREATMENT

Network Support treatment has been tested in one major clinical trial, with results available for patients up to 2 years of follow-up. The complete reports of this trial have been published in the *Journal of Consulting and Clinical Psychology*. In this initial study 210 alcohol-dependent men and women were recruited from the community and received one of three outpatient treatments: Network Support (NS), Network Support + Contingency Management (NS + CM), in which patients were rewarded for completing between-session assignments, or Case Management (CaseM), a control condition in which no mention was made of changing social networks.

The results indicated that, in terms of drinking rates, both of the Network Support treatments led to better outcomes than the CaseM condition. Additional analyses indicated that the NS conditions did not reduce social support for drinking relative to the CaseM condition, but did increase social support for abstinence, as well as AA involvement. Furthermore, the increased support for abstinence and the increased AA attendance were partly responsible for the improved results. One important finding was that the addition of just one abstinent person to a social

network increased the probability of abstinence for the next year by 27%.

These findings indicate that drinkers’ social networks can be changed by a treatment that is specifically designed to do so and that these changes contribute to improved drinking outcomes. After 2 years the decreases in drinking seen in the NS condition were maintained, with over 45% reporting total abstinence at the 2-year mark. In contrast, those patients who received the CaseM treatment, and those who received the NS + CM treatment, reported increasing drinking over the 2-year follow-up.

NETWORK SUPPORT: CONCLUSION

The development of Network Support treatment, and the clinical testing that has been conducted, has so far yielded the following conclusions: (1) Network Support interventions can help patients change their social networks. (2) The social networks of patients tend to become more supportive of abstinence, but support for drinking may not change. That is, patients may adopt new acquaintances but are reluctant to abandon their old friends. (3) If changes in the social network are made, the patient’s chances for improvement increase. It is particularly important to add at least one nondrinking person to the social network.

Network Support treatment may hold promise for helping patients change their social networks and thereby lessen the chance of relapse. The current Network Support treatment has been enhanced with additional interpersonal skills training to improve patients’ ability to develop more adaptive social networks. It is hoped that this enhanced treatment may further improve the chances of recovery for alcohol-dependent patients.

Empirical Bases for MST	84		

Multisystemic Therapy (MST) is an intensive family- and community-based treatment targeting youth at imminent risk for out-of-home placement, including juvenile offenders with substance abuse. Drs Scott Henggeler and Charles Borduin – the original developers of MST – and their collaborators have led most investigations on MST, with more recent investigations on MST effectiveness conducted by independent investigators. The empirical evidence for MST, including 20 published outcome studies (18 randomized trials and two quasi-experimental studies), has led the National Institute on Drug Abuse, the President's New Freedom Commission on Mental Health, and the US Surgeon General to recognize MST as one of the most extensively validated evidence-based psychosocial treatments for youth antisocial behavior, including substance abuse. The Surgeon General selected MST as one of only three empirically supported treatments for juvenile offenders, and the Substance Abuse and Mental Health Services Administration specified MST

as a model program for treating antisocial substance-abusing adolescents. Based on findings from over two decades of research, MST has become one of the most widely transported treatments for antisocial behavior in adolescents, including substance use. This chapter describes the application of MST for treating substance use in adolescent offenders, including an overview of the MST treatment model for adolescent substance use and a summary of the evidence for MST specifically with this population.

THEORETICAL BASES OF MST

The MST model draws from Bronfenbrenner's social-ecological and Minuchin's and Haley's family systems theories, viewing youth as embedded within multiple, interconnected systems (nuclear and extended family, peer, community, school). The reciprocal interplay of these systems influences behavior,

either directly (e.g. through parenting practices) or indirectly (e.g. through community factors that might influence parenting practices). Thus, antisocial behavior is viewed as multi-determined, with pertinent risk and protective factors identified in individual (e.g. cognitive biases), family (e.g. affective and instrumental relations), peer (e.g. prosocial versus antisocial nature of peers), school (e.g. academic performance), and community (e.g. criminal subculture) levels. Interventions used in MST pull from theoretical perspectives that complement the social-ecological models underlying MST. These include cognitive behavioral theory (e.g. problem-solving skills), behavioral theory (e.g. behavior plans), social learning theory (e.g. modeling and reinforcement influencing behavior), strategic formulations (e.g. understanding recursive sequences of behavior and family hierarchy), and Minuchin's structural formulations (e.g. attention to boundaries and repeated patterns of interactions that regulate family members' behaviors).

CHARACTERISTICS OF MST TREATMENT

Treatment is intensive, with a team of 2–4 full-time master's-level therapists each carrying caseloads of 4–6 families. Treatment includes an average of 60 direct contact hours over 3–5 months. The team is supervised by an advanced Master's- or doctoral-level supervisor. To remove barriers to participation, sessions occur at times (e.g. afterschool, evenings, weekends) and locations (e.g. home, school, community) that are convenient for the family. Further, therapists rotate being on-call, ensuring 24/7 availability for problem solving and emergencies. This model of service delivery allows flexibility in meeting families' needs while enabling rapid responses to crises that may threaten to disrupt treatment. Together, these elements support MST therapists in achieving high engagement and low treatment dropout rates.

In keeping with the systems approach, MST works with all pertinent systems in which the youth is involved, including peer group, school, neighborhood, immediate and extended family, and child welfare and juvenile justice agencies. Intervention protocols are relatively complex, however, given the multiple determinants of antisocial behavior and the need to target these determinants simultaneously across a complex and ever-changing ecology. To navigate these complexities, therapists and supervisors apply the nine core principles of MST within a standardized decision-making process that structures and guides treatment.

MST TREATMENT PRINCIPLES AND PROCESS

MST's fundamental goal is to empower caregivers to develop skills necessary for managing the problematic behaviors presented by their youth, both now and throughout their adolescence. The ability to individualize treatment and adapt to the family's changing needs is achieved through adherence to MST's nine core principles guiding the assessment process and structure planning, implementation, and evaluation of treatment. Treatment plans involve an MST therapist delivering a tailored set of evidence-based interventions targeted to each youth and family's unique strengths and struggles. This tailoring not only limits interventions to those that are necessary but also heightens the likelihood of achieving the family's buy-in to treatment and generalization of skill development. The nine core principles and treatment process are described next, accompanied by applications specific to adolescent substance use.

MST Principles

Principle 1. Finding the Fit – The primary purpose of assessment is to understand the “fit” between the identified problems and their broader systemic context.

MST relies heavily on a thorough, ecological conceptualization of youth antisocial behaviors. This conceptualization is the MST therapist's understanding of how the pieces “fit” together; that is, how is the behavior being sustained by variables in the youth's ecology? Accordingly, a “fit analysis” helps the MST provider make sense of the youth's problem behaviors in the context of his/her social ecology. Relying on what we know about the causes of youth problem behavior, MST providers investigate from an ecological and systemic perspective, identifying factors in the youth and his/her ecology that seem to be “driving” the youth to engage in problem behavior. These drivers become the “fit factors” for the fit analysis. To accomplish a thorough fit analysis, the MST therapist must be well informed about the most commonly observed youth (e.g. attitudes, cognitions, prenatal complications, drug exposure, cognitive functioning, biological processes, lack of prosocial activities, low academic functioning and involvement), family (e.g. ineffective parenting practices, low warmth and high conflict, caregiver psychopathology, substance use), community (e.g. poor housing quality, high crime, limited resources, easy access to drugs), and peer (e.g. access to drugs, modeling of substance use, beliefs, and norms) factors that drive antisocial behavior. The therapist's role is to assess what factors might be present for each youth

and family, and prioritize which fit factors should be targeted in treatment planning. Further, the process is dynamic, as the conceptualization is updated in response to newly identified or appropriately resolved fit factors.

Consider the case of a 13-year-old boy, referred for engaging in various delinquent behaviors, who uses drugs after school with his neighbor. The boy's single mother returns from work around 06.00 p.m., leaving a 3-h window where he is unsupervised and has access to drugs at the neighbor's. Primary fit factors for this case appear to be low monitoring and parental supervision (i.e. youth can access drugs without the parent knowing) and negative peer associations (and corresponding lack of activities with prosocial peers). When he returns home, he is able to shower, brush his teeth, and change clothes before his mother returns from work, therefore disguising outward signs of use. Thus, another fit factor is that the parent cannot detect drug use when it has occurred and is not knowledgeable about how her teen conceals use. Because the mother is ignorant of his drug use, there is no consequence for the behavior, so he lacks motivation to stop using. A therapist might hypothesize that the main factors to target include low monitoring and supervision, negative peer involvement, lack of prosocial peer involvement, and lack of meaningful consequences.

Another example involves a 17-year-old girl; she is in a relationship with a 19-year-old who sells drugs and regularly offers her drugs. She spends all of her free time with him, and he ridicules her when she turns down his offers to use drugs. In the recent past, she had a warm relationship with her parents, and she still appears to want their approval and support. Her parents are aware of their daughter's relationship but have never met the boyfriend. They believe that she can make her own decisions and, though disappointed that she uses drugs, they feel they can do nothing about it given her age. The primary fit factors overlap those described in the previous example, but with some key distinctions. Like the first example, this 17-year-old's use appears to be driven, in part, by negative peer association (and corresponding lack of positive peer associations or prosocial activities). Her parents also exhibit low monitoring and supervision (e.g. they have not met the boyfriend; they do not know when or where she is using drugs). The reasons for low monitoring, however, are different. The girl's parents are aware of the drug use and can recognize signs of use, but they believe they are powerless to do anything about it due to her age. Further, the 17-year-old admits to having ineffective peer refusal skills to decline her boyfriend's offers, even if she wanted to quit using and improve her relationship with her parents.

Principle 2. Positive and Strength Focused – Therapist contacts emphasize the positive and use systemic strengths as levers for change.

A positive and strength-based approach has numerous advantages for successful outcomes and improved engagement and alignment in treatment. Focusing on family strengths can decrease negative effect, build hopefulness, create an environment of mutual problem solving (improving chances for generalization; see Principle #9), and enhance caregiver's confidence. This approach is communicated to the family throughout the entirety of treatment by emphasizing their strengths, as well as the strengths within the various ecological contexts (Principle #1). Providers actively investigate youth factors (e.g. competencies, attractiveness, altruism), caregiver factors (e.g. resources, affective bonds, social support), peer factors (e.g. competencies, prosocial activities, inclusiveness), school factors (e.g. management practices, concern, prosocial activities), and neighborhood/community factors (e.g. law enforcement, business involvement, healthcare, neighbor concern), drawing upon strengths to develop individualized interventions.

A primary example of this principle is how therapists highlight any movement toward desired behaviors. Although eliminating substance use may be desired, any reduction in the behavior will be recognized; the therapist will attempt to understand the "fit" of the reduction, with the hope that the factors driving these reductions can be replicated or enhanced to further diminish/eliminate the behavior. Suppose that the 17-year-old girl described previously had two instant urine drug screens conducted over the past week by a parent: the first was negative (clean), but the second was positive (dirty). Although the youth has recently used drugs, the therapist will conduct a "positive fit analysis" to determine what factors drove drug abstinence earlier in the week versus drug use later in the week; perhaps the caregiver withheld cell phone usage earlier in the week, coincidentally eliminating the youth's ability to contact her boyfriend (i.e. a peer who promotes and provides drugs). This type of factor could be replicated to determine if it reduces the youth's drug use.

Another example of focusing on strengths involves MST clinicians (therapists, supervisors) avoiding blaming language. Even when faced with frustration resulting from a family not following through with the plan, the MST team attempts to see things from the family's perspective, identifying barriers the family may be experiencing that prevent them from following-through. Using the example of the 17-year-old, if a positive fit analysis indicates that limiting cell phone access might drive reduced drug use, the therapist could gain the parents' alignment to limit the youth's phone access. The therapist learns that the youth yielded positive drug screens and admitted to drug use later in the

month; after a fit analysis on the recent use, the therapist finds that the youth still had access to the cell phone. The therapist tries to identify barriers that prevented the parents from withholding the phone and finds that it is the primary means for the parents to communicate with their child, allowing them to know where she is and to coordinate transportation arrangements. Although the parents agreed to the plan of withholding the phone, they were unable to follow through due to practical barriers. Rather than expressing frustration or “giving up,” the therapist acknowledges the barriers preventing the parents from following the plan and engages them in problem solving to overcome these practical barriers (e.g. develop communication plans that do not rely on the cell phone; limit what calls she can make through the phone company).

Principle 3. Increasing responsibility – Interventions are designed to promote responsible behavior and decrease irresponsible behavior among family members.

The fundamental goal of MST is to empower caregivers to effectively manage and resolve serious clinical problems presented by their youth both now and throughout their adolescence (see Principle #9: Generalization). MST views caregivers as the key to long-term positive youth outcomes and are therefore the strongest lever for change (i.e. the “change agent”). With this in mind, caregivers participate in every step of assessment and intervention, engaging other indigenous supports where needed. Therefore, rather than relying on individual therapy for the youth, providers align with the caregivers on treatment goals and provide them with the instruction and support needed to implement the intervention.

Consider the case of the 13-year-old boy who accesses drugs after school. The parent and therapist completed the fit assessment and are in agreement that primary “drivers” for the drug use are low monitoring and supervision, negative peer involvement, lack of prosocial peer involvement, and lack of meaningful consequences for drug use. Through the assessment, the therapist learns that the youth used to be involved in baseball but was ineligible for school athletics due to poor grades. The parent and therapist align on a treatment goal to reengage the youth in positive afterschool programs through the community until grades improve. It would be easy for the therapist to contact the local baseball league to inquire about eligibility requirements; however, the therapist would be taking the responsibility away from the parent and would lose a valuable opportunity for improving the mother’s skills in accessing supports within her own ecology. A better approach is to train the parent on how to make the calls (e.g. guide her to create an agenda for the calls, role play the calls) and then support her as she makes the calls on her own.

Principle 4. Present-focused, action-oriented, and well-defined – Interventions are present-focused and action-oriented, targeting specific and well-defined problems.

Clear treatment goals form the basis for MST interventions and are behaviorally defined so it is obvious what is being targeted and, therefore, assessed. A family with a nonspecific goal such as “youth needs to respect authority” would be guided to identify what disrespect for authority looks like for this youth (e.g. violating rules in the home, school, or community; physical and verbal aggression) and a behaviorally defined goal would be developed (e.g. youth will demonstrate improved respect for authority as evidenced by following household, school, and community rules, eliminating physical aggression, and reducing verbal aggression). This clear goal allows the treatment team and family to be action-oriented in developing plans for targeting these well-defined goals, closely tracking progress, and identifying transparent criteria for treatment termination. MST is an intensive treatment, so therapists develop weekly subgoals that target the prioritized fit factors (Principle #1). Given this action-oriented approach, rapid treatment change is expected. Further, emphasis is placed on the fit factors presently sustaining the behaviors, as opposed to those responsible for the initial development of the behaviors.

Imagine the 17-year-old girl who is using drugs with her older boyfriend. One driver the family identified was decline in the relationship between the youth and her parents, corresponding to lack of warmth in the home and increased conflict. With further assessment, we learn that the parent–child relationship began to wane after the parents divorced and the mother remarried. Currently, the biological father and stepfather are both actively involved in parenting, but the youth has struggled to adjust to the change in family structure. The divorce may have been the initial trigger, but other protective factors have since been lost that could have brought an end to the drug use, including adult supervision, prosocial peer involvement, and skills to manage distressing cognitions. As these latter factors are currently sustaining the youth’s drug use, they are the fit factors that should be prioritized for intervention.

Principle 5. Targeting Sequences – Interventions target sequences of behavior within or between multiple systems that maintain the identified problems.

Problem behaviors are viewed from the social–ecological framework as having a multisystemic set of causal and sustaining factors. Interventions are thus focused on changing family members’ interactions with one another, as well as their interactions with the ecology (e.g. peer, school, community). While promoting responsible behavior of family members, this also

extends the family's informal support systems (e.g. friends, clubs) rather than relying on formal support systems (e.g. probation, social services) to sustain positive changes.

Take the example of the 13-year-old boy who uses drugs after school with his neighbor. The therapist guided the parent through contacting the baseball league and preparing for tryouts to reengage the youth in prosocial activities. With this driver targeted, the mother and therapist now begin focusing on the remaining drivers (low monitoring after school; lack of meaningful consequences). To target these fit factors, the family and therapist developed a behavior plan including random drug screens with appropriate negative consequences for positive or refused drug screens. Following a positive screen, the mother implements the consequence – “grounding” him from going out with friends until he has a clean screen. Knowing that this means he cannot attend the football game that evening, the youth becomes agitated and tries to aggravate his mother with name-calling, following her around, cursing loudly, and punching a hole in the wall. Unable to effectively diffuse the button-pushing, she eventually gives in because she can no longer tolerate his disrespect. The mother contacts the therapist to report the incident. In reconstructing the sequence, it became evident that the consequence of grounding, while meaningful (as evidenced by the youth's intense displeasure), may not be enforceable at this time due to both the youth's problematic responses and the mother's ineffective management of button-pushing. To overcome this barrier, the mother and therapist align on a plan to utilize the youth's uncle, with whom the youth does not get aggressive, to temporarily provide support when a negative consequence must be implemented. Meanwhile, the mother can work with the therapist to improve skills for managing the youth on her own and identify negative consequences that are not as taxing on the mother (e.g. uncle confiscating the youth's gaming system/computer until the youth has clean screens).

Principle 6. Developmentally Appropriate – Interventions are developmentally appropriate and fit the developmental needs of the youth.

The MST therapist and supervisor review interventions to ensure they are well-matched to the youth's and family's developmental needs. Thus, the competencies youth typically develop during adolescence are emphasized (e.g. peer relations, academic planning). To illustrate, a comprehensive fit analysis for a 12-year-old's drug use identifies three primary fit factors: low supervision after school (his use only occurs after school when home alone), poor anger management skills (he is most likely to use when angry), and inconsistent

consequences for drug use (he is not always held accountable for drug use). When choosing intervention strategies, the family and therapist decide to initially target the low supervision and inconsistent consequences, as asking the youth to evaluate and modify his response to anger (e.g. cognitive interventions) may be more difficult given a preteen's limited developmental capacity to monitor internal dialogue and processes.

Principle 7. Continuous Effort – Interventions are designed to require daily or weekly effort by family members.

Youths referred for MST demonstrate high-risk behaviors that place them at imminent risk of out-of-home placement. Given this, the case conceptualization, intervention development, and intervention implementation must occur rapidly. By attaining daily or weekly effort by family members, the stage is set for rapid change in problematic behaviors. This, in turn, provides more opportunities for identifying barriers to intervention effectiveness, and more opportunities for families to feel empowered as they come to learn they are the “change agents” (Principle #3) for altering the youth's behavior. The intensity of MST, compounded with therapists' low caseloads, results in frequent in-person and phone contact, but homework assignments also ensure daily or weekly effort by family members.

In the example of the 17-year-old girl who uses drugs with her older boyfriend, the family and therapist hypothesize that a main driver for the youth's increased involvement with her boyfriend is due to discontinued involvement in afterschool activities (school musical, softball). Therefore, factors driving the youth's drug use include increased access to negative peers (with low parental knowledge of peers) and disengagement from prosocial activities. To begin reducing access to negative peers, the parents and therapist might agree to start a daily log of whom the youth is seen with, who she mentions, or who appears on the caller ID. This daily tracking allows the parents to rapidly collect information on members of the youth's peer group, providing means for contacting the peers' parents or limiting access to certain peers if needed.

Principle 8. Evaluation and Accountability – Intervention effectiveness is evaluated continuously from multiple perspectives, with providers assuming accountability for overcoming barriers to successful outcomes.

The MST assessment process is ongoing and follows a circular form (see MST Analytical Process) that guides treatment. Because goals are well defined (Principle #4) and interventions are devised to require continuous effort from the family (Principle #7), measurable outcomes can be monitored and evaluated frequently.

Data from multiple sources are gathered to ensure accurate evaluation. The MST therapist is responsible for monitoring outcomes, as well as for identifying and problem-solving barriers to treatment progress. Such an approach avoids blaming or negatively labeling individuals as “resistant”; instead, the therapist focuses on generating creative ways to overcome impediments to success and ensuring a “can-do” attitude (see the example for Principle #2).

Evaluating treatment progress continuously from multiple perspectives as applied to drug use in the example cases described here included youth self-reports and instant-report urine drug screens. The therapists also educate parents on scenarios in which substance use might not be detected reliably through these methods (e.g. deception, drugs with short detection times, huffing). To increase accuracy of their evaluations, the therapist helps the parents develop a plan for conducting random screens frequently enough, though randomly, to detect use. In addition, the therapist also teaches them to conduct room sweeps and other measures to detect drug paraphernalia, in addition to utilizing drug screens.

Principle 9. Generalization – Interventions are designed to promote treatment generalization and long-term maintenance of therapeutic change by empowering caregivers to address family member’s needs across multiple systemic contexts.

Long-term therapeutic change is achieved by empowering caregivers to address the family and youth’s needs across the multiple systems in which they participate. By leveraging strengths (Principle #2), increasing parental responsibility (Principle #3), and requiring present-focused (Principle #4) continuous effort (Principle #7), caregivers can develop the skills necessary for achieving and continuing the progress made during treatment. As treatment continues, the role of an MST therapist rapidly changes from that of teacher/clinician to advisor/consultant; meanwhile the family begins to rely more on themselves and indigenous supports (e.g. extended family, neighbors, friends) to sustain favorable outcomes long after termination of services. Consider again the 13-year-old who accessed drugs at his neighbor’s while his mother was at work. The family and therapist determined that two primary factors driving the drug use were low monitoring and ineffective consequences. Working with the therapist, the parent develops a comprehensive monitoring plan, clear negative consequences for drug use, and rewards for clean screens. After 3 weeks of implementing the plan, the youth is no longer using drugs and has clean screens. To build on this success, the therapist guides the family in developing a plan to generalize the parent’s improved monitoring, effective reward system, and consequence interventions to another problematic behavior: poor

school performance. By building on the parent’s developed skill set, the family is better positioned for continuing to apply their skills targeting the youth’s substance use, in addition to any new problematic behaviors that might emerge as the youth ages.

MST Analytical Process

The MST Analytical Process (see Fig. 9.1) provides the framework for identifying youth and family problems, prioritizing drivers for change, designing interventions for implementation, and measuring successes and barriers to goal attainment. The MST team uses this framework to guide treatment while adhering to all nine MST principles. As denoted by the largest box in the figure, this process occurs within the environment of engagement and alignment, with the therapist taking full responsibility for obtaining and maintaining the family’s and other key participants’ engagement in treatment. Initially, the therapist must identify the referral behaviors and elicit the desired outcomes for treatment from key participants (e.g. immediate family, formal and informal supports). This information is then translated into well-defined overarching treatment goals, providing direction for the duration of treatment.

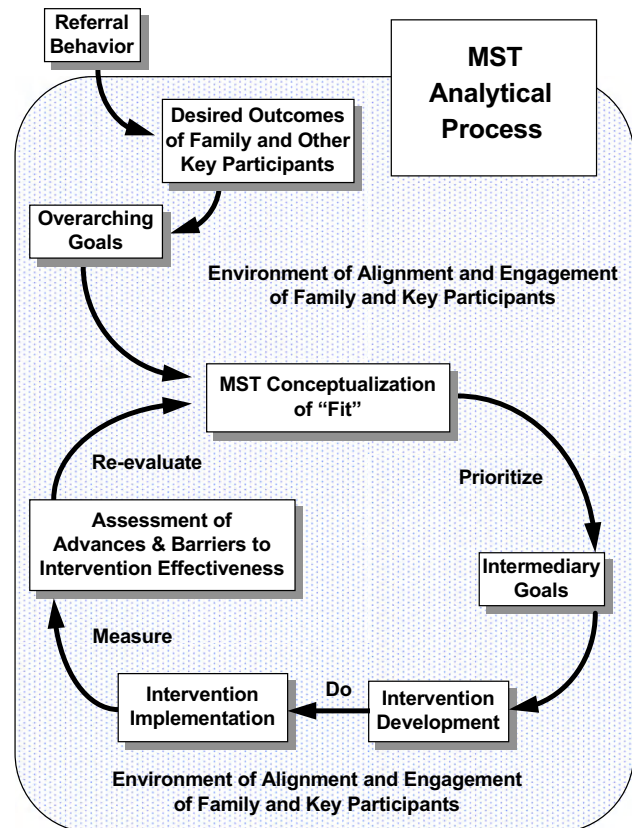

FIGURE 9.1 The MST Analytical Process guides treatment planning.

The therapist guides the family through fit analyses of the behaviors identified in the overarching goals, engaging key participants to identify multisystemic factors driving each of the behaviors. These factors are then prioritized based either on their potential for triggering antisocial behavior (including substance abuse) or on those that must be targeted prior to targeting the primary factors (i.e. prerequisite factors). The prioritized fit factors help the MST team generate working hypotheses the team uses to tailor interventions to the family. From this, the therapist and family determine the best-suited interventions, attempt the interventions, and evaluate the effectiveness of the interventions. Based on the evaluation, the conceptualization (i.e. fit factors, hypotheses) may be revised and new or redesigned interventions are implemented. This iterative process continues until the behaviors are targeted successfully, at which point the factors driving the sustained improvements are identified (understanding the fit) and concrete plans are developed for the family to sustain those factors into the future.

To illustrate the MST analytical process, consider the case of a 16-year-old male referred by the juvenile probation department for running away, car theft, drug abuse, and physical aggression. The MST therapist begins by building definitions of the problematic referral behaviors, including their intensity and frequency, and how long the youth has exhibited these behaviors. The assessment indicates that the youth began seriously acting out when he entered high school. He started running away overnight and had at least two instances where he disappeared for several days. During one of these instances, he was found with a peer in a stolen car and was placed on probation for the incident. After the last incident, his parents found marijuana in his bedroom. When they confronted him about using drugs, he became verbally aggressive and threatened to leave or harm them if they searched his room again. When his parents tried to enter his room, he pushed his mother, resulting in his involvement with the police for assault and drug possession. At the time of intake into MST, the youth's parents and probation officer reported that he was physically aggressive every few weeks, left the house whenever he wanted, and was using marijuana.

The MST therapist then works with the family to identify outcomes they hope to see in the youth post-treatment. The family wants the youth to decrease the referral behaviors and to complete his chores. The probation officer, school guidance counselor, and aunt are identified as key participants in treatment and are invited to participate in MST. In addition to the existing desired outcomes, the key participants want the parents to establish age-appropriate rules for the youth. Next, overarching goals for treatment are developed, which

must relate to the referral behaviors, achieve the desired outcomes, guide the direction of treatment, and establish the discharge criteria. All subsequent interventions tie directly back to the overarching goals. For this youth, the overarching goals for treatment are to (1) eliminate physical aggression; (2) eliminate illegal drug use; and (3) follow household rules including chores, obtaining permission before leaving, and reporting whereabouts.

The therapist now begins the "fit" assessment by gathering detailed information from the family and key participants on recent sequences of aggression, rule-breaking, drug involvement, as well as factors that may drive the youth's behaviors. The therapist and family then prioritize fit factors. Specific to drug use, prioritized fit factors are: access to money to purchase drugs, no immediate negative consequences for drug use, few rewards for drug abstinence, low monitoring and supervision, negative peer association, and boredom. They are now equipped to develop interventions targeting these factors, while ensuring the interventions adhere to MST's nine principles.

First, the family limits the money they provide the youth and asks documentation on how he uses it (e.g. provide receipts from purchases). The therapist educates the family about behavior modification strategies (e.g. increased monitoring of youth, rewarding abstinence, enforcing consequences for use), and they collaboratively develop a tailored behavior plan, including monitoring the youth's whereabouts, conducting instant urine drug screens purchased from an online source, identifying and delivering meaningful and immediate negative consequences for drug use (as documented by positive drug screens), and identifying and delivering appropriate and immediate rewards for drug abstinence (as documented by negative drug screens). Before beginning, the therapist helps the family identify possible barriers to successful implementation of the behavior plan. Transportation issues and long work hours being potential barriers, the family agrees to invite one of their key participants, the boy's aunt, into treatment for support. She agrees to provide transportation to activities he earns as rewards in the plan and will help monitor by making surprise house visits during times the youth is home alone.

Simultaneously, the family also aligns on targeting fit factors of negative peer association and boredom. Though the youth is unwilling to provide information about his peers, the family and therapist utilize the ecology for assistance. The guidance counselor knows the youth's peers at school, and the probation officer provides contact information and common peer "hang outs" where drugs are often accessible. The therapist, family, and probation officer work together to restrict the youth's time with specific peers who are known drug users. The family and therapist then generate

a list of the youth's strengths, talents, and previous pro-social activities. Using this list, they contact people to inquire about getting him back into these activities and present these options to the youth, with incentives for him return to these activities. Once the plans are set in motion, the family and therapist assess the youth's progress each week, problem-solving barriers as they proceed. MST is concluded following sustained reduction in the targeted behaviors and development of a long-term sustainability plan.

EMPIRICAL BASES FOR MST

MST was developed to target adolescent antisocial behavior. Thus, most research on MST has focused on delinquency outcomes, as opposed to substance-use outcomes. This section gives an overview of MST's effectiveness for the primary target outcome (i.e. juvenile delinquency), the process by which MST started focusing on substance use, and a summary of empirical findings related to substance use treatment (of antisocial youth).

MST for Juvenile Delinquency

To date, 20 efficacy (i.e. testing a treatment delivered under optimal circumstances) and effectiveness (i.e. testing a treatment delivered under "real world" circumstances) investigations have established that MST can decrease rates of antisocial behavior and other serious clinical problems, improve family and school functioning, and reduce out-of-home placements (e.g. incarceration, residential treatment, hospitalization). As mentioned previously, the majority of these investigations have been conducted by the treatment developers (Drs Henggeler and Borduin and their colleagues), although a portion has been independent replications (i.e. conducted by investigators other than the treatment developers). Given the competitiveness of research funding and the complexity of implementing clinical trials, independent replications of adolescent treatments are atypical, especially for complex family-based treatments. The length of follow-up in MST research also is remarkable and nearly unparalleled, including an almost 14-year investigation.

Specific clinical trials of MST have focused on violent and chronic offenders, inner-city juvenile offenders, juvenile sexual offenders, and substance abusing/dependent juvenile offenders. Further, single trials have evaluated the use of MST for serious emotional and behavioral disturbances, psychiatric emergencies, and chronic health conditions. A recent review by Henggeler and Sheidow includes an overview of all extant MST research (in addition to investigations on Functional Family Therapy, Multidimensional Treatment

Foster Care, and Brief Strategic Family Therapy). As summarized in this review, findings across studies of offending youth routinely favor MST compared to control conditions. Positive outcomes in MST clinical trials include immediate and meaningful reductions in rates of rearrest (e.g. 24 and 72% reduction in recidivism) and conduct problems, as well as sustained decreases (e.g. 54% reduction in recidivism at 13.7-year follow-up). Effect sizes have been substantial (e.g. 0.50 for criminal behavior based on official records, 1.01 for arrest seriousness). Given the paucity of positive findings for juvenile justice interventions and the high cost of delinquency and common juvenile justice interventions (e.g. detention), these rates are particularly notable.

MST for Substance-Using Delinquents

Given the well-researched link between juvenile delinquency and adolescent substance use, Henggeler and colleagues first examined the substance-related outcomes for the violent and chronic juvenile offenders who participated in two of the early randomized clinical trials (RCTs) of MST. These substance-related outcomes were favorable for MST compared to controls. Notably, the follow-up investigation of arrest records nearly 14 years posttreatment demonstrated that MST participants continued to have fewer drug-related arrests than did their control counterparts.

The initial promising findings prompted focused research on MST for juvenile offenders who had substance abuse problems. A study of juvenile offenders meeting criteria for abuse or dependence randomized youth to MST or usual community services. This was a noticeably disordered sample, which sometimes is not the case in clinical research of adolescents. In addition to expected MST outcomes (e.g. 50% decrease in out-of-home placement compared to control), posttreatment findings favored MST for targeting substance use in a delinquent drug-involved sample (i.e. lower self-reported alcohol and marijuana use compared to control). In addition to the primary clinical outcome, MST was more successful than control at effectively engaging the substance abusing and substance dependent youths (and their families) in treatment (i.e. 100% of families in MST retained through 2 months of treatment with only one dropout pre-completion). This is particularly noteworthy, as low client retention rates traditionally plague substance abuse treatments. MST is also one of few treatments to have established cost savings, with a cost evaluation for this RCT showing that the incremental cost of MST was fully offset by reduced detention and treatment placement costs. Sustained treatment effects for marijuana use and violent crime were found at 4-year follow-up. Specific to substance use, urine drug screens collected from the youth showed appreciably higher rates of marijuana

abstinence for MST participants (55%) versus usual services participants (28%).

Following a surge in the number of US drug courts and the surprising absence of research investigating the effectiveness of such courts and their treatment services, a second randomized MST efficacy trial with substance-abusing juvenile offenders was conducted. Unlike a standard RCT that would compare MST to a control treatment, this study proposed to determine the effectiveness of (1) juvenile drug court, (2) integrating an evidence-based substance abuse treatment (MST) into juvenile drug court, and (3) adding a contingency management (CM) protocol into MST to further enhance substance-use outcomes (CM techniques and research are described elsewhere in *Comprehensive Addictive Behaviors and Disorders*). The trial demonstrated that juvenile drug court was generally more effective than standard family court services in decreasing substance use and criminal behavior. There was also support for using evidence-based interventions (i.e. MST or MST enhanced with CM) within drug court to improve substance-related outcomes for adolescents. Data from urine drug screens indicated that drug court with either MST or MST enhanced with CM reduced substance use compared to drug court with typical community treatment. Notably, however, the juvenile drug court had a significant impact on both criminal and placement outcomes compared to standard family court services, but MST did not further enhance these effects. Long-term follow-up from this study is forthcoming and will extend knowledge on juvenile drug courts and the treatments provided in those courts.

Independent research replication of MST for substance abusing/dependent delinquents has yet to be completed, although two additional RCTs of MST have contributed to the empirical bases of MST for substance use outcomes within regular delinquent samples. Timmons-Mitchell and colleagues' independent replication of MST for juvenile offenders found decreased substance use problems for the 6 months post-baseline within the group receiving MST. Further, Letourneau, Henggeler, Borduin, and colleagues' randomized effectiveness trial evaluating MST to treat juvenile sexual offenders found that the number of youth using substances decreased in the MST condition (by nearly 50%) while it increased in the treatment-as-usual condition (by 65%) at 12-month follow-up. Thus, the use of MST for treating substance use in a wide array of juvenile offenders is supported through numerous research investigations, including efficacy, effectiveness, and independent investigations. Not all of these trials focus specifically on substance use, and trials are limited to offender populations. Thus, one must look carefully within trials to identify the array of findings specific to substance use and must recognize that generalization is limited to the juvenile

justice population. The empirical support for MST overall, which includes decades of efficacy and effectiveness randomized trials, and specifically the empirical support for MST in the treatment of substance use problems, makes the approach a preferred model for treating substance use in adolescent offenders.

DISSEMINATION OF MST

In general, large-scale transport of family-based treatments is difficult. That is, the extensive training required to prepare therapists (i.e. few graduate programs include adequate training in family therapy) combined with the practical demands for funding (i.e. group-based treatments are often more lucrative) diminish the likelihood of family-based treatments being promoted by community-based agencies. Additional concerns specific to MST and many other family-based treatments for adolescents include the need for a team of therapists to be funded (i.e. as opposed to a single therapist), initial investment in training therapists and high rates of turnover, and comparatively protracted time until effects emerge (e.g. in comparison to residential or boot camp types of treatments). Even the proven financial advantages cannot always compete with the initial "sticker shock" over the required investment of starting an MST program. Regardless, the research findings and cost comparisons are powerful tools for convincing funders and stakeholders of the need for MST as compared to nonevidence-based, and potentially detrimental, treatments.

An important finding during the research studies was that the therapist adherence to MST treatment principles was related to more favorable youth outcomes; thus, dissemination of MST has had a strong emphasis on treatment fidelity. As demand grew for MST programs, the developers were unable to provide adequate training and support of fidelity for new MST programs across the country. In the mid-1990s, a purveyor organization (MST Services, see mstservices.com) was developed by Mr Strother and Drs Henggeler, Schoenwald, and Rowland to meet the growing demand. This organization, licensed by the Medical University of South Carolina to transport MST technology and intellectual property, provides the program start-up preparation and ongoing training and quality assurance that the developers would be unable to provide on such a large scale. In addition, MST Services trains network partners to be purveyor organizations for program development and ongoing quality assurance. Purveyor organizations provide manuals (treatment, supervisor, expert consultant, and program manuals), training (initial 5-day orientation, quarterly booster training, weekly case consultation, and supervisor and consultant training),

organizational support (program operations manual, program development, program and agency leadership support), and implementation measurement and reporting (measures of therapist, supervisor, and consultant adherence, web-based system to track site performance and youth outcomes). Together, MST Services and their network partners provide support for the more than 480 MST programs in 30+ states and 12 countries.

CONCLUSION

Adolescent substance use represents a major public health problem. In particular, delinquent youth are at particularly high risk for substance abuse problems, and use is often associated with a range of negative outcomes (e.g. more severe delinquent behavior, continued offending into emerging adulthood, poor educational and occupational outcomes, elevated risk for HIV and other sexually transmitted infections) compared to nondelinquent youth. Thus, having effective treatments for juvenile offenders who abuse substances is of exceptional importance. MST is one such treatment that has been tested through a rigorous program of research and is widely disseminated in community-based practice across the United States and other countries. Existing texts provide details of MST as it applies to delinquent behaviors, but the present text provides an overview and examples of MST as it applies specifically to adolescent substance use.

Treating adolescent substance abuse is challenging. The clinical profile of referred adolescents is complex. It can include the secretive and illegal aspects of drug use; involvement in criminal activities with antisocial or drug-using peers; despairing, stressed and poorly functioning families; involvement in multiple social agencies and services that may but typically do not meet the youth's and family's needs; disengagement from school and other prosocial contexts of development; and lack of intrinsic motivation to change. Many

contemporary developments in the drug abuse and delinquency specialties offer guidance for clinicians and hope for parents, adolescents, and families. The volume and, more critically, the quality of basic and treatment research in the adolescent treatment area have increased. At least until the recent economic downturn, an increased funding for specialized youth services could be noticed. And an expanded interest in the problems of youth from developmental psychopathology researchers, applied prevention and treatment scientists,

policy makers, clinicians and prevention programmers, professional and scientific societies, mass media and the arts, and critically, from the public at large, can be documented without difficulty. Greater consensus exists today than ever before about preferred conceptualizations and intervention strategies for youth problems in general, and adolescent substance abuse and delinquency in particular. Leading figures in the field now conclude that drug abuse results from both intraindividual and environmental factors. And, as the reasoning goes, unidimensional models of drug abuse are inadequate; making the support and continued development of more complex, multicomponent, and integrated research and intervention approaches are all the more important.

This contribution summarizes multidimensional family therapy (MDFT), an empirically supported family-focused therapy specializing in the treatment of youth drug abuse and delinquency. A *developmental perspective* and the basic science knowledge base about adolescent and family development inform and organize all aspects of the treatment. The knowledge base teaches therapists about the course of individual adaptation and dysfunction through the lens and tasks of normative development. Youth and family developmental milestones are benchmarks that guide assessment and interventions in terms of their framing and form. The developmental psychopathology knowledge base moves beyond consideration of symptoms only to understand a youth's and family's ability to cope with the developmental tasks at hand. It specifies the implications of stressful experiences and developmental failures in one developmental period for adaptation or problems in future periods. Because multiple pathways of adjustment and problem development may unfold from any given life cycle point, emphasis is placed equally on understanding competence and resilience in the face of risk. Adolescent substance abuse is conceptualized as a problem of development – a complex, multifaceted deviation from the normal developmental pathway. Substance abuse involves difficulties in facing developmental challenges and it is a set of behaviors that compromises capacities to achieve future developmental milestones.

The *risk and protective factor* knowledge base teaches clinicians about the empirically derived determinants of problem formation. Perhaps more critically given the clinician's responsibility, specific knowledge of risk and protection in the multiple realms that have been filled in by longitudinal studies empowers clinicians with knowledge of the diverse *promotive* processes that might be located and facilitated to fight against risk and negatively cascading developmental slides. It identifies factors from diverse domains of functioning (psychological, social, biological, and neighborhood/community) relevant to positive adaptation and threats

to development. Thinking in terms of risk and protection also helps therapists to identify key interactional or process terms about the intersecting and mutually influencing dimensions of the adolescent's and family's current life circumstances.

Another framework and body of knowledge, the *ecological or contextual perspective*, specify the interconnected web of influences forming the context of human development. Regarding the family as a principal developmental arena, ecological and contextual notions take a keen interest in how both intrapersonal and intrafamilial processes are affected by and affect extrafamilial systems (i.e. significant others involved with the youth and family, such as school, job, or juvenile justice personnel), and of course how these external to the family processes and events affect family development, parenting, and parent-adolescent relationships. Ecological and contextual ideas coincide with contemporary theorizing and empirical work about reciprocal effects (i.e. dynamic systems theory) in human relationships, and it underscores how, like all behavior, problems are manifest at different levels, and in different ways with different individuals, and how circumstances in one domain can affect other domains. Taken together, the ideas and still accumulating research about development, context, ecology, and risk and protection have had an enormous, transformative influence on the conceptualization of youth and family problems, the program theory in both treatment and prevention that is thought to be needed to impact multiple embedded problems, and the corresponding interventions that aim to resolve individual and family dysfunction and burden.

TEN GUIDING PRINCIPLES

1. *Adolescent drug abuse is a multidimensional phenomenon.* Individual biological, social, cognitive, personality, interpersonal, familial, developmental, and social ecological aspects can all contribute to the development, continuation, worsening, and chronicity of drug problems.
2. *Family functioning is instrumental in creating new, developmentally adaptive lifestyle alternatives for adolescents.* The youth's relationships with parents, siblings, and other family members are fundamental areas of assessment and change. The adolescent's day-to-day family environment offers numerous, indeed essential opportunities to re-track developmental functioning.
3. *Problem situations provide information and opportunity.* Symptoms and problem situations provide assessment information as well as essential intervention opportunities.

4. *Change is multifaceted, multidetermined, and stage-oriented.* Behavioral change emerges from interaction among systems and levels of systems, people, domains of functioning, and intrapersonal and interpersonal processes. A multivariate conception of change commits the clinician to a coordinated, sequential use of multiple change methods, and working multiple change pathways.
5. *Motivation is malleable but it is not assumed.* Motivation to enter treatment or to change will not always be present with adolescents or their parents. Treatment receptivity and motivation vary in individual family members and relevant extrafamilial others. Treatment reluctance is not pathologized. Motivating teens and family members about treatment participation and change is a fundamental therapeutic task.
6. *Multiple therapeutic alliances are required and they create a foundation for change.* Therapists create individual working relationships with the adolescent, individual parent(s) or caregiver(s), and individuals outside of the family who are or should be involved with the youth.
7. *Individualized interventions foster developmental competencies.* Interventions have generic or universal aspects. For instance, one always wants to create opportunities to build teen and parental competence during and between sessions, but all interventions must be personalized, tailored, or individualized to each person and situation. Interventions are customized according to the family's background, history, interactional style, culture, and experiences. Structure and flexibility are two sides of the same therapeutic coin.
8. *Treatment occurs in stages: continuity is stressed.* Core operations (e.g. adolescent or parent treatment engagement and theme formation), parts of a session, whole sessions, stages of therapy, and therapy overall, are conceived and organized in stages. Continuity – linking pieces of therapeutic work together – is critical. A session's components and the parts of treatment overall are woven together – continuity across sessions creates change enabling circumstances.
9. *Therapist responsibility is emphasized.* Therapists (1) promote participation and enhance motivation of all relevant persons, (2) create a workable agenda and clinical focus, (3) provide thematic focus and consistency throughout treatment, (4) prompt behavior change, (5) evaluate, with the family and extrafamilial others, the ongoing success of interventions, and (6) per this feedback, collaboratively, revise interventions as needed.
10. *Therapist attitude is fundamental to success.* They are neither "child savers" nor unidimensional "tough

love" proponents; they advocate for adolescents and parents. Therapists are optimistic but not naïve or Pollyannaish about change. Their sensitivity to contextual or societal influences stimulates intervention possibilities rather than reasons for how problems began or excuses for why change is not occurring. As instruments of change, a clinician's personal functioning enhances or handicaps one's work.

CHARACTERISTICS OF THE TREATMENT PROGRAM

Multidimensional Assessment

Assessment yields a dynamic and evolving therapeutic blueprint – an indication about where and how to intervene across multiple domains and settings of the teen's life. A comprehensive, multidimensional assessment process identifies risk and protective factors in relevant areas, and prioritizes and targets specific areas for change. Information about functioning in each target area comes from referral source information and dynamics, individual and family interviews, observations of spontaneous and instigated family interactions, and interchanges with influential others outside of the family. There are four overall targets: (1) adolescent, (2) parent, (3) family interaction, and (4) community social systems. Attending to deficits and hidden areas of strength, we obtain a clinical "moving" picture (transactional perspective) of the unique combination of weaknesses and assets in the adolescent, family, and social system. This contextualized portrait includes a multisystem formulation of how the current situation and behaviors are understandable, given the youth's and family's developmental history and current risk and resilience profile. Interventions decrease risk processes known to be related to dysfunction development or progression (e.g. disengaged or conflict heavy family relationships, parenting problems, strong and patterned affiliation with drug-using peers, disengagement from and poor outcomes in school), and enhance protection and develop problem solving, first within what the therapist finds to be the most accessible and malleable areas. An ongoing process rather than a single event, assessment continues throughout treatment as new information emerges and experience accumulates. Assessments and therapeutic planning overall are revised according to feedback from our interventions.

A home-based or clinic-based family session generally launches treatment. But before this meeting, clinicians try to have brief telephone conversations with a parent, and sometimes the youth. These talks can be important

to relationship formation, ascertaining roadblocks to participation, and current crises. They begin the process of defining the treatment program, making it personal, and targeted to getting help to what can be a distressing set of immediate circumstances, given what can come with youth drug use and delinquent behavior. Motivation enhancement and assessment of the various corners of the youth's and family's life begins here. Even in the first session, therapists stimulate family interaction on important topics, noting to themselves how individuals contribute to the adolescent's life and current circumstances. We also meet alone with the youth, the parent(s), and other family members within the first session or two. These meetings reveal the unique perspective of each family member, how events have transpired (e.g. legal and drug problems, neighborhood and negative peer influences, and school and family relationship difficulties), what family members have done to address the problems, what they believe needs to change with the youth and family, as well as their own concerns and problems, perhaps unrelated to the adolescent.

Therapists elicit the adolescent's telling of his or her life story during early individual sessions. Sharing one's life experiences facilitates engagement. It also provides a necessarily detailed picture of the nature and severity of the youth's circumstances and drug use, individual beliefs and attitude about drugs, trajectory of drug use over time, family history, peer relationships, school and legal problems, any other social context factors, and important life events. Adolescents sketch out literally and in conversation an eco-map, a representation of one's current life space. This includes the neighborhood, indicating where the youth hangs out or buys and uses drugs, where friends live, and school or work locales. Per protocols, therapists inquire about health and lifestyle issues, including sexual behavior. Comorbid mental health problems are assessed by reviewing records and reports, the clinical interview process, and psychiatric evaluations. Adolescent substance abuse screening devices, including urine drug screens (used extensively in therapy), are invaluable in obtaining a comprehensive picture of the teen's and family's circumstances.

Parent(s)' assessment includes their functioning both as parents and as adults, with individual, unique histories and concerns. We assess strengths and weaknesses in terms of parenting knowledge, skills and parenting style, parenting attitudes and beliefs, and emotional connection to one's child. Inquiring in detail about parenting practices is essential, and this includes asking about available support for the parent, child care, other adults who help out or might be available for relationship or parenting help. Clinicians promote parent-adolescent discussions, and in this process watch for relationship indicators such as supportiveness,

autonomy giving, problem solving, or the triggering of relationship conflict or emotional disengagement. Parents discuss their experiences of family life when they were growing up since these may be used to motivate or shape needed changes in current parenting style and beliefs, or the parent-adolescent relationship generally. Nothing is more vital to ascertain and facilitate than the parent's emotional connection to and investment in their child. Parent's mental health status and substance use are also appraised as potential challenges to improved parenting. On occasion we make referrals for a parent's adjunctive treatment of drug or alcohol abuse or serious mental health problems.

Information on extrafamilial influences is integrated with the adolescent's and family's reports to yield a comprehensive picture of individual and family functioning relative to external (to the family) systems, events, and circumstances. A new component of our approach provides on-site educational academic tutoring that meshes with core MDFT work. We assess school- and job-related issues thoroughly, and well-planned parent-youth meetings with school personnel are frequent. Therapists cultivate relationships and work closely with juvenile court personnel, including probation officers who help to sort out the youth's charges and legal requirements. Facing juvenile justice and legal issues can be a complex and emotional matter for the entire family. Clinicians help parents understand the potential harm of continued negative or deepening legal outcomes. Using a nonpunitive tone, we help teens face and take needed compliance actions regarding their legal situation. Friendship network assessment encourages adolescents to talk forthrightly and in detail about peers, school, and neighborhoods. Friends may be asked to be a part of sessions. Frequently, they are met and included during sessions in the family's home. A driving force in MDFT is the creation of concrete alternatives that use family, community, or other resources to provide prosocial, development-enhancing day-to-day activities that become acceptable substitutes for drug and illegal activity involvement.

Adolescent Focus

Clinicians build a firm therapeutic foundation by establishing a working alliance with the teenager, a relationship that is distinct from, but related to, a working relationship with the parent. We present the program as a team process, following through on this proposition by collaboratively establishing therapeutic goals that are practical and personally meaningful to the adolescent. Goals become apparent as teens express their experience and evaluation of their life so far. Treatment attends to these "big picture" dimensions. Problem solving,

creating practical and reachable alternatives to a drug-using and delinquent lifestyle – all of these remediation efforts exist within an approach that addresses an adolescent's conception of his or her own life, values, life's direction, and meaning. Success in one's alliance with the teenager is noticed by parents. Parents expect and appreciate how clinicians reach out to and form a distinct relationship and therapeutic focus with their child. Individual sessions are indispensable and their purpose is defined in "both/and" terms. These sessions access and focus on individual and parent-teen and other relationship issues through methods that might be construed as an individual therapy (versus multiple systems) approach. Individual parent and teen meetings also prepare (i.e. motivate, coach, and rehearse) for joint sessions.

Parent Focus

A vital therapeutic task is to reach the parent or caregiver(s) as an adult with individual issues and needs, as well as a parent who may have declining motivation or faith in her or his ability to influence their child. Objectives with parents in every case include enhancing feelings of parental love and emotional connection, underscoring parents' past efforts, acknowledging difficult past and present circumstances, including the particular difficulties that their child brings them, generating hope, changing the parent-adolescent relationship, and of course, improving parenting practices. When parents enter into, think about, discuss and experience these processes, their emotional and behavioral investment in their adolescent deepens. This process, the expansion of parents' commitment to their child's welfare, has internal cognitive, emotional, and behavioral aspects is fundamental to the change model. Achieving these therapeutic tasks is instrumental to and sets the stage for later changes. Taking this first step in a parent's change, these interventions grow parents' motivation and, gradually, parents' willingness and capacity to address caring, reaching out (again), understanding the youth's point of view, and overall improvements in the parent-youth relationship and parenting strategies. Increasing positive parental involvement with one's adolescent (e.g. showing an interest, initiating conversations, creating a new interpersonal environment in day-to-day transactions) creates a new context for attitudinal shifts, enhanced behavioral and emotional repertoire, and behavioral changes in parenting. Parental competence is fostered by teaching and behavioral coaching about normative characteristics of parent-adolescent relationships, consistent and age-appropriate limit setting, monitoring, improved communication, and listening to one's child, and overt emotional support – all

research-established parental behaviors that enhance relationships, individual, and family development.

Cooperation is achieved and motivation is grown by discussing the serious, often life-threatening circumstances of the youth's life, and establishing an overt, discussable connection (i.e. a logic model) between that caregiver's involvement and creating, with the therapist's help, behavioral and relational alternatives for the adolescent. This follows the general procedure used with parents – promoting caring and connection through several means. First, through an intense focusing and detailing of the youth's difficult and sometimes dire circumstances, making sure that these realities are faced, discussed, and experienced deeply by the parent (although there is description of the youth's circumstances, the presumed mechanism of action here is experiential and not didactic or psycho-educational). This process, which is facilitated mostly in individual meetings with the parent and clinician seems to be ultimately a motivation for the parent. It is as if the parent concludes that they will not let their child continue to deteriorate, continue to get in trouble, or stay off track developmentally. Furthermore, parents moving through this process conclude that they can and should have a role in their child's change, and they begin, again with the partnership with the clinician, to craft a role and particular remedies that they can offer to help alter their child's current circumstance. The parent's re-engagement with their youth is seen not only as instrumental to the therapeutic process, but also something that evolves and emanates very much from the parent themselves, seemingly as a result of what some parents have called a soul searching about their child, their parenting, and most of all themselves.

Parent-Adolescent Interaction Focus

As discussed, some interventions begin with targeting and changing individual ideas, emotions, and behaviors (although these, eventually, have interactional aspects as well). But MDFT, as was the case with particular family therapy models over the years, also assess and change family transactions directly. Shaping changes in the interactions that are part of the parent-adolescent relationship are made in sessions through the structural family therapy technique of enactment. A clinical method and a set of ideas about how change occurs, enactment involves elicitation and frank discussion in family sessions of important topics or relationship themes. These discussions reveal relationship strengths and problems. Expanding their repertoire of experience, perceptions, and behavioral alternatives, therapists assist family members to express, expand, discuss, and solve problems in new ways. As

a behavioral activation strategy, this method also creates opportunities to search for behavioral alternatives as clinicians actively guide, coach, and shape increasingly positive and constructive family interactions. For discussions to involve problem solving and relationship healing, family members must be able to communicate without excessive blame, defensiveness, or recrimination. Therapists guide retreats from extreme stances since these actions undermine connection and problem solving, rekindle hurt feelings, and sap motivation and hope for change. Individual sessions review and process these important issues and prepare family members for family sessions where the topics can be discussed openly and expanded ways of relating attempted. The content focus of any given session is important. Skilled therapists focus in-session conversations on meaningful topics in a patient, sensitive way.

Focus on Social Systems External to the Family

Clinicians help the family and adolescent relate more effectively with extrafamilial systems. Families may be involved with multiple community agencies. Success or failure in negotiating these relationships affects short-term, and in some cases longer-term, outcomes. A give-and-take collaboration with school, legal, employment, mental health, and health systems influencing the youth's life is critical for engagement and durable change. An overwhelmed parent appreciates a clinician who can understand and coach or help negotiate directly with complex bureaucracies or obtain adjunctive services. Achieving these practical outcomes lessens parental stress and burden, enhances engagement, and bolsters parental efficacy. Therapists team with parents to organize meetings with school administrators, teachers, or probation officers. Since successful compliance with the legal supervision requirements is an instrumental therapeutic focus, therapists prepare the family for and attend the youth's disposition hearings. School or job placement outcomes are additional instrumental aspects of achieving an overall positive case outcome – they represent real world settings where youths can develop competence and build escape routes from deviant peers and drugs. In some cases, medical or immigration matters, or financial problems may be urgent areas of stress and need. We understand the interconnection and synergy of these life circumstances in improving family life, parenting, and a teen's reclaiming of his or her life from the perils of the street. Not all multisystem problems are solvable, nor are all or even most aspects of the youth's day-to-day social environment malleable. Nonetheless, in every case, our rule of thumb is to assess comprehensively, declare priorities, and as much as possible, work actively and directly to help the family achieve better day-to-day

outcomes relative to the most consequential and changeable areas in the four target domains, and in their interactions.

DECISION RULES ABOUT INDIVIDUAL, FAMILY, OR EXTRAFAMILIAL SESSIONS

MDFT clinical interventions work from “parts” (subsystems) to larger “wholes” (systems) and then from these larger units (families/family relationships) back down to smaller units (individuals). Session composition is not random or at the discretion of the family or extrafamilial others, although sometimes this is unavoidable. Session goals and stage of treatment drive decisions about session participants. Session goals may be multiple, existing in one or more categories. Typically there are session-specific goals suggesting who should be present for all or part of an interview. For instance, first sessions, from strategic (i.e. relationship formation, giving a message about family involvement) and information-gathering (i.e. family interaction is a key part of what therapists access, assess, and ultimately attempt to change) perspectives, include all family members for a significant part of the session.

MDFT works in four interdependent and mutually influencing subsystems with each case. The rationale for this multiperson focus is theory-based and practical. Some family-based interventions might address parenting practices by working alone with the parent for most or all of treatment. Others might only conduct whole family sessions throughout (i.e. family interaction as the single or most important pathway of youth change). MDFT is unique in how it works with the parents alone and with the teen alone as well, apart from the parent and family sessions, in addition to targeting family level change in vivo, and multisystems change efforts (i.e. multiple pathways of change). Individual sessions have communicational relationship-building and substantive value. They provide “point of view” information and reveal feeling states and historical events not always forthcoming in family sessions. We establish multiple therapeutic relationships rather than a single alliance as is the case in individual treatment. Success in those relationships connects to clinical success. A therapist's relationship with different people in the mosaic comprising the teen's and family's lives is the starting place for inviting and instigating change attempts. The strategic aspects of these actions are probably obvious by now. There is a leveraging, a shuttle diplomacy, that occurs in the individual sessions as they are worked to determine the most important focal content, and then grow motivation and

readiness to address other family members in joint sessions.

MANUALS AND OTHER SUPPORTING MATERIALS

A previous but standard version of the manual is available online and a new version of the complete MDFT manual containing all core sessions (the basics of which are outlined and described above, in the sections of the four domains of work), clinical and supervision protocols is forthcoming. MDFT has an online training program, which includes a curriculum, worksheets, and therapy video segments for clinical sites training in the approach. A multistep certification procedure includes site readiness preparation, clinical and supervision training procedures including supervisor/trainer preparation protocols, and adherence and quality assurance procedures. Independent MDFT training institutes have been established in the United States and Europe. Many clinical articles have been written over the years, and two MDFT DVDs are available.

Like the treatment, the training process is thought about in terms of stages and milestones to achieve in each stage. The methods of training and supervision are thought of in terms of what they are intended to achieve, and the goals of each stage have generic and idiosyncratic aspects. As with all therapies, there is content and knowledge at the outset that seems important. Certainly adolescent, parent, and family development are vital is content about how to think about the formation of problems that may be expressed primarily by individuals but can always be understood by pulling back the zoom lens and understanding surrounding rings of relationships and social settings. Training and supervision methods are multimodal; they involve case conceptualizations and presentations and discussion that focus on making sense of symptomatic behavior and, above all, generating options for action and intervention, live supervision where sessions are observed and help offers during the session via phone, and videotape review, where the pressure of a live supervision context disappears, and one can reflect and disentangle a session or particular segment. Like the four corners of the MDFT system, the supervisor uses different methods to offer clinicians the needed opportunities to stretch their clinical range and build repertoire, to think on their feet and improvise, and eventually, to become their own “supervisor” in sessions – capable of being both “in” and “meta” to an interview so as to allow redirection or persistence if that is what is needed given the feedback from the interview.

EVIDENCE ON THE EFFECTS OF TREATMENT

MDFT has been developed and tested since 1985. In 2012, the 12th MDFT controlled trial will be completed. This research program has presented evidence supporting the intervention’s effectiveness for adolescent substance abuse and delinquency. Four types of studies have been conducted – efficacy/effectiveness randomized controlled trials (RCTs), process studies, cost studies, and implementation/dissemination studies. The projects have been conducted at sites across the United States with diverse samples of adolescents (African American, Hispanic, and Caucasian youth between the ages of 11 and 18) of varying socioeconomic backgrounds. Internationally, a multinational MDFT controlled trial with over 440 clinically referred adolescents in Germany, France, Switzerland, Belgium, and the Netherlands is complete. Study participants across studies met diagnostic criteria for adolescent substance abuse disorder and included teens with serious drug abuse and delinquency. MDFT has demonstrated efficacy in comparison to several other state-of-the-art, active treatments, including a psychoeducational multifamily group intervention, peer group treatment, individual cognitive behavioral therapy (CBT), and residential treatment.

SUBSTANCE ABUSE

MDFT participants’ substance use is reduced significantly. Using an example from one study, MDFT youths reduced drug use between 41 and 66% from baseline to treatment completion. These outcomes remained consistent at 1 year follow-up. MDFT participants also have demonstrated abstinence from illicit drugs after treatment significantly more than youths in comparison treatments. For instance, in a recent study (at posttreatment and at 1 year follow-up) MDFT participants had 64% drug abstinence rates compared to 44% for CBT; in another study, MDFT achieved a 93% abstinence outcome compared to 67% for group treatment. MDFT has been effective as a community-based drug prevention program as well; and using a brief 12-session (over 3 months), in-clinic (community treatment setting) weekly protocol, MDFT has successfully treated clinically referred younger adolescents who recently initiated drug use.

SUBSTANCE ABUSE-RELATED PROBLEMS

Substance abuse-related problems (e.g. antisocial, delinquent, externalizing behaviors) were reduced

significantly in MDFT versus comparison interventions including manual-guided active treatments. Ninety-three percent of MDFT youth reported no substance related problems at 1 year follow-up.

SCHOOL FUNCTIONING

School functioning improves more dramatically in MDFT than comparison treatments. MDFT clients have been shown to return to school and receive passing grades at higher rates, and also show significantly greater increases in conduct grades than a comparison peer group treatment.

PSYCHIATRIC SYMPTOMS

Psychiatric symptoms show greater reductions during treatment in MDFT than comparison treatments (30–85% within-treatment reductions in behavior problems, including delinquent acts, and mental health problems such as anxiety and depression). Compared with individual CBT, MDFT had better drug abuse outcomes for teens with *co-occurring problems*, and decreased externalizing and internalizing symptoms, thus demonstrating superior and stable outcomes (1 year) with the more severely impaired adolescents.

DELINQUENT BEHAVIOR AND ASSOCIATION WITH DELINQUENT PEERS

MDFT-treated youths have shown decreased delinquent behavior and associations with delinquent peers, whereas peer group treatment comparisons reported increases in delinquency and affiliation with delinquent peers. These outcomes maintain at 1 year follow-up. Department of Juvenile Justice records indicate that compared to teens in usual services, MDFT participants were less likely to be arrested or placed on probation, and had fewer findings of wrongdoing during the study period. MDFT-treated youth have also required fewer out-of-home placements than comparison teens. Importantly, parents, teens, and collaborating professionals have found the approach acceptable and feasible to administer and participate in.

THEORY-RELATED CHANGE: FAMILY FUNCTIONING

MDFT youth report improvements in relationships with their parents. On behavioral ratings, family

functioning improves (e.g. reductions in family conflict, increases in family cohesion) to a greater extent in MDFT than family group therapy or peer group therapy (observational measures), and these gains are seen at 1 year follow-up. In another example, MDFT-treated youths report gains in individual, developmental functioning on self-esteem and social skill measures.

STUDIES ON THE THERAPEUTIC PROCESS AND CHANGE MECHANISMS

The MDFT studies have demonstrated how to improve family functioning by targeting in-session family interaction and how therapists build successful therapeutic alliances with teens and parents. Adolescents are more likely to complete treatment and decrease their drug taking when therapists have effective therapeutic relationships with their parents and with the teens as well. Strong therapeutic alliances with adolescents predict greater decreases in their drug use. Another process study found a linear adherence-outcome relation for drug use and externalizing symptoms. MDFT process studies found that parents' skills improve during therapy, and critically, these changes predict teen symptom reduction. Culturally responsive protocols have demonstrated increases in adolescent treatment participation. We are beginning to understand the relationship of particular kinds of interventions and key target outcomes. In one example, interventions focusing on actively shaping in-session family discussions and relationship issues change connected directly to differences in drug use, emotional and behavioral problems.

ECONOMIC ANALYSES

The average weekly costs of treatment are significantly less for MDFT (\$164) than standard treatment (\$365). An intensive version of MDFT has been designed as an alternative to residential treatment and provides superior clinical outcomes at significantly less cost (average weekly costs of \$384 versus \$1068).

IMPLEMENTATION RESEARCH

MDFT was integrated into a day treatment program for adolescent drug abusers. Key findings include following training, line staff therapists delivered MDFT with fidelity (e.g. broadened treatment focus post-training addressed more approach-specific content themes, focused more on adolescents' thoughts and feelings about themselves and community systems), and with model adherence at 1 year follow-up. Client

outcomes in the program improved after MDFT was introduced, and these outcomes maintained at follow-up. For instance, youths' association with delinquent peers decreased more rapidly after therapists received MDFT training and drug use was decreased by 25% before and 50% after an MDFT training and organizational intervention (and the probability of out-of-home placements for non MDFT youth was significantly greater before MDFT was used in the program).

CONCLUSIONS

The MDFT is an extensively studied therapy for youth substance abuse and delinquency. Several characteristics can be noted. The MDFT is a flexible treatment system. Different versions of the approach have been implemented in diverse community settings by agency clinicians, with both male and female adolescents from varied ethnic, minority, and racial groups. Study participants were clinically referred, drug-using teenagers, and generally showed psychiatric comorbidity, delinquency, and juvenile justice involvement. Assessments included standardized measures, theory-related dimensions, and measures of import to the everyday functioning of target youth and families (in addition to substance use outcomes, school outcomes, family relationships, for instance). The MDFT has been tested against active treatments, including individual CBT and high-quality peer group and multifamily approaches, as well as services as usual. It has been varied on dimensions such as treatment intensity and demonstrated favorable outcomes in its different forms. An intensive version of MDFT was found to be a clinically effective alternative to residential treatment. MDFT has been effective as a prevention program with at-risk, nonclinically referred youths, and as an effective, short-term intervention for clinically referred young adolescents. The research program has used rigorous designs in conducting efficacy/effectiveness trials, followed CONSORT guidelines, used intent to treat analyses, and participated in multisite RCTs. We developed psychometrically sound adherence measures, and trained therapists, supervisors, and trainers in drug abuse and criminal justice settings nationally and internationally. MDFT process studies have clarified some of the approach's mechanisms of action, and economic analyses indicate MDFT to be an affordable alternative compared to standard outpatient or inpatient treatments. MDFT has favorable outcomes in reducing delinquency, externalizing, and internalizing symptoms. In recent work, HIV and *sexually transmitted disease* (STD) risks have decreased as well. Process studies show change in key components of the outcome equation (affiliation with drug-using peers, family and school functioning, as examples). The RCTs track outcomes with 1 year

follow-ups, and outcomes retain at this assessment. A new study includes sustained positive outcomes at 4 years' post intake assessments. MDFT presents a well-defined clinical focus in how it establishes individual relationships with parent and youth, works with each alone in individual sessions, targets family interactional changes, and also works with individuals and parents vis-à-vis the teen's and family's social context.

List of Abbreviations

CBT cognitive behavioral therapy

MDFT multidimensional family therapy

Glossary

Context adolescent development and treatment necessarily includes the multiple psychosocial social contexts of teens and their families.

The context dimension reminds the clinician not to narrow his or her understanding to the individual or family level only. Interventions target many levels, aspects of functioning, and different individuals. Some of these pertain to adolescents' everyday functioning in social settings outside their families.

Multidimensional the dimensions of importance in MDFT include **research** (use of developmental theory and findings, different kinds of research in the MDFT research program), **multiple levels or domains of human functioning** (intrapersonal (cognitive, emotional, behavioral), and interpersonal (transactions and transactional patterns in family relationships and of individuals relative to extrafamilial individuals in relevant social systems and communities)), and **multiple determinants of problem behaviors and multiple determinants, pathways, processes and methods used to create change** (i.e. adolescent-focused sessions and interventions, and parent-focused sessions and interventions are important in and of themselves, and they also create opportunities to prepare for family sessions, and to process and review the family meetings).

Structural family therapy (Minuchin) the influences of SFT can be observed in MDFT's adoption of the enactment principles of change and intervention.

Strategic family therapy (Haley) emphasizes crafting a *strategy* for treatment, thinking in terms of *stages of therapy and of change*, and focusing on *out-of-session tasks* as a complement to in-session change enactments,

Treatment parameters refers to the organizational aspects of treatment. Sessions are held in clinical offices, home, school, juvenile court, or wherever the appropriate parties can be convened. Using the phone – to call the parent, adolescent, or other family members (e.g. to follow up after face-to-face contact, make more suggestions to follow the action plan set in the previous contact) – is common.

Substance use represents an intractable problem for many adolescents. According to national statistics, nearly 60% of US adolescents have tried alcohol and more than one-third have tried marijuana by age 15. Although most adolescents who use substances do so in moderation and on a time-limited basis, a subset of those adolescents who use substances will continue to do so into their adult years. In general, adolescents who are most at risk for these substance abuse trajectories are those who initiate drug use at young ages (usually before age 14 or 15), whose involvement is especially severe, and who have experienced traumatic events or come from families with maladaptive interactional patterns.

Adolescent drug use is multi-determined, with both intrapersonal (e.g. deviant attitudes and impulsivity) and social-contextual (e.g. family problems, association

with deviant friends, and neighborhood crime and disorganization) processes serving as contributing factors. However, the family is perhaps the strongest influence on adolescent behavior and development. A cohesive family, positive parenting and involvement, effective parental leadership, and other adaptive family characteristics can offset the effects of deviant friends, neighborhood crime, and underperforming schools on adolescent drug use. There is also evidence that the family context helps to influence adolescents' attitudes, beliefs, and sense of self. A series of literature reviews strongly suggest that the family is the most promising and powerful target for interventions aimed at preventing or treating adolescent drug use and abuse.

Severe adolescent drug use is often associated with maladaptive family relationships. For example, family conflict, lack of parental involvement, and poor

communication between and among family members predispose adolescents toward drug and alcohol abuse and related problems (such as delinquency, sexual risk taking, and dropping out of school). On the other hand, even when families are not maladaptive, when adolescents get into trouble (e.g. engage in more risky behavior compared to their peers), families can play a major role in bringing the adolescent back to a successful and adaptive developmental trajectory. As a result, family-based prevention and treatment interventions are among the most successful interventions for adolescent drug use/abuse. However, family intervention models differ in terms of how family relationships are conceptualized, in terms of the specific family processes that serve as targets for intervention activities, and in terms of the specificity with which family process interventions explicitly target adolescent drug use.

This chapter presents the Brief Strategic Family Therapy® (BSFT™) model, originally developed in the late 1970s. Empirically tested in a series of research studies, the BSFT model builds on the pioneering structural family systems work of Salvador Minuchin and the strategic approach of Jay Haley and Chloe Madanes. The *structural* dimension refers to the repetitive patterns of interactions among family members who are identified, and strengthened or transformed to better help the family achieve its goals; whereas the *strategic* dimension refers to interventions that are planned, problem focused, and intended to accomplish specific family goals such as reducing family conflict and adolescent drug use. Indeed, the integration of structural and strategic components is one of the innovations underlying BSFT.

BSFT PRINCIPLES

The BSFT model is guided by three primary principles. The first is that the family is a system, and thus family members are interdependent with one another. Therefore, what one family member says or does affects everyone else in the family. The second principle is that repetitive family patterns of interaction affect individual family members' development and behavior. As part of this principle, the BSFT model holds that improvements in family members' experience and behaviors require strengthening adaptive family interactions and transforming/restructuring maladaptive family interactions. The therapist brings the family together and may ask them to carry out an interactional task, such as discussing with each other what brings them to the therapist's office. As the family engages in its typical patterns of behavior, the therapist identifies those patterns that are adaptive and maladaptive. An example of the latter might be parent figures' inability to collaborate on parenting, which supports and maintains the

adolescent's drug use. The third basic principle that BSFT reflects is strategic quality – that therapy is planned, problem focused, and practical (i.e. intended to achieve specific objectives). Hence, adaptive repetitive patterns of interactions (e.g. nurturing behavior) will be strengthened, while maladaptive repetitive patterns of behavior (e.g. inability of parents to speak with a single voice and support each other around parental functions) will be transformed specifically because they impact the adolescent's problem behaviors. For BSFT to be effective, yet brief, family interactions unrelated to the family's presenting problems are usually not directly targeted.

THE BSFT INTERVENTION

The goal of the BSFT model is to correct only those family dynamics that are *directly* connected to the adolescent's drug use. Other family problems, such as marital discord, could be addressed but, for the sake of brevity, are generally not addressed in BSFT therapy except to the extent that they impact the adolescent's drug use.

The BSFT program is usually implemented in 12–16 sessions over 4 months. A core principle of the BSFT service delivery approach is that where therapy is provided, it should never interfere with the delivery of the service. Consequently, BSFT can be delivered in office, home, or any other setting that is convenient to the family. Often for disorganized families, getting the family to treatment is a challenge, which home-based treatment can overcome.

Specific therapist strategies are organized into four domains. Although some domains are more likely to occur earlier or later, in general all intervention domains are used throughout therapy. Earlier sessions are characterized by *joining* interventions designed to establish a therapeutic alliance with each family member and with the family as a whole. This requires that the therapist accept and respect each individual family member *and* the way in which the family unit is organized as a whole. The early phases of therapy are also more likely to include *tracking and diagnostic enactment* to systematically identify adaptive and maladaptive family interactional patterns, which can then be used to formulate a treatment plan. A core feature of tracking and diagnostic enactment is that the therapist encourages the family to behave in their usual manner (e.g. as though the therapist was not present). Family members are encouraged to talk *with each other* about the issues that brought them to therapy, rather than directing comments to the therapist. By observing the family's patterns of interaction – the ways in which family members behave with each other repeatedly – the therapist can then formulate an initial treatment plan to

transform family interactional patterns in specific ways that will reduce or eliminate the adolescent's drug use and related problem behaviors. As the family transforms or more candidly presents itself throughout treatment, the treatment plan is revised to keep abreast of the family's changes.

Over the course of treatment, therapists maintain an effective working relationship with family members through joining, facilitate within-family interactions through tracking, continuously assess evolving patterns of interactions through diagnostic enactment, and transform negative family interactions (while creating a motivational context for change) through reframing. However, during the later stages of treatment, the focus shifts to implementing *restructuring* strategies to transform family relations from problematic to effective and mutually supportive, and include (1) directing, redirecting, or blocking communication, (2) shifting family alliances, (3) promoting conflict resolution skills, (4) developing effective behavior management skills, and (5) fostering parenting and parental leadership skills. In illustrating the model, we will use the Lopez family, which consists of a mother, stepfather, and the mother's 15-year-old drug abusing son John. Other children in the family are married and live out of state or in the family's country of origin.

Diagnosis

In the BSFT model, therapists diagnose the family's repetitive patterns of interaction along six dimensions, each of which can be manifested in adaptive or maladaptive ways. These dimensions are organization, resonance, developmental stage, life context, identified patienthood, and conflict resolution. *Organization* refers to the hierarchies, alliances, and behavior control mechanisms within a family. For example, in a functional family with two parent figures, the parents must act with a united voice to reduce the likelihood of a youth "dividing and conquering" and becoming more powerful than his/her parents. In some families, however, one parent will form a cross-generational alliance with one or more of the children – such as Mrs Lopez and her son "bonding" against Mr Lopez. Such alliances are maladaptive because they place the teen in a position of power and responsibility for which he is not developmentally prepared – such as being burdened with Mrs Lopez's emotional needs. Moreover, it is difficult for Mrs Lopez to discipline John, with whom she is maladaptively allied. In such cases, Mrs Lopez is likely to undermine Mr Lopez's efforts to set limits for John. The parents' ability to work together as the leaders of the family is compromised. Indeed, an adolescent can occupy a position of power only if that power is *granted* – intentionally or otherwise – by one or both parents.

Resonance denotes the quality of the boundaries between family members, and between subsystems within the family (e.g. between the parents and the children). Ideally, these boundaries should be permeable enough such that family members can communicate effectively and can share emotional experiences with one another, but should be firm enough to prevent cross-generational alliances and to ensure that each family member is permitted to maintain her/his individuality as well as to play an age appropriate role within the family. Problems with resonance occur at the extremes of involvement, that is, with over- or under-involvement between family members. Mrs Lopez's very strong bond with John may have been appropriate when he was 2, but at age 15, his mother's over-involvement is preventing John from developing his own individuality. When family members are over-involved, individual family members' development is often stifled. Typically, youth in John's position will feel stifled and will rebel. Hence, in addition to being in a maladaptive alliance with his mother and against his stepfather and thereby being triangulated in their disagreements, John is likely to rebel. In turn, his rebellion will increase Mr Lopez's anger toward him – and toward Mrs Lopez for enabling John's drug problem.

At the other extreme are under-involved relationships, such as Mr Lopez's weak affective bond with both Mrs Lopez and John. Mrs Lopez's alliance with John has prevented Mr Lopez from establishing a meaningful relationship with his stepson. Where family members are under-involved from one another, it is difficult for those family members to be empathic to one another's experiences. Under-involved family members are like ships passing in the night. For example, John and Mr Lopez may sit next to each other without speaking to each other. In other cases, no parent figure may have adequate involvement with an adolescent, in that case the youth has little guidance or support. This is often the case when a single, drug-dependent parent finds drug seeking more urgent than caring for his/her child.

Perhaps more than any of the other dimensions, resonance must be considered within the family's cultural context. Many immigrant families, for example, come from regions of the world where familial closeness is especially valued. In more individualistic cultural contexts such as the United States, high levels of family closeness may be interpreted as over-involvement and may be experienced as suffocating and maladaptive, whereas in more collectivist and interdependent cultural contexts such as Latin America, Asia, and the Caribbean, high levels of closeness may not be viewed as problematic. The litmus test for whether a given degree of resonance is problematic is whether it is causing problems for the family or for a specific family member.

Developmental stage refers to the developmental appropriateness of family interactions. It is well known, for example, that parenting adolescents is a qualitatively different task than parenting young children. Adolescence is a time when young people begin to experiment with new behaviors, relationships, and identity choices – and adolescents require more autonomy than younger children do. When parents respond appropriately to the developmental needs of their children, the children are most likely to perform well in school, to associate with positive peers, to develop a positive sense of identity and purpose, and to have a more constructive relationship within the family. On the other hand, placing developmentally inappropriate expectations on a child – either by placing that child in a role intended for someone much older (e.g. the pressure on John to be his mother’s companion) or for someone much younger (e.g. not allowing some independence and privacy for a 16-year-old) – places the youth at risk for rebellion, drug abuse, and related problems. Developmental transitions represent moments of increased risk for families and their children. A family may be going through a divorce or immigrating to a new country, or the child may be moving into high school. Each of these developmental transitions creates challenges that require the family and its members to adjust to new conditions. Flexibility to change patterns of interactions is critical at times of transition, or else the family and the vulnerable adolescent are likely to develop symptoms.

Life context refers to the situations in which the family and its members find themselves. For example, parents may have to work long hours and may come home stressed and tired, or adolescents may attend a school or live in neighborhoods with high crime and drug use rates. Regardless of the specific life context in which a family operates, the context needs to be considered when conducting therapy with a family. If Dad works 12 h per day and comes home at 09.00 at night, one way to ensure that Dad remains a vital member of the family is to set aside time to spend with him on a day when he is free, including eating meals together. If an adolescent is exposed to a large number of delinquent peers, parents may need to make extra efforts to engage the youth with prosocial and goal-oriented friends. In contrast, Mr Lopez often comes home after 12-h shifts as a floor manager, and his wife and stepson do not show any interest in spending time with him. Moreover, John attends school in a high-crime area, but his parents rarely know where he is or what he is doing after school or on weekends.

Identified patienthood – otherwise known as scapegoating – refers to family members blaming a single family member for most or all of the family’s problems. For example, John is rebelling against Mr and Mrs Lopez, using drugs, and hanging out with the wrong

crowd – and both parents (especially Mr Lopez) have labeled him as “the problem.” Parents often bring their troubled adolescent to therapy and instruct the therapist to “fix him.” However, from a family-system’s perspective, symptoms displayed by individual family members result from maladaptive family interactions, and the interactional or life context challenges facing the family must be addressed for the adolescent’s behavior problems to improve.

For example, close examination of the Lopez family reveals that Mr Lopez feels isolated and Mrs Lopez feels overwhelmed and unappreciated. By attending to the each family member’s experience (e.g. “Mr Lopez, you seem to be saying that you don’t feel wanted”; “Mrs Lopez, I can see how overburdened you feel”; “John, you would like not to be yelled at all the time,”), the therapist can help the family redefine itself as facing multiple challenges, which reduces the emphasis on the adolescent as the only family problem, thereby creating a broader motivational context for change.

Conflict resolution – Families adopt a number of ways of addressing conflicts, some of which are effective and others that are ineffective in solving conflicts. Conflicts represent differences of opinion that often lead to emotionally and negatively charged situations. The conflict resolution strategies include denial, avoidance, diffusion, conflict emergence without resolution, and conflict emergence with resolution. Families may *deny* a conflict, such as cases where one parent is an alcoholic and no one is willing to address the problem openly. *Avoidance* occurs when a conflict begins to emerge but the family covers it up, minimizes it, or otherwise stops it from emerging (e.g. “Honey, you can see that your father had a rough day. Let’s not bring that up now.”) *Diffusion*, a frequently used conflict management tool in families with problem behavior youth, refers to attempts to change the topic of conversation when someone raises a contentious issue. Often diffusion takes the form of a personal attack against the family member who voiced the original complaint. For example, when John told Mr Lopez, “It really upsets me when you call me stupid,” Mr Lopez changed the topic by attacking John: “You! You with your hoodlum friends – you need to grow up!” Mr Lopez changed the topic of discussion by taking the focus off of himself and placing it onto John. *Conflict emergence without resolution* refers to situations where the problem is brought up and discussed, but no resolution is reached. Take, for example, the following exchange between Mr Lopez and John:

Mr Lopez: “I don’t like your friends!”

John: “Well, that’s too bad because I like them!”

The conflict is clearly stated, but the family cannot move to resolution of the differences of opinion. In this

case, family members may need help in coming to a better understanding of each other's needs to reach mutually agreeable solution (e.g. "I won't bug you about your friends as long as you do well in school, but you need to know what it is that worries me about your friends"). When the family becomes able to discuss *and* solve their conflicts, they have achieved *conflict emergence with resolution*. None of these approaches to conflict management are adaptive if overused. Effective conflict management requires families to use flexibly the whole range of conflict management styles. For example, it is essential that the family prioritize conflicts and determines which conflicts require resolution in the short-term, which must be delayed (diffused or avoided) in the short-term, to allow the family to focus on a single difference of opinion until resolution can be reached.

BSFT: THE INTERVENTION

To produce behavior change, the BSFT model increases motivation for behavior change, reduces concerns about change, identifies troubled family interactions, and corrects them. Four sets of techniques, *joining, tracking and eliciting, reframing/creating a motivational context for change, and restructuring* that comprise the BSFT intervention are used flexibly throughout the treatment process. As Fig. 11.1 indicates, there is a general sequence to their use, yet the sequence is used many times throughout the intervention; and some early interventions such as joining must be used often throughout the treatment process.

Joining

The strategic nature of BSFT becomes clear when the therapist embarks on the process of joining with the family. Joining is the process by which the therapist moves from being an outsider to becoming a member of the therapeutic team that includes the therapist and the family. The fundamental principle underlying

joining is that the therapist must empathize with each family member's wants and needs and must offer a tangible way to help each family member to reach her or his stated goals. For example, the therapist joined with John by suggesting that his participation in therapy would reduce Mr Lopez's screaming and criticism; with Mr and Mrs Lopez by suggesting that therapy can reduce or eliminate John's drug use; and with Mrs Lopez by saying that therapy would be able to reduce the tension at home. Therapists must be careful not to challenge the goals stated by any family member too early, because the whole family's co-operation is needed for change to occur.

Joining includes not only accepting, respecting, and initially following the family's unwritten rules and established power structure, but also behaving in ways that blend with the family. If family members use specific slang words, the therapist may use these same words when interacting with the family. Social-psychological research has demonstrated that groups have specific ways of behaving – that these patterns differentiate insiders from outsiders – and families are no different from other types of groups in this regard. Family members are most likely to trust the therapist when he/she behaves in ways that are familiar to the family.

Tracking and diagnostic enactment interventions are designed to systematically identify family interactional strengths and weaknesses that can be used to formulate a treatment plan. A core tactic of tracking and diagnostic enactment is encouraging the family to behave as they do when the counselor is not present. That is, encouraging family members to speak with each other about the concerns that bring them to therapy, rather than directing comment to the therapist. From these observations, the therapist is able to diagnose both family strengths and problematic relations. For example, Mr Lopez grumbled to his wife that "you let John get the best of you," and John interjects "Well, *you* never listen to me – only Mom does." The therapist is able to glean that Mr Lopez is irritated by Mrs Lopez's enabling of John's drug abuse, while John attempts to undermine any attempt by Mr Lopez to convince his wife to impose consequences on his stepson. In this way, John re-asserts his over-involvement with Mom and keeps Dad from undermining the comfortable alliance that he has with his mother. The therapist tracks or follows the interactional process. The therapist may also highlight the process: "Dad, is it always like this – that it is difficult to have a conversation with your wife about John, because John always responds when you talk to your wife about him?"

Diagnosis is the process by which the therapist identifies the interactional patterns within the family that are most closely related to the adolescent's symptoms.

FIGURE 11.1 BSFT circular theory of change.

Coming up with a diagnosis involves asking the family to interact and observing the specific interactions that involve the adolescent (either directly or indirectly) and that are most problematic. Families may interact spontaneously as is the case in the example above, or they may need to be asked to interact. One of the most straightforward ways to prompt an interaction is to redirect to the family communications that were initially directed toward the therapist. For example, when Mr Lopez told the therapist, “My wife is driving me crazy – she’s so wrapped up with that kid and is always making excuses when he comes home high on drugs,” the therapist can ask Mr Lopez, “Would you please say that to your wife?”. When Mr Lopez tells Mrs Lopez, John is likely to respond, prompting a family interaction – an enactment of what might happen when the therapist is not present.

Reframing/Creating a Motivational Context for Change

Research shows that families are more likely to remain in treatment if their interactions are positive and constructive, particularly during the first therapy session. Negativity is one of the strongest predictors of early dropout from family therapy – but it is also one of the primary reasons why families seek help. One of the most effective ways to reduce negativity in an interaction is to reframe (change) the perspective through which the interaction is viewed, thereby creating a motivational context for change. Consider the following situation where Mr Lopez confronts John when he comes home high:

Mr Lopez (to John, angrily and harshly): If you come home high one more time, I am calling your probation officer.

Therapist (to Mr Lopez): I can see how much you worry that drugs can hurt John; that something could happen to John when he is out late at night with his friends.

Mr Lopez: I always think he is doing drugs and having sex with street girls. If he goes to jail or gets AIDS, it will destroy his mother.

Therapist (turns to John): Did you know that your parents worry about you?

John: I wish my stepdad would stop screaming at me. He’s telling you he cares about me, but he really doesn’t.

Therapist (to Mr Lopez): Dad, what do you think about what John just said?

Mr Lopez: I only yell at him because he frustrates me. I don’t know how else to get through to him. But I worry about him.

Therapist (turns to John): Your dad worries because he cares. Did you know that?

John: I’m not sure I believe it. He’s only here because of my mom.

Therapist (to Mr Lopez): Please tell John how much you care about him.

Mr Lopez: I do care about you, John. I am angry with you, but you’re the closest thing to a son I’ve ever had. I don’t want to see anything bad happen to you.

Through this interactional sequence, the therapist transforms a negative interaction to one where concern is expressed positively, thereby creating a different context that leads to greater openness and a motivational context for change. When properly carried out, reframing, i.e. changing the meaning of interactions, is the technique that can best reduce negative affect and set the stage for change without eroding the alliance between the therapist and any family member.

BSFT ENGAGEMENT

The same intervention techniques – joining, tracking and diagnostic enactment, and reframing – are utilized to engage families into treatment. Family therapists face the daunting challenge of engaging multiple family members into treatment. Our research demonstrates that, if a family is characterized by maladaptive interactional patterns that prevent it from achieving its goals of eliminating a youth’s drug use and related problem behaviors, typically the same maladaptive interactional patterns serve as an obstacle to bringing the whole family into treatment. BSFT-specialized engagement strategies capitalize on the same basic principles (i.e. identifying patterns of interaction) and techniques used in the therapy model itself. Often one essential family member, such as the drug abusing youth or an alienated father figure, may not want to come to treatment. With the approval of the caller, the therapist will contact this family member directly and join with him in an effort to convey that she or he has something to gain from coming into treatment. Essentially, the therapist tries to get “around” the problematic interactional patterns of behavior by inserting himself/herself into the engagement process. When a family member, usually a mother, calls and asks for help, the therapist uses this first call as an opportunity to begin to explore the family interactions. Specifically, the therapist will give the caller a task – “bring all the members of the family into the first session.” The organizational structure of the family will become apparent when the caller either responds that “my son won’t come to treatment,” or “my husband won’t come to treatment,” or “it is best if just my son and I come – it is not necessary to bring my husband.” In the first and second cases, the caller lacks the influence needed to bring that family member into

treatment. In the third case, the caller either prefers not to bring her spouse, or is at best ambivalent about bringing him. In each case, and with the caller's approval, the therapist will reach directly to the family member: (1) who does not want to come to treatment or (2) whom the caller is not eager to bring to treatment. These specialized engagement strategies have resulted in much higher rates of full-family treatment engagement and treatment completion compared to standard engagement strategies.

In our research on how BSFT therapists achieve treatment engagement and retention, we have found that: (1) negativity among family members is a strong predictor of dropout; (2) the most effective way to reduce negativity is through reframing; and (3) an imbalanced relationship between therapist–father alliance and therapist–adolescent alliance increases the likelihood that the adolescent will drop out of treatment. Hence, reducing negativity through reframing and maintaining a balanced father figure-therapist to teen-therapist alliance increases engagement and retention in treatment.

BSFT RESTRUCTURING TECHNIQUES

Once the therapist has been accepted as a temporary member of the family, and maladaptive family patterns of interactions associated with the adolescent's problem behaviors have been identified, a treatment plan can be formulated (i.e. which patterns of interactions need changing). Once this plan is in place, the therapist is ready to restructure or change the targeted maladaptive family interactional patterns. Like all the BSFT interventions, restructuring interventions *work in the present*. Often family members may hold deep resentments toward one another and spend years fighting about old wounds. If family members begin to tell stories about the past, the therapist will ask them to direct their statements toward the family members involved in the story (e.g. "Tell, Dad how you feel"; "Dad, I hate that you are always working and never have time for me"). This direct communication between son and father becomes an enactment in the present. Such direct communication in the present provides an opportunity for the therapist to create a motivational context for change (Dad, I hear your son say that he cares about you and wants to spend more time with you. Is that what you hear also?), creating an opportunity for Dad to respond to the son's positive message "that I want to spend more time with you," rather than to the anger that he more typically experiences.

Reframing is perhaps the most commonly used restructuring technique in the BSFT. We have already

described reframing as a technique that creates a motivational context for change. As the therapist recasts a negative interaction or feeling in a more positive or tender way – so that the negativity is reduced – reframing is used as a springboard for encouraging family members to behave differently with each other. Anger can be recast as hurt or concern – for example, when Mrs Lopez yelled at John and called him a "disgrace to our family" because he had been arrested several times for drug possession, the therapist might say to Mrs Lopez, "I can see how upset you are. You had such dreams for your son and now... Now you are afraid that those dreams are impossible. The idea that your son may not be able to achieve your dreams for him... is breaking your heart." In turn, as the mother's emotions turn from anger to sadness and grief, John's defiance may soften. Once more tender emotions are expressed, the therapist can use them to build positive family interactions. For example, the therapist may ask John to ask his mother what makes her so sad. Because having a conversation about sadness, regret, and hurt is more productive than trading accusations, the interactional pattern of accusations and conflict diffusion is transformed into a conversation about "what binds us together." In turn, this shift in emphasis may help to elicit new ways of interacting between mother and son.

Shifting boundaries and alliances is another restructuring technique. For example, because John and his mother were allied against his stepfather, John was often triangulated into conflicts between his parents – that is, he became the punching bag in the fight. In therapy, the therapist began to redirect communication so that it occurred directly between Mr and Mrs Lopez, thereby "de-triangulating" John. One way to restructure this kind of maladaptive pattern of interactions is for the therapist to sit the parents facing each other and for the therapist and John sit to a side, next to each other. The therapist will then have the parents talk about a parenting issue. When John responds to Mr Lopez's accusations that Mrs Lopez has been protecting John, the therapist will warmly put his hand on John's shoulder and say "not now, let them talk"; and will turn to the parents and ask them to go on with their conversation. The therapist must do more than remove John from the triangle; he must also facilitate a more constructive discussion between the parents. For example, "Mr Lopez, it looks like you worry a great deal about John. Tell your wife what worries you!" which will typically lead to some agreement about what worries the parents about John. In this way, the therapist provides the parents with the opportunity to practice communicating directly with one another even when the adolescent is attempting to triangulate himself

into their interaction. Later in therapy, the therapist will ask the parents to practice keeping John out of their conversation.

Depending on the specific form that the triangulation takes, other strategies may be implemented as well. In triangles, in which there is usually a parent–teen alliance, with the other parent under-involved. The marginalized parent may be asked to carry out a task (e.g. spend leisure time with the adolescent – such as enjoying hobbies together) as a way of increasing the marginalized parent’s involvement with the teen. The goal of this task is to balance each parent figure’s alliance with the youth.

Tasks are an essential component of the BSFT. The first task given to a family is to “come to treatment as a complete family.” All other tasks are first assigned in-session to allow the therapist to help the family to carry out the task before assigning it outside the session. For example, an adolescent and an under-involved father may be given an in-session task to discuss an activity that the adolescent enjoys. The adolescent and father will be instructed to spend leisure time together (e.g. go bowling together) only *after* their in-session conversation has gone well. Other common tasks include asking parent figures to discuss rules and consequences, for the adolescent to practice explaining to the parent what makes friends so important (e.g. they validate me) or what makes school so aversive (e.g. I get picked on; I never do well in school; teachers don’t like me).

BSFT AND CULTURE

The BSFT model was originally developed in Miami, and the initial series of empirical evaluations were conducted using primarily Hispanic families with conduct problem, delinquent, or drug abusing adolescents. However, the BSFT intervention principles and interventions are culture-independent. For example, concepts such as systems, structure (interactional patterns), and problem focus can be used across cultures. However, the specific application of a concept may vary considerably by culture. Joining may vary according to the family’s cultural context, with some highly patriarchal cultures requiring much stronger father–therapist alliances than mother–therapist or son–therapist alliances. Developmental appropriateness may also differ across cultures, with some cultures allowing older adolescents and young adults considerable independence – such as an expectation that children move out of the house when they finish college, whereas other cultures require adolescents and young adults to obey their parents and live at home until they marry.

As noted, the “normative” distance between family members, or the strength of family bonds, vary across

cultures. In many traditional cultures, family members are typically closer and have stronger bonds with each other, as compared to the increased autonomy that characterizes more individualistic Western cultures. Families’ cultural backgrounds must be respected, and therapists must possess sufficient knowledge of the culture to be able to ascertain how far they can move the family away from cultural customs to change family interactions. Indeed, the BSFT approach has been implemented with Hispanic Americans, with White Americans, with African Americans, with some Asian immigrant groups, and in a number of European countries. Cultural *content* can be used to make the BSFT strategies relevant for a given cultural group – such as discussing the roles that mothers and fathers typically play in a specific cultural context – but the strategies themselves are applicable across cultural groups. One notable exception is when the culture is extremely hierarchical and teens are supposed to obey parents, but are not supposed to verbally respond to them (i.e. “seen but not heard”). Because the BSFT model encourages conversations between parents and their children, in families who have migrated to the United States from extremely hierarchical cultures, we have found it useful to include a brief psycho-educational component that teaches parents and children the differences between the parents’ culture of origin and the American culture to which the child may be acculturating. Such an understanding may create the motivational context for parents to be willing to discuss with their children the habits, mores, and challenges they confront in the new culture, recognizing that such challenges are outside of their culture of origin.

The BSFT model is well suited for families immersed in cultural change and where intergenerational and/or cultural conflicts occur between parents and adolescents. In many immigrant families, children, and adolescents adapt quickly to the new cultural context, whereas parents often do not. Perhaps more problematically, some children and adolescents in immigrant families relinquish their cultural heritage, which many parents find disrespectful – and among adolescents from immigrant families, research shows that those who relinquish their cultural heritage are at risk for drug abuse. For example, some Hispanic adolescents in the United States do not wish to speak Spanish, listen to American rap and hip-hop music, and prefer to spend time with their peers than with their parents. In these situations, intergenerational conflicts are compounded with cultural conflicts, and resolving the usual parent–teen intergenerational conflicts also involves addressing cultural conflicts within the family. Parents may feel hurt and disrespected because their adolescents have abandoned the family’s heritage, and adolescents may feel that their parents are old-fashioned and are nagging or

overburdening them. Fortunately, the BSFT approach is well suited to address this classic conflict between the traditional ways of parents and the modern and individualistic ways of adolescents.

BSFT RESEARCH: THERAPY PROCESS STUDIES AND OUTCOME EVALUATIONS

The BSFT model has been evaluated in a number of randomized clinical trials. The first generation of evaluations focused on: (1) the efficacy of BSFT treatment in reducing behavior problems and substance use, and (2) the efficacy of BSFT Engagement in bringing families into treatment. These studies demonstrated the usefulness of the BSFT model and led the US Department of Health and Human Services to label the BSFT approach as one of its “model programs” and to be included in the National Registry of Evidence-based Programs and Practices (NREPP). More recent evaluations of the BSFT approach have taken the form of effectiveness trials, where community providers are trained to implement the model in “real-world” settings. These more recent evaluations have also been conducted at multiple sites across the United States.

BSFT Efficacy

The efficacy of the BSFT model in reducing behavior problems and drug abuse has been tested in two randomized clinical trials. The first trial focused on younger children with behavior problems that can lead to drug abuse in adolescence. José Szapocznik and colleagues randomized maladjusted 6–11-year-old Cuban boys to BSFT, individual psychodynamic child therapy, or a recreational placebo control condition. Both treatment conditions were implemented by highly experienced therapists – and both were found to be equally efficacious, and more efficacious than recreational control, in reducing children’s behavioral and emotional problems and in maintaining these reductions at 1-year post-termination. However, at 1-year follow-up, the BSFT condition was associated with a significant improvement in observer-rated family functioning, whereas individual psychodynamic child therapy was associated with a significant deterioration in observer-rated family functioning.

In a second study, Daniel Santisteban and colleagues randomly assigned Hispanic (half Cuban and half from other Hispanic countries) behavior problem and marijuana using adolescents to receive either BSFT or group counseling. The BSFT condition was significantly more efficacious than group counseling in reducing conduct problems, associations with antisocial peers, and

marijuana use, and in improving observer-rated family functioning. In contrast, group counseling was associated with increases in adolescent marijuana use.

BSFT Engagement

The efficacy of BSFT Engagement was tested in three separate studies with Hispanic adolescents with behavior and drug problems and their families. In the first study, Hispanic (mostly Cuban) families with drug abusing adolescents were randomly assigned to BSFT + Engagement as Usual (i.e. the control condition) and BSFT + BSFT Engagement (i.e. the experimental condition). The Engagement as Usual condition was modeled after community-based adolescent outpatient programs’ approaches to engagement in the Miami area.

The efficacy of BSFT Engagement was measured using two criteria, first engaging client-families to attend the intake session and, second, retaining the client-families to the completion of treatment. Retention in treatment was measured because it is the ultimate goal of engagement interventions and reflects whether or not the family received an adequate dose of therapy. The results of the study revealed that 93% of the families in the BSFT Engagement condition, compared with only 42% of the families in the Engagement as Usual condition, were engaged into treatment. Moreover, 75% of families in the BSFT Engagement condition completed treatment, compared with only 25% of families in the treatment as usual (TAU) condition.

In a second study by Daniel Santisteban and colleagues, we found that the efficacy of BSFT Engagement procedures was moderated by Hispanic nationality. Among the non-Cuban Hispanics (composed primarily of Nicaraguan, Colombian, and Puerto Rican families) assigned to the BSFT Engagement condition, the rate of engagement was high (93%) compared to the lower rate for Cubans assigned to this same condition (64%). There is evidence that, in Hispanic families, acculturation to American values and behaviors is associated with decreased familism. As a result, it is possible that the lower engagement rate found for Cubans was due to higher rates of Americanization in the Cuban families, in which the parents had been in the United States for many years and the adolescents were primarily US-born. It is possible that such families perceive less need for family involvement in adolescent drug abuse treatment. On the basis of this finding, specific reconnection strategies have been incorporated into the current version of BSFT Engagement.

A third study tested the ability of BSFT + BSFT Engagement to engage and retain adolescents and their families in comparison to a *community* control condition. An important aspect of this study was that the control condition was implemented by a community treatment

agency and, as such, was less subject to the influence of the investigators. The Hispanic adolescents and families in this study were primarily Cuban or Nicaraguan. Findings in this study showed that BSFT Engagement had an 81% engagement rate, significantly higher than the 61% rate in the community control condition. Likewise, among families who were successfully engaged, 71% of BSFT cases, compared to 42% in the community control condition, were retained to treatment completion.

BSFT EFFECTIVENESS

In real world implementation of evidence-based family therapy models, groups of therapists are assigned to administer only the evidence-based family therapy intervention (i.e. they have no other caseload). By practicing only BSFT and working with a team of therapists who all practice BSFT, fidelity to the model is fortified.

An effectiveness trial of the BSFT approach was conducted within the National Institute on Drug Abuse's Clinical Trials Network (CTN). Due to constraints imposed by the CTN's approach to clinical trials, both therapists and participants were randomized to condition within each site. This is in contrast to the way in which BSFT and other similar family-based interventions are implemented in real-world settings (i.e. by creating therapist teams dedicated to the conduct of BSFT). The CTN randomization approach represents a limitation of the study that likely affected our ability to obtain optimum results.

The study compared BSFT and treatment as usual (TAU) (which was allowed to vary to be specific to whatever treatment the agency typically provided for drug-using adolescents) by randomizing 480 adolescents and their families (213 Hispanic, 148 White, and 110 Black; 377 male, 103 female) referred to 8 community drug abuse treatment agencies around the United States. 72% of the adolescents had been referred for treatment by the juvenile justice system. Services in both conditions were delivered by therapists in community agencies.

Compared to BSFT families, families in TAU were 2.33 times (11.4% BSFT; 26.8% TAU) more likely to fail to engage (defined as not completing at least two sessions) and 1.41 times (40.0% BSFT; 56.6% TAU), more likely to fail to retain (defined as completing less than eight sessions) compared to families in BSFT. These differences were statistically significant and generalized across ethnicity. Whereas the usual expectation is that BSFT therapy should last approximately 4 months, the median length of treatment for those participants who were retained in treatment was 8 months in both conditions.

Drug use was operationalized as the number of self-reported drug using days within each 28-day period during the year prior to assessment. The median number of self-reported drug use days per month at the 12-month (final) follow-up was significantly higher in the TAU condition (3.5 days) than in the BSFT condition (2 days). The low number of drug using days may have been a result of the overwhelming majority of adolescents having been referred from residential treatment or from the juvenile justice system – where adolescents are subjected to continued surveillance.

There were significantly greater improvements in the BSFT condition, relative to TAU, in *parent-reported* family functioning (positive parenting, parental monitoring, effectiveness of parental discipline, parental willingness to discipline adolescents when necessary, family cohesion, and absence of family conflict). However, *adolescents* in both conditions reported significant improvements in family functioning, with no statistically significant differences by treatment condition. In addition, BSFT was effective in reducing alcohol use in *parents*, and this effect was mediated by parental reports of family functioning. In addition, BSFT had its strongest effect in reducing adolescent drug use among youth whose parents used drugs.

To measure the extent to which BSFT therapists adhered to the treatment protocol, adherence items were developed to index joining, tracking and eliciting enactments, reframing, and restructuring. These items were completed by trained independent raters who watched videos of therapy sessions and rated each therapist on these BSFT behaviors. Restructuring and Reframing (reducing negativity) were associated with *engagement* (defined as family attending a second treatment session). The impact of adherence on *Retention* (family attending at least eight sessions – a minimal dose of BSFT) was evaluated using adherence ratings for sessions 2–7. Higher levels of all four-therapist behaviors predicted significantly higher rates of retention. Additional findings indicated that joining was related to improvements in observer-reported *family functioning*, and that the effects of therapist behaviors on *adolescent drug use* varied across the course of treatment. Across time, as would be expected, joining tended to decrease and restructuring tended to increase. Smaller declines in joining and larger increases in restructuring predicted significantly less adolescent drug use at the 12-month follow-up; and therapists whose attempts to restructure maladaptive family interactions increased most during the course of treatment were also associated with “better” adolescent drug use outcomes. These results indicate that, within a sample of therapists from community agencies, therapists' clinical interventions follow a pattern that is consistent with the theory behind the BSFT model.

BSFT IMPLEMENTATION

Although treatment researchers know how to successfully treat drug abuse, they have not been successful in achieving widespread adoption of evidence-based treatments in the front lines of practice. The most important lesson in implementing the BSFT model is that three types of interventions are required. One is the evidence-based intervention, in our case Brief Strategic Family Therapy® (BSFT™), which we have described above. The two other interventions needed are not in realm of treatment, but rather in the realm of BSFT implementation. One of these interventions involves the training of therapists to fidelity in conducting the BSFT model. The other is a systemic intervention involving the treatment agency.

To conceptualize the need for an additional intervention focusing on the BSFT implementation, it is useful to refer back to our systems orientation: there is an inevitable relationship between changes in the behavior of the system and changes desired in a target unit. In the BSFT model, the system is the family and the target unit is the adolescent. However, in implementing an evidence-based intervention, the system is the agency that must change to support the adoption and sustainability of the BSFT model and the target unit is the team of therapists trained to implement the BSFT approach with fidelity. To promote adoption and sustainability, the agency must also target funders, judges, and legislators whose support is needed to facilitate the use of the BSFT in the community.

The BSFT implementation begins with a site readiness assessment. Site readiness refers to the process of engaging organizational leaders, agency staff, and community stakeholders in preparing them to adopt the BSFT program. The goal of the site readiness process is for agency staff at all levels, from therapists to agency leaders, to obtain a full understanding of the requirements (including changes in therapist behavior and organizational structure) that must be met to implement the BSFT program. Site readiness activities begin with joining strategies to ensure that the BSFT trainer is viewed as a member of the “agency team” working to produce better adolescent treatment results and continued funding for the program. Once this is achieved, it is possible to discuss therapist eligibility, select the BSFT team, and explain and discuss training and supervision issues. Because the vast majority of agencies implementing the BSFT program are adopting an evidence-based program for the first time, changes in their standard practices are required to successfully implement the BSFT model.

The next phase of BSFT implementation is the training phase, which includes 3-day workshops and 2 h of weekly group supervision of videotaped sessions for approximately 1 year. Workshops cover the research

evidence supporting the BSFT model, the philosophy of the model, and the theoretical principles such as understanding the family as a system; that patterns of interaction in a family are repetitive and predictable; and that lasting change can be created by carefully planning interventions targeting those patterns of interaction that are directly linked to the adolescent’s problem behavior. Ultimately, BSFT trainers must demonstrate to therapists that the BSFT approach will better help them to reach their own clinical goals. Each workshop is conducted at the agency site by a BSFT trainer and includes interactive lectures, taped demonstrations of family therapy sessions, live case consultations, and interactive class exercises. Weekly supervision helps therapists integrate the didactic information into their behaviors in therapy. A critical step toward an agency’s BSFT sustainability is the selection of the BSFT on-site supervisor. In weekly supervision during the first year, an especially competent BSFT therapist will emerge and will be nominated as a supervisor whose role is to lead weekly group supervision sessions. The BSFT on-site supervisor is selected and trained during the second year of BSFT implementation. The BSFT on-site supervisor is selected jointly by the BSFT Trainer and the agency leadership. The primary responsibility of the BSFT on-site supervisor is to ensure fidelity to the model – which is crucial given our research linking BSFT adherence to good clinical outcomes. The BSFT on-site supervisor is guided and supported through weekly supervision meetings with the BSFT trainer. During these weekly meetings, the BSFT trainer provides guidance and coaching on how to supervise and maintain fidelity to the BSFT model, offers techniques to implement when therapists “drift away” from the model, presents guidelines for successful case closures, and supports the BSFT on-site supervisor in monthly meetings with agency leaders.

The next step in the BSFT sustainability plan is officially licensing the agency’s BSFT unit. Agencies are granted a license to practice the BSFT model once staff have been trained and once the agency possesses the necessary resources to implement the model. In the second year of licensure and beyond, agencies are required to participate in an annual 2-day booster workshop and an annual 2-day advanced training visit. Booster workshops address areas in which the therapists may have drifted away from the model. Live consultation occurs wherever therapy is being delivered (usually at the clinic office or in clients’ homes).

A final aspect of sustainability is supporting agency leadership with funders and other stakeholders by presenting the model and the research evidence. As we stated above, joining with funders and stakeholders is essential because their support is needed to facilitate therapist training and good clinical outcomes for adolescents and families.

CONCLUSIONS

Nearly four decades of research has shaped the BSFT model as it is disseminated today. The model was originally developed to address conflicted parent-adolescent relationships in immigrant families and has evolved into a broadly applicable treatment approach. Indeed, the model has evolved in response to specific clinical needs – engagement interventions were added to bring reluctant family members into treatment; reframing became increasingly prominent as a way to reduce negativity and to increase engagement and retention; and in response to the frustration of being unable to sustain programs in community agencies, we established the BSFT Implementation program and a BSFT Institute to carry it out. Achieving the three core goals of implementation – adoption, fidelity, and sustainability – in community-based practices involves a great deal more than just the BSFT model. In fact, successful implementation involves three layers of intervention: (1) the BSFT model that the therapist uses to treat the family; (2) the BSFT training program used by the trainer to help therapists to achieve high fidelity to the program; and (3) an organizational intervention conducted by the BSFT consultant that ensures adoption and long-term sustainability.

Glossary

Avoidance a conflict emerges, but the family does not discuss it. For example, if a mother yells at her son, the father might say, “Let’s not do this now – Juan has a big game coming up tomorrow.”

Conflict resolution style a family’s typical ways of handling disagreements between or among family members.

Denial a family’s refusal to acknowledge conflicts when they appear. For example, “Your mother is not really angry with you. She just had a rough day at work.”

Developmental stage family members behave in ways, or are placed in roles, that are appropriate for their age and stage in life. For example, asking a child to spend most weekends with the family is appropriate for a 6-year-old, but not for a 16-year-old.

Directing/redirecting therapists’ attempts to change family interactions by encouraging a family member to behave in new ways; or to block a family member from interacting in her/his usual way.

Drug abuse any use of illicit drugs.

Family alliances the pattern of close and distant emotional or instrumental relationships between and among family members.

Identified patienthood blaming all of the family’s problems on one family member, often the drug-abusing adolescent.

Joining the process of accepting (e.g. through validation) and being accepted by the family and its members.

Life context the circumstances in which the family and its members live. For example, poverty, immigration, normative (e.g. births, deaths), and nonnormative (e.g. bullying, homelessness) life events that must be considered when evaluating family interactions.

Maladaptive interactional patterns patterns of family interactions that are not successful in achieving the family’s own goals (e.g. preventing or stopping adolescent drug use).

Organization the internal structure of the family – including who is most closely allied with whom and who has authority in the family.

Reframing creating a motivational context for change by redefining a situation or interaction in a way that creates new opportunities for interactions. For example, a mother’s anger at a son being arrested for drug possession might be reframed as “I can see how much you care for your son. You are so worried that your dreams for him will not happen.”

Resonance emotional closeness or distance between and among family members.

Restructuring interventions used to change patterns of family interactions. Restructuring techniques include reframing, directing/redirecting, and shifting family alliances.

Tracking and diagnostic enactment creating the opportunity for diagnosing a family’s repetitive pattern of interactions by encouraging family members to behave as they would if the therapist was not present. For example, when the mother begins to tell the therapist about how her daughter makes her angry, the therapist asks the mother to tell the daughter (rather than telling the therapist).

Triangulation when two family members in conflict with each other place a third, less powerful person into the midst of their conflict.

OVERVIEW

The influence of a family on the development and maintenance of substance use problems has long been recognized. Parental and sibling use, family members' attitudes toward use, poor family management practices, and disturbed marital and family functioning have been linked to adolescent substance abuse. The family has also been a major resource in the treatment of adolescents with substance abuse or dependence disorders. Treatment outcome research has shown that family-based interventions are associated with higher rates of treatment engagement and retention, significant reductions in substance use,

and improved functioning in other behavioral domains.

The focus of this chapter is the functional family therapy (FFT) approach for adolescents with addictive behaviors and their families. FFT is a widely disseminated evidence-based treatment developed for youth with conduct disorder, delinquency, and other disruptive behaviors. FFT has also been implemented with families of alcohol- and drug-using adolescents and has emerged as a well-established treatment for this population. The purpose of this chapter is to provide an introduction to FFT for clinicians who treat adolescents with alcohol and drug use or related problem behaviors. The philosophy and core

intervention components of the FFT model are presented, including examples of intervention strategies that can be integrated into FFT with families of adolescents referred for treatment of alcohol and drug use problems. A summary of the evidence supporting FFT for alcohol- and drug-using adolescents is provided.

THE FUNCTIONAL FAMILY THERAPY MODEL

Conceptual Overview

The FFT model conceptualizes alcohol and drug abuse as problem behaviors that develop and are maintained in the context of maladaptive family relationships. Thus, changing family interactions and improving relationship functioning are the keys to reducing adolescents' involvement with alcohol and other drugs. The essential core and distinguishing feature of family system models, relative to other treatment models, is that the locus of problem behavior is relational, transcending the individual, and therefore the focus of treatment should also be relational. The FFT model goes beyond systems theory, integrating and conceptually linking behavioral and cognitive intervention strategies to the ecological formulation of the family disturbance.

The treatment goals are threefold: (1) reduce adolescent substance use and other problem behaviors, (2) improve family relationships, and (3) increase adolescents' productive use of time. Underlying these goals is the emphasis on changing interaction patterns in the family such that the functions served by drinking or taking drugs are met through other, more adaptive, behaviors. The specific methods used to achieve treatment goals are accomplished in five distinct phases: engagement, motivation, relational assessment, behavior change, and generalization. Each of these phases has associated goals, intervention strategies and techniques, and therapist skills.

FFT usually involves 12–16 sessions of 60–75 min, often with sessions scheduled twice weekly at the beginning of the treatment to potentiate the initial change process. This is followed by a period of weekly sessions to space learning and allow time between sessions for practice, concluding with sessions that occur several weeks apart, as families are able to maintain new behaviors independently. Homework is an integral part of treatment. FFT is designed to include all family members who are living together and any other extended family members or significant others who are central to family functioning. With such an inclusive focus, getting the whole family to become involved in

therapy may be the therapist's first greatest challenge and initial target of intervention.

Engagement

Engagement includes activities that maximize family members' initial expectations about treatment. As such, these interventions begin the process of preparing family members for treatment and are meant to elicit a positive reaction to the therapist. This phase also involves high levels of responsiveness to referral systems and family members. Activities can include superficial aspects, such as wearing appropriate clothes, as well as matching (if possible) to families concerning ethnicity and gender, and being sensitive to issues of gender and culture.

A host of variables can influence treatment expectancies including characteristics of the service delivery system (e.g. reputation, location, and friendliness of staff), family attitudes and beliefs, and therapist characteristics (e.g. age, gender, ethnicity, cultural sensitivity, education, and interpersonal warmth). Adopting the language system used by the family, normalizing problems, and expressing confidence are only a few of the many ways therapists can influence family expectations for change.

Motivation

Families with substance use problems frequently enter treatment with an established pattern of interaction involving intense negative affect and malevolent attributions. These patterns and behaviors represent a major impediment to change at the onset of treatment. However, confrontation is associated with family resistance. Maintaining a nonblaming, nonjudgmental tone lowers family defensiveness and hostility and opens the way for change to occur without forcing family members to admit their fault for previous failures. The primary objective of the motivation phase of intervention is to create a motivational context within which change can occur. This objective is facilitated by interventions that help family members experience a reduction in negativity (anger, blame, and hopelessness). Decrease in negativity is essential in this early phase of intervention prior to initiating formal behavior change techniques because family members' intense negative emotions can preclude them from making a realistic commitment to change.

Two major classes of intervention are used to create a working context: change focus and change meaning.

Change focus techniques disrupt family conflict by redirecting, diverting, or interrupting escalating negative interactions. Therapists "divert" when they intercept a negative speech act made by a family member, thereby inserting themselves into potentially escalating blame or

anger. Therapists “interrupt” when they insert a comment, as respectfully as possible, before a family member can complete a negative statement. Often this takes the form of a clarifying question, but one that focuses on something other than the negativity itself. Therapists can also disrupt conflict by commenting on the process of how family members relate to each other in a nonblaming, strength-based manner. By “pointing process,” therapists are able to shift the focus from adolescent or other family member problem behavior to relational aspects that underlie patterns but are hidden from the family. Another technique, “sequencing/circular questioning,” is used to create depth of knowledge about a problem sequence including the actions each person took and their meaning. Finally, “strength-based relational statements” ascribe a positive attribution about one person’s efforts toward another. This includes seeing the positive side of apparently negative relational patterns, as in “at least we don’t have to guess about your anger.... You are quite open about it, which gives us something to work from.”

Change meaning techniques disrupt family conflict by changing the meaning of how family members understand themselves, each other, and their histories. The goal is not to create cognitive change by challenging “maladaptive” cognitions or providing interpretations. Rather, the focus is to provide a nonblaming and potentially more hopeful viewpoint as a basis or context for change.

“Relabeling” interventions are reflections that use similar but less harmful explanations. Relabeling often involves using a “softer” relational focus (e.g. concern versus nagging) to create a less negative tone in the family. Reframing involves introduction of a new perspective that changes the conceptual, attributional, or motivational viewpoint of family members. Reframes include an acknowledgment of the negativity to establish that the therapist understands the relevance of the problem but to go beyond this reflection to offer an alternative and possibly benign motive for the behavior.

In FFT, therapists also work to create new themes (explanatory frames) for understanding family interactions differently, and if possible more benignly. “Behavioral themes” involve identifying sequences of problem interactions in which all the negative elements are identified but reframed in a more positive way. “Relational themes” switch the focus to relationships rather than behaviors. Relational themes maintain the basic elements of reframes but provide new perspectives on the relational meaning of events or behaviors.

Substance Use-Specific Motivation Strategies

The FFT therapist will encounter many different types of family dynamics, and there is no single approach that will be effective for all families. This

section identifies some of the common therapeutic challenges encountered when working with these families.

Establish the “Meaning” of Substance Use in the Family

Therapists should attempt to identify current or prior experiences that may be exacerbating views about substance use. Substance use often “means” different things to different members of the family, and the differences in meaning lead to difficulty in communication within the family. For example, suppose mom had a brother who died of a drug overdose. She sees her son using drugs and is very frightened that he will escalate his drug use like her brother. For mom, the son’s drug use is perceived as potentially life threatening. Dad, on the other hand, was a drug user in high school, just like his son, and stopped using over time. For dad, drug use is a “normal” teenage activity that elicits little concern. In a family dynamic like this, mom will tend to address the drug use as zealously as dad minimizes it, leaving her feeling increasingly unsupported and frustrated. The son will receive a mixed message from his parents, hearing tacit approval from dad while engaging in heated exchanges with mom as she exerts pressure on him to stop using drugs. By examining differences in meaning, the therapist can focus the intervention on providing reframes that highlight the relational nature of the problem: “Mom’s reaction is so strong because her life experience leads her to be much more worried about what might happen to you with the drug use. Dad isn’t as worried because he didn’t suffer the same loss as your mom. The bottom line for mom is: this is about making sure nothing bad happens to the son she loves so much. The drug use brings up the pain your mom feels over the loss of her brother and it’s a regular reminder of how vulnerable she feels. That’s why she tries so hard to control what you’re doing. So when mom yells, that’s her way of saying ‘I’m really frightened.’”

When parents disagree about the importance of drug use as a problem, the therapist should not directly challenge positive beliefs about drug use. Instead, the therapist should point out how the difference of opinion limits the ability of the parents to work together as a team, creating bad feelings with the more concerned parent, who ends up feeling less supported. It also sends the message to the adolescent that the more the parents disagree, the more he or she will probably be able to get away with continuing the problem behavior.

Punitive Stance toward Drug Use

Some families adopt a rigid, punitive parenting approach in response to drug use. The adolescent is viewed primarily in terms of his problem with drugs. There is limited attention to other aspects of the

relationship. Many times these families tend to get stuck in a cycle of escalating negative consequences. Rules are set for the adolescent, the rules are broken, and then increasing punishments are applied. The adolescent often becomes defiant under this punitive interaction style, with the result of escalating conflict and confrontation in the family. While this pattern is also common in families facing other adolescent disruptive behaviors, the unique issue with substance-abusing families is that a substance use “lapse” is a normative occurrence in the recovery process. Recovery is rarely an “all-or-nothing” phenomenon and the event of a lapse can provide a useful opportunity to evaluate what went wrong with the recovery plan and how to avoid the same pitfall in the future. Thus, parents who define any evidence of recurring substance use as a rule violation and failure will likely set the stage for crises that disrupt treatment and interfere with the expected process of recovery. While providing relational reframes for these families, the therapist should specifically work to eliminate the threat of removal from the home. The adolescent’s absence from home limits the ability of the family to heal wounds, constructively resolve problems, and provide basic support. It sends the message that the parent’s love is conditional to a set of behaviors, the parents will worry about the safety and well-being of the adolescent even more, and it will further damage the relationship without solving the problem the parent is most concerned about. One particularly effective reframe is to offer a longer term perspective for the family, “As Johnny moves toward adulthood, one of the goals of the family is to help him launch into being an independent and successful adult. It might be time for Johnny to move toward independence and living on his own, but we want that to happen as constructively as possible. So he knows he has your support to be successful when he leaves home, and he’s not moving out in anger.”

A second key intervention is to expand the focus of parent–youth relationship beyond the negativity that currently defines the relationship (e.g. emphasis on rules) to re-establish a strong positive bond. Strengthening the bond is a critical component because it will provide the motivation to change behavior.

Parental Substance Abuse

A particularly challenging situation occurs when one parent is a chronic alcoholic or drug user, and the family enters therapy with the united belief that the parent’s use is responsible for the adolescent’s drug use problem. The parent’s acceptance of blame and regular apology for both his own drinking or drug use, as well as for the adolescent’s drug use, allows all the drug use to continue. Rather than accepting the families’ interpretation of the problem, the therapist must reframe the

parent’s drinking or drug use behavior to provide an alternative relational focus for the problem. “It sounds like it has been really important to the family to have someone who takes responsibility for all the problems, and that’s clearly your role, but I’m wondering whether the family has really done everything they can to communicate to you how important it is to have you available for the other aspects of family life. I’m talking about the fun parts of being a member of this family, like being together for dinner, or coming home early so everyone can see a movie together. And, I’m curious, are you responsible for Sally’s talent in art too, or is mom the one who gets credit for the good stuff?” The intent of this type of reframe is to help the family think about the “roles” in a different way. In this scenario, we have a “good parent, bad parent” dynamic that actually reinforces the current behavioral patterns and allows the dysfunctional behavior patterns to continue. By challenging the rigid roles defined by the family, the therapist helps everyone take responsibility for the dysfunctional behavior.

Talking about Drug Use in Sessions: Individual Problem versus Relational Focus

In substance-abusing families where the substance use is a direct component of the relationship (as when family members use drugs together), it is important to highlight the connection between use and relationship contact. However, the therapist needs to avoid allowing the family to focus on drug use content alone and maintain an emphasis on clarifying the meaning of drug use for the relationship. The therapist will also have to negotiate situations where the parent views his/her own drug use as acceptable but the adolescent’s use as a problem behavior. Because parental drug use is one of the strongest risk factors for adolescent use, the best outcomes will occur when parents are motivated to reduce or eliminate their own use. Again, focus on the relational nature of the drug use is a key approach to take. One effective technique in this situation is to use reframing in conjunction with questions about the circumstances and behavioral sequences associated with conjoint substance-using behavior. This is followed by a reframe that emphasizes the positive or negative role the drug use is playing in the relationship and points to a relational motivation for reducing the use.

Relational Assessment

Relational assessment takes place at two levels: (1) what change is needed (i.e. the behavioral targets of change) and (2) how the behavior change needs to occur to maintain the functions served by the behavior. The concept of the interpersonal function of behavior is unique to the FFT model and is an essential element in

determining how behavior change techniques should be implemented in the family.

Relational functions are defined in terms of the interpersonal relatedness or interdependency they allow each family member to achieve with each other. Each family member has a relational function, closeness, distance, or midpointing, with each other member of the family. The essence of understanding the interpersonal function of behaviors between members of each dyad is to look at the outcome of the behavior. If a behavior is associated with repeated interaction patterns that result in family members experiencing significant physical or psychological separation from one another, then the outcome, or function, of the behavior is distance. By contrast, if the outcome of behavior is that family members experience greater connection or interdependency, then the function of the behavior is closeness. Some relationships are characterized by marked distance and closeness, with the blending referred to as midpointing.

While certain behaviors more commonly produce certain functions (e.g. drunkenness produces distance), a particular behavior must never be assumed to create a specific function. For example, an adolescent's drug use could create considerable distance in that the youth spends the majority of free time with other drug-abusing peers. Alternatively, drug use may cue a repeated behavioral sequence in the family that routinely results in increased closeness when the mother and father rally around the adolescent. Drug use could also involve a mix of both closeness and distance when the youth alternates messages that cry for help with messages that reject parental attempts to help. Also, functions are unique to each relationship and any given behavior may simultaneously produce one function in one dyad and another in a different dyad (e.g. son's drug use elicits nurturance and concern from mom and simultaneously increases distance between son and dad, and husband and wife).

Although our society typically views closeness or intimacy as desirable in relationships and distance as undesirable, FFT functions are not conceptualized as inherently good or bad. In addition to healthy forms of closeness, "smothering" or enmeshed relationships represent maladaptive forms. While some forms of distance or autonomy are unhealthy (e.g. isolating oneself from other family members, being nonresponsive), maintaining distance from other people may facilitate the development of independent thinking and a sense of autonomy and competence. Midpointing can also be expressed in either adaptive or maladaptive ways. For example, a young adult with a drug problem may at times use his/her addiction as a way of escaping from the family and at other times use it as a way of connecting with them (e.g. "I lost my

license, so you need to drive me to work."). There can also be nonpathological expressions of midpointing, such as the teenager who remains active in the family's affairs but also participates extensively in the extracurricular school activities and spends prosocial time with friends. The critical concept is that while the behaviors by which functions are achieved can be maladaptive and may need to change, the functions themselves are simply descriptive of family relationships and are preserved rather than targeted for change. The identification of the functions for each dyad in the family allows the therapist to develop a change plan that will address maladaptive behaviors while ensuring that each family member's functions with others are maintained.

Behavior Change

The behavior change phase focuses on establishing and maintaining behavior change both at the individual level and for the family as a whole. The primary goal of the behavior change phase is to establish new behaviors and patterns of interaction that will replace old ones, preventing maladaptive patterns from reappearing and producing long-term change in the family.

In this phase, therapists draw from a menu of treatment strategies, such as communication training, contingency management, negative mood regulation, and increasing rewarding shared activities, to achieve the objectives for change of each target behavior in the treatment plan. In addition, therapists will need to be familiar with specialized evidence-based cognitive behavioral interventions for substance abusers. The particular selections and applications of techniques, however, depend on several considerations. An understanding of interpersonal functions is key; intervention attempts can lead to rapid change or resistance depending on how well the intervention strategy has been fitted to each family member's interpersonal function with each other family member. Even when the behavior change strategy is technically correct and well developed, resistance will arise if the intervention implemented is inconsistent with one or more of the family members' interpersonal functions. For example, a son using methamphetamine may achieve considerable distance from his parents, while at the same time creating a context for his father's merging function with his mother. That is, the son's substance use allows the couple to draw closer, discussing their concerns and attempting to solve the problem of how best they can help their son. Attempts to move the son into more interdependent interactions with his parents would be incompatible with the

family's relational functions and resistance to therapy would likely result.

An early goal in the behavior change phase is to enhance the family's experience of positive change by increasing positive activities and interactions. By maximizing the success experiences of families, the positive momentum and family motivation established in the engagement phase will continue.

The specific techniques introduced by the therapist can include any strategies capable of changing behavior. The FFT model has not created a new set of techniques for changing behavior. Rather, clinicians are directed to the broader literature on evidence-based cognitive and behavioral treatments to integrate change strategies into FFT as needed. Communication and problem-solving skills training are considered core strategies and are implemented in some form with virtually all families. Other topics may or may not be used and are presented as a menu of options. In addition, there are a host of technical aids that can be integrated into behavior change sessions to support families' change efforts.

Substance Use-Specific Behavior Change Strategies

There are specific behavior change techniques to address the unique problems associated with substance abuse. However, as with the FFT intervention more generally, the behavior change program selected for families will be based on the specific problems that are associated with each family.

When both the adolescent and the parent are involved in substance use, conducting a functional analysis of their use behavior (i.e. identifying antecedents and consequences of use, as well as the quantity, frequency, and circumstances surrounding use) can help reinforce the relational nature of the substance use and identify specific ways in which the adolescent and parent can support each other in reducing use. This technique can be effective in motivating parents to address their own use and can be introduced as an exercise for parents who resist changing their own behavior.

Drug use reduction can be hampered by difficulties coping with the urges and cravings. Several techniques exist for identifying and coping with urges and cravings. One strategy that can be implemented when the adolescent has a contact or midpointing function with one or both parents is to have the adolescent seek support from the parent(s) to help monitor and cope with urges to use. Similarly, relapse prevention techniques can be discussed with the entire family, and specific responsibilities can be assigned to family members to help support the adolescent's sobriety.

Helping individuals regulate negative moods and emotions (e.g. anger management, coping with negative

thoughts) can be effective in helping families break their established patterns of escalating conflict. The process involves examining and challenging automatic and irrational thoughts associated with a particular situation, and then demonstrating the link between these thoughts, negative moods, and poor family communication.

Generalization

The final phase of FFT is designed to facilitate maintenance of behavior change and generalization of treatment gains to the natural environment. As family members experience short-term changes, they are helped to consider alternative ways to continue positive change. A key goal of the generalization phase is for families to apply their newly acquired behavioral skills to novel situations outside the therapy room. For families with substance-abusing adolescents, this will include ongoing practice of both general and substance abuse-related strategies. Families tend to be more successful using the behavior change strategies over time when they are able to identify situations where they failed to use them outside the therapy room and examine the barriers they experienced putting them in place. Even one successful experience using the behavior change strategies outside the therapy room can have a very powerful impact on the families' motivation for change.

Finally, families are connected in a web of social, legal, cultural, economic, and community systems. In the generalization phase, the FFT model incorporates specific principles that govern the inclusion of these systems in the treatment process. Unlike generic treatment planning, which at times wraps services around the family with little consideration of family dynamics, FFT focuses on each family's interpersonal needs when considering adjunctive support services. Before an intervention is implemented, it is necessary to establish the validity of the intervention for the family and tailor the intervention to the family's relational needs. For example, job training for a 16-year-old may be valuable in providing necessary skill building. However, the mom may not support participation in such a program if it replaces the father's role and enables the father to further disengage from the family. By facilitating appropriate links to adjunctive services, treatment effects can be generalized to new contexts and sustained over time.

Therapy moves toward termination when (1) drug and alcohol use and other problem behaviors are reduced or eliminated, (2) adaptive interaction patterns and problem-solving styles have been developed and occur independent of the therapist, and (3) the family appears to have the necessary motivation, skills, and

resources to maintain a positive clinical trajectory without the support of ongoing services.

EVIDENCE FOR THE EFFECTS OF TREATMENT

In the early 1970s, FFT was initially developed for crisis intervention with juvenile offenders and their families. Over time, however, the effectiveness of FFT has been replicated across sites and settings for substance use problems and a wide range of other problem behaviors. Moreover, FFT can be implemented by professionals with diverse background and training, and it demonstrated effectiveness across cultural groups. In addition, evidence has been found for the preventive effects of FFT for siblings of problem youth and for the long-term effectiveness of the intervention.

With respect to drug use, one of the initial studies examining the effectiveness of FFT compared FFT to a parenting skills group intervention. Both the FFT and parent training groups showed significant reductions in substance use of more than 50% at follow-up. Although no differences were found between the two treatment groups for treated families, engagement rates differed dramatically (93% in FFT versus 67% in the parenting condition). In a reanalysis of this study, it was found that FFT had greater substance use reductions than the comparison condition.

Findings for FFT with families of adolescents with a substance use disorder have been replicated in a series of three randomized trials we have conducted comparing FFT to group and/or individual cognitive behavioral therapy (CBT). In the first study, FFT was evaluated alone and in combination with CBT (FFT-CBT). Adolescents in both of the FFT conditions showed significant reductions in marijuana use from pretreatment to 4 months following initiation of treatment and over time (up to 19 months). However, over time, the other interventions evaluated in this study were also effective. As such, these results provide support for the short-term benefit of FFT for substance-abusing youth. Support was also found for family relationship functioning improvement as a causal mechanism of change in the FFT conditions, but not in the group condition, suggesting that mechanisms underlying positive change in group treatment are distinct from those in FFT.

In a second study of youth referred for the treatment of alcohol-related problems, FFT (with and without CBT) was compared to individual and group CBT approaches. All four conditions were associated with significant mean reductions in alcohol use from pre- to posttreatment. Significant reductions in marijuana use, not the prime intervention target, were also shown in

the FFT only and with CBT conditions. The integrated FFT-CBT condition was the least effective in reducing marijuana use.

A third randomized trial evaluated the efficacy of an integrated FFT + CBT intervention to CBT alone for Anglo and Hispanic drug-abusing adolescents across two project sites, one in New Mexico and the other in Oregon. Results of the analysis revealed that the Hispanic participants in FFT experienced significant reductions in drug use at each posttreatment assessment point as compared to the pretreatment point, supporting the efficacy of FFT. Differences between the post and follow-up conditions for the CBT condition were not significant. Anglo youth in FFT and in CBT showed significant reductions in drug use at each posttreatment assessment point, but there were no differences between conditions.

TRAINING AND SUPERVISION

Training in FFT for adolescent drug abusers is a three-phase process. During phase I, the initial goal is to impact the service delivery context to build a lasting infrastructure that supports therapists to implement FFT with the highest integrity. By the end of phase I, the training objective is for therapists to demonstrate strong adherence and high competence in FFT. Training includes several on-site workshops as well as weekly consultations over the course of the first year. Assessment of therapist adherence and competence is based on data gathered through a web- or PC-based Client Services System (CSS). Phase I is designed to be completed in 1 year and, at most, not extend beyond 18 months.

The goal of the second phase of implementation is to foster increased self-sufficiency at the site, while also maintaining and enhancing site adherence and competence in the delivery of FFT. During phase II, a member of the local team is identified to receive specialized training as a site supervisor. This individual participates in an externship that involves 9 days of live supervision and case consultation over a 3-month period at the end of phase I or beginning of phase II. This person also attends two 2-day supervisor trainings, and is then supported by regular monthly phone consultations as well as one on-site training. In addition, training involves regular review of the site's database to monitor site/therapist adherence, service delivery trends, and outcomes and to develop and implement quality improvement plans in collaboration with the local site supervisor. Phase II is a 1-year process.

The goal of the third phase of training is to further enhance the self-sufficiency of a site in ensuring model fidelity, staff development, interagency linking, and program expansion. During this phase, the local site supervisor takes increased responsibility for monitoring

outcomes using the CSS database. The on-site supervisor continues to participate in regular consultation calls, but these occur less frequently than during phase II. A one-day on-site training is provided for continuing education in FFT. Phase III is an ongoing process.

SUMMARY AND CURRENT DIRECTIONS

FFT is an integrated systemic and cognitive behavioral intervention that produces change through a phase-based process. Each phase has its own unique goals, tasks, and interventions. FFT therapists are trained to be clear on the overall principles and perspectives that guide the integrative process, with a default mode that is relational and respectful but is accommodating enough to utilize other perspectives as long as they are consistent with the FFT model and to help intervene with this particular family, effectively, at this particular time.

Research on the efficacy and effectiveness of FFT has led to the widespread dissemination of the model into community settings including drug use, juvenile justice, mental health, and child welfare settings. To date, FFT Inc., the dissemination organization charged with training and monitoring the quality of implementation of FFT in community settings, has trained more than a thousand therapists from nearly 300 agencies/systems in nine countries. Information about training in FFT can be found at www.fftinc.com.

Acknowledgments

This research was supported in part by grants from the National Institute on Drug Abuse (R01 DA11955, R01DA13350, and R01DA13354) and National Institute on Alcohol Abuse and Alcoholism (R01 AA12183). We are also grateful to Hyman Hops for his ongoing support of our efforts and his editorial feedback on drafts of the manuscript.

Glossary

- Behavioral themes** therapist interventions that identify sequences of several problem and family member interactions in which all the negative elements are included but are reframed or at least relabeled (see descriptions for reframing and relabeling below) to reduce family blame, negativity, and hopelessness.
- Divert** therapist interrupts blaming or angry interactions by intercepting negative statements made by a family member toward another family member.
- Interrupt** therapist inserts a comment, as respectfully as possible, before a family member can complete a negative statement.
- Pointing process** therapist shifts the focus from the adolescent's or other family member's problem behaviors to relational aspects that underlie relational patterns that are hidden from the family.
- Reframing** therapist introduces a new perspective that changes the negative conceptual, attributional, or motivational viewpoint that family members have toward one another to a more positive (or at least neutral) or workable set of attributions and emotions.
- Relabeling** therapist reflections that use similar, but less harmful, explanations for family members' behaviors by introducing a "softer" relational focus (e.g. concern versus nagging) to create a less negative tone in the family.
- Relational functions** the interpersonal relatedness needs of individual family members, ranging from closeness/connection to distance/autonomous, that are inferred from family members' behaviors, verbalizations, and emotional reactions as well as the patterns of interaction in the family.
- Relational hierarchy** the pattern of relative influence that parents and youth have over each other in terms of "controlling" each others' behavior.
- Relational themes** therapist interventions that switch the focus to relationships rather than behaviors. Specific behaviors may be noted, but relational patterns become the major focus. These interventions maintain the basic elements of reframes but often seem more like "stories" and even "myths" rather than specific sequences of negative behaviors.
- Sequencing/circular questioning** therapist interventions that are used to create depth of knowledge about a problem sequence including the actions each person took and their meaning.
- Strength-based relational statements** therapist interventions that ascribe a positive attribution about one family member's efforts toward another.

Themes in Treatment by Stage of Recovery	120	Conclusions	124

Addiction counseling has been one of the most widely used treatments for substance use disorders (SUDs), and research has shown addiction counseling to be very effective for cessation of substance use. Sometimes, counseling comprises the entire treatment program for a patient. However, the introduction of new medications and other new types of interventions have led to a more multimodality treatment approach, which usually includes counseling as one component. Such multimodality approaches can usually provide greater intensity of treatment and can simultaneously address biochemical, psychological, and behavioral aspects of SUDs.

Individual Drug Counseling (IDC) and the parallel group model Group Drug Counseling (GDC) were developed as a treatment approach based on what competent, conventional drug counseling typically involved. In developing these models, numerous expert drug counselors were interviewed, and they shared their treatment philosophy, themes in counseling, and interventions or other tools they used in drug counseling. This led to the development of a drug counseling model that basically relied on the conventional interventions but was very well organized and manualized. Counselors were carefully trained in the model, and ongoing supervision was provided. The reason this

model set out to be fairly conventional was that it was designed for use in research protocols that wanted to compare more novel treatments with an approach that approximated drug counseling “treatment as usual” or what drug counselors typically do. Sometimes this model has been used in research as the basic counseling program to which different treatments being studied can be added.

These manuals for individual and group counseling were designed to be components in a more comprehensive treatment program. In the research for which they were designed, these counseling models were combined with initial medical and psychosocial assessments, detoxification and stabilization, family involvement, and ongoing participation in a mutual support program. However, these treatments can be used individually, by a counselor in outpatient practice, who can draw upon additional resources as needed. Also, these counseling models may be used in conjunction with pharmacotherapy, other medical therapies (e.g. acupuncture), family or couples therapy, or professional psychotherapy.

This model of addiction counseling does not focus much attention on the role of family members in treatment, not because it is not important in treatment but because this model was not intended to provide an all-inclusive treatment. When this model was used in the cocaine collaborative study, in addition to the group and individual counseling, a multifamily psychoeducational group was provided. This was found to be very beneficial for patients and families.

OVERVIEW OF THE IDC AND GDC MODELS

The primary goal of drug counseling is to help the client achieve and maintain abstinence from addictive chemicals and behaviors. The secondary goal is to help the client recover from the damage the addiction has done to the client’s life. The following are the most important elements in the IDC/GDC approach. In counseling, these elements are not independent of one another; the concepts are related, and there is a fair amount of overlap.

- Based on the disease model
- Focus on behavioral change
- Mutual support program participation
- Family involvement
- Drug testing
- Preventing relapse
- Lifestyle changes
- Spirituality

BASED ON THE DISEASE MODEL

Drug dependence is believed to be a multidetermined, maladaptive way of coping with life problems that often becomes habitual and leads to a progressive deterioration in life circumstances. Habituation of drug use is dependence, which is a disease in its own right that damages the addict physically, mentally, and spiritually. The disease model conceptualizes alcohol and drug addiction as a biopsychosocial illness that affects the social, psychological, spiritual, and physical dimensions of an individual. This disease is said to be progressive in nature, and there is no cure, but it can be arrested through treatment and abstinence. Recovery requires changes that reflect a lifelong commitment to abstinence and recommends a more balanced and spiritual way of living, with the aid of ongoing mutual support participation.

FOCUS ON BEHAVIORAL CHANGE

Addiction counseling is usually primarily present oriented, fairly directive, and focused on behavioral change. Counseling involves a combination of (1) psychoeducation, which teaches the client strategies and provides information important to recovery; (2) monitoring, which makes the client more aware of and holds them accountable for their drug use or related behaviors; and (3) support, which provides the client with an ally in the process. Addiction counseling emphasizes specific behavioral change with the primary goal of achieving and maintaining abstinence from all substances. It is important to establish clear goals related to cessation of drug use early in treatment and keep abreast of the patient’s success with abstinence and with compliance in other aspects of the treatment.

Addiction counseling focuses primarily on drug use or close calls, triggers, urges to use substances, social pressures to use substances, impact of SUDs on family and other relationships, building a recovery support system, identifying and managing relapse warning signs or risk factors, and addressing other addictions. Using active coping skills and monitoring any movement toward relapse are also emphasized in addiction counseling. Other issues may be discussed in counseling but only as they relate to drug use and recovery. This is in contrast to some psychotherapy models that may devote time to analyze past experiences or significant relationships. Treatment programs that provide a multimodality approach may offer other behavioral treatments in addition to addiction counseling, and these treatments may address issues such as family recovery or psychiatric needs, but these should always be in

addition to, and never instead of, counseling that focuses on the drug use and desired abstinence.

MUTUAL SUPPORT PROGRAM PARTICIPATION

This philosophy of the 12-step program is integrated into the counseling, and ongoing participation in a 12-step or other mutual support programs is strongly encouraged. Active participation in 12-step programs such as Alcoholics Anonymous (AA) or Narcotics Anonymous (NA) is generally associated with improved outcomes. AA, NA, and other 12-step programs are abstinence oriented and foster a network of healthy social support for individuals in recovery. Key aspects of the 12-step philosophy for therapists treating SUDs are (1) the belief that addiction is a disease rather than a bad behavior; (2) the belief that addiction damages the whole person physically, mentally, and spiritually and that recovery must address all these domains; (3) the belief that healing or recovery comes from connecting to something larger than oneself, referred to as “higher power” in AA or NA; (4) the paradox of surrendering power in order to ultimately be empowered to attain sobriety; (5) the idea that interpersonal support is critical for recovery; and (6) the belief that recovery is a lifelong process that encompasses sobriety as well as continued personal growth.

Introducing the client to the idea that ongoing mutual support program participation is an important factor in recovery, during formal treatment, can promote continued participation after treatment has ended. Ongoing participation in 12-step or other mutual support programs is thought to be helpful in preventing relapse. There are other models of self-help programs, such as Rational Recovery, SMART Recovery, Women for Sobriety, and Men for Sobriety, that are also useful, but these tend to be less widely available than the 12-step programs. However, they also foster continued recovery, and they may be a better “fit” for some people than the 12-step programs. Self-help programs such as Dual Recovery Anonymous or Double Trouble are also available for individuals with substance use and psychiatric disorders.

FAMILY INVOLVEMENT

Significant family member involvement is associated with more successful addiction recovery. Increasingly, treatment programs try to involve family members in their addicted member’s treatment. This may be through individual family therapy, a multifamily group, or occasional family workshops, which are

psychoeducational in nature. Through these interventions, the counselor can teach family members about the nature and consequences of addiction and the treatment, recovery, and relapse processes. This enables families to more effectively support their addicted member through the process of recovery as well as determine what they may need in terms of help and support for themselves since addiction has many adverse effects on family members. Also, family involvement allows the counselor to explore historical and relationship factors in the family that can undermine treatment.

DRUG TESTING

In addiction treatment programs, clients are usually tested for drug use to help promote abstinence and honesty. Drug testing most often involves Breathalyzer to test for alcohol and urinalysis to test for other drugs. Other methods that are less frequently used include testing of blood, saliva, or hair, and each method has its pros and cons. The therapeutic aspects of drug testing are that the client is aware that drug use will be monitored so there is less likelihood of deception. Also, regular monitoring gives the therapist repeated opportunities to reinforce abstinence and address any lapses almost immediately. It is valuable to pair drug testing with self-report of any drug use. In each counseling session, the therapist and client will review any recent drug use or near use. Drug testing encourages honesty, and it helps hold the patient accountable for his or her behavior. Prompt results and feedback on drug tests assures the patient that the therapist is knowledgeable and concerned with his or her progress in recovery.

PREVENTING RELAPSE

Relapse prevention is a set of treatment strategies taught to the client in addiction counseling to help the client avoid a relapse to substance use. Relapse prevention is also a cognitive behavioral model in itself, but the basic concepts are widely used in addiction counseling. These strategies help the client by identifying and managing high-risk situations, including negative emotional states, and interpersonal situations, such as social pressures to use. Treatment involves helping the client reduce relapse risk by examining which emotions or interpersonal situations are perceived to be high risk for relapse, and then, specific strategies are taught to reduce risk in these situations.

Clients are given the skills to identify and manage relapse warning signs, including changes in attitudes, thoughts, feelings, and behaviors. Counseling assists

clients to manage lapses and relapses to substance use by developing a plan to interrupt a relapse ahead of time, before one's thoughts are clouded by the urge to use substances. Clients are also taught to challenge addictive thinking that would promote relapse.

LIFESTYLE CHANGES

The IDC/GDC model promotes living a healthy lifestyle. It takes a holistic view of the person and promotes improved health and wellness in a variety of areas, including physically, mentally, and spiritually. Counseling holds that recovery must address all these domains. Making lifestyle changes is encouraged as a part of the process of recovery, and engaging in new healthy activities is an important part of establishing alternative behavioral routines.

It is not unusual for addicts in their active addiction to neglect aspects of their health, including not eating nutritious meals, not getting regular sleep, not getting healthy exercise and recreation, and in cases of severe addiction, possibly not maintaining good hygiene. Also, substance dependence requires a lot of time, so there is a narrowing of the addict's behavioral repertoire to the point where they are no longer seeing the friends or doing the activities once they enjoyed. Addiction counseling will address and promote eating nutritious food, establishing a healthy sleep routine, and getting appropriate exercise through healthy recreational activities. This may involve a significant amount of education or just a little reminder depending on the client's level of knowledge in this area.

SPIRITUALITY

Spirituality is a significant aspect of addiction counseling. In IDC and GDC, spirituality is defined in a manner consistent with how it is viewed in the 12-step approach, which is acknowledgment of some form of higher power, a sense of connection to something larger than the individual, and a need for honesty with oneself and importance of others in one's life. Spirituality is viewed broadly and not in association with any specific religion or belief. Addiction is assumed to damage the addict's spirituality, and recovery involves the process of reconnecting to one's spiritual nature. For many patients, spirituality is an important and useful concept in recovery from addictions as well as other mental illnesses. Despite that the concept is somewhat nebulous and the meaning is different for different individuals, based on their prior exposure to religion, spirituality gives us a way of assisting clients to grapple with deep emotional needs to feel connected to the

universe and connected to one's self. For many clients, it reinvigorates a sense of purpose and that can be very healing.

STAGES OF RECOVERY

In this model, treatment is conceptualized as occurring in stages, although the stages are flexible and clients can move back and forth between stages in their process of recovery. The first stage of treatment is about acknowledging a problem and committing to treatment. Much of this stage may take place before the patient even gets to treatment. The second stage is establishing abstinence, and the third stage is maintaining abstinence. Most of the information in the IDC and GDC manuals focuses on the establishment and maintenance of abstinence stages. The last stage is advanced recovery, and this is considered to be a long-term, if not lifelong, process that occurs after the active treatment phase, which was 6 months in this model.

- Acknowledging the problem
- Establishing abstinence
- Maintaining abstinence
- Advanced recovery

THEMES IN TREATMENT BY STAGE OF RECOVERY

These topics are to be discussed within the individual counseling sessions, and many are also addressed in the psychoeducational group. The individual counselor chooses the theme or themes relevant to the client's current needs or point in recovery and introduces that topic. The counselor considers the client's stage in recovery and tries to review the topics appropriate to one stage before moving to the next. However, the counselor has flexibility in determining what theme is most appropriate for the client at the time. The manual provides background information on each topic in recovery that will guide the counselor in a discussion of the topic. Approximately half of these topics come from a relapse prevention approach and the other half comes from the 12-step model. The IDC and GDC manuals provide more detailed suggestions and guidelines for each topic.

- Acknowledging the problem
 1. Acknowledging one's use is a problem
 2. Confronting denial
 3. Motivation for treatment
- Establishing abstinence
 4. Addiction and associated symptoms
 5. People, places, and things

6. Structure of personal time
7. Craving
8. High-risk situations
9. Social pressures to use
10. Compulsive sexual behavior
11. Postacute withdrawal symptoms
12. Use of other drugs (other than the primary addiction)
13. Mutual support participation (12-step or other programs)
- Maintaining abstinence
 14. The relapse process and tools for preventing it
 15. Relationships in recovery
 16. Development of a drug-free lifestyle
 17. Spirituality
 18. Shame and guilt
 19. Personal inventory
 20. Character defects
 21. Identification and fulfillment of needs
 22. Anger management
 23. Relaxation and leisure time
 24. Employment and finances
 25. Transference of addictive behaviors
- Advanced recovery

Advanced recovery presumes that the client is stable in abstinence and is working on the bigger issues of creating a meaningful and satisfying sober life, while continuing to attend to the personal program of recovery. This stage of treatment is not specifically addressed in the manuals, which focus on the active phase of treatment, which precedes advanced recovery. However, many of the themes are the same, and the client returns to process them from a different point in recovery. Themes that are usually prominent in advanced recovery include maintaining a healthy lifestyle, healing relationships or establishing healthy relationships, life goals, and personal responsibility. Some of the topics in the maintaining abstinence stage, particularly relationships in recovery, identification and fulfillment of needs, and relaxation and leisure time, set the stage for the client to move into advanced recovery. In advanced recovery, the client may choose whether he or she wants to continue in regular counseling, although it is strongly recommended that a mutual support program is continued.

LOGISTICS OF THE INDIVIDUAL COUNSELING SESSION

Sessions typically run about 45 min in an outpatient setting; however, 30 min may be adequate for some clients. In the original research, clients began with two individual sessions, and then reduced to one session

per week, after 12 weeks. It was hoped that this would coincide with the clients' increasing stability and abstinence. Within each session, the counselor follows a structure that adheres to the following format:

1. Inquiring as to the last time the patient used substances
2. Discussing recent substance use or close calls
3. Addressing any urgent problems the patient has
4. Providing feedback about drug screens
5. Discussing relevant recovery-related topics

The discussion topics refer to the themes listed above.

COMBINING GROUP AND INDIVIDUAL THERAPY

A combination of GDC and IDC seems to work best for many clients. Some clients feel more comfortable sharing personal information with an individual counselor, while others benefit greatly from the connection and mutual support of the group. In this model, IDC and GDC present very similar information and teach the same strategies, but in a different format. Each format offers some unique treatment elements that are beneficial to the therapeutic process. Both individual and group sessions have a clear structure. However, within the framework of the structure, the content of the discussion is largely up to the client(s). An effort is made to effectively address the client's individual needs at any point in treatment while also recognizing the commonality of many issues in addiction and recovery.

GROUP DRUG COUNSELING

Group counseling is considered a very important and necessary part of most drug counseling programs because there are some aspects of recovery that groups can tackle particularly well. Groups provide a forum for peer feedback and support among individuals recovering from substance dependence. Through groups, individuals can hear other people's experiences and learn ways to change behaviors. This creates a feeling of connection and support, which hopefully fosters the optimistic belief that "together we will accomplish this." Also, peer feedback about someone's behavior is often more powerful and may be more easily "heard" and accepted than feedback from professionals whom patients sometimes view as different from them.

In the groups, as in individual counseling, recovery is conceptualized as occurring in stages. The GDC model focuses on the stages of establishing abstinence, which correlates with phase I group, and maintaining

abstinence, which correlates with phase II group. Each group phase lasted 12 weeks, with one group per week, in the original research protocol.

During phase I, group members meet weekly for 12 weeks for a psychoeducational group session, in which they receive information about addiction and recovery. During the psychoeducational group sessions, patients receive information and participate in discussions about various topics on recovery (addiction, recovery, cravings, people, places and things, relationships, mutual support programs, support systems, managing feelings, warning signs of relapse, coping with high-risk situations, and maintaining recovery). These topics are basically the same as those addressed in the individual counseling sessions, but in the group session, there is a different format for their presentation. Each topic presented has a lecture and discussion along with handouts and written assignments to facilitate learning. Group members are encouraged to interact with each other and share experiences regarding the topics. In this way they can develop relationships and give and receive encouragement and support.

The second phase of treatment is called the problem-solving group. Clients continue to meet weekly for 12 more weeks. This phase is a less-structured group where members solve problems of various life issues without resorting to substance use. Group members are encouraged to discuss current problems or concerns for the group to process. The group leader will facilitate feedback, encouragement, confrontation, or any other form of interaction among group members to help with these problems. Our experience was that many clients liked the accomplishment inferred by graduating from one group phase and moving to the next. They received certificates and recognition from their counselors and fellow members for abstinence and for graduating from each group phase, and many appreciated this.

LOGISTICS OF THE GROUP COUNSELING SESSION

Groups typically run about 75–90 min, depending on the number of members present and the specific setting. Our groups had rolling admissions, so each session might have some new members. When new members were present, the group counselor would go over the group ground rules during the introduction/check-in portion of the group. Groups are led by a group drug counselor or sometimes coled by two counselors, if possible. Group sessions have the following format:

1. Group members submit a urine sample and take a Breathalyzer test.
2. Members introduce themselves, admit to their addiction, and state their date of last use of any type of drug or alcohol.
3. Members are encouraged to talk briefly about how they are doing and about any cravings or temptations experienced since the previous group meeting.
4. If any members have used since the last session, the group will help them process the event and develop a plan to prevent further relapse.
5. If there is a topic, the group leader will introduce it and encourage members to discuss how it relates to their recovery. (In the more advanced problem-solving group, members are encouraged to describe a current problem or concern and get feedback from one another.)
6. In the final 10 min, members are asked to state their plans for the next few days in an effort to help them structure their time. Members are also encouraged to mention the self-help meetings that they are attending and perhaps invite others to attend with them.
7. The session ends with members reciting the Serenity Prayer aloud.

This group structure and program worked very well. Clients liked it; usually attended, shared, and learned things in the group; respected the process; liked the group leaders; and supported each other in recovery. These groups are structured, while still providing opportunities for clients to express themselves openly and get needs appropriately met by the group and the counselor.

STRATEGIES FOR DEALING WITH COMMON PROBLEMS IN THE IDC/GDC MODEL

Not Attending Sessions

Clients are repeatedly urged to arrive for all sessions promptly, to call if they are going to be late, and to call at least 24 h in advance if they must cancel a session. If they fail to fulfill these obligations, the counselor will confront them about it in the session.

If a client arrives late for a session, the consequence is a shorter session because the counselor should end the session on time. Repeated missed sessions without appropriate cancellations and rescheduling will eventually result in dismissal from the program, but clients in the original research protocol were given many chances before termination from treatment for nonattendance.

Being Sober for Counseling Sessions

Clients are requested to arrive sober for all visits. If a client arrives obviously intoxicated, the counselor will remind the individual of the responsibility to

come clean and will reschedule the session. If a client arrives for a group or an individual session mildly under the influence but not intoxicated it is at the counselor's discretion whether to continue with or reschedule the session.

When a Crisis Occurs

If the client presents with an urgent, addiction-related problem such as marital dissolution or financial problems as a result of the addiction, the counselor should try to address these problems in the session, with an emphasis on how they are related to the addiction or addictive behavior. The counselor should then help the client develop strategies for dealing with the problems in a manner consistent with recovery, including identifying how to obtain appropriate assistance from social services. If the client presents with a true crisis (e.g. becoming suicidal after spending all of his or her money on a cocaine binge), the counselor should organize a team effort among the appropriate treatment staff to provide any medical or psychiatric services that the client requires in order to remain safe.

Slips and Relapses

If a relapse occurs, the counselor and client should use the session immediately following the relapse to identify and process the events, thoughts, and feelings that precipitated the relapse. Relapse to drug use is a common occurrence that can be devastating to the client. The counselor must communicate to the client that relapse to drug use does not mean that the entire treatment program has been a failure. The counselor should educate the client about relapse and about how important it is to take corrective action rather than be overcome by feelings of depression or failure. Some episodes of drug use can be managed without seriously interrupting the treatment program and can be used in a positive and educative way to strengthen the recovery process. In dealing with a relapse, the counselor should use the general principle that relapse is caused by failure to follow one's recovery program. Thus, the counselor should identify where the client deviated from his or her recovery plan and help the individual do all that is reasonable to prevent such a deviation from recurring.

Relapse can be viewed as having differing levels of severity that determine the appropriate therapeutic response. The counselor must understand the appropriate interventions to be used in each case. The least severe type of relapse is a slip. A slip is a common occurrence involving a very brief episode of drug use that is associated with no recurrence of symptoms of dependence. Such an episode can serve to strengthen the client's recovery if it is used to identify areas of

weakness in the recovery plan and point out solutions and alternative behaviors that can help prevent future drug use from occurring.

The next most severe type of relapse is when the client resumes drug use for several days, and the use is associated with some of the signs and symptoms of addiction. In such a case, clinically the counselor might want to intensify treatment temporarily, although this was not done in the original research protocol. Intensified contact may help reinstitute abstinence. The client should be encouraged to think about what was done and learn from the experience how to avoid relapse in the future. The client should also be encouraged to recommit to his or her recovery program.

The most serious form of relapse is a sustained period of drug use during which the client fully relapses to addiction. Often a client who relapses to this extent will also drop out of treatment, at least temporarily. In this case, if the client returns to treatment, he or she should most likely be detoxified again, either in an inpatient or outpatient setting. The decision to detoxify a client as an inpatient or outpatient should be made conjointly by the treatment staff involved. The decision should be based on the severity of the relapse, availability of social support, and presence of unstable medical or psychiatric conditions.

RESEARCH ON THE IDC/GDC MODELS

These treatment manuals were developed for use in the National Institute on Drug Abuse (NIDA) Cocaine Collaborative Study. This was a multicenter investigation examining the efficacy of four psychosocial treatments for cocaine-dependent patients. Four hundred and eighty-seven patients were randomly assigned to one of four manual-guided treatments: IDC plus GDC, cognitive therapy plus GDC, supportive-expressive therapy plus GDC, or GDC alone. Treatment was intensive, including 36 possible individual sessions and 24 group sessions for 6 months. Primary outcome measures were the Addiction Severity Index–Drug Use Composite score and the number of days of cocaine use in the past month. Compared with the two psychotherapies and with GDC alone, IDC plus GDC showed the greatest improvement on the Addiction Severity Index–Drug Use Composite score and on number of days of cocaine use in the last month. Overall, compared with professional psychotherapy, IDC was more effective at reducing cocaine use in this study.

Another study attempted to make the IDC and GDC models more "community friendly" in order to facilitate the dissemination of evidence-based treatments to the community setting and to support effectiveness testing. Revised versions of IDC and GDC treatment manuals

for cocaine dependence were developed, and a preliminary study of their effectiveness was conducted. It was concluded that counselors were able to implement the new treatment manuals with acceptable levels of adherence and competence. Results found that substantial change in drug use was evident, but the amount of abstinence obtained was limited.

CONCLUSIONS

IDC and the parallel group model GDC were developed as a treatment approach based on what competent, conventional drug counseling or “treatment as usual” typically involves. The models were initially developed for use in the NIDA Cocaine Collaborative Study and found to be efficacious in that protocol. These manuals for individual and group counseling can be used as a stand-alone treatment, but they were originally designed to be components in a more comprehensive treatment program. Combined with detoxification, initial medical and psychosocial assessments, and ongoing participation in a self-help program, individual and group addiction counseling makes a complete treatment package.

The primary goal of IDC/GDC is to help the client achieve and maintain abstinence from addictive chemicals and behaviors. The secondary goal is to help the client recover from the damage the addiction has done to his or her life.

The IDC/GDC approach is based on the disease model. The disease model conceptualizes SUDs as a biopsychosocial illness that affects social, psychological, spiritual, and physical dimensions of the individual. There is no cure for the disease, but it can be arrested through treatment and abstinence. Recovery requires changes that reflect a lifelong commitment to abstinence and recommends a more balanced and spiritual way of living. This philosophy of the 12-step program is integrated into the counseling, and ongoing participation in a 12-step or other mutual support program is strongly encouraged. IDC and GDC address addiction and related behaviors in a straightforward, present-oriented manner. This model helps the client by setting present-oriented, behavioral goals and focusing directly on ceasing the substance use. Relapse prevention is incorporated in the model, in that the client is helped to develop behavioral tools and basic cognitive coping strategies to abstain from drug use and then maintain abstinence. Drug use is monitored via testing with frequent feedback given for abstinence or drug use. Family involvement is encouraged.

IDC and GDC present very similar information and teach the same strategies, but in a different format. Each format offers some unique treatment elements

that are beneficial to the therapeutic process, and clients do seem to benefit from a combination of GDC and IDC.

Glossary

- Behavioral** model of counseling or therapy relating to or emphasizing behavior.
- Biopsychosocial** concerned with the biological, psychological, and social aspects of a disorder, rather than only the medical aspects.
- Cognitive** model of counseling or therapy relating to or emphasizing thinking.
- Mutual support program** programs, like AA and SMART recovery, through which one can access information and support.
- Psychoeducational** relating to psychological aspects of education.
- Relapse** return to substance use following a period of abstinence.

SELF-HELP PARADIGM

Self-help groups (SHGs) operate within the self-help paradigm alongside sociopolitical movements, community development initiatives, and peer mentoring schemes, and they share the following ten principles:

1. The peer principle

The egalitarian spirit of the groups is fostered by the social homogeneity of group participants.

2. Self-determination and new forms of participation

Self-governance is exercised to direct the group and the degree of involvement for each individual.

3. Helper therapy and the restructuring of help

Group participants are helped most by being helpful to others, and thus engage in reciprocal support.

4. The consumer as producer and consumer capital

Group participants are no longer mere recipients of help; they are also the providers of support.

5. Strength versus pathology

Groups emphasize the fundamental role of inner strengths, be they of the individual, group, or community. This is opposed to a focus on pathologies, problems, or afflictions.

6. Noncommodification

The support inherent in SHGs is not a commodity that can be bought or sold. This lies in contrast to service provision, which includes human services and self-help materials that can usually be purchased for a profit.

7. Social support

This type of support enables group participants to reinterpret their personal situation more positively and helps them develop a resiliency to stress.

8. Ethos

Ethos is said to encompass a group's behaviors, practices, and values. These values are typically characterized by anti-dependency, antielitism, antibureaucracy, sharing community, informality, anti-addiction, a spiritual bias, and participatory democracy, particularly when it comes to helping others.

9. The self-help solution

Given the indigenous leadership of SHGs, they offer a solution to some of the limitations associated with human services.

10. Internality

Self-reliance (be it on the group or the self) offers an alternative to reliance on conventional treatments. It also offers healing or recovery whereby group participants are able to resolve a problem of the body, mind, or spirit. This differs to curing, which is typically imposed by a human service provider.

Together, these principles illuminate the underlying values of SHGs. Although there is much variety in their operationalization, management, and governance, they help to transform problems into manageable issues.

Definitional Issues

Although the self-help paradigm offers a useful tool for understanding SHGs, there is currently no single definition of these groups. This is largely due to the following factors:

1. Various labels

Various terms are used to refer to these groups, both by the groups themselves and those who research the area. In addition to SHG, other terms include support group, self-help organization, mutual help group, as well as the relatively more encompassing terms of mutual aid self-help and self-help support group, both of which capture both the autonomous and supportive components of these groups. With regard to addiction, examples include Alcoholics Anonymous (AA),

a 12-step fellowship for individuals who identify as an alcoholic, Secular Organizations for Sobriety or Save Our Selves (SOS), the Mental Illness Addiction Support Group (MASG), and the Calix Society.

2. Various definitions

Some definitions indicate that SHGs bring together individuals with a shared problem or an affliction. Others assert that group participants are drawn together by common experience and/or attributes. For example, Narcotics Anonymous (NA), a nonprofit fellowship for individuals who experience drug problems, is tailored to individuals "who feel they may have a problem with drugs," while Birds of a Feather supports "troubled airmen toward sobriety." However, Moderation Management "empowers individuals to accept personal responsibility for choosing and maintaining their own path, whether moderation or abstinence."

3. Operational variation

At a functional level, SHGs typically perform two major roles: support and education. Some, however, are also involved in advocacy. Advocacy can occur at a personal level on behalf of individual group participants or a sociopolitical level on behalf of the constituency group participants are part of. However, at an operational level, there is greater heterogeneity between and within SHGs, even when groups share a common label. Differences emerge between group aims, the principles adopted to achieve these aims, the nature of participant involvement, the involvement of human service providers, degrees of group membership, and so forth. For instance, within AA, meetings are typically chaired by a member, while Women For Sobriety (WFS) groups are "run by a WFS Certified Moderator." Such diversity contributes to a lack of consistency among SHGs. It is therefore unlikely that one operational definition can be developed. It is also unlikely that research into the area can be readily generalized to all SHGs. However, such diversity promotes access to appropriate support among individuals who may otherwise remain isolated and disengaged.

4. Involvement of human service providers

There is a lack of consensus about the degree of involvement from human service providers, particularly those who do not share the experience(s) of group participants. Although some groups operate in isolation from human service providers, either by choice or because they lacked credibility among human service providers, most groups have established links with human service providers, who serve as an advisor, a consultant, guest speaker, or provider of in-kind support (like a venue at which to meet) and/or

administrative support. For instance, some AA chapters convene within public hospitals and public mental health services.

5. Confusion with other support systems

Given their similarities, SHGs are often considered part of other support systems, either naturally occurring or part of the human services paradigm. All systems, be they formal or informal, may involve groups of people who demonstrate support and understanding, as well as learning through the experiences of others. However, SHGs retain a uniqueness that has perhaps accounted for their appeal among group participants. For instance, all 12-step fellowships offer solidarity with individuals who share similar experiences.

These factors help to explain why understandings of the SHG remain clouded. Despite this, these groups operate within a shared self-help paradigm. They bring together individuals with common experiences and operate at the discretion of group participants.

SIGNIFICANCE

The popularity of SHGs is evident when attempting to locate support for almost any health or mental health issue, including substance use. One Australian directory includes over 700 different bodies within that nation alone. In the United States, their presence is even greater with an SHG for every illness identified by the World Health Organization. The popularity of these groups in the United States is matched by the support of political structures and human services. This is evident in the prevalence of self-help clearinghouses across the United States, each established to support new and existing groups, as well as refer interested individuals to appropriate groups. This compares with the few Australian self-help centers, each of which differs in structure and function. For every Australian self-help center, there are approximately 10 self-help clearing houses in the United States.

Perhaps partly because of difficulties in defining SHGs, there is limited information about the number of individuals accessing these groups. Similarly, there is also limited information about who is using these groups, and how they are using them. There is some information about particular SHG organizations, like AA. Although official statistics are not available, there are estimated to be over 2 million members in over 150 countries, internationally. Similarly, NA convenes over 58 000 meetings per week, in approximately 131 countries. GROW, a community of individuals who progress toward recovery using 12-step program, is said to attract approximately 10 000 Australians.

However, collated information from a range of SHGs is lacking.

International literature might provide some direction. Epidemiological research suggests that within a 12-month period, approximately 3–7% of Americans, potentially representing over 15 million individuals, frequent a SHG of some kind, and lifetime participation rates are estimated at about 25 million.

The popularity of SHGs in Western societies has been attributed to several factors. These include the dissatisfaction experienced by users of human services, the decline of supportive institutions, and the sociopolitical climate. This popularity exists within a climate of capitalism and its push for individualism.

SHGs have proven to be quite cost-effective. Historically, the United States and Britain have demonstrated the viable existence of SHGs within both a free enterprise health system, and under a centralized national health service. European countries have demonstrated this viability with systems that lie somewhere in between.

Group Participants

SHGs may not be suitable for everyone. Research concerning groups that meet around mental health and/or substance use issues appear to paint a portrait of the typical participant. Despite discrepancies concerning sex, level of education, and class, research suggests that group participants tend to be female, Caucasian, aged between 30 and 50 years, and of middle class. These demographic details reflect research findings concerning self-care practices. In the management of health and mental health, middle-age and middle-class females have been found to have the most success.

Membership surveys within 12-step fellowships portray a slightly different image of the typical member. For instance, a 2007 survey of over 8000 AA members in the United States and Canada indicated that the average age was 47 years and 67% were male. Similarly, a 2009 survey of over 11 000 NA members revealed an average age of 43.5 years, that most members were in full-time employment (61%), and 58% of all members were male.

Research about SHGs suggests that group participants, particularly those with serious mental health and/or substance use issues, tend to be socially isolated. They have markedly reduced social networks, are typically unemployed, and usually not married. This was partly reflected in the aforesaid survey of NA members. A large proportion of respondents indicated that participation had helped to improve family relationships (92%) and/or social connectedness (88%). However, social isolation alone is unlikely to

predict group involvement. Rather, it is likely to be influenced by a combination of factors, including (but not limited to) personal issues, individual attributes, and cultural norms. This was affirmed in the aforesaid surveys of AA members, which suggested that the largest proportion of respondents were married (35%) and employed (65%).

Well-being has also been implicated in the depiction of the typical group participant. Group participants are believed to have experienced very poor mental health, if not a crisis point, a rock bottom, during which they realize change is needed. And most participants come to realize that the change they desire can only result with the help of others. However, some research suggests that group participants participate in a SHG following a period of recovery. This research suggests that group participation necessitates a degree of self-manageability and sociability.

Although group participants may experience poor mental health, if not a crisis, their ill health should not serve to immobilize them. Research suggests that participants need to be somewhat functional, as well as sociable in order to participate effectively. This is partly affirmed in the aforesaid survey of NA members, with the largest proportion indicating their capacities to manage their own affairs, prior to membership (45%). These include employability, ability to retain their own residence, ability to support a family, and the ability to maintain relationships.

From this literature stems three propositions. First, it suggests that the people who experience very poor mental health may not be appropriate candidates for SHGs. Second, it suggests that group participants typically have an extended experience with the issue that brought them to the group, whereby they have reached a low point, or have somewhat progressed. Third, there is a select population of people that may reap the benefits of group involvement. This population predominantly includes those who are between 30 and 50 years of age and who are relatively functional and sociable, despite poor well-being.

REASONS FOR GROUP PARTICIPATION

Most individuals who come to SHGs want change in their personal circumstances. They would like to experience change at a personal level (that is, their well-being and emotional state) and/or at a social level (that is, their connections with support networks). Although SHGs encourage group participants to help each other, group involvement appears to be motivated by an identified need for help, which is not being met elsewhere.

Group participants have often accessed conventional human services to address this need, prior to group

involvement. This finding pertains to groups that specifically meet around substance use issues. This suggests some inadequacies in conventional sources of support.

BENEFITS

Participation in SHGs, particularly in groups that address mental health and/or substance use issues, is associated with several benefits. Beneficiaries include not only the individual participant, but also the group, and the wider community. Although these benefits collectively speak of change, for clarity, they are presented at the personal, social, and structural levels.

Personal Level

Supported by people who share common experiences, group participants have been found to experience behavioral, cognitive, and spiritual transformation. This is made possible through several group processes. For instance, within the group, participants are exposed to others with similar issues. This can normalize, if not promote, the experience, which may be particularly important for those who experience the effects of stigma. Personal issues that were once shameful are transformed into a qualification for group membership. Furthermore, fellow group participants, particularly those who have experienced greater personal growth, also make for positive role models.

Group participants also learn new information and hear an array of opinion. This can improve self-understanding, particularly in relation to the predicament that brought them to the group (for instance, possible external manifestations and/or causes). This serves as a cognitive antidote to personal issues.

In learning new information, group participants become aware of suitable coping strategies and treatments that might be of benefit. They also have a forum in which to discuss fears and concerns about treatments they are ambivalent about. The information shared in SHGs holds particular relevance for group participants, as much of it is born from the experiential knowledge of fellow participants who have had comparable experiences. They are able to compare their personal situation and monitor any progress.

The inherent processes of SHGs can give rise to many personal benefits for group participants. They can develop greater communicative skills, experience an improved ability to control undesirable behaviors, and/or adapt to the issue that initially brought them to the group. Mental health benefits also abound, for group participants are thought to experience a greater

sense of hope, improved self-image and personal identity, and an enhanced self-esteem.

If nothing else, SHGs can offer increased access to helpful support that might otherwise be limited from conventional sources. This advantage becomes apparent when the cessation of undesirable behaviors, like addiction, leaves an individual with excessive time on their hands.

Other noted benefits include the encouragement given to participants to become more active in the management of their own affairs. Exposure to diverse information not only increases appreciation for the diverse views and experiences of others, but also encourages the group participant to self-determine the opinions and/or practices they incorporate into their own knowledge base.

The practice of reciprocal support is an important part of SHGs, whereby group participants support each other. Because the support is offered by people who share similar experiences, it is more likely to meet the needs of the recipient. Yet, more importantly, this process is of benefit to both the helper and the helpee. The importance of reciprocity is demonstrated by the suggested benefits experienced by participants, regardless of whether they adopt a passive or active role in the group. For instance, while the listening audience learns from the insights offered by more verbal group participants, those who share their personal narrative are believed to benefit from the cathartic experience.

Social Level

SHGs are said to offer an environmental antidote to the social isolation often experienced by individuals with substance use issues. They facilitate the development of support networks and a subsequent sense of belonging. This is especially because group participants share similar experiences and (at times) common identities. These networks can serve to increase not only the number of friendships, but also the types of relationships.

The networks developed by group participants have been regarded as particularly beneficial to mental health. It is widely believed that social support acts as a buffer to stress and is thus implicated in the promotion of health. The support offered by SHGs can be both emotional (through affirmation and encouragement) as well as practical (aiding with daily affairs). Yet of particular benefit is the long-term nature of this support and the fact that it can be tapped into when it is most needed.

Changes to support networks can extend beyond the group context. SHGs can play an important role in improving relationships with significant others, either directly or indirectly. In a direct way, some

groups encourage the involvement of family members, friends, and human service providers. This is aptly demonstrated by 12-step fellowships like Al-Anon and Co-Anon, which are specifically for relatives and friends of people with an addiction. This serves to raise awareness of the particular issues faced by the different parties and improve communication channels. In an indirect way, the communicative skills and coping strategies developed in the group can be used to enhance relationships with those outside of the group. This includes family members and friends as well as human service providers. SHGs can provide greater insight into personal issues and available treatments. They can also demystify the jargon typically used by service providers. Armed with this knowledge, group participants become better able to communicate their needs and preferences to others. This demonstrates the relationship between SHGs and other life domains.

Structural Level

SHGs have also been discussed as part of a recovery program. Through their emphasis on empowerment, self-reliance, and reciprocal support, they can efficiently address long-standing problems with conventional human services. SHGs allow the ratio of helper to helpee to be dramatically altered. Furthermore, with improved social functioning, group participants are able to make greater contributions to the wider community. This includes partaking in education and/or employment.

Critical Success Factors

Several factors appear to increase one's propensity to continue involvement in, and derive benefit from a SHG. These include best-fit, structure, the sharing of narratives, reciprocal support, as well as active and prolonged involvement.

Best-Fit

Best-fit between the SHG and the participant appears to be crucial. Continued involvement in a SHG is more likely if an individual believes they share similarities with fellow group participants and is thus compatible. This includes demographic characteristics, personal attributes, and ideology.

Structure

Some SHGs, like 12-step fellowships and GROW, adopt an explicit structure, which directs the group ethos. Such structure is thought to be particularly beneficial for people who have limited social skills or lack of confidence. It provides these individuals with direction

about the way they should engage with the group. It also promotes a framework for learning and subsequent personal development through the use of explanation, repetition, and uniformity.

Narrative Sharing

The disclosure of personal narratives is deemed an essential practice of SHGs, fostering both group intimacy and personal development. This is especially true of groups like 12-step fellowships and GROW, where group participants are encouraged to identify with the successful efforts of fellow participants as they share their own story.

Reciprocal Support

Opportunities for group participants to help each other can benefit both the helper and the helpee. In fact, the benefits of group involvement can diminish when group participants are primarily involved in only one of these roles.

Active and Prolonged Involvement

Active involvement and affiliation are said to influence the perceived usefulness of SHGs. Active participation has several meanings and can refer to efforts both within and beyond the group context. Active participation can include speaking at group meetings, welcoming newcomers, organizing social and/or political events, or performing administrative tasks. It can also refer to the extent to which group philosophies and practices are incorporated into daily life.

GROUP TYPES

12-Step Fellowships

Of all the SHGs that meet around mental health and/or substance use issues, 12-step fellowships are arguably the most well-known. For this reason, they are described in further detail.

Twelve-step fellowships were born with the advent of AA in 1935, when an alcoholic from New York, Bill W, was introduced to Dr Robert S who shared a similar view about recovery. By sharing their personal narratives with each other, they came to recognize the spiritual support they received and the personal strength they developed to work toward sobriety. These experiences helped them to conceive a path for others who are affected by addiction.

Twelve-step fellowships are highly structured, encouraging participants to adhere to a 12-step program. This provides instruction for a manageable lifestyle, particularly for those who experience an addiction, a compulsion, or other behavioral problems. In fact,

there is a 12-step fellowship for a wide array of issues (see Table 14.1), each of which adapts the 12-step program accordingly. For instance, the 12 steps of Cocaine Anonymous are as follows:

1. We admitted we were powerless over cocaine and all other mind-altering substances – that our lives had become unmanageable.
2. Came to believe that a Power greater than ourselves could restore us to sanity.
3. Made a decision to turn our will and our lives over to the care of God as we understood Him.
4. Made a searching and fearless moral inventory of ourselves.
5. Admitted to God, to ourselves, and to another human being the exact nature of our wrongs.
6. Were entirely ready to have God remove all these defects of character.
7. Humbly asked Him to remove our shortcomings.
8. Made a list of all persons we had harmed and became willing to make amends to them all.
9. Made direct amends to such people wherever possible, except when to do so would injure them or others.
10. Continued to take personal inventory, and when we were wrong promptly admitted it.
11. Sought through prayer and meditation to improve our conscious contact with God as we understood Him, praying only for knowledge of His will for us and the power to carry that out.
12. Having had a spiritual awakening as the result of these steps, we tried to carry this message to addicts, and to practice these principles in all our affairs" (Cocaine Anonymous® World Services, 2011).

Twelve traditions guide the meetings stipulating accepted practices and ideology (see Table 14.2 for an example). These offer all subgroups a degree of consistency and means that almost anyone could establish a group or facilitate a meeting with the regular rotation of the facilitator role, or chairperson.

A key belief within the 12-step approach views problem behaviors, like addictions and compulsions, as a disease, rather than a learnt behavior or a symptom of other issues. This disease is believed to manifest psychologically, physically, and spiritually. It is also thought to have an enormous impact on significant others. For this reason, 12-step fellowships also encompass groups for family members and friends of individuals with the disease (see Table 14.3).

Within groups (or chapters), diversity is typically rich with respect to age, cultural background, and socioeconomic status. However, some chapters attempt to target particular populations, like young people, to narrow this diversity. Most groups convene weekly for approximately 90 min. A community agency or religious facility

* Given the absence of a universal and comprehensive database of SHGs, this information is likely to be incomplete.

(like a church hall) is the usual meeting place. However, some meet in a public setting, like a café.

Chapter diversity is also apparent in their foci. For instance, some are “closed” to individuals who identify as having an addiction, while others are open. Some chapters are speaker meetings, at which members share their personal narrative, while other chapters offer greater time for discussion. Furthermore, some chapters (or some of the meetings within a chapter) are devoted to studying the 12 steps and traditions of AA, or the Big Book of AA, a 164-page publication that documents a guide to recovery. To optimize access, 12-step fellowships are also available in alternative (non-face-to-face) forms. This includes the Loners International Meeting, which provides AA in print-form.

Following an opening rite, the chairperson typically acknowledges the need to observe confidentiality and anonymity. The chairperson then invites individual group participants to share their experiences and thoughts, and usually extends this invitation to a different gender consecutively. In accepting this invitation, a group participant will share without interruption or feedback from others, as cross talk is discouraged.

Halfway during the meeting, participants are typically invited to I.D – or identify themselves. They state their first name, the attribute that brought them to the group, and the number of days they have experienced

a manageable life (or, in the case of those with substance use issues, sobriety or clean time). Another identification rite involves marking birthdays, not of biological birth, but birth into recovery. These birthdays are typically recognized at the end of the meeting.

In closing the meeting, the chairperson invites participants to stand and recite a prayer. Despite references to God (also evident in the 12 steps and traditions), participants are encouraged to adopt a personalized understanding of a Higher Power, which can take any desired form. Following the prayer, participants are then encouraged to stay for the second part of the meeting to meet each other informally, and in a more personal way. Group participants also meet at the social activities and annual conventions that are organized within some fellowships. Regular newsletters also serve as a network tool. Funding for these and other expenses come solely from group participants who donate money at the end of meetings.

The 12-step approach advises that the act of helping others aids personal recovery. It is a repeated theme in meetings and manifests in various ways. One key example is that of sponsorship. Senior group participants become mentors to newcomers, offering personalized guidance as they attempt to understand and adhere to the 12-step program. One 12-step fellowship, Alateen, an SHG for young relatives and friends of alcoholics,

TABLE 14.2 Traditions of Alcoholics Anonymous*

- | | | | |
|---|--|----|--|
| 1 | Each member of Alcoholics Anonymous is but a small part of a great whole. AA must continue to live or most of us will surely die. Hence our common welfare comes first. But individual welfare follows close afterward. | 7 | The AA groups themselves ought to be fully supported by the voluntary contributions of their own members. We think that each group should soon achieve this ideal; that any public solicitation of funds using the name of Alcoholics Anonymous is highly dangerous, whether by groups, clubs, hospitals, or other outside agencies; that acceptance of large gifts from any source, or of contributions carrying any obligations whatever, is unwise. Then, too, we view with much concern those AA treasuries which continue, beyond prudent reserves, to accumulate funds for no stated AA purpose. Experience has often warned us that nothing can so surely destroy our spiritual heritage as futile disputes over property, money, and authority. |
| 2 | For our group purpose there is but one ultimate authority – a loving God as He may express Himself in our group conscience. | 8 | Alcoholics Anonymous should remain forever nonprofessional. We define professionalism as the occupation of counseling alcoholics for fees or hire. But we may employ alcoholics where they are going to perform those services for which we might otherwise have to engage nonalcoholics. Such special services may be well recompensed. But our usual AA Twelfth Step work is never to be paid for. |
| 3 | Our membership ought to include all who suffer from alcoholism. Hence we may refuse none who wish to recover. Nor ought AA membership ever depend upon money or conformity. Any two or three alcoholics gathered together for sobriety may call themselves an AA group, provided that, as a group, they have no other affiliation. | 9 | Each AA group needs the least possible organization. Rotating leadership is the best. The small group may elect its secretary, the large group its rotating committee, and the groups of a large metropolitan area their central or intergroup committee, which often employs a full-time secretary. The trustees of the General Service Board are, in effect, our AA General Service Committee. They are the custodians of our AA Tradition and the receivers of voluntary AA contributions by which we maintain our AA's General Service Office at New York. They are authorized by the groups to handle our overall public relations and guarantee the integrity of our principal newspaper, the AA Grapevine. All such representatives are to be guided in the spirit of service, for true leaders in AA are but trusted and experienced servants of the whole. They derive no real authority from their titles; they do not govern. Universal respect is the key to their usefulness. |
| 4 | With respect to its own affairs, each AA group should be responsible to no other authority than its own conscience. But when its plans concern the welfare of neighboring groups also, those groups ought to be consulted. And no group, regional committee, or individual should ever take any action that might greatly affect AA as a whole without conferring with the trustees of the General Service Board. On such issues our common welfare is paramount. | 10 | No AA group or member should ever, in such a way as to implicate AA, express any opinion on outside controversial issues – particularly those of politics, alcohol reform, or sectarian religion. The Alcoholics Anonymous groups oppose no one. Concerning such matters they can express no views whatever. |
| 5 | Each Alcoholics Anonymous group ought to be a spiritual entity having but one primary purpose – that of carrying its message to the alcoholic who still suffers. | 11 | Our relations with the general public should be characterized by personal anonymity. We think AA ought to avoid sensational advertising. Our names and pictures as AA members ought not be broadcast, filmed, or publicly printed. Our public relations should be guided by the principle of attraction rather than promotion. There is never need to praise ourselves. We feel it better to let our friends recommend us. |
| 6 | Problems of money, property, and authority may easily divert us from our primary spiritual aim. We think, therefore, that any considerable property of genuine use to AA should be separately incorporated and managed, thus dividing the material from the spiritual. An AA group, as such, should never go into business. Secondary aids to AA, such as clubs or hospitals which require much property or administration, ought to be incorporated and so set apart that, if necessary, they can be freely discarded by the groups. Hence such facilities ought not to use the AA name. Their management should be the sole responsibility of those people who financially support them. For clubs, AA managers are usually preferred. But hospitals, as well as other places of recuperation, ought to be well outside AA – and medically supervised. While an AA group may cooperate with anyone, such cooperation ought never to go so far as affiliation or endorsement, actual or implied. An AA group can bind itself to no one. | 12 | And finally, we of Alcoholics Anonymous believe that the principle of anonymity has an immense spiritual significance. It reminds us that we are to place principles before personalities; that we are actually to practice a genuine humility. This to the end that our great blessings may never spoil us; that we shall forever live in thankful contemplation of Him who presides over us all. |

TABLE 14.3 12-step Fellowships for Relatives and Friends*

ACA	Adult Children Alcoholics	COSLAA	Codependents of sex and/or love addicts
Al-Anon	For relatives and friends of alcoholics	FA	Families Anonymous for relatives and friends of addicts
Alateen	For young relatives and friends	Gam-Anon	For relatives and friends of gamblers
Co-Anon	For relatives and friends of addicts	Gam-A-Teen	For young relatives and friends of gamblers
CoDA	Codependents Anonymous, for people wanting to develop healthy relationships	Nar-Anon	For relatives and friends of addicts
COSA	Codependents of sex addicts	S-Anon	For relatives and friends of sex addicts

* Given the absence of a universal and comprehensive database of SHGs, this information is likely to be incomplete.

includes examples of a different form of sponsorship. Given that group participants include minors, a participant of an equivalent adult fellowship, like Al-Anon, sponsors the group as a whole. The role of this person is to ensure that young participants understand and adhere to the steps and traditions of the fellowship. The structure in this group tends to have greater flexibility, allowing for discussion during the meetings.

The popularity of 12-step fellowships should not detract from the range of SHGs worldwide that aim to facilitate well-being through peer-driven support. To demonstrate this array, several examples are briefly described.

Other SHGs

Birds of a Feather

Commencing in 1975, this international organization is premised on the principles of AA, offering peer support to active or inactive pilots and cockpit crew members who experience addiction to alcohol and/or other drugs. Group participants convene at individual nests. That is, local groups that gather to work through the 12 steps of recovery.

Calix Society

Founded in 1942, the Calix Society brings together individuals who identify as Catholic and who maintain recovery through affiliation with and participation in AA. As such, it offers a community of faith to individuals working the 12-step program.

GROW

Starting in Australia in 1957, GROW offers a peer-driven community in which mutual support and

friendship are fostered among people who experience mental health issues, including addiction. Reflecting a 12-step fellowship, GROW is premised on a recovery program that encourages individuals to actively address personal issues within a safe and nonthreatening group meeting, this includes the assignment of practical tasks that help to translate the group discussion into daily life.

Moderation Management

Moderation Management is a behavioral change program complemented by a support network for individuals who have a desire to address their use of alcohol and live a healthier lifestyle. This is supported by a nine-step program that offers practical guidance on matters such as ways to monitor alcohol consumption as well as self-management strategies.

Save Our Selves

Commencing with an article in 1985, the SOS provides a nonreligious and nonspiritual alternative to 12-step fellowships. It aims to support individuals who may be uncomfortable with the spiritual components of 12-step fellowships, by encouraging individuals to assume active responsibility for their recovery. This is further reflected in the organization's recognition of science to understand and address addiction.

Self Management and Recovery Training

SMART (Self Management and Recovery Training) Recovery brings together individuals with a shared experience to offer a unique type of support. Although it integrates elements of cognitive behavior therapy and motivational interviewing and espouses seven stages of change, it is situated in the self-help paradigm, valuing non-commodified experiential wisdom.

Women for Sobriety

Since 1976, WFS has provided peer support to women who aim to remain abstinent from alcohol and other drugs. This is demonstrated through its SHGs, during which women work through a 13-step program that espouses positivity and personal growth. This program is said to enable women to form a personalized journey toward long-term recovery.

CRITICISMS

Some groups, like 12-step fellowships, have been criticized for their practices. This includes the practice of self-labeling. Group participants are encouraged to identify (at least within the group) with the issue that initially brought them to the fellowship, for instance, as an alcoholic and/or addict. These issues are considered life-long diseases, for group participants are never recovered, but are always in recovery. This concern is not isolated to 12-step fellowships, but also extends to other SHGs.

Furthermore, it is believed that the life-long disease of group participants cannot be managed independently. It requires life-long involvement in a 12-step fellowship. This has been criticized as transferring one's addiction to another form of dependency, that of group membership. This can serve to absorb the individual into one particular lifestyle, much to the exclusion of all other activity, thus limiting personal growth and re-engagement with family or broader social networks.

The quest for abstinence, as opposed to moderation, is also questioned in the literature. Twelve step fellowships endorse complete sobriety from substance use for those who identify with an addiction (bar nicotine and prescribed medications). Yet this somewhat conflicts with harm minimization practices. Although recent research suggests that the two approaches can be complementary, many argue that the aim of harm minimization is to reduce drug-related harm, and abstinence is but one method toward this.

Furthermore, if one does not agree with 12-step beliefs and practices, the dissenter is typically considered not ready for the fellowship, akin to the notion of denial. This view tends to regard the nonconformist as unenlightened and perhaps inferior to group participants.

Literature highlights additional drawbacks associated with SHGs. However, most are born from the concerns of authors, human service providers, or potential group participants, not empirical research with current group participants. Some authors for instance, argue that SHGs are mere examples of the blind leading the blind. Group participants are thought to be provided

with false or misleading information from peers who lack academic credentials. This is further compounded by the lack of accountability often found in SHGs.

It is also thought that associating with people in similar situations may actually propagate undesirable behaviors and encourage the acquisition of stigmatized identities. This is a particular concern for young people who are thought to be impressionable. However, recent research suggests that this is not necessarily the case.

There are concerns that SHGs deter group participants from conventional human services, and that this may justify funding reductions to the human services sector. In contrast to this, others suggest that negative group experiences will leave service providers with a greater workload in having to pick up the pieces. This view is firmly juxtaposed by recent research, which found SHGs served to re-engage individuals with conventional human services.

There are also concerns about the practices of particular groups. Some practices are thought to be too lax, too structured, or suspect in their effectiveness. This includes the use of peer pressure to encourage conformity among group participants. An additional matter is the stigma often associated with substance use issues. This can serve to deter potential participants. Furthermore, it is argued that some SHGs, like 12-step fellowships, do nothing to address the problem of stigma. They simply medicalize the issue to increase social acceptability.

Despite the aforementioned concerns about SHGs, research suggests that the concerns of those actually involved in these groups are far more moderate. Collectively, the studies speak of problems associated with the operational structures of a group or its processes. In reference to the structures, some individuals have found the 12-step approach limiting. They believe that it fails to appreciate the complexities of their personal situation. This problem becomes particularly evident when individuals concurrently access human service providers who operate from a different paradigm.

A number of other problems in SHGs have been identified. These include a lack of strong leadership, a leadership role that is not shared among group participants, disorganized agendas, and groups that are stagnant.

The processes and dynamics that unfold within the group can also be problematic. For some individuals, this includes the presence of those who behave inappropriately, fail to demonstrate empathy, or breach confidentiality. Others have found their group experiences to diminish personal well-being, leaving them feeling overwhelmed or less efficacious. This is particularly the case when there is sole focus on the problems associated with substance use issues.

Further to this is the negativity of fellow group participants, which can even lead to the termination of group

involvement. This is a possible concern of all SHGs, particularly those that meet around chronic conditions, like substance use issues. However, some researchers argue that group participants cannot be sheltered from reality forever, but the truth must be delivered in a timely fashion. For if this truth falls on unprepared ears, the group experience may be discouraging and unhelpful.

These aforesaid problems are not exclusive to SHGs. They hold relevance to other group environments. Nevertheless, ideal group conditions are still no guarantee that experiences with a SHG will be favorable.

Without wanting to detract from the possible weaknesses of SHGs, the aforesaid problems might simply reflect limited fit between the group and the individual. However, some researchers advise that the complexities of this relationship should not be used to justify negative research findings.

Like formal treatments, SHGs may not be appropriate for all individuals who experience substance use issues. However, like formal treatments, the potential value of SHGs may be optimized when complemented by other resources and support systems, like human services. This is supported by current literature.

SUMMARY

SHGs can form an important part of recovery for people who experience substance use issues. Through the provision of noncommodified peer support, they can facilitate personal, social, and structural change. Furthermore, given their relative accessibility, SHGs can help to sustain such change. More specifically, they are economically accessible, as no fees are required. Typically, they are geographically accessible, given the number of established groups and chapters. They are also cognitively accessible, as group participants can self-determine their degree of involvement.

Caution is warranted before becoming overly optimistic about the preponderance of positive findings. There are inherent methodological issues in many studies to date, these include the reliance on self-reports from group participants, the use of retrospective data, the lack of comparison groups, and the use of cross-sectional designs. Notwithstanding some methodological exceptions, a systematic review of 12-step fellowships for alcohol dependence identified a need for more efficacy studies (Ferri et al., 2006).

Although SHGs may not be the panacea for everyone with substance use issues, several factors appear to increase their perceived value. These include best fit between the group and the participant, a structure that guides group processes, the sharing of personal narratives, the reciprocity of support, as well as active and prolonged group involvement. Some of these factors

appear to reflect those associated with successful treatments.

Given the complex and chronic nature of substance use issues, SHGs may be best perceived as a supplement to a suite of strategies toward recovery. This is because SHGs can offer a unique type of support (be it psychological or practical) and can be accessed if, and when deemed appropriate by the individual.

Glossary

- Disease concept** although not officially promulgated by 12-step fellowships, this term conceives addiction as a ailment with psychological, physical, and spiritual dimensions.
- Higher power** a belief in a greater entity that helps to relinquish control over perceived willpower and embrace hope for personal growth and recovery.
- Powerlessness** a belief that individuals who experience an addiction largely lack the capacity to control their destructive behaviors.
- Sponsor** a member of a 12-step fellowship who mentors newcomers by providing guidance to work the 12-steps, sharing personal experiences, and provides support toward recovery.

WHAT IS TWELVE-STEP FACILITATION THERAPY?

In the literature on the treatment of substance dependence, authors typically refer to Twelve-Step Facilitation (TSF) Therapy as a specific, structured, and manual-based intervention that is delivered by professionals to persons with alcohol and/or other drug dependence. TSF Therapy has multiple objectives that support two overarching goals: (1) to increase abstinence from alcohol and other non-medically indicated psychoactive drugs and (2) to increase participation in Twelve-Step Organizations (TSOs) such as Alcoholics Anonymous (AA) and/or Narcotics Anonymous (NA).

The first goal of TSF Therapy is based on a conception of substance dependence as a chronic, incurable disease that is characterized by an inability to control the amount of a specific substance that is consumed. The goal of abstinence and the conception that undergirds it have generated much controversy and debate over the years. Nevertheless, they are endorsed generally

by the American public and leading health organizations in the United States and many countries worldwide. The goal and conception are supported by most relevant research. Whereas some studies suggest that controlled drinking may be possible for persons with less severe alcohol problems, most indicate that it is not a practical goal for persons with alcohol dependence. There is considerable evidence that the etiology of substance dependence is influenced by genetic or other physiological factors that lessen the capacity of certain people to control their level of consumption. Moreover, people who abstain from alcohol and drugs following substance-dependence treatment experience significant physical, psychological, and social improvements relative to those who use varying amounts of these substances in the posttreatment period.

The second goal of TSF Therapy is based on a conception that TSOs are uniquely suited to assist substance-dependent persons in achieving abstinence. Evaluating this conception empirically has been challenging as ethical and practical constraints have precluded using

randomized clinical trials (RCTs) to examine the relative effectiveness of participating in these organizations. Nonetheless, observational studies have consistently shown that participation in TSOs following substance-dependence treatment is associated with higher levels of abstinence and psychosocial functioning. These findings have emerged from studies that used objective measures of TSO participation and substance use, included long-term follow-up assessments, and controlled statistically for motivational and other potentially confounding factors.

As has been stated often by others, participating in TSF Therapy and TSOs are separate experiences. Whereas TSF Therapy is a professionally delivered and time-limited intervention designed to prepare substance-dependent persons to achieve abstinence, TSOs provide interventions that are delivered by peers in the community and designed to provide assistance for sober living on an ongoing or continuous basis. On the other hand, the two interventions share common conceptions about substance dependence and the most effective ways to address it. Because TSF Therapy is based on principles and practices of TSOs, it cannot be fully understood without adequate knowledge of the nature of these organizations.

WHAT ARE TSOs?

TSOs primarily serve people who are dependent on a psychoactive substance or who engage in some other compulsive behavior such as gambling or excessive eating. AA is the original TSO and the one on which all the others are based. It took shape in the mid-1930s in two cities (Akron and New York) in the northeastern United States. NA was established a decade or two later in Los Angeles. TSOs also exist for persons who are concerned about a family member or a friend who has a substance-dependence problem and/or who engages in some other compulsive behavior. Ala-Anon was the first TSO for significant others, founded in the early 1950s for the purpose of assisting family and friends of alcoholics.

The TSOs that target persons with substance dependence tend to be international in scope and are governed by a set of 12 traditions and a highly democratic structure. They are decentralized entities, with a central office serving a coordinating role and relatively autonomous, individual chapters located in communities throughout the world. Leadership is provided largely by participants on a voluntary, nonpaid, and rotating basis. With their emphasis on anonymity, TSOs maintain no rosters or lists of members. Moreover, they do not charge fees or require a written or verbal commitment to join. These organizations do not take public positions on controversial issues,

including those related to substance use. They have rules that prevent individuals or entities from exercising inordinate influence on any of their policies or practices.

The 12-step approach for addressing addictive behaviors advocated by these organizations has remained remarkably consistent over time. As with TSF Therapy, the 12-step approach conceptualizes substance dependence as an incurable disease or a condition that has physical, emotional, and spiritual concomitants. The approach is not preoccupied with whether the concomitants are causes or consequences of substance dependence; it is also not preoccupied with whether or not substance dependence satisfies criteria of a true disease. The approach does maintain that the continued use of substances by dependent persons will inevitably lead to more physical, emotional, and spiritual problems. The 12-step approach also holds that the best, if not the only, way that dependent persons can avoid substance use and associated problems is through ongoing participation in TSOs.

The 12 steps for AA are listed in Table 15.1. They are ordered sequentially to reflect the process of recovery. In the parlance of influential, *subsequently developed* psychological theories that have shaped understanding of behavioral change, Steps 1–3 are concerned with preparation, Steps 4–9 are concerned with action, and Steps 10–12 are concerned with maintenance. However, most experienced participants in TSOs report using many if not all of the 12 steps on a regular basis. The steps place a heavy emphasis on spirituality that is absent from most empirically validated theories of behavioral change. Honesty, humility, atonement, service to others, and reliance on God or a higher power are specified as ingredients for recovery. Nonetheless, participants are granted considerable latitude in interpreting the meaning of each step as well as the strategies they may use to work it. Most notably, they are allowed or even encouraged to conceptualize God or a higher power in whatever way they choose. Whereas the majority of participants in TSOs conceptualize a personal, forgiving God that is consistent with Christian precepts, others conceptualize specific worldly forces (e.g. nature, a TSO) as their higher power.

People can participate in TSOs in a variety of ways, including working the 12 steps, attending mutual help group meetings, reading organizational literature, using a sponsor, and eventually sponsoring another member. Among these different activities, meeting attendance and sponsorship have received the most emphasis by clinicians and researchers.

The meetings of TSOs are normally held in public settings such as churches, treatment centers, or hospitals. They are led by temporary chairpersons, who typically begin them by reciting a nonsectarian prayer and reading the organization's guidelines. The meetings are then

TABLE 15.1 The 12 Steps of AA

1. We admitted that we were powerless over alcohol – that our lives had become unmanageable.
2. Came to believe that a power greater than ourselves could restore us to sanity.
3. Made a decision to turn our will and our lives over to God as we understood Him.
4. Made a searching and fearless moral inventory of ourselves.
5. Admitted to God, to ourselves, and to another human being the exact nature of our wrongs.
6. Were entirely ready to have God remove all these defects of character.
7. Humbly asked Him to remove our shortcomings.
8. Made a list of all persons we had harmed and became willing to make amends to all of them
9. Made direct amends to such persons wherever possible, except when to do so would injure them or others.
10. Continued to take personal inventory and when we were wrong promptly admitted it.
11. Sought through prayer and meditation to improve our conscious contact with God, as we understood Him, praying only for knowledge of His will for us and the power to carry that out.
12. Having had a spiritual awakening as a result of these steps, we tried to carry this message to alcoholics and to practice these principles in all our affairs.

conducted generally according to one of two formats. In the speaker format, one or two participants share their story, talking at length about their experiences with substance dependence and the TSO. In the discussion format, participants take turns talking about various topics related to substance dependence and recovery.

A sponsor is an experienced member of a TSO who provides guidance and support to another member with a typically shorter period of abstinence. The nature of this guidance and support can vary considerably depending on the expectations of members who are sponsoring or being sponsored. A sponsor serves as a resource for a member to call for advice or consultation and often provides guidance on working the 12 steps.

Several multi-item survey instruments have been developed to tap involvement in specific TSO activities. These instruments have been used in research on predictors and outcomes of TSO participation. Studies of predictors have found that persons with more severe substance dependency, higher network support for substance use, and who perceive more benefits than barriers to participating in TSOs subsequently have higher levels of participation. Studies on outcomes have found that attending meetings and using a sponsor are positively associated with subsequent levels of abstinence and psychosocial functioning.

TSOs AND PROFESSIONAL TREATMENT

AA emerged in the midst of the Great Depression and in the aftermath of the Prohibition Period in the United States. Alcoholism and other forms of substance dependence were highly stigmatized conditions that generated limited public sympathy. Most hospitals in urban areas did not welcome alcoholics for treatment but were compelled to serve those who presented acute medical issues. Treatment resources were devoted mostly to detoxification and alcoholic-related morbidity, with limited attention given to assisting alcoholics to maintain abstinence following detoxification. With its focus on maintaining sobriety, AA led to a shift in treatment emphasis from managing acute aspects of substance dependence to facilitating long-term sobriety in the community.

With its early success, the AA organization gave consideration to operating treatment programs for alcoholics. However, a policy of independence was soon adopted that declared that the organization would not become involved directly in treatment endeavors. Be that as it may, AA and other TSOs have never precluded participants from establishing or working in alcohol treatment programs. Early participants in AA were instrumental in the development of new programs that were established as separate units in general hospitals in Akron and New York City. Physicians and nurses supervised the detoxification process and attended to other medical needs that were presented by the patients. Volunteer and paid staff members who were also AA participants provided an intensive indoctrination to the AA approach through educational classes as well as individual and group counseling sessions. Patients read AA literature, attended AA meetings held in the hospital or surrounding community, and worked on the 12 steps. Sponsorship was emphasized heavily: some programs required patients to have a sponsor at the time of admission and/or would discharge patients only in the presence of their sponsors.

The 12-step approach of AA provided a treatment model that could be adopted by other programs. As news about AA spread and chapters formed in more cities, additional 12-step-based treatment programs surfaced in general hospitals and other settings (e.g. private, free-standing facilities, public psychiatric hospitals, and prisons). The additional programs tended to extend and expand on the original model established in Akron and New York City, delivering more services through a longer length of stay.

A program that was developed in Minnesota, initially at Willmar State Psychiatric Hospital and later at the private Hazelden Foundation, evolved to represent the exemplary 12-Step Model of substance-dependence treatment. As with TSF Therapy, the Minnesota/Hazelden or

12-Step Model aimed to motivate patients to accept substance dependence as an illness, abstinence as the only viable solution, and AA or other TSOs as the vehicle to achieve the solution. The program was designed for a 28-day stay, which became the standard duration of 12-step-based treatment programs. It was distinguished by a philosophy of genuine respect toward patients. Treatment was administered in a voluntary and noncoercive manner, with patients housed generally in unlocked units and not prevented or unduly pressured from discharging themselves against medical advice. Moreover, the 12-Step Model bolstered the status and potential usefulness of alcoholics by maintaining that they were uniquely qualified to help others to recover from alcoholism.

Although counselors who were active in AA or other TSOs became the cornerstones of 12-step-based programs, other recovering and non-recovering professionals were hired to assist with the emotional, spiritual, and physical concomitants of substance dependence. Many programs used family therapists to assist spouses, parents, children, and siblings who may have been affected adversely by a patient's substance use but in a position to influence his/her recovery. Other professional staff included clergy members who helped patients with spiritual aspects of the TSO approach and recreational therapists who aided patients to develop new interests and activities as alternatives to using substances.

The Minnesota/Hazelden or 12-Step Model has been evaluated empirically in diverse populations. The model has been compared to other forms of treatment in quasi-experimental and randomized experimental designs. These studies mostly have found higher rates of abstinence, psychosocial functioning, and participation in TSOs among those who received 12-step-oriented treatment.

THE STRUCTURE AND COMPONENTS OF TSF THERAPY

TSF Therapy was manualized for implementation in a large, multisite RCT known as Project MATCH, or Matching Alcoholism Treatments to Client Heterogeneity. Funded by the National Institute on Alcohol Abuse and Alcoholism, Project MATCH was conducted in the early to mid-1990s for the primary purpose of determining whether specific client characteristics moderated the effects of TSF and two other treatments for alcohol dependence.

The TSF Therapy Manual developed for Project MATCH specifies that therapists deliver 12 weekly individualized sessions. Table 15.2 presents the topic, purpose, and one sample activity for each of the

sessions. Project MATCH was delivered to persons who were dependent on alcohol but not on cocaine, stimulants, or opiates and thus AA was presumed to be the most appropriate TSO for them to participate. Since the TSF Manual refers specifically to AA and not other TSOs, this description of the TSF intervention also refers only to AA. However, as described below, the TSF Manual has been used as a guiding framework in interventions with persons with other types of substance dependence who were encouraged to participate in TSOs more broadly.

The TSF Manual includes additional guidelines for therapists that are informative about the nature of the TSF intervention. The guidelines refer to therapists as "facilitators," "resources," and "advocates" of the 12-step approach. Therapists are instructed to adhere to 12-step conceptions and philosophy as well as to advocate continuously for the TSF goals of abstinence and AA participation. Therapists are advised to perceive any resistance to these goals as acts of denial and as justification for using "nonjudgmental confrontation" with the patients. That is, when perceiving resistance from patients, therapists are expected to express concerns in a direct, honest, caring, and noncritical manner. At the same time, therapists are cautioned against using heavy-handed or controlling tactics. The guidelines state that therapists do not need to be personally recovering from alcohol dependence but they do need to be knowledgeable of AA philosophy, literature, and vernacular. To be qualified to deliver the TSF intervention, therapists are expected to have attended at least 20 AA meetings and to be able to refer patients to specific meetings and potential sponsors.

Session 1

The first session provides an introduction to the TSF intervention. It has a unique format consisting of two parts. In the first part, patients are asked about their alcohol use, alcohol-related consequences, and prior attempts to decrease or discontinue drinking. It is designed to conclude with the patients being informed that their responses indicate they have developed tolerance and loss of control in relation to drinking and that these consequences are indicative of alcohol dependence. In the second part of the introductory session, patients are presented a descriptive overview of TSF Therapy with its dual goals of abstinence and AA participation.

The abstinence goal is straightforward. The manual instructs therapists that it applies to alcohol and other psychoactive substances that are not medically necessary. In contrast, the second goal is more ambiguous given the different ways and amounts that patients can participate in TSOs. The TSF Manual provides some specificity for this goal by instructing therapists to give

TABLE 15.2 Structure of TSF Therapy as Specified for Project MATCH

Session Number and Topic	Purpose	Sample Activities
1. Introduction	Stimulate clients' interest in participating in AA	Clients document their history of alcohol use and consequences
2. Acceptance	Facilitate clients' acceptance of their alcohol dependence	Clients interpret and discuss Step 1
3. Surrender	Facilitate clients' commitment to attend AA meetings	Clients interpret and discuss Steps 2 and 3
4. Getting Active	Encourage clients' involvement in different AA activities	Clients identify three desirable characteristics in a sponsor
5. Genogram	Depict intergenerational nature of alcohol dependency and its implications for clients	Clients construct a family history of alcohol dependence across three generations
6. Enabling	Increase clients' commitment to address enabling relationships	Clients are encouraged to address three enabling relationships
7. People, Places, and Things	Illuminate common risk factors for relapse in clients' lives	Clients complete a lifestyle contract detailing actions they will take to reduce relapse risk
8. Hungry, Angry, Lonely, and Tired	Continued focus on risk factors for relapse in clients' lives	Clients write a goodbye letter to alcohol
9. Moral Inventory	Promote honest self-appraisal and release guilt among clients	Clients identify their character defects and assets
10. Sober Living	Promote lifestyle changes	Clients are encouraged to set goals for nutrition and exercise
11. Conjoint Therapy	Garner partner support for clients' recovery	Partners are asked about their alcohol use and informed about AA
12. Termination	Promote continued abstinence and participation in AA	Clients are asked to make commitments to continue to participate in AA

Note: TSOs = Twelve-step organizations

patients a list of meetings in their geographical areas of residence and to ask the patients to indicate the number of meetings they plan to attend over the ensuing week. Patients are also asked at this time to commit to read specific AA literature over the ensuing week. Therapists are instructed not to require patients to attend a specific number of meetings or to read a specific amount of literature. However, they are expected to encourage patients to attend an average of one meeting per day over a 90-day period, which is consistent with recommendations made within AA itself. At a later point of the intervention, additional specificity is provided for the second goal when patients are strongly encouraged to obtain a sponsor. The TSF Manual specifies criteria for sponsors, which include being of the same sex as well as having maintained continuous abstinence for at least the preceding 12 months.

The structure of the first session conforms to value expectancy theoretical frameworks like the Health Belief Model and the Theory of Planned Behavior that have guided the implementation and delivery of numerous interventions to reduce unhealthy behaviors. TSF assumes that people who are alcohol dependent will value or favor abstinence when they are presented

with a clear, readily implemented behavioral alternative to alcohol use. Thus, the first session is structured first to sensitize alcohol-dependent patients to the need to abstain and then to present AA as a suitable or appealing mechanism through which this change can be readily achieved.

Sessions 2–11

Among the 10 interim sessions, three cover core or essential topics that are intended to be delivered to all patients immediately following the introductory session. The remaining seven sessions can cover various elective topics or repeat core topics. Additional information about the intervention is provided in the following descriptions of the sessions.

Three-Part Format

The interim sessions follow a standard three-part format. For the first part, the manual instructs therapists to conduct a review of the patients' experiences with drinking and AA participation since the prior session. Patients may be asked to share any feelings or thoughts in relation to these goals that have been recorded in journals that they are expected to use. Therapists are advised

to extend congratulations for nondrinking days and to react in nonjudgmental ways to any “slips” that may have occurred, interpreting instances of the latter as direct manifestations of the disease of alcoholism. Patients are also asked about their AA participation since the prior session, including the number of meetings attended and specific literature read. To the extent patients have participated, they can be asked about their reactions to these activities. Any patients who report negative reactions to specific meetings and/or literature should be referred to alternative meetings and readings. Any patients who report that they have not participated in AA should be queried about their reasons for this in a firm but noncoercive manner.

In the second part of these sessions, therapists present new material and activities corresponding to one of the core or elective topics. They are allowed some flexibility when presenting new material in the second part “so long as the presentation remains consistent with the AA view of alcoholism.” The manual designates therapeutic activities that can be used during this part to facilitate progress toward the TSF goals.

In the third part, therapists suggest recovery tasks and activities that patients can implement in the ensuing week to reinforce the topical material and activities that are covered in each session. The recovery tasks and activities may touch on specific core or elective topics but concentrate on promoting engagement in AA. Consistent with AA practice, the manual advises therapists to present the tasks or activities as suggestions and not assignments. Patients are asked to indicate a specific number of AA meetings they will attend and specific literature they will read following each session.

Brief Description of Interim Sessions

As indicated above, [Table 15.2](#) depicts the topic, purpose, and one sample activity for each of the interim sessions. Session 2 deals with Step 1 of AA and is designed to help patients accept that they are dependent on alcohol and need to receive external help for the condition. The manual advises therapists that acceptance often occurs in stages and encourages them to exercise patience with clients who are working through the process.

Session 3 focuses on Steps 2 and 3 of AA. It aims to facilitate surrender of self-reliance and acceptance of the AA approach. Patients are asked questions for the purposes of reminding them how they have lost control over alcohol and prompting them to contemplate the benefits of abstinence, spirituality, and the social support of AA participants.

Session 4 aims to enhance the patients’ motivation to participate in AA. Therapists explain the greatest benefits accrue to those who participate fully in AA activities. Patients are encouraged to develop a supportive social

network by asking participants for phone numbers and permission to call them. Many AA participants seek support, advice, and understanding through telephone conversations with other members. However, the use of the telephone for such conversations has been understudied.

Session 5, the first to cover an elective topic, leads patients through the process of developing a genogram for family alcoholism. The manual states that a genogram is intended “to reinforce the concept of alcoholism as a disease and to motivate the patient to break the cycle of addiction by working the AA program.” Though producing a genogram for family alcoholism would be expected to increase patients’ acceptance of their alcoholism and increase their motivation to change, it is unclear whether or not this notion has been confirmed through empirical methods. Among patients with a limited family history, the genogram exercise may serve instead to reduce acceptance of an alcohol problem and motivation to change.

Sessions 6, 7, and 8 are intended to facilitate continued abstinence and AA participation by attending to malleable risk factors for drinking that may operate in the patients’ lives. Accordingly, Session 6 covers ways that significant others may have intentionally or unintentionally encouraged the patients’ drinking behaviors. It may be conducted only with the patients or conjointly with their significant others. Session 7 illuminates how patients need to make changes in relation to certain people, places, and things that have contributed to their drinking. Session 8 emphasizes the importance of avoiding or minimizing adverse physical and emotional states such as hunger, anger, loneliness, and feeling tired.

Session 9 examines Steps 4 and 5 of AA, which, respectively, calls for constructing a moral inventory and sharing its contents with another person. The act of constructing a moral inventory of one’s strengths and limitations is presumed to produce more self-awareness and a balanced self-concept. The act of sharing the inventory is believed to relieve guilt and to promote trust in others. However, as with the genogram, the discrete effects of performing Steps 4 and 5 have not been carefully evaluated through empirical studies.

Session 10 is aimed toward assisting patients to develop a healthy lifestyle. Patients are asked to discuss how their alcohol use harmed their diet and restricted their involvement in exercise and hobbies. Patients are also asked to set goals for proper nutrition, exercise, and hobbies.

Session 11 is used for conjoint therapy or to repeat a core or an elective topic. If conducted as conjoint therapy with a significant other, the session may focus on the need for appropriate detachment. The manual indicates that significant others can appropriately detach by allowing the alcoholic-dependent persons in

their lives to experience and manage the negative consequences of their drinking. Al-Anon is described as a resource that significant others can use to cope effectively with instances of alcohol dependence among family members and friends.

Session 12

The last session provides a termination for the therapeutic intervention. Through a series of questions, patients are asked to evaluate the intervention and to reflect on how it has influenced or affected them. They are queried about ways that the experience has altered their views toward alcoholism and AA, which can illustrate specific changes that have occurred. Patients are encouraged to set goals for AA participation in the post-treatment period, which can improve the likelihood that the changes will be maintained or enhanced over time.

EVALUATIONS OF TSF THERAPY DELIVERED IN PROJECT MATCH

The TSF intervention has been rigorously evaluated through at least six RCTs. Project MATCH generated the first and most exemplary evaluation. The sample for this project included 1724 alcohol-dependent individuals who were enrolled in either outpatient ($n=772$) or aftercare ($n=952$) programs located in geographically diverse areas across the United States. Within each type of program, the study participants were randomly assigned to receive TSF, CBT, or Motivational Enhancement Therapy (MET) for a 3-month period. CBT was designed primarily to teach or instill skills to avoid relapse and to enhance general coping. MET was designed primarily to help patients recognize the need for change and assist them to channel their internal motivational resources for the purpose of addressing their alcohol problems.

The therapists who delivered the treatments in Project MATCH were selected to be representative of the types of therapists who would deliver these treatments in settings across the country. This feature resulted in a few systematic differences in therapist characteristics between the three conditions. Compared to therapists delivering CBT and MET, those delivering TSF were less educated and more likely to have participated in AA.

Although Project MATCH was intended primarily to test hypotheses related to treatment matching, the rigor with which it was conducted has provided the strongest test to date on the relative effectiveness of TSF in relation to its goals of promoting abstinence and AA participation. The sample was large and geographically diverse, albeit more stable socially than the population of persons who receive treatment for alcohol dependence in the United States. The therapists who worked on

the project received extensive training, supervision, and monitoring to ensure fidelity to the treatment protocols. Biological and collateral data were used along with self-reported data to assess substance-use outcomes among all participants at 3-month intervals for 1 year following treatment completion and for participants in outpatient programs at 3 years following treatment completion. Follow-up rates were excellent, with more than 90% of the participants being retained at each assessment over the first 12 months of follow-up and roughly 85% of the outpatient sample retained at the 36-month follow-up.

Effects of TSF Therapy on AA Participation

The effects of TSF Therapy on participation in AA have been investigated extensively with data from Project MATCH. The findings have shown higher levels of AA participation among patients assigned to TSF than patients assigned to the other treatments. These findings were expected given that TSF was the only one of the three treatments that advocated strongly for such participation. Notably, however, substantial proportions of the patients who received CBT and MET also participated in AA in varying degrees over the follow-up period.

Effects of TSF Therapy on Abstinence

Project MATCH compared the effects of the three treatments on two alcohol consumption variables: (1) percentage of days abstinent (PDA) and (2) drinks per drinking day (DDD). Analyses of these variables revealed no robust or consistent differences between CBT, MET, and TSF. However, when reviewing findings on these variables at specific assessment points, TSF performed somewhat better than the other treatments in the analyses of PDA scores. Accordingly, participants who received TSF had significantly higher PDA scores than those who received CBT or MET in the aftercare sample at the 15-month follow-up as well as in the outpatient sample at the 36-month follow-up. The effects of TSF Therapy on abstinence at these assessment points were found to be at least partly mediated by AA participation (i.e. participants in TSF had higher rates of abstinence as a result of participating more in AA).

The relative benefits of TSF on PDA as opposed to DDD are sensible when considering the emphasis placed by TSF and AA on total abstinence as an essential goal. Discussions that occur in the TSF sessions as well as AA meetings and literature focus on strategies to avoid the first use of alcohol. Controlled use of alcohol is antithetical to AA precepts, and participants are discouraged from considering it as a viable possibility. The delayed effect of TSF on abstinence also seems sensible when considering that TSF was the only one of the three interventions that promoted continued use

of an abstinence-oriented, community-based resource following treatment completion.

Patient Characteristics as Moderators of TSF Therapy

Project MATCH assessed numerous patient characteristics as potential matching variables, or moderators of treatment effects, on PDA and DDD. Ten of the matching variables were designated as primary and 11 as secondary. Two reliable patient characteristic \times treatment interactions involving the TSF outpatient sample have emerged in reported analyses of the primary matching variables. First, among patients with low psychiatric severity, PDA scores at the 15-month follow-up were higher for TSF than for CBT. Second, among patients who had social networks that were highly supportive of drinking at baseline, PDA scores were higher at the 15- and 36-month follow-up in TSF than in MET, and higher in TSF than CBT at the 36-month follow-up. Among the different patient characteristics examined as secondary matching variables, only one (i.e. degree of alcohol dependence) was found to moderate the effects of TSF aftercare treatment on PDA and DDD. More specifically, aftercare patients with high alcohol dependence had better outcomes when treated with TSF than CBT; conversely, aftercare participants who were relatively low in alcohol dependence had better outcomes with CBT than TSF.

In terms of outpatient treatment, the findings indicated that TSF was more effective than the other treatments for persons who had low levels of psychiatric severity, high levels of alcohol dependence, and social networks characterized by high levels of alcohol use. These findings are logical when considering the nature of alcohol dependence and TSF's emphasis on total abstinence and participation in TSOs. Accordingly, alcohol dependence is a chronic condition that is remitted by practicing abstinence. People who are in remission from alcohol dependence continue to face the threat of relapse to drinking. The threat of relapse is larger among persons who are more severely dependent. Participation in TSOs includes activities that promote continuous vigilance to this threat. These activities provide opportunities to interact in an alternative social environment, but they may contribute to anxiety among persons with high psychiatric severity.

EVALUATIONS OF TSF THERAPY IN OTHER RCTs

Since the outcome data were disseminated from Project MATCH, results have been published from at least five other RCTs that compared TSF with CBT or a related form of psychotherapy as treatments for

substance dependence. The subsequent RCTs have differed methodologically from Project MATCH in significant ways. First, the subsequent RCTs have been conducted with smaller samples and have experienced more attrition, thereby resulting in less statistical power than in Project MATCH. Second, the subsequent RCTs have recruited samples from specific geographic areas and thus have been less geographically representative than the one in Project MATCH. Third, the patients in the subsequent RCTs have possessed a comorbid condition (e.g. major depression, opiate dependence, cocaine dependence, domestic violence perpetration) that was one exclusion criteria in Project MATCH. Fourth, the subsequent RCTs have addressed the comorbid conditions with various interventions (e.g. antidepressant medications, methadone maintenance (MM), exercises to control violent tendencies) that were not provided in Project MATCH. Fifth, the treatments delivered in three of the subsequent RCTs have varied in intensity and length from Project MATCH, with one including 10 weekly sessions and two including more than 12 sessions delivered over periods longer than 12 weeks. Sixth, the level of training of therapists has varied across the subsequent RCTs as well as systematically between conditions in the same RCT, with the latter introducing a potential confound that was not present in Project MATCH. Seventh, the format for delivery of TSF and comparison therapies also has differed across the subsequent RCTs: two trials used individual sessions exclusively as was done in Project MATCH, two used therapeutic groups alone, and one combined therapeutic groups and individual sessions. Eighth, the assessment strategies in the subsequent trials have diverged from Project MATCH as well as among themselves, with some reporting posttest but no follow-up results, some not reporting any results for biological measures of substance use, and some not reporting if TSF had any effect on participation in TSOs. Even though these methodological variations constrain comparisons of results between the subsequent RCTs and Project MATCH, as well as among the subsequent RCTs themselves, they have expanded knowledge regarding the effectiveness of slightly varied forms of TSF for persons with different types of substance-dependence and comorbid conditions.

The first of the subsequent RCTs to publish results was conducted in New Haven, Connecticut. It included a sample of 122 patients who were diagnosed with cocaine dependence as well as alcohol dependence or abuse. This RCT had five conditions: (1) TSF with disulfiram, (2) TSF without disulfiram, (3) CBT with disulfiram, (4) CBT without disulfiram, and (5) disulfiram with clinical management (CM). Disulfiram, which is a medication that has been prescribed for alcoholism for more than 50 years, produces adverse physical

reactions (e.g. nausea, headache) in persons who consume alcohol. The CM condition provided nonspecific psychotherapy primarily for the purpose of promoting adherence to disulfiram. Post-baseline assessments of PDA for cocaine and alcohol occurred at the end of treatment (i.e. 3-month posttest) and at a 12-month follow-up assessment. Patients who received TSF reported longer periods of sustained abstinence from cocaine, but not from alcohol, at posttest relative to those who received CM. On the other hand, patients who received TSF did not differ from those who received CM on abstinence from cocaine or alcohol at the 12-month follow-up. Moreover, patients who received TSF did not differ from those who received CBT on abstinence at any of the assessments. Although the published findings did not include any data related to participation in TSOs at posttest, results did indicate no significant differences in meeting attendance between the three conditions at the follow-up assessment.

Another RCT conducted in New Haven compared TSF and CBT among 75 alcohol-dependent individuals who had been arrested for domestic violence in the preceding year. The content of these interventions was based largely on the manuals used in Project MATCH, with some modifications made for addressing issues related to domestic violence. Data on substance use and physical violence were collected from the patients during treatment as well as at 12 and 24 weeks posttreatment. Analyses revealed that patients who received CBT reported more PDA from alcohol during treatment relative to those who received TSF. However, participants in the two conditions did not differ on PDA or biological measures of drug use collected during treatment and also did not differ on the PDA measures of alcohol use or drug use collected in the posttreatment assessments. Similarly, the analyses of measures of physical violence revealed no differences between the conditions during or following treatment. No comparative data on participation in TSOs have been published from this project.

A third RCT to publish findings after Project MATCH compared TSF and relapse prevention (RP) as aftercare interventions in a sample of 131 patients who had completed an intensive residential or outpatient treatment program for substance dependence in Montreal. The RP intervention was designed to provide patients with cognitive and behavioral skills that they could use to refrain from using substances in risky settings. Both the TSF and RP interventions were delivered in 10 weekly sessions, each lasting 90 min, to small groups comprising four to eight patients. The primary analyses examined the extent to which patients were working the 12 steps and abstaining from alcohol at a follow-up assessment, which occurred 4 months after the patients had completed one of the aftercare interventions. The

results revealed no significant differences in working the 12 steps or in abstinence rates between patients in the TSF and RP interventions. Secondary analyses showed that patients with elevated levels of psychological distress had higher rates of abstinence when treated in TSF than in RP, which conflicted with the findings of Project MATCH.

A fourth RCT following Project MATCH compared TSF and Integrated CBT (ICBT) in a predominately male sample of 148 patients recruited from an outpatient psychiatric program operated by the Veterans Administration in San Diego. In addition to being randomly assigned to either TSF or ICBT for treatment of substance dependence, each patient was administered psychotropic medication for the treatment of major depression. The TSF and ICBT treatments were delivered to small groups over a 24-week period in two phases of equal length. The first phase included 24 sessions that were delivered twice weekly. The second phase included 12 weekly sessions that were largely designed to review and reinforce topics covered in the first phase. The primary outcome variables were assessed with relatively low attrition at the midpoint and the end of the 24-week treatment period. The analyses found that clients who received TSF had higher levels of PDA and participation in TSOs, and lower levels of depression, at mid-treatment and posttreatment relative to clients who received ICBT. The results for depression may have been tied directly to the higher levels of PDA for clients in the TSF condition, but this has not been reported in the literature. Whether these findings endured into the posttreatment period also does not seem to have been reported.

A fifth RCT to publish findings subsequent to Project MATCH compared the effectiveness of TSF and Acceptance and Commitment Therapy (ACT) in 138 opiate-dependent patients in Reno, Nevada. Each of the patients was receiving clinic-administered methadone, which is a synthetic opiate that blocks cravings and other effects of withdrawal without producing the intense euphoria of other opiates. Both the TSF and ACT interventions were composed of 32 individualized sessions and 16 group sessions that were delivered over 16 weeks, with 16 of the individual sessions in TSF being delivered by the patients' sponsors. The study design allowed for comparing the two interventions against a randomly determined, control condition of patients that was provided only MM. Biological and self-reported outcome measures of drug use, as well as self-reported outcome measures of psychosocial functioning, were assessed at a 24-week follow-up, or 8 weeks following the conclusion of treatment. Analyses of the outcome variables revealed that participants in TSF and ACT had less drug use than those who received MM only but did not differ between themselves. On the

other hand, analyses of the self-reported drug use, psychological distress, and social adjustment measures found that the two interventions did not differ in effects from MM or themselves at the follow-up assessment. Findings related to participation in TSOs appear not to have been reported.

CONCLUSIONS

Although the manual for TSF Therapy was created for Project MATCH in the early 1990s, the guiding principles and practices included in it have been exerting a leading influence on the delivery of substance-dependence treatment at least since the 1950s. This chapter describes these principles and practices, highlights their origins in AA, and reviews findings from projects that have examined the effects of TSF Therapy on one or both of its primary goals of promoting abstinence and participation in TSOs.

Among the six projects reviewed in the chapter, Project MATCH used the most rigorous methodology. Increased participation in AA occurred across the three therapeutic interventions, even though this outcome was not an explicit goal of CBT or MET. Because recipients of different types of substance-dependence treatment are apt to increase their participation in AA or other TSOs, and because such participation is strongly associated with abstinence, it is difficult to detect unique effects for TSF in relation to its primary goals. Nonetheless, at least some superior outcomes for TSF were reported in three of the six projects that examined abstinence and three of the four projects that examined participation in TSOs. In contrast, only one of the projects found more improvement in abstinence in CBT than TSF, and this advantage did not persist into the posttreatment period. Unsurprisingly, none of the four projects that examined participation in TSOs found benefits for the CBT-related treatments relative to TSF.

Abstinence appears to be the most appropriate goal for substance-dependence treatment as it is associated with marked improvements in physical, social, and psychological functioning. Participation in TSOs also appears to be an appropriate goal for substance-dependence treatment as it is associated consistently with higher levels of abstinence. The Project MATCH Manual for TSF Therapy outlines specific strategies for increasing such participation, and these were generally found to be effective for this purpose in the evaluations reviewed in this chapter. However, there are practical obstacles to the widespread use of these strategies in treatment programs, primarily in terms of costs. With recognition of this, several researchers recently have developed brief TSF interventions that reinforce the need for abstinence and participation in TSOs.

Evaluations of these efforts have illuminated the value of linking clients directly with active members who can provide assistance, while also suggesting that sustained participation probably cannot be achieved through a single-session intervention.

List of Abbreviations

AA	Alcoholics Anonymous
ACT	Acceptance and Commitment Therapy
CBT	Cognitive Behavioral Therapy
CM	clinical management
DDD	drinks per drinking day
ICBT	Integrated CBT
MET	Motivational Enhancement Therapy
MM	methadone maintenance
NA	Narcotics Anonymous
PDA	percentage of days abstinent
RCTs	randomized clinical trials
RP	relapse prevention
TSF	Twelve-Step Facilitation
TSOs	Twelve-Step Organizations

Glossary

- Discussion format** one of the two general formats used in support group meetings of TSOs, whereby participants take turns talking about issues associated with substance dependence.
- Disease concept** the notion of substance dependence as a disease with physical, emotional, and spiritual symptoms that is progressive unless arrested through abstinence.
- Genogram** an exercise used in TSF Therapy, whereby patients identify cases of substance dependence among family members for the stated purpose of reinforcing the notion that substance dependence is a disease.
- Higher power** a term used by participants in TSOs to refer to God or other potentially healing force that operates in the universe.
- Minnesota Model/12-Step Model** an approach to substance-dependence treatment that prescribes abstinence from alcohol and other drugs through continuous participation in TSOs.
- Moral inventory** a specific exercise used in TSOs, TSF Therapy, and 12-Step Model Programs, whereby persons identify their strengths and weaknesses (Step 4) and disclose them to another person (Step 5).
- Speaker format** one of the two general formats used in support group meetings of TSOs, whereby one or two participants talk at length about their experiences with substance dependence and TSOs.
- Sponsor** an experienced participant in TSOs who provides support and guidance to less experienced participants.

<i>Mechanisms of the Spirituality–Recovery Relationship</i>	150		

Faith-based organizations have historically played an important role in supporting people, and their families, experiencing substance use problems. As governments increase their outsourcing of substance abuse resources to non-government agencies, the role of these faith-based organizations is becoming increasingly important. In conjunction with this, outsourcing is a growing demand for faith-based organizations to be economically accountable and adopt evidence-based practices. Thus, there is an increasing need to understand the mechanisms and importance of religious or spiritual components of treatment in relation to recovery outcomes. However, there is great diversity in the way faith-based organizations express and utilize their faith in the provision of substance abuse treatment. These differences complicate attempts to define what constitutes a “faith-based” program and understand how relevant “faith” is to treatment.

Faith-based programs can generally be understood to lie on a continuum. At one end of the continuum are

treatment services that are essentially “faith-based” in name only, using secular treatment approaches and only being linked to faith through administrative relationships with a larger religious organization. On the other end of the continuum are the more religiously driven service providers, using treatments that are based only on religious material. Overall, the ways in which faith-based organizations integrate “faith” into their services can be generalized into the following categories: (1) religious affiliated providers whose treatment content is completely religious, (2) religious affiliated providers who amalgamate religious and non-religious treatment content, (3) religious affiliated providers whose treatment is secular but whose organization’s values are religious, and (4) treatment providers who are affiliated with a religious organization but use secular treatment components and are minimally influenced by the affiliated religious organization. A broad range of religions provide faith-based treatment services (e.g. Islamic and Native American), but there is very

little empirical work written outside of Christian-based services. Subsequently, Christian substance abuse agencies are by far the most common and are the focus of this chapter.

THE STRUCTURE OF FAITH-BASED TREATMENT PROGRAMS

Christian faith-based programs can be distinguished from secular services primarily by a unique Christian theory of addiction. This theory acknowledges the role of biological, environmental, and psychological determinants but fundamentally views substance abuse as a sin that both results from and maintains a person's separation from God. Christianity teaches that sin is overcome through an acceptance of Jesus Christ and a subsequent process of sanctification. Sanctification is broadly considered to be a progressive growth in holiness that occurs as one commits to the Christian faith and connects with God, Christ, and the Holy Spirit. Hence a relationship with Christ as the driving force in the recovery process is central to the Christian theory of addiction. Thus, both patients and providers of faith-based programs often passionately emphasize that it is the salutary role of Christ in the treatment process that ultimately differentiates their program from other secular approaches.

A limited number of studies have attempted to contrast faith-based substance abuse treatment programs with secular programs. These studies have generally found that the structure of faith-based programs is often common to secular programs. Dimensions of treatment that are common to both secular and faith-based programs include the provision of detoxification services, group therapy, the provision of work opportunities, and referrals to health-care providers and social support services. Additionally, as with secular programs, faith-based programs may be residential or outpatient based, and participants are usually free to discharge whenever they please. Faith-based service fees are often minimal, if any, so they often service individuals from lower socioeconomic backgrounds. Though the majority of faith-based programs are Christian, they usually also provide treatment to individuals with non-Christian views. Faith-based programs can be differentiated from secular programs by their use of spiritual activities that are designed to cultivate a relationship with the divine. These can include chapel or religious services, group and private prayer sessions, pastoral counseling, and bible study. These activities are also used to foster cohesion within the therapeutic community, which plays an important role in the faith-based recovery process.

One of the major treatment approaches that blurs the lines between faith-based and secular programs are the Twelve Steps of Alcoholics Anonymous (AA).

THE TWELVE STEPS OF AA AND FAITH-BASED ORGANIZATIONS

The Twelve Steps of AA are one of the primary frameworks of substance abuse treatment used today. Much of the empirical research about spirituality and recovery is related to Twelve Step-treatment approaches, so an overview of this theory is highly relevant to any discussion of faith-based treatment approaches. The founders of the Twelve Steps were members of the Christian-based Oxford Group, so there are many similarities between the Christian and Twelve Step theories of substance abuse. In particular, as with the Christian theory, Twelve Steps approaches acknowledge the role of biological, psychological, and sociological determinants in substance abuse, but conceptualize substance abuse as a spiritual disorder. Specifically, the Twelve Steps theorize that dependence occurs when a person's inherent relationship with God (also known in AA as a "Higher Power") has been replaced by substance use. The concept of "character flaws," such as resentment, pride, and laziness – which were based on the seven deadly sins of Christianity – are theorized to both result from this spiritual void and contribute to it by inhibiting treatment engagement and maintaining substance abuse. Thus, Twelve Step programs focus on reconnecting a substance abuser with their Higher Power and, through the experience of a spiritual awakening, transcend the character flaws that maintain the addiction. Hence, just as the Christian approach focuses on acceptance and sanctification through Christ, the Twelve Steps focus on spiritual surrender and transformation through a Higher Power.

Though spirituality is central to the Twelve Steps, AA fellowships are not affiliated with religious institutions. There is also a great deal of variation in the way they use spirituality in their treatment. For example, some AA fellowships are essentially secular, even substituting the Higher Power for a secular conceptualization such as the group itself, while others maintain the theistic conceptualization of the Higher Power. Thus, some AA fellowships lean more heavily toward a faith-based definition while others are closer to being secular programs. Overall, there is a trend within the empirical literature to consider AA fellowships as being more closely aligned with faith-based services than secular, though in reality they do not neatly fit either distinction.

AA fellowships can often be confused with other treatment approaches that are not specifically affiliated with AA but incorporate the Twelve Steps into treatment. In

particular, Twelve Step Facilitation programs and “Twelve Step-based” treatments are frequently mistaken as AA fellowships. Twelve Step Facilitation is a manualized intervention designed to facilitate AA involvement while Twelve Step-based treatments generally combine the Twelve Steps with other treatment approaches. Often, these Twelve Step-based treatment programs may use the Twelve Steps as a foundation to treatment while also integrating secular (e.g. empirical psychotherapies) or religious (e.g. Christian theology) theories and components. Because of the similarities between the Christian and Twelve Step theories of substance abuse, many Christian faith-based treatment programs are able to combine the Twelve Step framework with their Christian values (e.g. promoting Jesus Christ as the Higher Power of the Twelve Steps). Empirical research has shown the Twelve Steps to be an effective treatment approach and so this integrative approach helps legitimize the inclusion of spirituality within treatment. The integration of faith-based approaches (such as Twelve Steps) into secular programs and the use of secular approaches in faith-based treatment programs, makes clarifying the relative treatment effectiveness of faith-based programs and their elements a challenge.

EMPIRICAL RESEARCH AND FAITH-BASED SUBSTANCE ABUSE PROGRAMS

Research on spirituality and substance use disorders is generally considered to be limited in scope. Though there is probably more research on the topic than is generally acknowledged, several issues do hinder the progress in this area. Firstly, and possibly most importantly, research is generally inhibited by the lack of guiding theories – so systematic research is rare. Rather, studies often investigate isolated hypotheses or take broad exploratory approaches. Results are rarely tied together in the context of a unified theory. As a result, research is fragmented and not as progressive as it otherwise might be. Secondly, both “spirituality” and “recovery” are difficult constructs to define and their many dimensions may interact in a variety of complex ways. Thirdly, empirically trained scholars interested in the mechanisms of behavior change often hold secular attitudes and overlook or minimize the potential influence of spirituality and religiosity in the recovery process. Matters of spirituality or religion are rarely a part of undergraduate or postgraduate behavioral science curricula and are often seen as being more suited to philosophy or theology. Thus, scholars whose primary interest is religion or spirituality rarely publish in the substance abuse field. Fourthly, substance abusers participating in research may also be suffering withdrawal symptoms and have long

histories of abuse and potential cognitive impairments. These factors may impair their ability to reliably participate in research. Finally, it can be difficult to differentiate the effects of spiritual development from the effects of program participation and commitment. Despite these barriers research is progressing in the field across three broad fronts. Firstly, early research focused on establishing a negative relationship between religiosity and substance use behaviors. Secondly, research has explored the effectiveness of faith-based programs. Thirdly, research has begun to explore how religiosity and spirituality may operate on recovery-based outcomes. Each of these will be briefly discussed.

Religion and Spirituality as “Buffers” against Substance Abuse

Religion is associated with numerous positive physical and psychological health benefits, including decreased rates of cardiovascular disease, hypertension, depression, suicidality, and mortality rates. Religion and spiritual beliefs and practices are also negatively related to substance use. Though alcohol and other substances can be used in some religious services (e.g. the use of wine in the Christian Eucharist), the majority of religions denounce intoxication. Individuals who are very religious or spiritual may more frequently engage in practices that support their spirituality, such as church service attendance, prayer, meditation, scripture reading, and bible study. Ideally, the very nature of these activities requires the individual to be calm, open to experience, cognitively alert, and self-disciplined. While intoxication can certainly calm an individual it also inhibits the cognitive abilities and affective states required for serious spiritual practices. Thus, individuals who are more religious or spiritual often have lower rates of substance use and so, within the empirical literature, religion and spirituality are generally considered to protect an individual from substance abuse. This in turn has provided further rationale for research into the role of religion and spirituality in the treatment of substance abuse.

The Effectiveness of Faith-Based Programs

Researchers have explored whether faith-based programs (usually Twelve Step programs) are effective treatment options. A limited number of multisite clinical trials exploring the outcomes of Twelve Step Facilitated, Cognitive Behavioral, or Motivational Enhancement residential programs have been conducted. Results suggest that clients generally have significant improvements in their substance use

behaviors and psychosocial functioning after discharge, irrespective of program structure. However, it has also been demonstrated that patients from the Twelve Step programs can have significantly higher levels of post-treatment abstinence. This is possibly a result of the Twelve Step philosophy which emphasizes complete abstinence, as opposed to the controlled drinking/usage philosophy adopted by many secular programs.

The use of post-discharge social support systems also plays an important role in maintaining recovery. Participation in outpatient self-help groups after discharge can help validate and normalize the difficulties associated with maintained abstinence. Clients who engage with Twelve Step fellowships after discharge not only have significantly greater chances of long-term abstinence, but are also significantly less likely to utilize professional services (e.g. counselors or psychologists) after treatment in comparison to those who participate in Cognitive Behavioral programs. Furthermore, though they use less professional services, Twelve Step clients have been shown to still maintain the same level of psychological well-being as seen in those who do rely heavily on health professionals. This may be because the support provided from participation in Twelve Step self-help fellowships after discharge substitutes the support that is otherwise obtained from professional health services. As a result, the total cost of care for Twelve Step programs can be significantly less than Cognitive Behavioral programs.

Thus, research currently suggests that Twelve Step programs can be as effective as secular programs and potentially more cost effective. Whether this research applies to Christian faith-based programs that are not Twelve Step-based remains unclear.

Mechanisms of the Spirituality–Recovery Relationship

In addition to explorations of effectiveness, research has also investigated the mechanisms by which religious participation and spirituality may affect recovery. Particularly relevant themes include the role of spiritual development, spiritual maturity, and spiritual experiences on recovery outcomes; religious coping in substance abuse treatment; the relationship between purpose in life and recovery outcomes; and psychological well-being and recovery.

Spiritual Development and Spiritual Awakenings in Substance Abuse Treatment

The Twelve Step and Christian theories of addiction theorize that an absence of God is central to a substance use disorder. Therefore, faith-based programs often focus on developing a relationship

with the divine. Central to this aim is the assumption that spirituality can change during participation in substance abuse treatment programs. In support of this, scholars have highlighted the role of spiritual development and spiritual awakenings in the recovery process. Longitudinal research has shown that though not all faith-based clients experience a spiritual awakening, those who do have a significantly higher chance of prolonged abstinence. Furthermore, other dimensions of spirituality, such as spiritual beliefs, spiritual practices, spiritual maturity, and the day-to-day experiences of a spiritual life (e.g. feeling a loving connection with God, feeling supported by God, drawing inner strength from one's faith) have all been shown to increase after participation in faith-based treatment and be associated with improved recovery outcomes. Additionally, individuals who relapse after treatment also tend to experience significantly greater decreases in spirituality constructs, such as spiritual experiences and maturity. This suggests that research and faith-based treatments may need to focus not just on cultivating spirituality and spiritual awakenings, but also teaching strategies for maintaining spiritual gains post-treatment.

Religious Coping and Faith-Based Treatment

Trauma, psychopathology, unemployment, the degradation of family and social systems, and inefficient stress management strategies are all positively associated with substance use disorders. In fact, substance abuse itself is often an ineffective coping strategy for stress and adversity. Faith-based programs invite clients to replace dysfunctional substance use coping strategies with religious ones. There are a variety of ways that a person's religion may help them cope with distress, both functional and non-functional. For example, positive ways of coping via religion may include viewing God as loving and forgiving, seeing adversity as part of God's plan, trusting that God will provide support and guidance, drawing support from religious communities, or using prayer to sooth affective arousal. Negative coping strategies may include seeing God as negative and punishing; blaming the devil for adversities; pleading with God for miracles; arguing with others about faith, God, and religion; or abandoning religion and spirituality altogether. Research has shown that use of negative coping strategies is associated with poorer psychological health and psychopathology. Individuals who adopt negative religious coping strategies may also manage stress and adversity less effectively. In contrast, positive religious coping is associated with improved physical and psychological health. In the context of substance abuse treatment, research exploring the role of religious coping is in its infancy. It has been found that participation in faith-based programs

increases the adoption of positive religious coping strategies. It has also been demonstrated that individuals who use positive religious coping strategies also have longer histories and higher frequencies of attendance at AA self-help groups. This implies that participation in Twelve Step fellowships increases one's use of positive religious coping – potentially through the spiritual transformation process. Religious coping is also positively correlated with abstinence self-efficacy and negatively associated with cravings and post-treatment substance use. Subsequently, the increase in religious coping that occurs via participation in faith-based programs may operate on substance use behaviors by increasing abstinence self-efficacy and reducing cravings. However, because the research is limited it is difficult to draw any definitive conclusions. For example, some researchers have failed to find associations between religious coping strategies and reduced substance use behaviors. Research also shows that religious coping strategies are not always negative or positive; often their functionality is dependent on the situation at hand. Thus, research findings must be treated as preliminary. The adoption of religious coping strategies in faith-based substance abuse treatment, which strategies are most effective for which issues, and how they operate on substance abuse is still a relatively unexplored area of research.

Meaning and Purpose in Life in Substance Abuse Treatment

The theologies and philosophies underlying religious traditions shape peoples' beliefs and ways of understanding the world. Thus, religion and spirituality have a profound impact on peoples' values, purpose in life, and behaviors. It is not surprising then that the experience of being in a faith-based program can dramatically affect how substance abusers understand their life history and current life circumstances. For example, Christian theology has many explanations for why suffering exists and its function in a person's life. Suffering exists because the person lives in a "fallen world" (a world corrupted at every level by sin) and because God is absent in their lives. Suffering also acts as an invitation to reconnect with God and his divine purpose, which in turn results in personal growth. Thus, an introduction to Christian theology can help validate and explain the sufferings associated with a life of substance abuse (e.g. loss of relationships, career, finances, health, and self-respect), potentially allowing the substance abusers to accept and appreciate the struggles associated with their addiction. (The process of coming to an acceptance and appreciation of suffering through an exploration of Christian theology is based on anecdotal evidence and needs to be empirically validated.)

Because of the centrality of meaning and purpose in life in religion, research has begun to explore their role in the spiritual–recovery relationship. Less purpose and meaning in life has been associated with alcohol use, cocaine use, heroine use, depression, resentment, and suicidal ideation. Purpose in life is significantly lower in alcoholics compared to non-alcoholics. Purpose in life is also negatively associated with post-treatment drinking and drug use and mediates a relationship between depression and alcohol use. Research has also shown that purpose in life can significantly increase after participation in residential treatment programs and is predicted by an individual's daily spiritual experiences and feelings. This implies that the day-to-day experiences associated with a person's spirituality (e.g. feeling loved by God) can promote greater levels of purpose in life and through this less substance use. This provides some support for the underlying theology and theories used in faith-based substance abuse programs: that a reconnection with God fills the spiritual void inherent in substance abuse and reduces substance use behaviors by giving the person purpose in life. However, it is important to note that purpose in life alone may be insufficient for producing sustained recovery. Research has also demonstrated that purpose is ineffective if the individual does not have the skills to manage or attain the desired goal. In these cases, a sudden growth in purpose in life has the potential to merely produce over confidence and set the individual up for failure and future hardships. Treatment providers must therefore be aware of the need to establish appropriate skill sets alongside religious/spiritual education if they are to maximize the benefits drawn from a spiritually based purpose in life. The cultivation of meaning and purpose in life in substance abusers via the religious conversion/spiritual awakening process is one of the growing areas for future research.

Spirituality and Psychological Well-Being in Substance Abuse Treatment

Among substance abusers, religious faith and spirituality are positively associated with indicators of psychological well-being, including optimism, social support, hardiness to stress, and life satisfaction. They are also negatively correlated with indicators of poor psychological well-being and psychopathology including trait anxiety, depression, resentment, and stress. Correlations between religion, spirituality, and psychological well-being indicators, such as these, tend to be in the low to moderate strength range, suggesting there is some degree of variability in the degree to which they may affect (or be effected by) psychological well-being.

Forgiveness is also an indicator of psychological well-being, being negatively associated with anger,

resentment, and depression, and also central to Christianity and the Twelve Steps. Hence, interest in how or if forgiveness is associated with a spirituality–recovery relationship has greatly increased. There are several types of forgiveness, including forgiveness of others, self-forgiveness, receiving forgiveness from others, and receiving forgiveness from God, but at their core they all involve the purposeful releasing of anger and resentment (whether it be directed at others or self). Currently, there is little research on the role that feeling forgiven by others or God has on a recovery from substance abuse. What is known is that a client’s spirituality can predict the degree to which they feel forgiven and that feeling forgiven in turn predicts lower levels of resentment and greater purpose in life. How this directly contributes to substance use behaviors after treatment is unclear.

Research has predominately explored forgiveness of others and forgiveness of self. What is supported by current research is that forgiveness of others and forgiveness of self can be predicted by a person’s level of spirituality, can increase during participation in faith-based treatment, and are negatively associated with resentment. This suggests that as people in treatment explore their faith and become more religious or spiritual they may also become more forgiving of others and themselves. Furthermore, forgiveness of self and forgiveness of others are associated with a reduction in the negative consequences of drinking, prolonged abstinence, and improved mental health. Generally, forgiveness of others is more strongly associated with anger and hostility, whereas forgiveness of self is more consistently associated with anxiety-based symptomatology (e.g. anxiety, somatization, obsessive compulsive measures). In particular, self-forgiveness has emerged as being at least as influential on recovery outcomes as forgiveness of others (which has traditionally been the emphasized type of forgiveness).

Substance abusers are highly stigmatized and it has been theorized that the anger, resentment, and pride that often hinders engagement in treatment and degrades social systems may actually be a defense against the shame associated with stigmatization. Thus, treatment that focuses on reducing shame and low self-esteem via increasing self-forgiveness may help promote recovery.

SUMMARY OF THE EMPIRICAL LITERATURE ON FAITH-BASED PROGRAMS AND SPIRITUALITY

Spiritual-based treatment programs can be as effective, and potentially more cost effective, than secular

programs. Furthermore, the empirical evidence suggests that spirituality can develop during brief treatment periods and that the development of spirituality, the experience of a spiritual awakening, spiritual maturity, and daily spiritual experiences can all be positively associated with recovery outcomes. Because spirituality and recovery are multidimensional constructs there are likely to be many ways in which the two are associated. This complicates the task of determining how spirituality within a faith-based program operates on recovery. What has been empirically demonstrated is that spirituality may operate through purpose in life, forgiveness, optimism, self-worth, social support, resilience to stress and anxiety, as a comforter in time of distress, and through improved self-efficacy. However, it is important to note that the majority of the findings supporting these mechanisms have not been replicated and should be considered preliminary. Furthermore, correlations and predictive relationships tend to be reliable but at a low to moderate strength. Additionally, though Christian faith-based programs are one of the most common treatment options for substance misuse, most of the research available relates to Twelve Step programs. There is a real need to research spirituality within the context of Christian faith-based programs and to determine if the psychological benefits of religion and spirituality are unique to clients of these programs or common to all individuals recovering from substance abuse. Nevertheless, faith-based programs appear to be a valid treatment option for individuals with substance use disorders and produce psychological well-being and reduced substance use behaviors that are equivalent to secular approaches.

Glossary

AA Alcoholics Anonymous

Abstinence self-efficacy the degree to which a person believes that they will be able to abstain from substance use even in the face of adversity.

Cognitive behavioral therapy a psychological treatment approach that aims to improve functionality by addressing a person’s thought processes and behaviors.

Daily spiritual experiences the day-to-day experiences and feelings associated with a person's religious faith or spirituality.

Motivational enhancement therapy a therapeutic treatment that aims to facilitate behavior change by resolving ambivalence and increasing motivation.

Recovery a reduction in the symptoms of substance use disorders and an improvement in psychological and physiological well-being that results in a return to functional normality.

Religion a formalized and institutionalized method of cultivating spirituality.

Sanctification a growth in holiness that occurs in conjunction with a deepening of the Christian faith.

Spirituality the thoughts, feelings, experiences, and behaviors that develop from a search for and connection with the sacred.

Spiritual awakening a sudden or gradual transformation of character that results from an individual's spiritual exploration and/or experiences.

Spiritual maturity often resulting from a dedication to spiritual growth or exploration, spiritual maturity is characterized by an ability to draw support and security from one's faith while also being open and accepting of another's faith.

Twelve Steps the Twelve Steps of Alcoholic Anonymous is one of the most prolific models of substance abuse treatment. It proposes that substance abuse can be overcome by following 12 sequential steps, commencing with a spiritual surrender to God.

Twelve step facilitated a manualized therapeutic intervention that is designed to facilitate involvement in the Alcoholic Anonymous treatment approach.

INTRODUCTION

Cigarette smoking is a leading preventable cause of morbidity and premature mortality around the world. In the United States, the smoking prevalence rate in adults is estimated from 20 to 22% and one in five smokers die from smoking-related illness. Worldwide, about a third of adults smoke and 1 in 10 smokers die from related illness. Illnesses causally linked to smoking include cardiovascular disease, lung disease, many cancers, reproductive effects, and other adverse health consequences. Moreover, the increased smoking-related morbidity and mortality extends to nonsmokers regularly exposed to secondhand smoke. For instance, there are approximately 50 000 deaths related to secondhand

smoke each year in the United States. Infants and children living in homes where parents smoke experience increased risk of respiratory illnesses, asthma, and sudden infant death syndrome. The annual economic cost of smoking is approximately \$96 billion in health-care costs and \$97 billion in lost productivity in the United States; clearly, a global perspective magnifies costs substantially. Over a lifetime of smoking, the financial toll is an estimated US \$33 per pack for the smoker, \$5.56 per pack for the smoker's family, and \$1.44 per pack for the society. Undeniably, cigarette smoking remains a widespread and an extremely serious public health problem.

Fortunately, about 70% of smokers express at least some interest in quitting. About a third of smokers in

the United States make a serious attempt to quit each year. Most people quit “cold-turkey” or with self-help materials and without formal treatment; about a third seek formal treatment. This chapter focuses on effective behavioral interventions for cigarette smoking, which can be used alongside pharmacotherapies, or in combination, which is the recommended and most effective choice when intensive treatment is appropriate. The information presented is drawn from the scientific research literature and a leading clinical practice guideline published by the US Department of Health and Human Services.

BRIEF CLINICAL INTERVENTIONS

There is a dose–response relationship between treatment intensity and efficacy, with more intense interventions generally producing relatively increased quit rates. However, not all smokers require intensive interventions. Further, intensive treatment is not always feasible or practical. In hospitals and many clinical settings, a premium is on maximizing the extent to which all smokers receive at least some intervention for their smoking. There are substantial opportunities to reach smokers via clinical healthcare settings. For example, an estimated 70% of smokers have contact with a primary care physician each year. This potential capacity for a wide reach has driven the call for the routine identification and assessment of smokers in clinical care. While identification and assessment are necessary elements to address smoking with all patients, they have not yet translated into increased quit rates. Lack of resources devoted to smoking cessation services and the need to develop organization and systems support have been offered as likely explanations. One meaningful and relatively obtainable goal is the brief (<3 min) clinical intervention delivered by healthcare practitioners to all smokers regardless of the reason for presenting for care. Brief clinical interventions are effective when provided by a variety of healthcare professionals and can relatively easily conform to the constraints of the typical busy clinical practice. Two models for such interventions are briefly presented below, and the practice guideline should be consulted for more information.

The 5 A’s

One model for the brief clinical intervention is presented in the practice guidelines and is referred to as the 5 A’s: ask, advise, assess, assist, and arrange. The first step is to *Ask* about tobacco use and document smoking status for every patient. To that end, there has been a systems-level push to add smoking status as

the “5th vital sign.” Second, for current smokers, clearly and strongly *Advise* about the importance of quitting in a manner that considers health circumstances, costs related to smoking, and effects on relationships. Third, *Assess* the individual’s motivation to quit on a scale of 0–10. Fourth, for persons willing to try to quit, *Assist* with the development of a quit plan, with elements like setting a quit date, creating a plan to tell family and friends, planning for risky situations, removing smoking-related products from the environment, and recommending pharmacotherapy, if appropriate. The fifth step is to *Arrange* for follow-up after the target quit date to reassess smoking status and provide support. Inclusion of at least one follow-up visit is beneficial and recommended.

The 5 R’s

For smokers not willing to try to quit, motivational interviewing techniques are recommended, and the model recommended is referred to as the 5 R’s: relevance, risks, rewards, roadblocks, and repetition. That is, focus on the personal *Relevance* of quitting smoking by emphasizing specific factors important by the patient (e.g. health problems, family history). Identify the *Risks* of continued smoking to short- and long-term health. Discuss *Rewards* of quitting, including proximal and distal benefits (e.g. improved health, saving money). Identify *Roadblocks* to quitting (e.g. nicotine withdrawal, concern about weight gain, low self-efficacy to quit) and create a plan to deal with them if the situation arises. Finally, motivational counseling is *Repeated* as needed.

Several factors are known to affect outcomes from brief clinical interventions. For example, the involvement of more than one type of healthcare professional in the delivery of the intervention, not necessarily at the same time, is associated with improved abstinence rates, as are the inclusion of practical counseling and intratreatment social support. Practical counseling involves reviewing past quit efforts for relevant information including strategies that helped and/or did not help, risky situations, and challenges related to other smokers (e.g. spouses), and developing strategies to deal with such situations are developed. Intratreatment social support refers to providing support and encouragement as part of an empathetic therapeutic process.

INTENSIVE INTERVENTIONS

The availability of effective brief clinical interventions is crucial to casting a wide net over addressing smoking with all smokers. However, there is a dose–response relationship between treatment intensity and effectiveness,

and practice guidelines recommend providing intensive behavioral interventions to any smoker interested.

Framework and Specific Interventions

Smoking interventions are most often multicomponent, deriving from and invoking a number of cognitive frameworks and models. As such, it is difficult to parse effects to specific treatment components, but there is some evidence in the literature including a few recent meta-analyses that allows some conclusions to be drawn. In general, cognitive-behavioral and social learning theory frameworks inform some of the predominant behavioral treatment components including cognitive-behavioral therapy, motivational interviewing, and relapse prevention.

Cognitive-Behavioral Framework

A central premise of cognitive-behavioral models of addiction is that substance use is a learned behavior that is largely established through modeling, operant conditioning, and classical conditioning processes. Factors that are considered to play crucial roles in substance use are positive expectancies associated with use; the behaviors, beliefs, and norms exhibited by one's social network; and the role of stress and the coping skills and self-efficacy for dealing with it. Consequently, interventions that have cognitive-behavioral roots involve anticipating and planning for situations that place one at risk for relapse. The antecedents and consequences (cognitive, emotional, environmental, physical, and social) of smoking are explored, strategies to deal effectively with triggers and risky situations are modeled and role-played to master new skills, and meaningful alternative reinforcers are identified to strengthen commitment and rewards from not smoking.

Stemming directly from this framework is cognitive-behavioral therapy, which takes a goal-oriented, directive, and systematic approach to changing dysfunctional cognitions, behaviors, and emotions. A functional analysis is used to identify triggers or antecedents of smoking behavior, cognitions, and emotions that are contributing to the maintenance of smoking, and positive and negative consequences of smoking and abstinence. Once functional analysis is complete, coping skills and support systems can be brought to bear on establishing and maintaining abstinence. Most studies in the research literature find that cognitive-behavioral therapy improves abstinence compared to no-treatment control groups. When compared to other active treatment conditions, outcomes tend to be comparable, as with other effective treatments. In addition, there is limited evidence that cognitive-behavioral therapy

may be associated with reduced weight gain following quitting under some conditions.

Motivational Interviewing

Motivational interviewing is a client-centered counseling style focused on developing motivation to change. The therapist's role is to uncover and help build rapport, resolve ambivalence, provide normative feedback, and evoke commitment to change in an empathetic and collaborative manner. The principles of motivational interviewing are to express empathy, develop discrepancy, roll with resistance to change, and support self-efficacy to make changes. Content covered includes personalized relevance of change, risks and rewards of change, roadblocks to change, and the need for repetition in these efforts. The overall goal is to evoke the client's own intrinsic motivation and to empower the client to make decisions rather than having decisions imposed by others. Conceptually, this therapeutic style should be most effective in persons who demonstrate low motivation to change, although the research literature is mixed in that regard. A recent meta-analysis by the Cochrane Collaboration found that motivational interviewing was associated with increased abstinence at 6-month follow-up compared to brief advice or usual care, and counseling contact longer than 20 min was especially effective. Findings of increased odds of smoking cessation with motivational interviewing are further supported by two additional meta-analyses to date. Beneficial effects may be less substantial in pregnant women compared to nonpregnant women. In general, though, improvements in outcomes with motivational interviewing seem on par with benefits with other effective psychosocial therapies.

Relapse Prevention

Even with effective treatment, rates of relapse to smoking are high. In general, counseling strategies consistent with Marlatt and Gordon's relapse prevention model seem to decrease the likelihood of relapse compared to usual care conditions, at least in the relative near term. Developed in the context of alcohol abuse and dependence, the relapse prevention model has been extended to other substance use disorders including tobacco use and dependence. The model is based on social-cognitive theory and involves behavioral and cognitive strategies for identifying, dealing with, and preventing situations that place the individual at high risk for relapse. Several cognitive processes are considered key to understanding why relapse occurs, including self-efficacy or a belief in one's ability to abstain from substance use, outcome expectancies or beliefs about the positive/negative consequences of use and/or abstinence, and abstinence violation effects,

when initial lapses are perceived as recovery failures that increase the chances of a full-blown relapse. Relapse is considered a process that can theoretically be prevented and interrupted by addressing these cognitive processes as they occur. The immediate antecedents and consequences of use are identified and coping strategies developed to monitor for and deal with such situations. The process involves use of specific strategies for improving coping skills and self-efficacy, correcting endorsed myths about substance use, and dealing with lifestyle factors that increase the likelihood of relapse, like stress. While effective, a meta-analysis by Irvin et al. found that the effect size of relapse prevention interventions for smoking were significantly smaller than those for alcohol and polysubstance abuse, and all effect sizes were the strongest when assessed immediately posttreatment relative to 1-year follow-up, suggesting the need to develop programs that more adequately address the needs of ex-smokers. While motivational interviewing components are associated with improved abstinence, there are no specific interventions that reliably prevent relapse following treatment. There is some evidence that self-help materials can decrease long-term relapse in individuals who quit without formal treatment. In the absence of reliable evidence-based interventions for relapse prevention at the time of the last practice guideline in 2008, the authors report a consensus that for some smokers, use of intensive evidence-based behavioral and pharmacological treatments are likely needed to produce the best outcomes including preventing relapse but does not make further recommendations. More recently, a number of studies have examined the use of extended therapies to maintain abstinence or prevent relapse. Results suggest that cognitive-behavioral therapy for an extended duration (i.e. 40 weeks) following intensive pharmacotherapy combined with behavioral therapy produces high long-term abstinence rates (i.e. 2-years follow-up).

There is a large literature on self-efficacy and its predictive relation to relapse or the maintenance of abstinence. A meta-analysis by Gwaltney et al., however, suggests that relationships between self-efficacy and relapse largely reflect smoking status at the time that self-efficacy is measured and that controlling for smoking status at the time of assessment substantially reduces its predictive value, although it does remain a significant predictor and its assessment may be useful for treatment development.

Transtheoretical Model

According to the transtheoretical model, individuals progress through a series of stages of readiness to intentionally change a problem behavior, like smoking. Individuals who do not yet recognize the need to quit

smoking or have no immediate intention to quit are said to be in the precontemplation stage. Those thinking about quitting in the relatively near future and considering the pros and cons are in the contemplation stage. In the preparation stage, people are taking steps toward quitting, like collecting information on effective treatments. People actively engaged in trying to quit are said to be in the action stage. Finally, those who have quit and for whom relapse prevention is the focus are in the maintenance stage. The transtheoretical model has intuitive and clinical appeal and is widely applied. However, it is not without criticism including that the model oversimplifies how individuals plan for change, and that it neglects the role of reward and punishment in the formation of entrenched habits. A recent meta-analysis by the Cochrane Collaboration calls into question the utility of using a stage-based approach to adjust counseling. Results found that stage-based counseling interventions were no more or less effective at producing long-term (at least 6 months) abstinence compared to their nonstage-based counterparts. The authors do note that it is possible that future research will uncover benefits of using a staged approach with interventions that could not be included in analyses because the literature was too small (e.g. telephone-based counseling). By contrast to findings in adults, there is some evidence for the efficacy of treatments that have stage-based components relative to control conditions in youth (less than 20 years old).

Format and Modality

Counseling and Self-Help

Group counseling and individual counseling of comparable durations and intensities typically produce similar quit rates. Counseling is especially effective when it is proactive and includes practical counseling and intratreatment social support, as noted above. A meta-analysis by Fiore et al. found that counseling alone (i.e. no pharmacotherapy) increases the odds of smoking cessation by a factor of 1.49–1.76. Use of multiple formats (e.g. proactive telephone counseling, individual counseling) seems to confer improved effectiveness over the use of a single format. Proactive counseling (telephone or face-to-face), group and individual counseling are more effective than self-help materials but do not have as broad a reach. As a stand-alone intervention, self-help materials do not improve outcomes over no-treatment control conditions but there is evidence of marginal effectiveness when used as an adjunct to face-to-face counseling. Nevertheless, from a public-health perspective, self-help materials play an important role in increasing awareness of the consequences of smoking, importance of quitting, availability of support

services, and the range of evidence-based treatment options available.

Personalized Interventions

Individualization of treatment can occur at the outset and during the course of treatment. Treatment can be customized based on personal characteristics of the smoker like quit attempt history or some dimensional variable like readiness to quit, although no specific method of tailoring has consistently improved outcomes. Another example of customization is stepped care, a process of starting with a minimal intensity intervention and incrementally increasing treatment intensity for nonresponders. Stepped care is cost-effective in that expensive resources are reserved for those who demonstrate a need for them. There is some evidence for improved outcomes with this approach in hospitalized patients while benefits for others are as of yet unclear. Throughout the treatment, personalization can occur via ongoing adjustments in emphasized coping skills, strategies, and other elements based on success-attaining goals. In regard to effects of ongoing personalization on outcomes, dynamic feedback in particular (i.e., collecting data and using it to produce tailored feedback via human or computer-based algorithmic computation) is associated with improved short-term and long-term quit rates compared to standard (static) self-help materials and no treatment. Examples of customized written materials include those produced via printed feedback forms and interactive websites.

Technology

Telehealth refers to the use of telecommunication technology and electronic information to deliver health-related care, information, and other services and support educational and administrative activities. Telehealth interventions for smoking are increasingly prevalent and popular. Advantages include increased access to care, decreased time to care, potentially lower costs, and improved efficiencies. These can be stand-alone options or adjuvant treatments, provided via human resources, automated or interactive systems, or some combination thereof.

A large-scale example of a telehealth initiative for smoking is the US National Network of Quitlines. Quitlines can provide proactive follow-up calls, mailed self-help and informational materials, assistance obtaining pharmacotherapy, and referral and triaging of callers to other services, and some have associated websites with additional resources. Trained staff can provide reactive and/or proactive counseling if available. Most quitlines target the general population but some target specific groups like pregnant women, adolescents, and low-income smokers. Proactive telephone counseling is especially effective, and there may be a dose-response

relationship with three or more calls more likely to produce benefits. Importantly, there is empirical evidence that proactive counseling (telephone-based or otherwise) increases quit rates compared to minimal or no counseling and that proactive counseling plus medication are more effective than medication alone.

Fax-to-quit services are proactive programs designed to identify smokers in primary care settings and link smokers to smoking cessation treatment. Typically, a smoker completes a form in the physician's office and it is faxed to a designated quitline call center. The call center then attempts to contact the individual usually within 48 h to engage him/her in a quit plan, which can include one or several counseling sessions. The effectiveness of fax-to-quit programs has only been investigated in a small number of studies but with positive results compared to control conditions. The focus on proactive outreach and telephone counseling makes fax-to-quit approaches particularly likely to engage smokers who have not sought services independently.

Mobile phones are another technology being increasingly used to deliver interventions and monitor and manage smoking. Mobile technology is integrated into daily life for most people, with an estimated >70% of the world's population currently subscribing to mobile phone service. It is a potential means to reach audiences who do not access traditional treatment services, and it allows for individualization, interactivity, and immediacy. Mobile phone technology includes voice service, applications ("apps"), e-mail, short message service and multimedia service, and Internet access. The literature on smoking interventions that include mobile phone-based elements is currently small. There is some evidence for improved short-term (6-month) quit rates with text messaging-based interventions, as reported in a meta-analysis of four studies by Whittaker et al. Overall, the popularity of and growing access to mobile phone technology suggest that a rise in the number of interventions that have phone-based components is likely. Mobile phone-based applications and programs that are consistent with evidence-based guidelines are needed along with accompanying outcomes-based research.

Advances in computer-based technology and exponential growth in computing have led to an increase in their application to smoking cessation. The first generation of computer-based interventions involved computer-generated feedback forms subsequently mailed to individuals. Currently, interventions delivered on a single computer or via the Internet can include specific quit plans, multiple feedback opportunities, e-mail reminders or other information, Flash technology, interactivity (e.g. chat rooms, social networks), and audio-video streaming. Computer-based interventions offered to individuals in medical care settings (e.g. using

the 5A's/5R's approach) have demonstrated acceptability and a small number of studies thus far suggest these interventions can be effective at reducing smoking. Web-based interventions are potentially even more desirable because of features like increased accessibility but there is limited research supporting the use of the Internet as a smoking treatment access point. Some research suggests benefits of sites that are tailored, interactive, and used frequently and in conjunction with a more intensive intervention relative to less intensive or static or control conditions. Overall, Internet-based interventions combined with evidence-based treatment may improve quit rates, but there are few studies to date and the results are mixed.

Treatment Intensity

Treatment intensity is defined in the practice guideline as (1) minimal intensity (3 min or less), (2) low intensity (3–10 min), and (3) higher intensity (10 min or more). For all these intensities, consistency with practice guidelines is important to treatment effects. Even brief advice to quit smoking that is consistent with practice guidelines is effective when delivered by physicians, and possibly other healthcare professionals, increasing quit rates by 1–7% above quit rates of about 2–3% in untreated smokers, with some evidence of benefits remaining long-term (e.g. 12 months). For high intensity interventions, a total of 30–90 min of total contact time spread out over at least four sessions is especially effective, with further increases not seeming to produce additional benefits. In terms of the types of providers, in general, interventions delivered by trained physicians and nonphysician clinicians produce comparably increased abstinence rates compared to control conditions, but effects by the type of provider have not been examined taking treatment intensity into account. Practice guidelines recommend that intensive treatment be provided to all interested smokers.

SPECIFIC POPULATIONS

Separate attention is given to some populations of smokers because of particular vulnerabilities, disproportionate smoking-related morbidity and mortality burden, and other considerations. Behavioral interventions that are effective in the general population of smokers tend to be effective in specific populations, although treatment effect sizes can differ.

Women Versus Men

Recent evidence suggests that women are at greater risk than men for smoking-related illnesses, including

lung cancer, which is second next only to breast cancer in cancer prevalence among women. Women smokers also have elevated rates of diseases related to pregnancy, oral contraceptive use, and menstrual function, as well as increased cervical cancer rates. Several studies have revealed that women may have more difficulty in quitting smoking than do men. Specifically, while women and men are equally likely to initiate quit attempts, women appear to have greater difficulty maintaining abstinence. This gender discrepancy has been found in studies of self-directed quit attempts as well as behavioral and nicotine replacement treatments. Some work suggests that women are more likely to use smoking to manage negative affect and prevent weight gain than men. Research is needed on underlying mechanisms and effective treatments to address gender disparities (also see the Exercise section below).

Racial and Ethnic Minorities

There is evidence for racial and ethnic differences in smoking and smoking-related health outcomes. Compared to Caucasians, African Americans are less likely to have ever been smokers, although rates of current smoking appear similar. These data may reflect that African American smokers have greater difficulty in quitting smoking. African American smokers are as likely as Caucasians to want to quit smoking, but they are less likely to utilize smoking cessation treatment. A similar scenario is evident with Hispanic smokers. Lower utilization may be related to lower income and lower likelihood of health insurance coverage. Receipt of healthcare advice to quit smoking is positively associated with utilization of smoking cessation treatment among these groups, suggesting that improving access to healthcare has the potential to improve outcomes. The availability of culturally appropriate treatment options may improve outcomes for some as it does in other areas related to health.

Employees

Several natural aspects of the workplace lend themselves to promote smoking cessation including regular long-term opportunities to provide access to services and monitor progress, and the potential for various forms of social support throughout the organizational structure. Treatments that are effective outside the workplace are similarly effective when offered within the work setting. Incentives (distinct from contingency management interventions; see below) and competitions that target the workforce of smokers increase participation in quit smoking programs but the literature is mixed in terms of effects on actual quit rates.

Hospitalized Patients

Hospitalization presents a unique opportunity to identify and connect smokers with evidence-based smoking cessation treatments due to indoor smoking restrictions, Joint Commission on Accreditation of Healthcare Organizations (JCAHO) accreditation requirements, and the negative impact of smoking on recovery from illness, which can drive motivation to quit. Intensive smoking cessation treatment with at least one contact and a minimum follow-up of 1 month postdischarge increases the odds of quitting in all hospitalized smokers and in specific subgroups like coronary heart disease patients. There is limited evidence of improved quit rates with longer duration treatment or with pharmacotherapy added to less intensive behavioral therapy.

Pregnant and Postpartum Women

About 12% of women report smoking cigarettes during pregnancy. The most commonly recognized health consequences of smoking when pregnant are increased risk of premature birth, low birth weight, and sudden infant death syndrome. Less well publicized is the substantial increased risk of having a baby born with malformations like deformed limbs. Effective behavioral interventions of moderate or high intensity are effective in pregnant women who want to quit but as with other populations, a significant proportion of those treated do not quit. Further, amongst those who do quit, an estimated 70% relapse within 6 months postpartum. Strategies to improve quit rates and prevent relapse in this population are needed urgently.

Smokers with Other Substance Use Disorders

The prevalence of smoking in individuals with other substance use disorders is an estimated 67 to more than 90%, depending on substance of abuse. Substance abusers who smoke experience more smoking-related morbidity and mortality than nonsmokers. Most substance abuse treatment patients express some interest in quitting smoking but few treatment programs address smoking. Of those who do, most address smoking within the context of counseling generally; few offer pharmacotherapy and formal smoking cessation counseling is rare. Organizational barriers to integrate smoking into substance abuse treatment include difficulty with reimbursement; belief that smoking is not important in treating other substance abuse; concerns that quitting smoking will jeopardize other treatment outcomes; lack of staff and organizational support, training and resources, lack of smoke-free policies and grounds, and a smoking staff culture. Importantly, there is now strong research evidence that

treating smoking does not jeopardize and by contrast may benefit substance abuse treatment outcomes. For example, individuals who continue to smoke are at higher risk of relapse to other substance use. Several leading organizations now advocate for treating smoking along with other substance use disorders, and initiatives like the 1999 New Jersey decision to make licensure contingent on the provision of smoke-free grounds, ban use of tobacco by staff during work hours, and make assessment and treatment of tobacco use available to all substance abuse treatment patients are making headway. In general, treatments that are effective for the general population are effective in substance abusing smokers, but relatively less so. Quit rates tend to be lower, but what constitutes a clinically significant effect is also likely lower given the very high rates of smoking-related morbidity and mortality in this population. Overall, more research on strategies to improve long-term smoking cessation outcomes in this population is needed as are continued efforts to integrate smoking into treatment for other substance use disorders.

Other Psychiatric Diagnoses

Rates of nicotine dependence among individuals with mental health diagnoses are substantially higher than smokers without mental health problems across most Axis I and Axis II disorders, with resulting increased burden on these populations in terms of smoking-related morbidity and mortality. Complicating treatment of smoking in people with mental health problems is that dependence may be entangled with psychiatric symptoms. For example, among smokers with schizophrenia, who are far more likely to smoke than nonpsychiatric individuals, it has been proposed that nicotine may play a role in regulating negative symptoms (e.g. apathy, avolition), possibly through its ability to raise dopamine levels in the nucleus accumbens and prefrontal cortex. Nicotine may also improve cognitive deficits via improved sensory gating. Thus, for individuals with schizophrenia, smoking may provide a self-medication role that is difficult to counteract with behavioral interventions. There is some evidence that contingency management, a systematic application of positive reinforcement to promote behavior change like quitting or reduced smoking, may reduce smoking in people with schizophrenia but larger trials are needed.

Depression symptoms and nicotine dependence also seem to be highly associated. Smokers are more likely to report depressive symptoms and more likely to meet diagnostic criteria for major depression than are nonsmokers. Depressed smokers have higher nicotine dependence scores and smoke more cigarettes than nondepression smokers. Further, depressed smokers are

more likely to relapse to smoking during times of high stress and experience more protracted withdrawal effects. However, there is evidence that history of depression is not an independent predictor of smoking cessation failure.

Relatively few studies have examined the efficacy of smoking cessation interventions for individuals with serious mental illness like psychotic disorders. Treatment does not appear to worsen mental state when applied to patients with stabilized psychiatric conditions. However, long-term abstinence is rare. It has been suggested that behavioral interventions may best be utilized as adjunctive treatments to assist individuals with mental illness to establish coping skills to maintain abstinence, but more research is needed.

Adolescents

Adolescence is a time of particular vulnerability to developing nicotine dependence. Monitoring the future data from 2010, for example, suggest that about 3% of 8th graders and nearly 11% of 12th graders are daily cigarette smokers. Behavioral therapies are the treatment of choice for adolescent smokers as there is insufficient evidence to support the use of pharmacotherapy in this cohort, although this is an active area of research. Effects of behavioral interventions such as motivational interviewing or structured brief advice tend to be modest. Additional findings suggest that adolescent smoking and quit attempts are significantly associated with parental smoking and cessation. Specifically, teens of parents who quit smoking are less likely to become smokers and more likely to quit if already a smoker than teens with a parent who currently smokes, suggesting that family-based smoking interventions may be useful, but more research is needed. A group that has received less attention in the research literature is young adults (e.g. age 18–24), in whom the smoking prevalence rate is about 22%. A recent review of the few published studies to date concluded that the extent of methodological heterogeneity and lack of scientific rigor in the current literature largely preclude conclusions.

ALTERNATIVE STRATEGIES

Hypnosis

Hypnotherapy is proposed to help individuals quit smoking by weakening the desire to smoke and increase motivation to quit. Relatively few controlled trials have been conducted comparing hypnosis to no treatment, brief advice, or counseling and that literature does not show clear effects of hypnosis on smoking outcomes.

Acupuncture

The empirical evidence on acupuncture for smoking cessation including two meta-analyses does not support improved outcomes with active compared to sham acupuncture (i.e. acupuncture at sites not expected to affect smoking). There is limited evidence of improved short-term outcomes with acupuncture compared to no-acupuncture control conditions. Larger and more rigorous trials are needed to improve understanding of possible effects of acupuncture on smoking treatment outcomes.

Exercise and Physical Activity

Physical activity and exercise are associated with lower levels of cigarette smoking in several cross-sectional studies. Proposed possible mechanisms of action include reduced cravings to smoke, reduced withdrawal effects, a rising of self-esteem, and slowing of postquitting weight gain. However, there is limited evidence of direct effects of exercise on smoking outcomes in the empirical literature to date. Most promising are observations of some benefits of exercise on psychological outcomes including reduced tension, anxiety, stress, irritability, and restlessness, even in the absence of differential smoking reduction between exercise and nonexercise treatments. Another approach may be to apply exercise-based interventions to moderate weight gain during a quit attempt or following cessation but research results are thus far equivocal. For example, exercise has been found not to be associated with reduced postcessation weight gain at the end of treatment but there is some support for reduced weight gain long-term (i.e. at 12 months). There are also no clear benefits of exercise for smoking cessation in specific populations (e.g. women, problem drinkers, postacute myocardial infarction patients). It is important to note that several methodological issues complicate the current literature including small sample sizes, poor adherence to exercise regimens, and lack of objective outcomes. For example, research suggests possible differential efficacy with vigorous versus moderate activity levels, but poor adherence to exercise regimens is associated with worse outcomes and adherence appears to be worse with vigorous exercise. Overall, more research is needed to directly compare moderate versus vigorous activity, to examine strategies for improving adherence to all exercise levels, and to address methodological issues that complicate interpretation of research results.

Contingency Management

Contingency management is primarily a process of systematically using positive reinforcement to promote

clinically relevant behaviors that has demonstrated efficacy for improving abstinence in a diverse range of substance abuse treatment populations and settings (*see* Contingency Management). Briefly, contingency management is based on the behavioral principles of operant conditioning that predict that behaviors (e.g. smoking abstinence) that are reinforced or rewarded are more likely to recur. With this procedure, a target behavior is identified, like abstinence, and defined objectively (e.g. drug-negative urinalysis). It is monitored often to maximize chances for reinforcement and minimize failing to detect competing behaviors (e.g. drug use). When the target behavior occurs, tangible incentives or rewards (e.g. voucher) are provided, and incentives are not provided when the target behavior does not occur. A large body of research demonstrates that substance use can be modified by changing environmental consequences of use like the availability of alternative (nondrug) reinforcers, thus supporting the use of contingency management to treat substance abuse.

Most research on contingency management for smoking has been conducted under tightly controlled experimental conditions and in samples not seeking treatment. Results generally indicate substantial short-term reductions in smoking when procedures include elements essential to the efficacy of this intervention. Contingency management may be particularly helpful for individuals trying to quit smoking for whom pharmacotherapy is not appropriate and for those disproportionately affected by smoking but not commensurately aided by standard treatment options. One such group is pregnant smokers, for whom the general consensus is that pharmacotherapy is contraindicated. Research on contingency management for smoking in this population indicates significant smoking reductions that, for many, endured throughout the postpartum period. Another group for whom contingency management may be helpful is adolescents. About 20–25% of adolescents who try smoking progress to daily smoking and nicotine dependence but there is insufficient evidence to support pharmacotherapy for this group. Notably, contingency management alone or in conjunction with other therapy (e.g. cognitive-behavioral therapy) can substantially reduce smoking among adolescents. Contingency management might also be helpful for individuals with co-occurring substance use disorders, who are at elevated risk of smoking-related morbidity and mortality. Research in residential treatment patients, methadone-maintained opiate-dependent patients, and in the Veteran's Administration hospital population demonstrates that contingency management can reduce smoking and promote abstinence in this group. Results from a few small trials in individuals with schizophrenia are also promising. Application of this

intervention to improve adherence with smoking cessation medications is another area of interest. Despite promising results, this literature remains relatively small, in part because of technological limitations on detecting smoking via breath or urine tests in the context of contingency management (*see* Contingency Management for a more detailed discussion).

CHALLENGES

Effective behavioral interventions for smoking exist but there are challenges and limitations to overcome to optimize outcomes for many smokers. Some issues relate to access to and utilization of effective treatments. On the side of the smoker, limited knowledge about the harmful effects of smoking and effective treatments; lack of desire, motivation, or self-efficacy to quit; the potential stigma associated with receiving treatment, for the first time or after already having attempts to quit; and the costs of treatment can limit demand. Public health campaigns and policies are two means through which information dissemination occurs. For some groups of smokers, information presented in a culturally specific manner may improve the impact of outreach efforts. The availability of affordable healthcare and health insurance coverage for smoking treatment is also crucial to widespread utilization of services. On the healthcare setting side, limited training on how to counsel patients who smoke and on the availability of evidence-based treatments and related community resources can negatively impact treatment referrals. Myriad other demands, insufficient resources, and limited incentives to address smoking with patients remain serious barriers. The need for specialized training on how to counsel patients who smoke and on treatment options are now widely recognized and such training is being incorporated into medical school curriculum and continuing medical education programs. Many hospitals now require that smoking status be documented for all patients, a practice sometimes referred to as the fifth vital sign. This practice improves the extent to which smokers are identified but organizational support, resources, and other attendant issues need to be addressed to improve translation of assessment into delivery and utilization of services, including delivery of the most effective treatment strategy – combine behavioral and pharmacological treatment.

Of those who do use formal treatment, a substantial gap exists between the number of smokers who seek treatment and the number who achieve initial abstinence. Larger still is the gap between the number who quit and those who successfully remain quit long-term. There is a pressing need for methods to maximize treatment efficacy for the general population of smokers and for specific subgroups like those

discussed above. To develop these methods will likely require innovative strategies and an improved understanding of the moderators and mediators that impinge on treatment effects. Further, even with current best practices and with knowledge of situational, environmental, and other factors that increase relapse risk, relapse rates are high and strategies to prevent relapse reliably are forthcoming. Relatively highly intensive interventions are associated with improved short-term and long-term outcomes but also sometimes with higher attrition.

Another challenge includes the identification of the active components of efficacious interventions. Discussions of effective behavioral therapies for smoking in the scientific literature and in practice guidelines largely consist of generalizations about intensity, contact time, and other structural and content elements that impact treatment effectiveness. Motivational interviewing and cognitive-behavioral therapy are widely used in practice and examined empirically but several factors complicate evaluation of these and other specific methods. Examples include the often composite nature of counseling without clear distinctions between therapeutic approaches, confounding of counseling and noncounseling components, individualization of counseling based on clients' needs which can lead to heterogeneity within and across studies, and the use of comparison conditions that are brief advice or treatment as usual and not consistently matched in intensity and duration. Further, there are differences between studies in patient characteristics, treatment fidelity, and other elements that make cross-study comparison, systematic replication, and meta-analytic assessment problematic.

CONCLUSIONS

Cigarette smoking remains a leading preventable cause of morbidity and mortality around the world with disastrous health and economic costs. Effective behavioral interventions for smoking exist, and effect sizes overall are in the range reported for approved smoking cessation pharmacotherapies. Improvements in access to and utilization of evidence-based treatments, the systematic integration of smoking treatment into healthcare and other settings, and innovative strategies and scientifically vetted methods to improve treatment effectiveness and prevent relapse are needed to more fully realize the potential individual and public health benefits of treating smoking.

Glossary

Classical conditioning a behavioral learning process whereby an individual responds in a particular way to a (conditioned) stimulus that was previously neutral but has been repeatedly paired with a (unconditioned) stimulus that occurs naturally with the desired response.

Effect size a standardized measure of the strength of an effect of an independent variable (e.g. type of treatment) on a dependent variable (e.g. percent who quit smoking). It represents the change (measured in standard deviations) in an average person's outcome (the dependent variable), if given the treatment (the independent variable).

Lapse after some period of abstinence, a brief return to some smoking (e.g. a few cigarettes) that does not progress to regular prolonged smoking and is followed by a return to abstinence.

Modeling learning through observing others.

Operant conditioning a learning process whereby behaviors that are reinforced tend to occur more frequently while those that are not reinforced (or are punished) occur less frequently.

Reinforcement in behavioral science, a response or behavior is followed by the presentation of a desirable stimulus and the frequency or likelihood of subsequent responses is increased.

Relapse a return to regular smoking after some period of abstinence.

INTRODUCTION

Adolescent Treatment

Survey data from 2009 suggest that 4.6% of adolescents in the United States meet DSM-IV criteria for alcohol abuse or dependence and 4.5% meet criteria for illicit drug abuse or dependence. These prevalence rates translate into large numbers of adolescents who need treatment for one or more substance use disorders. It is important that effective treatments are available because research has shown early initiation of substance use and its associated problems often results in more severe and longer lasting alcohol and other drug problems. Fortunately, for those adolescents entering treatment there are several empirically supported behavioral treatments available. These treatments began to be systematically adapted for adolescents with substance use disorders and studied through randomized clinical trials in the 1990s. Most of the treatments

have been evaluated in outpatient settings; however, brief treatments also have been evaluated in hospital emergency rooms (ERs) and school settings.

In this chapter, we review theories of change that support behavioral treatments for adolescents, common features of these approaches, specific approaches that have been supported in randomized clinical trials including brief and combination treatments, research related to the effectiveness for gender and racial groups, and future research needs.

Theories Underlying Behavioral Treatments

There are three different theories that serve as the basis for behavioral treatments. Classical conditioning theory was articulated after Ivan Pavlov noticed that hungry dogs would salivate at the sight of assistants who were associated with their feeding. The major concept underlying this theory is that given repeated

pairings over time, a given stimulus elicits a certain response. This theory suggests that alcohol and substance use are a response to stimuli that could be any number of people, places, or things that have been associated with an individual's use. The goal of treatment is to help an individual avoid certain stimuli that elicit substance using behavior.

Operant or "Skinnerian" conditioning outlines rules for increasing and decreasing behavior based on the consequences of that behavior. A behavior increases when it is positively reinforced, so for example, alcohol or drug use increases when an individual finds that using substances has pleasurable consequences. A clinician will help the individual identify alternative reinforcers to compete with substance use. These reinforcers are most effective when they are individualized and can range from verbal praise from a therapist or parents for efforts of an adolescent to decrease alcohol or substance use to a tangible reinforcer like money or prizes.

Social learning theory was developed by Albert Bandura and explains behavior based on the interaction of cognitions with behavioral and environmental influences. Modeling and observing the behavior of others plays a large role in learning new behavior. So, for example, an individual might learn to use alcohol or drugs in response to stress or happy occasions in life due to observing this behavior by a significant adult. An adolescent might learn better communication skills by observing other adolescents model these skills in a group. Regardless of the theory underlying the particular behavioral approach, they share several common features.

Common Features of Behavioral Treatments

Behavioral treatments are rooted in the scientific method and rely on methods of training clinicians that include specifying the desired clinical behaviors, observation of the clinician providing the treatment, and feedback to shape desired behaviors. It is generally understood that the rationale for the rigorous monitoring of therapists' in-session behavior helps maintain fidelity to the model and will result in therapeutic outcomes similar to those in clinical trials that established the intervention as an evidence-supported treatment. Treatment manuals provide background on a particular approach and break down aspects of the treatment into smaller steps and decision rules to help the clinician determine when it is appropriate to use different treatment components. Usually, video or audio recordings of simulated or real sessions are reviewed in order to provide clinicians feedback to learn to deliver an approach competently. The feedback is typically based on rating guidelines used to evaluate the quality

of a clinician's in-session behavior. Even after clinicians have demonstrated the ability to implement the approach well, there may continue to be periodic reviews of their work to assess ongoing fidelity to the established intervention. In research studies, the use of these approaches is typically time-limited based on a fixed treatment period, but in practice, lengths of treatment vary based on the level of care, need, and available financial resources to pay for treatment. Next, we provide descriptions of several specific behavioral approaches.

APPROACHES

Cognitive-Behavioral Therapy

One behavioral approach that is widely used for adolescents with alcohol and substance use problems is cognitive-behavioral therapy (CBT). As noted by Yifrah Kaminer and Holly B. Waldron, this approach draws from all three behavioral theories. It is important to note that the content of CBT sessions varies greatly across the different research studies that have evaluated it and in practice settings.

CBT techniques that are based on classical conditioning help adolescents identify stimuli that lead to their alcohol or substance use and teach them how to interrupt a chain of events or "triggers" so that the end result is not substance use. Stimuli can be places, people, things, or even emotions like sadness or boredom. Thus, avoiding a friend's house where drugs are typically available and used would interrupt the antecedents that lead to alcohol or drug use. Learning to substitute a positive thought for a negative one might help avoid substance use for an individual who uses alcohol or drugs to help forget about bad feelings.

Operant conditioning principles suggest that repeated alcohol or drug use can be at least partially explained by the reinforcing effects adolescents experience from their alcohol and drug use. A therapist may help adolescents find alternative reinforcing activities that provide opportunities to experience socially positive outcomes that will compete with their substance using behavior. One of the most common features of CBT is teaching individuals several different coping skills. Consistent with Albert Bandura's theory of self-efficacy, if individuals learn to use coping skills to decrease stressful situations in their lives, confidence in their ability to control situational outcomes will increase, and they will be less likely to use alcohol or drugs to relieve stress.

Typical skills that are the focus of CBT sessions are problem solving, communication skills, anger management, coping with cravings or urges to use, and alcohol

or drug refusal skills. However, the number of coping skills taught can be quite expansive and might include topics like improving social support or depression management. A CBT session will generally include a brief discussion of the adolescent's status since the last session and any significant events that have occurred, a review of the homework that was agreed upon in the prior session, the rationale for the coping skill being presented, didactic instruction related to the topic, modeling or demonstrating the desired skill, an opportunity for the adolescent to practice or rehearse the behavior with feedback, and discussion of homework to be completed prior to the next session so that the individual has the opportunity to "try out" the coping skill in his or her natural environment. A critical aspect of the approach is reviewing the homework assignment when an individual returns for the next session. If the homework was completed, the therapist praises the adolescent's efforts and discusses what was learned from the experience. If the homework assignment was not completed, the therapist discusses with the adolescent why it was not completed and helps the individual overcome any obstacles or discomfort so that he or she is more successful the next time.

In keeping with the principles of social learning theory, a therapist may help the adolescent identify positive adult or peer models whose behavior he or she might want to imitate. These could be individuals who have had problems with alcohol or drugs themselves and are now active in recovery or individuals that have never had problems, but live their lives in a way that the adolescent feels is successful. Social learning theory also supports the use of CBT in groups, and research suggests that it can be quite successful in group delivery. There has been some research to suggest that peer influence in groups for delinquent youth can have a negative impact on group members, but this research has not been validated in groups for alcohol or drug use treatment. On the contrary, meta-analyses by Holly B. Waldron and Charles W. Turner indicate that group delivery of CBT can be as or more effective than individual CBT approaches. The next approach described shares several aspects of CBT.

Adolescent Community Reinforcement Approach

The Adolescent Community Reinforcement Approach (A-CRA) is adapted from an adult treatment approach, the Community Reinforcement Approach (CRA) that was first developed and tested in the 1970s. It was modified for adolescents and evaluated as part of a multisite study of treatment approaches for adolescents who presented with cannabis abuse or dependence, and later evaluated with young people who were homeless and

who had other types of alcohol or drug abuse and dependence diagnoses. The approach has been widely disseminated in the United States through special federal grant mechanisms to treatment organizations and is spreading to Canada and Brazil. In the earliest CRA studies for adults, there were a number of different treatment procedures that were used, including "reinforcer access counseling," "social/leisure counseling," "job finding counseling," and "problem prevention." Over time, these procedures have been described in more detail in books and manuals, and additional procedures have been added. A-CRA incorporates several CBT procedures, and this treatment approach illustrates how a package of different treatment components can be grouped in a treatment manual that therapists can draw upon to individualize treatment.

One of the identifying features of A-CRA, which has its basis in operant conditioning theory, is the emphasis placed on determining each individual's reinforcers, which might be used to motivate behavior change. For example, a young person might want to please a girlfriend who wants him to be substance free, finish high school, participate on an athletic team, or complete juvenile justice probation requirements. The approach also acknowledges that alcohol and other drugs have taken on reinforcing properties for the young person, so it is important to find alternative, healthy behaviors that can replace the using behavior so that the individual learns to have an enjoyable life without the use of alcohol or drugs. A-CRA procedures can be grouped into (1) assessment and planning procedures (e.g. functional analyses of substance use and pro-social behavior, the Happiness Scale, and Goals of Counseling), (2) skill building procedures (e.g. communication, problem solving, relapse prevention, and job finding), and (3) a miscellaneous group that helps promote pro-social reinforcer access (e.g. systematic encouragement) or sobriety (e.g. sobriety sampling). There are a total of 18 different procedures that a therapist can choose from based on discussion during a treatment session. Important additions for adolescents are the sessions that involve parents or other important caregivers in adolescents' lives. The overall goal of the family sessions is to improve the home environment for both adolescents and their parents by teaching them better communication and problem-solving skills. Once learned, these skills also help facilitate changes in areas assessed as needing improvement via the Relationship Happiness Scales.

A-CRA has been evaluated as a relatively short (12–14 sessions) intervention. The procedures can all be used in individual therapy sessions, and many also are appropriate for use with groups (e.g. communication skills, problem solving, and relapse prevention). In a continuing care application known as Assertive Continuing Care

(ACC), clinicians deliver A-CRA procedures in the home along with case management.

Results of clinical trials of A-CRA as a primary outpatient treatment and when used as a part of ACC have been favorable when compared to treatment as usual conditions. When compared to two other evidence- and manual-based treatments, A-CRA was found to be the most cost-effective.

Family Behavior Therapy

Family Behavior Therapy (FBT) was developed by Nathan Azrin and Bradley Donohue over a 20-plus-year period and also is based on CRA. Its developers conceived substance use as a strong reinforcer, and the eight components described for this approach target (1) building skills that are incompatible with drug use, (2) modifying the environment so that there is reinforcement available for engaging in activities incompatible with drug use, and (3) setting up a "level" system of tiered awards for achievement of goals related to actions incompatible with drug use. Like A-CRA, it has primarily been tested in outpatient settings. It is designed to be delivered in up to 16 sessions that are 60–90 min in length over 4–6 months. It is not surprising that, since it has the same lineage as A-CRA, there are several similarities between the two approaches. Both are designed to increase positive interactions between the clinician and treatment participants, as well as between adolescents and others in their lives. Both are youth and parent centered in that clinicians are trained to seek input and direction for treatment goals from participants. They have some similar components, including communication and job getting skill training. The most striking differences between the two approaches are the FBT expectation that a primary significant other attend every session, the contingency contracting-based level system, and the steps of the self-control component.

Clinicians are expected to work on specific tasks with parents or other appropriate significant others during treatment planning, different aspects of communication training, environmental restructuring, and the development of the level system. Basically, the level system provides a structure so that adolescents earn rewards from their parents for staying substance free and not getting into trouble at home, school, or with the criminal justice system. First, the clinician works with adolescents to identify potential daily and bonus rewards. These might include items that adolescents already have access to noncontingently like money, transportation, or the use of a cell phone, or something they might like access to like a certain video game. Next, the clinician works with the parent to develop three levels of goals in specified areas (e.g. chores, curfew, and school) and assesses what parents feel are acceptable daily

awards for each of the three levels of goals and bonus awards that could be given if the adolescent accomplishes specific goals on consecutive days. Finally, the parent and adolescent meet together with the clinician and review what is basically a contract that outlines which behaviors would result in rewards for the adolescent. Each day at home, the contract is reviewed and parents provide rewards as per the agreement.

The urge control or self-control component was developed to provide adolescents with the skills to identify their thoughts related to substance use and redirect those thoughts so that they do not end up using. This component involves seven distinct steps, beginning with thinking or saying "Stop!", thinking of negative consequences of substance use, relaxation, thinking of pro-social alternatives, choosing an alternative behavior, telling an important other person in the adolescents' lives how they avoided the substance use behavior, and thinking about positive consequences that are likely to result from avoiding substance use. These steps are practiced during sessions in what is called a "trial," while the clinician provides the adolescent specific praise and help so that they execute the steps correctly.

As of 2012, the developers have made available a manual and materials to support the dissemination of FBT. These materials include a detailed guide to the approach, checklists to guide clinicians in the delivery of each component, and a method for assessing treatment integrity.

Contingency Management

Another behavioral intervention that first showed promise in the treatment of both adult and adolescent substance disorders is contingency management (CM), also known as Motivational Incentives. This approach is based on the central operant learning principle: behavior is a function of its consequences. Behavior that produces a positive, pleasurable consequence will increase the likelihood of future occurrence; similarly, behavior that results in avoiding or escaping a negative consequence may also serve to increase the frequency of that behavior. CM is an intervention for reinforcing positive behavior (e.g. no drug use) while associating negative behavior (e.g. drug use) with an absence of reinforcement in an attempt to have the individual begin linking abstinence with desirable pro-social goods or services.

There are two main types of CM that have been used in the treatment of substance use disorders: voucher-based reinforcement therapy and the "fishbowl," or the variable magnitude of reinforcement procedure. Both procedures offer rewards for negative urine/breath tests, but the method of reward differs. Developed by Stephen Higgins and colleagues, vouchers for goods or

services are given in an attempt to re-establish positive behaviors that occurred prior to drug use. For example, if an adolescent enjoyed rollerblading prior to becoming addicted to alcohol and/or other drugs, vouchers earned through treatment could be used to purchase equipment or admission to an indoor skate park. If drug/alcohol screens indicate recent use, no vouchers are given. This particular approach has been shown to result in clinically significant periods of abstinence.

Some CM interventions for drug-free behavior also have been supplemented with contingent reinforcement to increase pro-social behaviors that compete with drug use. This dual reinforcement approach is consistent with the proposed change mechanism in CRA, namely, to increase the density of positive reinforcement by increasing desirable social, recreational, and leisure activities in the adolescents' environment such that relapse or return to use results in time-out from positive reinforcement. Thus, instead of or in addition to earning a reward for providing a negative urine or breath sample, an adolescent could earn one for participating in an agreed upon social or recreational behavior while drug-free between therapy sessions.

The fishbowl, or variable magnitude reinforcement procedure, was developed by Nancy Petry and her colleagues and it has been used to reward participants for negative urine/breath screens and for increasing pro-social behaviors. For each negative screen, participants receive a certain number of "draws" from a fishbowl or similar container. Each draw has a chance of winning a prize. Typically, the majority (half) of slips of paper in the bowl have "good job" written on them, while the other half are associated with prizes. The majority of prizes are small, consisting of items that typically cost \$1. A smaller amount of prizes are large, and are worth approximately \$20. There is a much smaller chance of drawing a jumbo prize, which is typically worth up to \$100. Consecutive negative urine screens earn escalating bonus prize drawings. Thus, if an individual is drug-free on three consecutive urine tests, he or she would earn a drawing plus three bonus draws. At any time that a urine screen indicates drug use, bonus draws would start over or reset to one with the next negative urine test result. Initial research suggests that results of the variable magnitude reinforcement procedure are comparable to and less costly than the voucher method.

When the fishbowl method is used to increase pro-social activities, an individual is required to produce verification that an activity was completed to earn the prize drawings. Using this approach, Godley and colleagues helped adolescents with substance use disorders select from activities including 12-step meeting attendance, movies with friends, and doing activities with parents. So, in this study, adolescents had the opportunity to earn prize drawings for negative urine screens, and

also when they presented verification (e.g. movie theater ticket stub; signed attendance sheet by 12-step meeting chairperson) for participation in pro-social activities.

Several scientists have studied whether monetary reinforcement could be used to increase abstinence from cigarette smoking in adolescents. During these experiments, youth were given monetary rewards or gift certificates based on providing breath samples that showed carbon monoxide levels related to abstinence. Samples were taken daily, and reinforcements were provided for each sample that indicated abstinence, and in one study, additional rewards were provided for consecutive readings indicating abstinence. These studies revealed much higher rates of abstinence for those receiving the rewards for abstinence readings than for those in the comparison group.

One study examined the effectiveness of variable magnitude reinforcement procedures. Participants were adolescents in a substance abuse intensive outpatient program that involved CBT and family systems therapy. Participants submitted once weekly biological samples and received draws for negative samples. No draws were received if the adolescent tested positive for any substance. A bowl containing tokens was used for the draws. Approximately half of the tokens were labeled "good job." A smaller amount were labeled "small," which entitled the participant to a small prize, such as a candy bar or drink. Approximately 8% of the tokens were labeled "large," and could be used to obtain a \$10 gift certificate. Another 0.2% of the tokens were labeled "jumbo," and could be exchanged for a \$60 gift certificate. Participants earned two draws the first time they submitted a negative sample. For every subsequent negative sample, the number of draws increased by two. If at any time a participant tested positive, his/her number of draws was reset to two. The results of this study again showed that adolescents in the test group were three times as likely to remain abstinent as adolescents in the same treatment program who did not receive incentives.

Researchers have provided a rationale why CM might be easier to implement with adolescents and some guidelines for its use. John M. Roll and Donnie Watson suggest that since adolescents typically live with their parents, they could be taught to administer a CM protocol in the home environment and thus the nature of their environment could be more susceptible/malleable to the reinforcement/punishment regime of CM. Yifrah Kaminer also has summarized seven steps/tips to use when adapting CM specifically for adolescents: (1) target the most important behavior to be changed; (2) pick rewards that adolescents would find desirable; (3) provide rewards either at a fixed rate or use a progressive scale in which each consecutive positive behavior (e.g. negative urine screen) results in an increase in reward; (4) be specific about the

procedures to be used; (5) provide rewards immediately once the positive behavior is observed; (6) make use of priming, which involves giving a reward prior to beginning implementation; and (7) follow an evidence-supported approach to implementing CM.

BRIEF TREATMENTS

To improve the accessibility of behavioral treatments for adolescents, researchers have developed and studied brief interventions in locations that are thought to be more conducive to engaging young people than specialty substance use clinics. This is important because even though several adolescent alcohol or other drug (AOD) treatments have been found effective, less than one out of 19 adolescents with a substance use disorder actually receives treatment. Adolescents appear to be slow to acknowledge they have an alcohol or drug problem and rarely seek treatment on their own. Most are required to attend treatment by juvenile justice authorities, their parents, or due to requests from school administrators. Barriers to treatment attendance include transportation, parent work schedules, or parents who are occupied with the care of other children. The possibility of intervening with adolescents, particularly those whose substance use has not involved external agencies and authorities, has been studied in brief, school-based, and hospital ER interventions using motivational interviewing (MI) and CBT.

School-Based Interventions

Many schools in the United States offer some type of school-based services. Eric F. Wagner and his colleagues developed the Teen Intervention Program (TIP) for delivery in schools to address multiple factors they theorized influence the development of substance problems. In 10 weekly sessions, the intervention includes exercises that explore environmental influences, beliefs, and expectancies, and learned behaviors associated with AOD problems. Central to the TIP model is the theory that giving adolescents the ability to make choices about their treatment will help them move toward a decision to change their behavior. The intervention also incorporates components that allow adolescents to determine their readiness to change and to set goals related to changing their substance use and other aspects of their lives. The didactic material, discussion topics, and exercises have the following objectives: (1) educate adolescents about their use; (2) raise awareness about the reasons for their use; (3) help the participant understand the “antecedents, consequences, and patterns associated with their personal use habits”; (4) help the adolescent set and meet goals for reducing or

ceasing use; and (5) develop coping skills to manage stress and other factors related to use. Clinicians who provide TIP are chosen based on their experience providing adolescent group treatment and are not school employees. In a randomized trial, both the TIP and the control conditions resulted in initial improvement in substance use, but the response to TIP was significantly greater and longer lasting.

Another school-based intervention is a brief motivational and cognitive behavioral intervention developed and evaluated by Ken Winters and his colleagues. The investigators compared a two-session intervention for the adolescent only with a three-session intervention that included the same two adolescent sessions with an additional session for parents. The two adolescent sessions were 1 h in length, used an MI approach (nonconfrontational and supportive), and were identical for both conditions. The focus for Session 1 was obtaining information about substance use and consequences for use, discussing the participant’s willingness to change and the benefits of change, and discussing what goals for change the participant would like to set. In Session 2, progress toward goals was discussed, including discussion of barriers and whether the participant wanted to continue previously agreed upon goals or set new ones. In the condition that included the parent, the third session consisted of using the same MI style to discuss the adolescent’s substance use problem, parental attitudes/behaviors toward the substance use, parental monitoring to promote the participant’s goal progress, and healthy drug use behaviors and attitudes by the parent. In a randomized trial, both groups performed well relative to an assessment and referral only control group, but the brief intervention that included parents demonstrated greater reductions in alcohol use than the adolescent-only version of the brief intervention.

Hospital ER Interventions

Adolescents who are taken to a hospital ER for an alcohol-related event may be more receptive to an intervention provided in that setting. Due to the large number of adolescents who use and abuse alcohol, Peter Monti and colleagues created a one-session MI intervention that targets adolescents in hospital ERs. The focus of the MI was the alcohol consumption and risky behavior related to alcohol use, especially driving after drinking. The session typically lasted between 30 and 45 min after potential participants were given a small mental status exam to ensure that they were able to understand and participate in the intervention. The basic components of the MI included an introduction, participant assessment, exploration of motivation, enhancement of motivation, and establishment of a plan to help reduce additional problems related to drinking. A randomized

trial of this MI approach compared to standard care for adolescents in the ER for alcohol-related events revealed significantly better outcomes for reported drinking and driving, subsequent moving violations, alcohol-related injuries, and alcohol-related problems.

COMBINATION BEHAVIORAL TREATMENTS

Researchers have examined the effectiveness of various combinations of behavioral interventions. The theory that underlies combination treatments is that they will be more effective than one treatment component by itself. So, for example, if an effective treatment that focuses on enhancing motivation is paired with CBT, then the adolescent will be more motivated to practice new CBT techniques to change their behavior, thus improving overall treatment effectiveness. Additionally, if the intervention includes the family, and targets family communication, for example, then this might also increase treatment effectiveness. The studies below illustrate, however, that it is not always true that higher dose interventions or ones with more components are more effective or maintain desired changes for a longer period of time.

Motivational Enhancement and CBT

One example of the combination of two treatments is Motivational Enhancement Treatment (MET) with CBT. MET is a variation of MI, and the goal is to increase the adolescent's motivation to change. It is based on the premise that change is more likely to occur if the decision to change is the adolescent's rather than an external requirement (i.e. the justice system or parents). MET draws from five core principles: (1) empathic listening, (2) highlighting discrepancies between what an adolescent wants out of life and their behaviors, (3) avoiding argumentation, (4) what is called "rolling with resistance," which involves responding to resistant statements with empathy rather than confrontation, and (5) reinforcing self-efficacy statements or statements that suggest an individual believes he or she can change. In the multisite Cannabis Youth Treatment study, there were three interventions evaluated that included this approach. All three had two sessions of MET. One condition included the addition of three group CBT sessions that targeted refusal skills, enhancing social support, and planning for relapse (MET/CBT5). The second condition, MET/CBT12, added seven more CBT sessions (problem solving, anger management, communication, coping options for cravings and urges, managing depressed feelings, and managing thoughts about substance use). The third combination treatment also added family therapy and education sessions to MET/CBT12 and was called the

family support network (FSN). One of the surprising results from the comparison of these treatments was that the brief five-session treatment was as effective as the 12-session version of MET/CBT and the multicomponent FSN model. The research design did not allow examination of whether the combined treatment was more effective than the MET or CBT intervention alone.

MET/CBT and CM

Catherine Stanger and her associates compared the combination of MET/CBT12, a voucher-based reinforcement therapy, and a family management curriculum developed by Thomas J. Dishion and colleagues. The voucher schedule allowed adolescents to earn escalating vouchers worth up to \$570 for testing negative (both urine and breath) for all substances, provided these tests were corroborated by parents' reports. The family management curriculum was augmented by a fishbowl variable magnitude CM approach. Parents earned up to six fishbowl draws per week by (1) attending therapy, (2) attending mid-week urine testing appointments, (3) implementing substance monitoring contracts with their adolescent twice per week, (4) completing homework, and (5) administering breathalyzer tests.

The control condition received MET/CBT12 and a structured psychoeducational parent curriculum, which had little overlap with the family management curriculum provided in the experimental condition. Control participants also earned \$5.00 vouchers twice per week for attending scheduled counseling and urine testing appointments. Both groups were offered 12 more weeks of once weekly substance testing following the 14-week active treatment phase to reinforce parent monitoring of their adolescent's substance use or nonuse.

The results indicated that both conditions reduced marijuana use, with significantly more consecutive weeks of marijuana abstinence for the experimental condition during the treatment phase. These results compare favorably to other outpatient adolescent studies; however, there was considerable erosion of treatment effect over the follow-up period. This study also found that regardless of treatment condition, reduced negative/inconsistent parental discipline and improved parental monitoring were important predictors of posttreatment marijuana use.

EFFECTIVENESS OF BEHAVIORAL APPROACHES BY GENDER AND CULTURE

Epidemiological data suggest that problems associated with substance use can vary by gender. There is also a widespread concern that treatments must be

culturally appropriate, as behavioral and other evidence-based approaches are implemented in countries that have great cultural diversity and are exported from developers in one country to another. Thus, a logical question is whether the effectiveness of behavioral approaches for adolescent substance use disorders generalizes across gender and cultural groups. There are a number of problems inherent in addressing this question, and paramount among them is the scarcity of studies with sufficient sample size, gender and racial diversity, quality implementation, and process and outcome measures. Danielle Barry and colleagues combined data from three different adult CM studies and found that ethnicity was not related to treatment outcome. Susan H. Godley and colleagues examined several process (e.g. engagement and satisfaction) and outcome measures (e.g. days abstinent) for more than 2000 adolescents participating in a large federally funded A-CRA dissemination and implementation effort. Results indicated that the intervention was equally well implemented across gender and racial groups and equally effective across racial groups, with males having equivalent gains in abstinence and recovery compared to females despite males having greater intake severity and differential outcomes at 6 months. There is an obvious need for more studies to examine this important topic, especially when transporting treatments developed and tested in one group to another group.

SUMMARY

Behavioral treatments for adolescent substance use disorders have an impressive record of controlled research with strong comparative effectiveness data. As with other evidence-based treatments, there are limitations related to treatment effectiveness and in understanding the mechanisms related to the underlying theory of change for each therapeutic approach. For example, CBT has improved substance use outcomes for adolescents in some controlled trials. Researchers have hypothesized that the reason for these changes is an improvement in self-efficacy (i.e. a belief in one's ability to change). However, more research is needed to determine whether improvement in self-efficacy is a result of specific improvements in coping skills or nonspecific factors, such as therapeutic alliance or treatment engagement. Similarly, A-CRA has demonstrated improvement in substance use outcomes. However, more research is necessary to better examine the extent to which improvements in drug-free pro-social activities improved coping skills, or both mediate clinical outcomes compared to other variables, including nonspecific treatment factors. The CM intervention

change mechanism appears much more straightforward due to the clear specification of reinforcement contingencies and reliance on biological measures to verify drug use/nonuse. Adolescent studies with posttreatment follow-up suggest that after the withdrawal of reinforcement, drug use behavior begins to increase again. While this finding is not unique to CM, it may receive more attention because of the well-specified, time-limited nature of reinforcement used in these studies. CM research with adults has shown that the achievement of at least 12 consecutive weeks of abstinence dramatically increases the odds of abstinence 1 year later. Research is needed with adolescents to test for this effect, as it would provide useful information for the design and conduct of future CM protocols. For example, protocols that start with high magnitude reinforcement for a 12-week period may prove helpful in studying whether CM can achieve 12 or more weeks of consecutive abstinence with sufficiently high numbers of adolescents to predict sustained abstinence during a subsequent 9-month posttreatment phase.

All the behavioral approaches described above, while effective, would benefit from additional research explicitly designed to provide continued assistance (for poor responders) or to maintain therapeutic gains made during the active treatment phase. Such approaches are beginning to be studied in both adults and adolescents and involve various continuing care strategies that require ongoing monitoring of behaviors such as substance use, relapse antecedents (e.g. internal feeling states such as boredom or loneliness, substance using friends, etc.), and competing pro-social activities. Goal setting and negotiated assignments to deal with problems in any of these areas can be implemented with appropriate follow-up by the clinician, including re-intervening to provide more intensive treatment in the event of a sustained relapse. Early signs of promise in this line of continuing care research have been demonstrated in the work of Kaminer and his colleagues as well as Godley and colleagues, but it is very early yet, and more tests with greatly expanded monitoring periods (e.g. 4 years or more) are needed. Relatively brief behavioral interventions in schools and ERs have proven to be useful in expanding both access to treatment and improving substance use outcomes/reducing harm for adolescents whose substance use problems are less severe or at least have not precipitated problems with the juvenile justice or other social systems that remand them to treatment. These approaches are noteworthy in that they can be relatively easily imbedded within settings where youth are found and do not require additional, often complicated, steps to initiate treatment in specialty clinics. However, while available, these brief interventions still are rarely implemented in schools, hospital ERs, or other youth-serving

organizations in the community. Future research is needed to learn how to expand implementation of the existing brief approaches in these settings and to develop and evaluate other brief models of monitoring, support, and re-intervention.

Addiction is increasingly recognized as a disorder beginning in adolescence, and research in behavioral treatments for adolescents has grown in volume and acceptance over the past decade. This trend is expected to continue. Researchers will continue their efforts to understand underlying change mechanisms and improve outcomes during active treatment. Consistent with adult substance use research, greater emphasis will be placed on ways to sustain gains over an extended posttreatment period and to re-intervene with more intensive care when needed. It is expected that this research will benefit from technological advances that are “adolescent-friendly” and make use of the Internet (e.g. programmed e-therapy; chat rooms for convenient *impromptu* or scheduled continuing care sessions), smart phones with global position technology (e.g. to warn of certain antecedent locations associated with use), and short message services (e.g. text messages to ask for monitoring information or provide support).

INTRODUCTION

Since the 1970s, the field of substance abuse treatment has witnessed tremendous growth in the availability of substance abuse treatment services developed specifically for women. Traditionally, substance abuse treatment programs were designed for male clients who were predominantly referred into treatment through the criminal justice system. However, the proportion of women substance abusers in treatment has steadily increased in the past several decades. At present, women comprise approximately 30% of all admissions into substance abuse treatment, although these rates vary by type of treatment modality and setting. Concurrent with the increase in women

seeking or receiving treatment has been the development of treatment approaches, services, and programs designed specifically for women with substance use problems.

DEVELOPMENT OF “GENDER-SPECIFIC” TREATMENT FOR WOMEN

Prior to the 1970s, a generic treatment model was prevalent, in which there was little recognition of the specific treatment needs of women, as compared with those of men. Beginning in the 1970s, spurred by the women’s movement’s emphasis on the role of gender in social life and gender-based discrimination, there

was an increasing sensitivity to the issue of gender with regard to substance use and addiction. The focus at this time was primarily on gender differences in the initiation of substance use and progression to dependence, and in the physiological effects of alcohol and drug use; social stigma attached to alcohol and drug use among women, especially among mothers; and barriers encountered by women in seeking and receiving services.

This focus on gender differences logically led to the development of separate treatment programs for women in order to better address their treatment needs, particularly those related to pregnancy and parenting. Several national treatment demonstration projects focusing on substance abuse treatment for pregnant and parenting women were implemented in the 1980s, within the context of public concerns about cocaine/crack use among pregnant women and mothers. These initiatives helped to foster the growth of women-specific treatment facilities and new treatment approaches. Subsequently, a body of research emerged that examined the characteristics of women who enter into substance abuse treatment; the organizational characteristics of treatment programs designed for women, or in which women are predominant; and the outcomes of women in gender-specific programs or of women who receive "specialized" treatment services within mixed-gender programs.

A review of state guidelines regarding gender-specific treatment services for women has shown that there is substantial variability in treatment standards for women and pregnant women across the states. At present, over half of the states and the District of Columbia have some kind of standards for women and/or pregnant women beyond the block grant requirements. Variability exists in how these standards are implemented; these include the areas of licensing/certification standards; administrative rules, regulations, and statutes; contractual requirements; treatment guidelines; and funding applications. Moreover, there is a lack of uniformity in how the states define key constructs, including "gender-specific treatment," and in the level of specificity regarding expected treatment services for women.

PROFILE OF WOMEN WITH SUBSTANCE USE PROBLEMS

Women with substance use disorders typically have complex treatment/service needs given their multiple problems and the barriers they may face to obtaining needed services. Women often present to treatment with co-occurring substance abuse and mental health problems, limited employment skills and work history,

and prior interactions with the criminal justice system. Considerable research has shown that most women with substance abuse problems have been exposed to abuse, trauma, or violence as children and/or as adults. Most women substance abusers who enter into treatment are mothers and many have been separated from their children, either through informal arrangements with other family members or because their children have been put into foster care by the child welfare system.

In addition, many women substance abusers have physical health problems that stem from the consequences of their substance abuse and associated unhealthy and risky behaviors, including risks for HIV. These health problems are further compounded by their lack of access to or utilization of health care services, including preventative and reproductive health care services. Moreover, as compared with men with substance use problems, women tend to have more severe family and social problems; have higher rates of co-occurring mental disorders, particularly mood and anxiety disorders; and are less likely to have viable work skills or a history of paid employment.

Substance use among women may co-occur with other types of addictive behavior, such as shopping, Internet gaming, and gambling. Women with substance use problems may also have co-occurring eating disorders or engage in self-harming behaviors, as an outgrowth of anxiety and depression. Experience of intimate partner violence is pervasive among women substance users. Women with substance use problems may also perpetrate violence toward others, often within the context of abusive relationships in which alcohol and drug use are embedded within the relationship dynamics. Further, addiction may propel women into income-producing activities that distinguish them from women in the population at large, such as drug- or property-related criminal behavior and prostitution. Women substance users also face risks for HIV to a greater extent than men as a consequence of having drug-using partners who may have other sex partners; sharing injection equipment with sexual partners; and engaging in sex work for drugs or money.

It is important to note that women with substance use disorders are heterogeneous with regard to age (e.g. adolescents, young adult women, and older women), sexual orientation, race/ethnicity, ability, parenting status, location (e.g. rural versus urban), and socioeconomic status, and that these factors may influence clinical profile and treatment needs. Thus, the diversity among women with substance use problems needs to be addressed within the context of gender-specific treatment.

GENDER-SPECIFIC TREATMENT APPROACHES FOR WOMEN

Gender-specific substance abuse treatment services and programs for women generally focus on the psychosocial profile of substance-abusing women and their need for comprehensive services, particularly in regard to pregnancy and parenting, physical and mental health problems, employment and housing, and history of trauma and victimization. Some research suggests that women may be more responsive to treatment within women-only treatment facilities or groups because they feel less intimidated or concerned about being stigmatized in such settings, because of a desire to obtain services specific to their needs (e.g. for pregnancy or parenting), or because they seek shelter from intimate partner violence. Women may also feel safer and less vulnerable to harassment as well as better able to express their needs and feelings in gender-specific programs or groups. These emergent treatment approaches have been characterized as “gender-specific,” “woman-focused,” “gender-sensitive,” or “gender-responsive.”

Gender-specific treatment programs typically adopt treatment approaches or modalities that are modified from traditional treatment models. For example, many gender-specific treatment programs for women incorporate “empowerment” and supportive approaches to treatment, rather than traditional approaches that rely upon confrontational strategies to address “denial” among substance abusers. Empowerment approaches focus on identifying and building upon a woman’s strengths, such as her nurturing and relational capacities, rather than focusing solely on her deficits. Such approaches are particularly important given the generally higher levels of psychological distress, trauma exposure, and co-occurring mood and anxiety disorders that characterize women who enter into substance abuse treatment and the need to enhance their sense of competency and self-efficacy.

Another factor that differentiates gender-specific treatment approaches is the greater emphasis on addressing relationship issues within treatment, including relationships with family members, spouses or partners, children, and others. Upon entry into treatment, women typically report more interpersonal problems and conflicts with others than do men. Women may be more willing to self-disclose interpersonal problems, but they may also place more primacy on their relationships with others within their identity and self-concept. However, women with substance use disorders may have more conflicted family relationships for a variety of reasons, including family members who are less tolerant of their alcohol or drug use, sexual partners who are not supportive of their efforts to stop their

alcohol or drug use, and problematic relationships with children stemming from the mother’s substance use and lack of parenting skills.

CHARACTERISTICS OF GENDER-SPECIFIC TREATMENT SERVICES AND PROGRAMS

The proliferation of gender-specific programs in the past several decades has enabled the development of a rich body of research on the organizational characteristics of these treatment programs and the types of treatment services they provide. An early study conducted in the 1980s of 53 alcohol-treatment facilities in California showed that facilities in which there were higher proportions of women clients provided more services overall, and in particular more services for children, child care, and aftercare services. Subsequent studies have shown that treatment facilities that provide services to women only, or in which there is a higher concentration of women, typically provide a wider range of services designed to meet women’s specific treatment needs.

Data collected from an annual national survey of treatment providers show that approximately 41% of all treatment programs (among those that accept women as clients) provide either a “special” treatment program or services specifically for women. Among these programs, 41% provide domestic violence services, 17% provide services for pregnant or postpartum women, 18% provide child care, and 9% provide residential beds for clients’ children. Moreover, a greater proportion of programs that provide women-specific services, compared with those that do not, also provide other comprehensive services typically needed by women; these included housing assistance, employment counseling, and assistance with social services. Facilities providing a special program or service for women are more likely than other programs to be operated by private, nonprofit organizations and less likely to be operated by private, for-profit groups.

Surveys of treatment programs that receive a majority of their funding from private (i.e. nongovernmental) sources have shown similar findings regarding organizational characteristics as surveys of publicly funded providers. Private-sector programs with a “majority female caseload” are more likely than those in which women are a minority to provide child care, to have more family involvement in treatment, to provide treatment for psychiatric disorders, to employ counselors with master’s level degrees, to receive more referrals from mental health sources and fewer workplace referrals, and to accept payment through public insurance. Another survey of outpatient substance abuse treatment

programs examined the organizational factors related to the provision of women's health services, such as gynecological exams, reproductive services, and prenatal services. Programs providing these services are more likely to receive funding earmarked for women's treatment, to be methadone providers, to have a greater proportion of staff who have been trained in women's treatment issues, and to be private not-for-profit units and public units, rather than for-profit.

National survey data have shown that the proportion of programs that provide services typically associated with women's treatment needs (i.e. child care, domestic violence counseling, family counseling, prenatal and postnatal care) gradually increased from mid-1980s, peaked in the mid- to late 1990s, and subsequently declined. The largest proportion of gender-specific facilities for women are among residential/therapeutic community (TC) programs (~20%); hence, women also constitute a greater proportion of clients treated within residential programs (~35%) compared with their representation in other modalities. Therefore, the vast majority of women receive treatment in mixed-gender outpatient programs, which has the lowest rates of providing women-specific services.

In addition, national survey data show that programs that provide "special services" for women (e.g. a women-specific program, group, or treatment track) are more likely to provide other services that address women's treatment needs (e.g. child care, transportation assistance, housing assistance, domestic violence counseling, employment counseling). Other studies have shown that gender-specific treatment programs for women provide a wider range of comprehensive services than mixed-gender programs, including prenatal, postpartum, and well-baby services; job training, life skills training, client advocacy, transportation, housing assistance; and peer support groups and aftercare. In addition, programs that are primarily publicly financed or not-for-profit are more likely to provide these services than those that are for-profit.

A recent panel study compared the provision of services relevant to women's treatment needs (e.g. prenatal care, child care, single-sex therapy, same-sex therapists, staff trained in women's treatment) in outpatient substance abuse treatment programs in 1995 and 2005. The study found that there were significant declines over this period in the provision of single-sex therapy and the percentage of staff trained to work with women in outpatient programs. Furthermore, private for-profit treatment units became more prevalent over the study period, and these programs are less likely than others to provide the range of services defined by women's treatment needs. There were also significant declines in the provision of same-gender group therapy in methadone programs from 1995 to 2000, as well as declines in

same-gender individual and group therapy in nonmethadone outpatient programs from 1995 to 2005. Taken together, these surveys indicate that the growth in gender-specific services for women has slowed within outpatient programs and that provision of these services may be influenced by the sources of financing for these programs.

Although women are a minority within the criminal justice system, in the past several decades there has been a more rapid increase in the incarceration rates of women for drug-related offenses, as compared with men. This difference primarily stems from women's greater involvement in drug- and property-related crime, as opposed to other types of criminal behavior, compared with men. Given the increased rates of incarceration of drug-using women, gender-specific treatment programs for women offenders have been developed in both correctional and community-based treatment settings. Substance-abusing women offenders have substantial needs related to mental and physical health problems, trauma history, HIV risks, parenting, employment, and economic self-sufficiency. In addition, women offenders face numerous stressors upon their reentry to the community, including their reexposure to social networks and relationships that may precipitate their relapse to substance use and criminal activity. Gender-specific treatment programs developed for women offenders place an emphasis on providing parenting skills training; assistance with family reunification, when appropriate, including with children who have been placed in the child welfare system; assistance with educational needs, literacy training, vocational skills, and employment; and supportive social networks to sustain recovery and avert recidivism.

Despite the greater availability of services that directly address women's treatment needs in women-only programs, there remain gaps in the provision of needed services to women. As seen in one study of women who were referred into a gender-specific program for women by the child welfare system, fewer than half of the women who indicated they had specific treatment needs for child care, family counseling, job training, housing assistance, and benefits assistance actually received these services while in treatment. Thus, the provision of gender-specific services for women is neither universally available nor comprehensive throughout the broader treatment system.

OUTCOMES OF WOMEN TREATED IN GENDER-SPECIFIC PROGRAMS

Several early studies, predating the expansion of gender-specific programming for women, examined the outcomes of women who received treatment in

women-only versus mixed-gender programs. An experimental study conducted in Sweden in the 1980s, conducted with women who were in the “early stages” of alcohol dependence, demonstrated reduced alcohol use and better social adjustment for women treated in women-only programs compared to those who were treated in mixed-gender programs. The authors surmised that women may be more likely to enter into women-only programs at an earlier stage of their addiction careers. In contrast, a nonexperimental study conducted in Australia in the 1990s, which enrolled women who had more severe alcohol and drug disorders, found no outcome differences in drug use, severity of depression, self-esteem, or social support network between women treated in women-only and those treated in mixed-gender programs. However, lesbian women, women with a history of childhood sexual assault, and women with dependent children were less likely to drop out of the women-only program.

In the ensuing years, based on data from the various treatment demonstration projects that enabled the expansion of services dedicated to women as well as from single-site clinical studies, a growing body of research has accumulated regarding the characteristics of women treated in gender-specific programs, and their posttreatment outcomes, as well as the outcomes of their children who also receive services. Several studies show that there are differences in the characteristics of women who receive treatment in gender-specific and mixed-gender treatment programs. In an early study, women treated in women-only residential programs were more likely to have been sexually abused as children, to be lesbians, and to have dependent children, compared to women in mixed-gender residential programs. In another study, women who were treated in women-only residential programs had more severe problems and service needs at treatment entry (e.g. pregnant, homeless, longer duration of drug use, under legal supervision), but they were twice as likely to complete treatment as compared with women who were treated in mixed-gender treatment programs.

Several national and site-specific studies have shown that women who are treated in programs that provide gender-specific services are retained longer in treatment and have better outcomes, as compared to women treated in traditional mixed-gender programs that do not provide gender-specific treatment services. A national treatment outcome study found that pregnant and parenting women who were treated in residential programs in which there were higher proportions of other such women had longer stays in treatment and that longer stays, in turn, were positively associated with posttreatment abstinence. These programs also provided more comprehensive services, including those that addressed family, parenting, and mental health

needs. A nonexperimental study conducted in California compared women treated in women-only and mixed-gender programs, including both residential and outpatient programs. As found in other studies, women treated in women-only programs had greater problem severity in a number of domains including alcohol, drug, family, medical, and psychiatric. Moreover, they utilized more treatment services and had better drug and legal outcomes at follow-up as compared to women who were treated in mixed-gender programs.

In another study, providing women with transportation, outreach, and enhanced treatment services was associated with receipt of a greater number of services overall, which in turn was related to lower posttreatment drug use. Moreover, another study has shown that women who are treated in specialized long-term residential treatment programs for women are more likely than those treated in standard, mixed-gender programs to be referred to services (e.g. medical, dental, mental health, vocational) and to self-help groups at the time of discharge, and that they are more likely to participate in continuing care following their discharge. Further, this effect was enhanced among women who had completed the specialized residential treatment.

Taken together, this body of research has demonstrated that women have higher rates of treatment completion and better outcomes: (1) in residential treatment programs that have live-in accommodations for children; (2) in outpatient treatment that includes the provision of family therapy, individual counseling, and family services; and (3) when treatment includes comprehensive supportive services, such as case management, pregnancy-related services, parenting training/classes, child care, vocational training, and aftercare. In addition, women in substance abuse treatment who receive more health and social services report better outcomes and greater satisfaction with treatment, particularly when services are matched with their needs.

GENDER-SPECIFIC TREATMENT COMPONENTS ASSOCIATED WITH OUTCOMES

The proliferation of research on women-specific treatment has allowed for several reviews that examine the common elements associated with improved outcomes for women in substance abuse treatment. A meta-analysis of 34 treatment outcome studies showed that women who received substance abuse treatment in women-only programs, compared to those treated in mixed-gender programs, had better drug use outcomes following treatment. Similarly, women who were treated in women-only programs that had enhanced

programming (i.e. more intensive or specialized services), compared with those in standard women-only programs, had better outcomes in several areas, including psychological well-being, attitudes and beliefs, and HIV risk reduction. Although overall effect sizes for these differences were modest, the largest effects were found in the area of psychiatric outcomes, with smaller effects for reductions in alcohol use, other drug use, and criminal activity.

Another systematic review of program factors related to successful treatment outcomes among women in 35 studies identified five factors: (1) single- versus mixed-gender programs; (2) treatment intensity; (3) provision of child care; (4) case management; and (5) supportive staff and the provision of individual counseling. Similarly, a systematic review of 38 studies of substance abuse treatment for women, most of which were nonexperimental designs, identified six elements that are associated with better outcomes regarding treatment completion, length of stay, decreased use of substances, reduced mental health symptoms, improved birth outcomes, employment, self-reported health status, and HIV risk reduction. These elements are (1) child care, (2) prenatal care, (3) women-only program composition, (4) supplemental services and workshops that address women-focused topics, (5) mental health services, and (6) comprehensive programming.

An important consideration with regard to the adoption of gender-specific services is the generally higher cost of these services, due to the longer duration of treatment and inclusion of comprehensive services that increase costs, such as medical services, live-in capacity, and/or services for children, vocational services, mental health services, housing, and so forth. Yet, several studies have shown that despite the generally higher costs of gender-specific treatment for women, these costs are offset by the improved outcomes they yield. Cost-benefit analyses have shown favorable results in residential versus outpatient treatment for women; in specialized versus standard residential programs for women; in substance abuse treatment that integrates “trauma-specific” services versus usual care; and in a multidisciplinary, comprehensive treatment program for pregnant women versus standard care.

METHODOLOGICAL ISSUES IN RESEARCH ON GENDER-SPECIFIC TREATMENT

Several methodological shortcomings to the extant body of research on women’s treatment programs have been identified. These include (1) a limited range of treatment outcomes examined; (2) lack of experimental studies with randomized assignment to

conditions; (3) lack of standardized measures; (4) inconsistent definitions for treatment factors and outcomes; (5) small sample sizes that lack statistical power, particularly for conducting subgroup comparisons; (6) lack of thorough program description that allows for replication of program models; (7) lack of thorough statistical analyses; (8) small effect sizes for observed outcomes; and (9) limited duration of follow-up periods. These limitations in methodological rigor, although not unique to this area of research, clearly qualify the conclusions that can be drawn from the extant literature on treatment outcomes for women who are treated in gender-specific programs or who receive specialized treatment services.

In addition to these methodological considerations, several exceptions to the findings regarding superior outcomes for women treated in gender-specific programs should be noted. An experimental study that randomly assigned participants to women-only versus mixed-gender day treatment programs found no beneficial effects of women-specific treatment. Moreover, other research has found no differences in the rates of retention and completion among either males or females who were treated in mixed- versus single-gender programs. However, research findings may be inconclusive because these studies failed to differentiate the client composition of the programs from the content of treatment/services that were provided. Thus, the construct of “gender-specific” treatment, and the “active ingredients” of treatment approaches designed for women, needs to be carefully defined and measured.

For example, traditional TC programs, even if gender-specific, may be clinically inappropriate if their emphasis on confrontation is not modified to accommodate the greater likelihood of trauma and abuse history among women, particularly among women in the criminal justice system where TC programs have been widely adopted. Further, it is assumed that the therapeutic dynamics within gender-specific programs for women differ from those in mixed-gender programs, yet many outcome studies examine only time in treatment or types of services provided, rather than the therapeutic aspects or key components of women-specific treatment that may be related to outcomes.

EVIDENCE-BASED TREATMENT APPROACHES FOR WOMEN WITH SUBSTANCE USE DISORDERS

Increasing emphasis has been placed on incorporating treatment approaches that have received empirical support from scientific research on treatment effectiveness and outcomes. Several treatment approaches have

emerged as the primary evidence-based treatment practices within the field of addictions treatment. These include pharmacotherapy, relapse prevention/cognitive behavioral interventions, motivational interventions, contingency management, and trauma-specific interventions. These treatment approaches have either been modified or have the potential to be, in order to address the specific treatment needs of women. The evidence on effectiveness of these approaches for women, and their potential to address gender-specific treatment for women, is briefly described below.

Pharmacotherapy

Pharmacotherapy, mostly opiate-substitution therapies, has addressed the use of medications in the treatment of pregnant women, given considerations of prenatal exposure and birth outcomes, and the need to adjust dosing appropriately. Pharmacological treatment of opiate-dependent pregnant and postpartum women requires careful consideration of assessment and selection of appropriate maintenance medication; induction and stabilization; and medication management in relation to the various stages of pregnancy, delivery, postpartum, and aftercare. A large, multisite double-blind study recently showed that opiate-dependent pregnant women who receive buprenorphine have similar or improved outcomes (with regard to treatment adherence, birth outcomes, neonatal status) as pregnant women who receive methadone maintenance treatment. Apart from issues related to pregnancy, few clinically significant gender differences have been identified in the use of buprenorphine (a medication with both opioid agonist and antagonist properties) and methadone (an opioid agonist).

There is some evidence suggesting that, among patients with cocaine and alcohol dependence being treated with naltrexone (an opioid receptor antagonist), women have more side effects, less treatment adherence, more treatment attrition, and lower rates of abstinence in response to the same dose, as compared with men. Gender differences in pharmacokinetics (e.g. processes related to the absorption, distribution, metabolism, and elimination of a drug) may underlie differential responses to medications and their effectiveness in treating alcohol or drug dependence; however, research in this area is still limited.

Relapse Prevention

Relapse prevention approaches focus on teaching clients to recognize “cues” or “triggers” for substance use and to use cognitive behavioral strategies for coping with these triggers and avoiding relapse in those

situations. Generally, gender differences have not been identified in response to relapse prevention interventions; however, there are differences in the factors and social contexts that are associated with relapse to substance use for men and women. For males, these include living alone, positive affect, and social pressures, whereas for females, relapse has been associated with not living with one’s children, being depressed, having a stressful marriage, and being pressured to use by their sexual partners. Several factors that influence likelihood of relapse among women have been identified across studies: (1) low self-worth and its connection to intimate partner relationships with men; (2) interpersonal conflicts and/or negative emotional states; (3) less ability to sever relationships with one’s drug-using network and to establish new relationships with nonusers; and (4) a lack of knowledge about alcohol and drug processes and relapse prevention coping skills.

Cognitive behavioral approaches can be tailored to help women identify the specific triggers and situations that may be likely to precipitate relapse, and to utilize effective coping strategies for dealing with those situations. In particular, given the higher rates of co-occurring mood and anxiety disorder among women, the role of psychiatric symptoms in precipitating relapse needs to be identified and appropriate mental health treatment provided. Current research in this area is focusing on identifying the key ingredients of cognitive behavioral approaches that are effective in reducing relapse for women. Thus, it is unclear whether the group dynamics in all-women groups that provide these interventions, or the gender-specific content provided within these groups, such as women’s specific antecedents to substance abuse and cues and triggers to relapse, improve women’s responses to cognitive behavioral interventions, or some combination of both process and content.

Motivational Interventions

Motivational interventions use therapeutic strategies to increase the individual’s awareness of problems that stem from their substance use, to engage their commitment to behavior change, and to support ongoing efforts at behavior change that includes an understanding of relapse within the recovery process. Behavioral change is conceptualized as a dynamic process across stages, including precontemplation, contemplation, action, and maintenance. Brief motivational interventions may be delivered by counselors, nurses, or social workers in health care or social services settings, in conjunction with screening and referral to substance abuse treatment, or can be integrated within the therapeutic process of substance abuse treatment.

Few studies have actually examined gender differences in the effectiveness of motivational approaches, either in treatment engagement or outcomes. Motivational interventions can build upon the issues that are central to motivating women to address their substance abuse problems, particularly related to their identity, self-esteem, health, and relationships with children, other family members, and friends. Brief motivational intervention has been used to address alcohol and tobacco use among pregnant women in primary health care or prenatal care settings by providing information on the health effects of alcohol or tobacco use during pregnancy, with the aim of motivating women based on their desire to protect the health of their child.

Contingency Management

Contingency management approaches employ a schedule of rewards to strengthen the practice of desired behaviors (e.g. abstinence, prosocial activities). These rewards may be small gifts, cash, or vouchers, which can be accumulated based on the duration of abstinence attained, as well as reversed upon a relapse. Although few studies have identified gender differences in response to contingency management, some interventions have been developed specifically for women.

Most commonly, contingency management has been successfully used in smoking reduction programs for pregnant women who are receiving treatment for drug abuse and for pregnant women who are in treatment for alcohol or cocaine dependence. Contingency management for women can effectively utilize personal hygiene, household, or children's items as "prizes" for attaining or sustaining abstinence, based on urine test results. Contingency management interventions have also been combined with brief motivational interventions within the context of case management services for pregnant women.

Trauma-Specific Interventions

Several interventions have been developed to integrate treatment for the effects of trauma exposure, including co-occurring posttraumatic stress syndrome (PTSD), within the context of substance abuse treatment. Examples of these trauma-specific treatment approaches include *Seeking Safety*, which integrates cognitive behavioral strategies with group psychotherapy to address both PTSD and substance abuse disorders; *Beyond Trauma*, a curriculum that was developed specifically for women and employs "relational theory" to build upon the importance of relationships in women's emotional well-being; and the *Trauma Recovery and Empowerment Model*, which uses group therapy to

promote recovery skills and social functioning. Outcomes studies have shown promising outcomes for women who receive trauma-specific interventions, although mainly on reducing trauma-related symptoms, rather than in reducing alcohol and drug use.

CONCLUSIONS

There have been tremendous gains in recent years in our understanding of the influence of gender on the course of substance use disorders, the differential pathways into treatment, the clinical and service need profiles of women with substance use problems, and the factors related to treatment retention and outcomes in gender-specific programs. There is a rich body of research on the organizational characteristics of the programs in which women receive substance abuse treatment, the types of services that are provided in these programs, the changes in services provision over time, and the relationship of services received to treatment outcomes, including the cost effectiveness of gender-specific treatment for women.

The emphasis on evidence-based treatment approaches within the field of addiction treatment provides further opportunities to tailor treatment protocols to increase their effectiveness with women, particularly behavioral approaches that use cognitive behavioral therapies, motivational enhancement interventions, contingency management, and trauma-informed interventions. At the same time, more developed conceptual models are needed that identify the mechanisms that underlie gender-specific treatment approaches and their effectiveness for women, as well as the comparative effectiveness of these approaches for different subgroups of women.

Glossary

Gender differences with regard to substance use, gender differences focus on how men and women differ in their background

characteristics, initiation, and progression of substance use, family and social support, education and employment history, mental and physical health, parental status, service needs, patterns of treatment utilization, and treatment outcomes.

Gender-responsive treatment according to Covington and Bloom (2006), gender-responsive treatment is “creating an environment through site selection, staff selection, program development, content, and material that reflects an understanding of the realities of women and girls and that addresses and responds to their strengths and challenges.” Also referred to as “woman-focused” or “gender-sensitive” treatment.

Gender-specific treatment refers to treatment programs or services that are specifically for women or men and are typically sex segregated, in contrast with “mixed-gender” programs or services.

Program characteristics refers to the organizational features of treatment programs that may influence treatment processes and outcomes. These include program size; characteristics of staff, such as sociodemographics, education, training, and rate of turnover; revenue sources and program resources; stability of the program, such as its duration; types of services provided to individuals in treatment; linkages with other service providers; and overall program “culture” and “climate” that reflect the shared beliefs of staff about their mission and goals and attitudes toward treatment.

Trauma-informed services according to Morrissey et al. (2005), trauma-informed services refer to the provision of a comprehensive array of services that include outreach, assessment, crisis intervention, trauma-specific counseling, ongoing treatment, parentskills training, resource coordination and advocacy, and peer-run services; trauma-specific service interventions; appropriately trained staff; integration of counseling and other services for treatment for mental health, substance abuse, and trauma-related problems; and inclusion of input from consumers.

Treatment outcomes with regard to substance use, treatment outcomes refer to posttreatment relapse to substance use and may also broadly include mental and physical health status, employment, criminal activities and/or involvement in the criminal justice system, family and social functioning, and overall psychosocial functioning. Research has focused on gender differences in specific outcome domains and in the factors that are correlated with positive treatment outcomes.

Psychological Trauma, PTSD, and ASUD	189	Screening for PTSD in ASUD Treatment	192
Psychological Trauma History and PTSD as Prognostic Factors in ASUD Treatment	190	Conclusion	193

Individuals in treatment for alcohol and other substance use disorders (ASUD) often have faced adversity in their lives, including psychologically traumatic events. Community and clinical epidemiologic studies have found that individuals in treatment for alcohol and other ASUD, especially involving opiates, are likely to have experienced psychological trauma (e.g. 67–90% prevalence) and post-traumatic stress disorder (PTSD, i.e. 25–48% prevalence) at some time in their lives. These prevalence estimates for lifetime exposure to psychological trauma and PTSD are substantially higher than those from community epidemiological studies of adults and adolescents, which estimate 33–60% prevalence of exposure to psychological trauma and 4–7% lifetime prevalence of PTSD.

There also is substantial clinical evidence that PTSD and ASUD tend to exacerbate and sustain each other. Men and women with alcohol- or cocaine-related ASUD and PTSD were more likely than those without PTSD to report a craving for substances if reminded of past trauma or substance use. Women in ASUD treatment with comorbid PTSD–ASUD report more extensive trauma histories and severe PTSD symptoms (particularly avoidance, emotional numbing, and sleep difficulties) than women with PTSD only. Read and colleagues found that higher substance use levels or problems also are associated with more severe intrusive

and avoidance PTSD symptoms. Similarly, Seedat and colleagues found that higher substance use levels were associated with more severe dissociation symptoms. Conversely, Stewart and Conrod found that accident survivors or women who have been raped were more likely to have persistent PTSD if they had prior alcohol disorders than those with no alcohol disorder.

Given the frequent comorbidity of PTSD and psychological trauma history with ASUD, and the impairment resulting from this combination, clinical research and treatment development efforts have focused on three approaches to addressing PTSD in ASUD treatment services:

1. Determining whether, and how, psychological trauma history and PTSD can serve as prognostic factors in ASUD treatment.
2. Developing and evaluating interventions that simultaneously treat PTSD and ASUD in an integrated concurrent or sequential intervention.
3. Developing and evaluating screening for PTSD in ASUD treatment settings, in order to facilitate targeted delivery of integrated ASUD/PTSD treatment.

Research on the impact of psychological trauma and PTSD in ASUD treatment is nascent but could contribute to enhanced treatments for comorbid ASUD–PTSD. A

brief introduction to the definition and clinical features of psychological trauma and PTSD, and their relationship to ASUD, will be provided before reviewing relevant research in the three areas described above.

PSYCHOLOGICAL TRAUMA AND PTSD

Psychological trauma is defined in the American Psychiatric Association's *Diagnostic and Statistical Manual*, Fourth Edition Text Revision (DSM-IV-TR) as:

a traumatic event in which both of the following were present: (1) the person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury or a threat to the physical integrity of self or others (2) the person's response involved intense fear, helplessness, or horror.

Thus psychological trauma is a special case of the larger class of life stressors which is defined by objective threat of death (directly or as a witness) or of physical integrity (i.e. sexual assault or abuse) and intense subjective distress at the time of or shortly after the event(s).

PTSD is further defined in the *DSM-IV-TR* as present if, for more than 1 month, three types of symptoms occur and cause "clinically significant distress or impairment in social, occupational, or other important areas of functioning." The PTSD symptoms are as follows:

- *Intrusive re-experiencing* – unwanted disturbing memories of traumatic event(s), including but not limited to flashbacks (experiencing the event as if it was occurring at the present moment) and psychologically or physically distressing reminders of past traumatic events, while awake or asleep (e.g. nightmares).
- *Avoidance and emotional numbing* – efforts to avoid thoughts, feelings, discussion, people, places, or activities that are reminders of past traumatic events, amnesia for important portions of those events (which must be "psychogenic," that is, not due to physical injury or illness), generalized anhedonia, emotional numbing, detachment from relationships, and a sense that life will be cut short ("foreshortened future").
- *Hyperarousal* – sleep difficulties, anger or irritability, problems concentrating, extreme watchfulness ("hypervigilance"), and an exaggerated startle response.

In order to qualify for a diagnosis of PTSD at least one intrusive re-experiencing symptom, three avoidance and emotional numbing symptoms, and two hyperarousal symptoms must occur.

In the proposed criteria for PTSD in the American Psychiatric Association's *DSM-5*, psychological trauma

has been re-defined as exposure to "death or threatened death, actual or threatened serious injury or actual or sexual violation," in one or more of the following ways:

1. Experiencing the event(s) him/herself.
2. Witnessing, in person, the event(s) as they occurred to others.
3. Learning that the event(s) occurred to a close relative or close friend; in such cases, the actual or threatened death must have been violent or accidental.
4. Experiencing repeated or extreme exposure to aversive details of the event(s) (e.g. first responders collecting body parts; police officers repeatedly exposed to details of child abuse); this does not apply to exposure through electronic media, television, movies, or pictures, unless this exposure is work-related.

Two key changes are proposed to the trauma criterion *DSM-5*. First, the requirement that the person experiences a subjective reaction of intense fear, helplessness, or horror at the time or soon after the traumatic event(s) has been removed. This may be relevant for individuals who have ASUD when exposed to psychological trauma or who develop ASUD thereafter, given evidence from a study by Ouimette and colleagues that comorbid ASUD/PTSD often involves heightened emotional numbing which may involve (or be exacerbated by) substance use as a self-medication tactic. Second, events are explicitly included that were not directly experienced or witnessed but that were learned about or seen in the aftermath and that involve family or close friends or gruesome death or bodily harm. The latter additions are particularly relevant in light of evidence of increased risk of ASUD (particularly problems involving alcohol use) among victims of political or domestic violence, and among first/emergency responders, military personnel, and others who routinely face extreme hazards or give aid to victims of psychological trauma.

Several revisions of the symptom criteria for PTSD proposed in the *DSM-5* also may have a bearing on the ASUD-PTSD relationship and treatment for comorbid ASUD-PTSD. The symptoms of emotional numbing that formerly were grouped with avoidance symptoms have been expanded and separated out as a distinct feature labeled: "negative alterations in cognitions and mood that are associated with the traumatic event(s)." Specifically, symptoms have been added to describe post-traumatic alterations in beliefs ("persistent and exaggerated negative expectations about one's self, others, or the world" and "persistent distorted blame of self or others about causes or consequences of the traumatic event(s)") and emotions ("pervasive negative emotional state – for example, fear, horror, anger, guilt, or shame"). Exemplars of altered post-traumatic beliefs provided in the *DSM-5* proposed revision are similar

to cognitive distortions that have been found to occur commonly among individuals with ASUD (e.g. "I am bad," "No one can be trusted," "I've lost my soul forever," "my whole nervous system is permanently ruined," "the world is completely dangerous"). The inclusion of persistent negative emotions as PTSD symptom is relevant to ASUD treatment because pervasive negative mood has been found to be associated with alcohol craving, and difficulty with negative emotion regulation may share biological and behavioral substrates with addiction. Thus, the expanded cognitive and affective symptoms proposed for PTSD in the *DSM-5* potentially offer additional addiction-related foci for addressing PTSD in ASUD treatment.

PSYCHOLOGICAL TRAUMA, PTSD, AND ASUD

Epidemiologic studies have shown that adults with ASUD (especially when those disorders involve opiates or cocaine) are at least 150% and as much as 10 times more likely to have PTSD than other adults, and adolescents with ASUD show a similar but somewhat lesser (i.e. 50–200%) increased risk of PTSD. PTSD is also associated with the risk of ASUD, particularly among adolescents for whom the risk of ASUD is as much as 14 times greater when PTSD occurs. Adults with PTSD have a 50–350% increased risk of ASUD.

PTSD and ASUD may co-occur for many reasons. The theoretical model with strongest empirical support is the "self-medication hypothesis," which suggests that ASUD represent an attempt to use substances to cope with PTSD symptoms. Both epidemiological and ASUD treatment studies provide additional support for the self-medication hypothesis, showing that PTSD more often pre-dates ASUD than vice versa, with only one exception in which 18-year olds were slightly more likely (54%) to report that alcohol dependence preceded PTSD than vice versa (46%). A prospective study of primarily white middle-class adults in a health maintenance organization (age 21–35 years) found that PTSD led to a fourfold increased risk of developing ASUD independent of the influence of prior conduct problems or depression, but ASUD did not increase the risk of either exposure to psychological trauma or PTSD. The strongest relationship between PTSD and ASUD was with abuse or dependence upon prescription drugs but not street drugs, consistent with the higher levels of use of prescription drugs versus street drugs by this particular subgroup of young adults. Similar findings of ASUD leading to an increased risk of PTSD (but not of trauma exposure per se) have been reported with alcohol and street drugs in studies of women, military veterans, and disaster victims. Thus, ASUD may

pre-date and lead to PTSD, but it is more likely that ASUD develop or are worsened as a result of attempts to cope with PTSD symptoms.

However, certain forms of illicit drug use may have a more complex relationship to PTSD symptoms than simply increasing their likelihood, prominence, or severity. Substances that are associated with increased arousal (e.g. cocaine, amphetamines) may be used to heighten PTSD hyperarousal and hypervigilance symptoms, or to counteract or compensate for post-traumatic dysphoria and emotional numbing. Consistent with this view, studies by Shiperd and colleagues and Waldrop and colleagues which found only partial support for the self-medication model reported no relationship between, respectively, "hard drug" use and PTSD, and greater use of cocaine at times of "pleasant interaction with others" by individuals with PTSD and ASUD.

PTSD also may play a role in the etiology of ASUD in adolescence. In the National Survey of Adolescents (NSA), Kilpatrick and colleagues found that PTSD increased the risk of ASUD and of associating with "deviant" peers (i.e. peers involved in delinquent activities, including substance abuse and conduct problems). Another study by Cornelius and colleagues assessed sons of men who had a lifetime history of substance abuse at several intervals from ages 12–14 to 25 years old, finding that PTSD was associated with both deviant peer associations and cannabis use disorders. Moreover, PTSD mediated the relationship between deviant peer associations cannabis use disorders. Further indirect support for this view comes from secondary analyses of NSA data by Ford and colleagues, which showed that youth who are exposed to multiple forms of traumatic stressors were particularly likely to develop both PTSD and ASUD, and to engage in delinquency and with deviant peers. Thus, among youth involved in delinquency or with deviant peers, PTSD may contribute to the development of ASUD.

Adults or adolescents who experienced extensive maltreatment or multiple forms of traumatic victimization are at risk not only for ASUD but also for severe problems with emotion dysregulation, dissociation, self-harm, impulse dyscontrol, and relational conflict and instability. Although not codified as a psychiatric diagnosis, this constellation of self-regulatory deficits has been described as a complex variant of PTSD. Complex PTSD symptoms may interfere with engagement, motivation, active participation, learning, and retention in ASUD treatment, and with the ability to inhibit substance cravings and impulsive substance-seeking, and to sustain substance-free relationships and relapse prevention behaviors. Therefore, it is important to examine the potential role of complex PTSD as a prognostic indicator in ASUD treatment.

PSYCHOLOGICAL TRAUMA HISTORY AND PTSD AS PROGNOSTIC FACTORS IN ASUD TREATMENT

PTSD has been found to negatively influence the course and outcome of ASUD treatment. Co-occurring PTSD and ASUD have been shown to be associated with poorer ASUD treatment recruitment and retention and outcomes. In a large multi-site study, Najavits and colleagues found that cocaine-dependent outpatients with comorbid PTSD improved less than ASUD-only participants on measures of alcohol use and psychosocial problems.

However, these findings of PTSD as a negative prognostic factor were not replicated in other studies. Pharmacotherapy, either associated depression symptoms with the selective serotonergic reuptake inhibitor antidepressant Sertraline or for alcohol craving with disulfiram and naltrexone, has been shown to be safe and effective with adults with comorbid PTSD and alcohol use disorders. Trafton and colleagues found that chart-diagnosed PTSD was not associated with differential opiate substitution treatment outcomes with military veterans. Similarly, Jaycox and colleagues found that PTSD was not related to poorer ASUD residential treatment retention by adolescents. However, teens in the latter study who had histories of psychological trauma were more likely to discontinue ASUD residential treatment than adolescents with no history of psychological trauma.

Although the evidence is sparse, PTSD (and psychological trauma history in adolescents) warrants careful attention clinically in ASUD treatment. Further evidence of the importance of addressing PTSD in ASUD treatment comes from a recent study by Norman and colleagues comparing cognitive-behavioral therapy for ASUD and depression with a 12-step Facilitation intervention. Participants with PTSD benefited equally to those without PTSD in terms of reduced severity of depressive symptoms and ability to achieve consistent abstinence from substances in treatment and for the first follow-up period. However, at a subsequent (18-month) follow-up assessment they reported a small proportion of days abstinent (i.e. 75% versus 91%).

A recent study by Cohen and Hien found that, although cognitive behavior therapy (CBT) for comorbid ASUD and PTSD had positive results for PTSD and substance use outcomes, there were no differences between persons receiving CBT and those who received no active treatment on outcomes consistent with the self-regulatory deficits in complex PTSD (e.g. depression, dissociation, social and sexual problems). Thus, complex PTSD symptoms may require treatment that specifically targets self-regulation skills, as discussed by Ford and

colleagues in their review of treatment models for complex PTSD.

Because complex PTSD symptoms may interfere with ASUD treatment, Ford and colleagues conducted secondary analyses of data from a multi-site study of the efficacy of contingency management (CM) in community-based clinics to examine both PTSD and complex PTSD symptom severity as prognostic indicators. Over and above the strong effect of CM intervention, the severity of complex PTSD symptoms – but not history of trauma exposure, PTSD symptom severity, or overall psychiatric symptom severity – predicted poorer outcomes in terms of retention in treatment and objectively verified continuous abstinence from cocaine and heroin use during treatment. Brief measures of PTSD and complex PTSD symptoms were used which did not permit inferences about either PTSD or complex PTSD as diagnostic syndromes, and a more definitive test of the study hypotheses would require the use of a structured interview (for PTSD or complex PTSD) or questionnaire (for PTSD) with continuous scores based upon the full set of PTSD and complex PTSD symptoms. Nevertheless complex PTSD symptoms emerged as an independent prognostic factor for cocaine- and heroin-use disorder treatment outcomes, but only in the CM condition. Complex PTSD symptoms also accounted for a relationship between having witnessed an assault and poorer treatment retention.

Although PTSD and complex PTSD symptoms were interrelated, only complex PTSD symptoms predicted immediate treatment outcome, consistent with Ford and Kidd's earlier findings with military veterans in treatment for chronic PTSD. Comorbid PTSD-ASUD often involves particularly severe PTSD symptoms, as does complex PTSD. Therefore, complex PTSD rather than PTSD per se may interfere with ASUD treatment if its symptoms are sufficiently severe to induce persistent self-medication. Another possibility is that complex PTSD's cognitive and emotional impairments might lead to poorer engagement in ASUD treatment. However, participants reporting more complex PTSD symptoms completed CM activities just as often as other participants, suggesting that complex PTSD does not reduce motivation or follow-through with ASUD treatment activities. Moreover, a high level of baseline PTSD symptoms was the strongest predictor of achieving abstinence at 9-month follow-up assessments, in contrast to prior studies' findings suggesting that PTSD symptoms are a negative prognostic indicator in ASUD treatment – but consistent with a recent study by Williams and colleagues with adolescents in ASUD treatment. The positive prognostic effect of PTSD held only for patients receiving CM, with 84% of PTSD participants achieving abstinence at 9-month follow-up compared to <67% by CM participants with no PTSD.

Thus, CM may provide a welcome distraction from and adaptive focus for persons experiencing intrusive trauma memories or hyperarousal and hypervigilance, and an adaptive alternative focus for people experiencing these PTSD symptoms. CM also may serve as a source of predictability, controllability, and positive emotions in contrast to PTSD's negative cognitive biases and emotional distress and numbing. It is also possible that patients with severe PTSD symptoms received more services than those with less severe PTSD.

In light of the strong association between complex PTSD symptoms and a history of child abuse, the role of child abuse history as a prognostic factor in ASUD treatment warrants study. A study by Lester and colleagues with homeless cocaine-dependent adults who had extensive histories of childhood psychological trauma provided indirect support for this view, showing greater improvements in PTSD and related symptoms in CM treatments than in less-intensive treatment. CM could offer a sharp positive contrast to the confusion and coercion that characterizes child abuse, by providing concrete and relatively immediate positive reinforcement contingencies to establish a predictable and controllable opportunities to achieve tangible positive outcomes. Although child abuse is prevalent among homeless adults, the study by Lester and colleagues did not directly investigate the role of abuse history specifically as a predictor of treatment outcome.

Petry and colleagues conducted a more direct test of the prognostic role of child abuse in CM using data from three randomized trials of CM on in-treatment outcomes (retention, proportion of negative urine samples submitted, and longest duration of abstinence) and abstinence at a 9-month follow-up. Compared to patients without sexual abuse histories ($N = 316$), those with sexual abuse histories ($N = 77$) submitted a significantly higher proportion of negative urine samples in treatment. In CM, but not in standard care, patients with sexual abuse histories had significantly longer durations of abstinence during treatment than those without sexual abuse histories. Although sexual abuse history was not associated with abstinence 9 months after treatment, longest duration of abstinence in-treatment was significantly associated with this long-term outcome. Results suggest that ASUD patients with childhood sexual abuse histories may accrue particular benefits during CM treatment which are associated with long-term abstinence.

Thus, psychological trauma history and PTSD may have quite different prognostic (and treatment planning) implications depending upon the type of psychological trauma, complexity of PTSD symptoms, and type of ASUD treatment. In order to capitalize selectively on these challenges and opportunities, several approaches to integrated PTSD/ASUD treatment have been

developed. A brief overview of models of integrated PTSD/ASUD treatment is provided in the next section.

INTEGRATED PTSD-ASUD TREATMENT INTERVENTIONS

ASUD clinicians and treatment programs do not consistently report evaluating PTSD nor offering PTSD treatment. Traditionally, individuals with ASUD have been recommended to seek PTSD treatment only after lengthy periods of substance use abstinence. Yet, even more than 10 years ago when the PTSD-ASUD link was just beginning to gain scientific and public attention, a study by Brown and colleagues reported that adults with co-occurring PTSD and ASUD preferred treatment for both PTSD and ASUD, and in an integrated manner rather than delaying PTSD treatment. Since then, several integrated PTSD-ASUD therapies have been developed and shown to have promising preliminary outcomes.

Three integrated treatment models combine CBT for PTSD with CBT for ASUD. Brady and colleagues developed a 16-session intervention combining a well validated behavior therapy for PTSD, prolonged exposure, with cognitive therapy, and pilot tested the model with cocaine-dependent adults with promising results for completers, but a high (60+%) drop out rate. A 12-week partial hospital group CBT treatment for military veterans with comorbid PTSD/ASUD ("Transcend") was developed by Donovan and colleagues, using a modified version of prolonged exposure. In a pilot study, they reported clinically significant reductions in PTSD and alcohol and drug use that were maintained at 6- and 12-month follow-ups. Triffleman and colleagues developed Assisted Recovery Trauma and Substances (ARTS), a 40-session one-to-one therapy that sequentially provides 11 sessions of CBT for ASUD followed by 29 sessions of CBT for PTSD. When ARTS was compared to CBT only for ASUD, it was found to achieve similar reductions in PTSD symptoms and superior attendance and abstinence.

Three other integrated PTSD/ASUD interventions address complex PTSD symptoms as well as PTSD and ASUD. Seeking Safety, developed by Najavits, teaches more than 80 "safe coping skills" for PTSD and complex PTSD symptoms. Unlike CBT models that use prolonged exposure, Seeking Safety does not include detailed review of specific trauma memories. A series of field and clinical trial studies have been reported evaluating Seeking Safety groups with women in substance abuse treatment, incarcerated or homeless women, juvenile justice-involved girls, and male military veterans. Seeking Safety consistently was associated with reductions in PTSD symptoms, but less consistent reductions

in substance use problems or in complex PTSD symptoms, compared to ASUD standard care or relapse prevention interventions or general health education. Initial results from a recent study found no added benefit from Seeking Safety versus health education, but subsequent analyses by Hien and colleagues showed that Seeking Safety was associated with greater mean reductions in AIDS risk behaviors in the overall sample, and in substance use for participants with more severe initial substance use problems if they also experienced a reduction in PTSD symptom severity in the treatment.

Trauma Recovery and Empowerment Model (TREM) was developed by Harris and Fallot as an educational group intervention (like Seeking Safety) for women or men with co-occurring major mental illness, ASUD, and PTSD. TREM particularly focuses on addressing the cumulative effects of living with poverty and stigma following victimization trauma. Although prolonged exposure is not used in TREM, the group offers opportunities to disclose memories of psychological trauma in the form of telling one's life story. A recent multi-site study of multi-component treatment models for women with co-occurring psychiatric and addictive disorders and histories of exposure to violence by Morrissey and colleagues included Seeking Safety and TREM at several sites. Although neither model alone was found to be superior to a usual care condition, "small but statistically significant" benefits were found in PTSD and mental health symptom reduction when results were aggregated for both integrated PTSD/ASUD psychotherapy approaches across all sites and interventions. Thus, integrated ASUD/PTSD treatment was supported in general despite no clear evidence of superiority by either Seeking Safety or TREM.

Trauma Affect Regulation: Guide for Education and Therapy (TARGET) was developed by Ford and colleagues to be delivered as either a group or individual therapy, and has been evaluated in field and clinical trial studies with adults in outpatient ASUD treatment, low-income and incarcerated women, and adolescent boys and girls in or at risk for involvement in the juvenile justice system. TARGET teaches a self-regulation skill sequence designed to address complex PTSD and ASUD simultaneously by enhancing both cognitive information processing and emotion regulation and reducing impulsive or habitual substance use in response to craving or triggers. Like Seeking Safety and TREM, TARGET does not involve prolonged exposure but focuses on PTSD symptom control. Studies by Ford and colleagues and by Frisman and colleagues have reported reductions in PTSD and complex PTSD symptoms and post-traumatic cognitions that were greater in TARGET than in problem solving or supportive therapy or ASUD treatment as usual, with

equivalent reductions in ASUD for both genders and all ethnocultural groups except for Black men. TARGET has also been found to be associated with reduced incidents of problem behavior and use of seclusion in juvenile detention centers.

SCREENING FOR PTSD IN ASUD TREATMENT

From a cognitive-behavioral standpoint, PTSD and ASUD result from dysfunctional (i.e. threat-based or addiction-based) beliefs, cognitive biases, and reactive behavior patterns that lead to an escalating sense of anxiety, anger, and helplessness. From a stress and coping perspective, PTSD and ASUD involve problematic coping with stressors that range in intensity from current reminders to traumatic events. The first step to ensure that these factors are addressed in ASUD treatment is to identify treatment recipients whose ASUD are impacted by PTSD or complex PTSD. Kimerling and colleagues found that a brief (<5 min) screening questionnaire had strong sensitivity and specificity for the identification of ASUD treatment recipients with undetected PTSD. In addition to providing information about clients' current functioning and treatment needs, initial PTSD screening provides an opportunity for psychoeducation that can enhance engagement in and motivation for ASUD treatment. For example, a screener could explain that unwanted trauma memories are actually signs of adaptive biological and psychological responses that are self-protective during traumatic events and problematic only when they persist and are unrecognized and unmanaged. In addition, persons with PTSD or complex PTSD may have difficulty gauging the severity of symptoms, potentially leading to under- or over-reporting. Education about PTSD in the screening process can facilitate more accurate identification and estimation of PTSD and complex PTSD symptoms.

A thorough review of traumatic stressors and PTSD or complex PTSD symptoms can be upsetting or demoralizing. Therefore, screening does not automatically involve obtaining a detailed trauma history or survey of PTSD symptoms. The validated brief screen does not specifically ask about any traumatic stressors and inquires only about the four types of PTSD symptoms (sub-dividing avoidance and emotional numbing into two separate items, consistent with research on the factor structure of PTSD) in general. Many PTSD-ASUD treatment recipients do not feel ready to disclose more than small amounts of information about traumatic experiences or PTSD symptoms until they have established a strong therapeutic alliance. In some cases, they may not be able to tolerate the intensity of their own reactions to disclosing the details of terrible personal

memories. For others, this is merely a fairly rote recitation of a familiar list of problems that they believe will never change. Still others feel compelled to “tell all” either to justify their distress and their right to treatment, or because they do not know how to select manageable amounts of past memories and how to regulate the associated emotions. Screening therefore should not focus singularly on past traumatic events, but on how current stress reactions interfere with the current relationships and the attainment of life goals – and how treatment can help with this. Further research is needed to determine if additional or modified screening protocols or items are needed in order to identify ASUD clients with complex PTSD.

CONCLUSION

In light of the extensive and growing empirical database demonstrating a bidirectional relationship between ASUD and PTSD, and suggesting that not only PTSD but also complex PTSD symptoms may require systematic attention in ASUD treatment, integrated ASUD/PTSD represents a challenging but evidence-based paradigm shift. Fortunately, a psychometrically and clinically promising brief screening measure is available for substance abuse (or primary care) providers to use in identifying patients for whom traumatic stress symptoms are particularly relevant in planning and delivering ASUD treatment. Promising interventions for ASUD with childhood sexual abuse survivors and for integrated treatment of comorbid ASUD/PTSD offer the clinician and researcher a growing variety of options. Further continued scientific and clinical studies nevertheless are needed in order to address unresolved questions related to the implementation of ASUD/PTSD treatment (e.g. timing, sequencing, and intensity of trauma-focused treatment) and how to ensure safety and enhance outcomes with cases complicated by complex PTSD impairment (e.g. self-harm, impulsivity, dissociation), continuing exposure to psychological trauma (e.g. ongoing domestic violence), and continuing substance use to self-medicate PTSD symptoms.

SUBSTANCE ABUSE AND CRIME

Substance abusers are disproportionately represented in the criminal justice system. More than 80% of offenders in the United States who were convicted of a drug- or alcohol-related offense, were intoxicated at the time of their offense, reported they committed the offense to support a drug habit, or have a significant history of substance abuse. Nearly one-half of prison and jail inmates meet diagnostic criteria for substance dependence or addiction. Conversely, approximately two-thirds of clients in residential substance abuse treatment and one-half of clients in outpatient substance abuse treatment are involved with the criminal justice system.

These figures are not merely attributable to individuals charged with drug offenses. In a national sample of United States booking facilities, positive drug tests

were obtained from the majority of arrestees for most categories of crimes, including violent, theft, property, and drug crimes.

Substance abuse is associated with a two- to fourfold increase in the likelihood of continued criminal offending. Fortunately, providing substance abuse treatment can reduce recidivism rates by 6–36%; however, drug-involved offenders are notorious for failing to comply with conditions to attend substance abuse treatment. If they are not closely supervised and do not receive meaningful consequences for failing to comply with treatment-related conditions, approximately 25% of drug offenders referred to substance abuse treatment fail to enroll in treatment; and of those who do enroll in treatment, approximately one-half drop out before receiving a minimally sufficient dosage of 3 months of services.

A major goal, therefore, of effective correctional programming is to ensure that drug-involved offenders

comply with their treatment and supervisory conditions. Despite traditional concerns that substance-abusing individuals cannot be coerced to get well, evidence suggests that individuals who enter substance abuse treatment under the threat of a legal sanction perform at least as well, and often appreciably better, than those entering treatment voluntarily.

A range of sentencing dispositions has been created to identify drug problems among offenders, refer them to treatment, and hold them accountable for showing up for the clinical interventions. The challenge is to select from among this array of options the most effective disposition for each offender that will optimize outcomes at the least cost to taxpayers and with the least threat to public safety.

SENTENCING OPTIONS

A continuum of sentencing options is available in virtually all US jurisdictions for intervening with drug-involved offenders. Programs at one end of this continuum emphasize public health or rehabilitation objectives using less restrictive means, whereas those at the other end emphasize public safety objectives applying restrictive conditions. Programs in the center strive to integrate elements of both public health and public safety approaches by combining criminal justice supervision with mandatory community-based treatment.

Pre-Plea Diversion

Offenders who have been charged with relatively minor crimes may have the opportunity to avoid a criminal record by remaining arrest-free for a specified period of time, satisfying minimal reporting obligations and completing applicable treatment requirements. Upon satisfaction of the conditions, the charges are dropped and the record may be expunged. Although the record may not be literally erased from criminal justice databases, record expungement ordinarily entitles the individual to respond truthfully on an employment application or similar document that the arrest or conviction did not occur.

Disposition Before Judgment

Most jurisdictions have statutory provisions offering certain drug offenders an opportunity for diversion “with teeth.” This model may go by various names, but has been generically referred to as disposition before judgment or probation without verdict. The offender is required to plead guilty or no contest (*nolo contendere*) to the charge(s) and the plea is held in abeyance while the offender completes a term of probation with

conditions for treatment and supervision. Satisfaction of the conditions leads to the plea being retroactively vacated or withdrawn, and perhaps to the opportunity for record expungement. Because the offender has already pled guilty to the charge(s), failure to complete treatment can lead to immediate sentencing. This arrangement offers additional coercive leverage to keep offenders engaged in treatment and compliant with their supervisory conditions.

Drug Courts

Drug courts are special dockets or calendars within the criminal court system, in which a judge supervises the diversion program. Participants appear in court frequently for “status hearings” during which the judge reviews their progress in treatment and may apply gradually escalating punitive sanctions for infractions or rewards for achievements. Participants must also complete a mandatory regimen of drug abuse treatment and random weekly drug testing. Typically, defendants must plead guilty or stipulate to (acknowledge) the facts in the criminal complaint as a condition of participation in drug court. Pre-adjudication drug courts often include a diversion component similar to disposition before judgment, in which graduates can have the charge(s) dropped and the record expunged. Post-adjudication drug courts enable graduates to avoid a sentence of incarceration, shorten the term of probation or consolidate multiple probation sentences.

Intermediate Punishment

Intermediate punishment refers to a category of community-based sentences that are imposed in lieu of incarceration. Examples include military-style boot camps, intensive supervised probation (ISP) programs, correctional halfway houses, day-reporting centers, home detention, and electronic monitoring. The aim of these programs is to safeguard public safety while at the same time reducing correctional costs and avoiding the debilitating effects of institutional incarceration.

Incarceration

Incarceration in county jail or state prison is authorized by statute or sentencing guidelines for many drug-related offenses, including possession, possession with the intent to distribute drugs, sales, and manufacturing. The recommended range for the term of incarceration is typically predicated on offense-based factors, including the amount and type of drug that was involved, the offender’s prior offense history, and whether the crime involved distribution or manufacturing as opposed to simple possession. There

may also be opportunities for a “downward departure” or “upward departure” outside of the recommended range based upon specified mitigating factors, such as demonstrated efforts at rehabilitation, or aggravating factors, such as dealing drugs near a school zone.

EVIDENCE-BASED SENTENCING

Although a range of sentences is often available for many drug-involved offenders, sentencing practices have tended to over-rely on certain dispositions for a wide range of cases. For example, the US “War on Drugs” of the 1980s imposed mandatory minimum sentences and longer prison or jail terms for various types of drug crimes, including some drug-possession offenses. Although this strategy appears to have contributed to a plateau or reduction in then-rising crime and violence rates, it paid insufficient attention to countervailing considerations of cost and the psychosocial impact of incarceration on individuals, their families, and their communities. The result has been skyrocketing correctional budgets, population caps imposed on some state prisons by the federal courts in response to unconstitutional overcrowding, and devastation for over-burdened minority and lower income communities.

At the other end of the sentencing continuum, a voter initiative known as *Proposition 36* in California emphasized a one-size-fits-all approach intended to be diametrically opposed to the War on Drugs. Pursuant to this initiative, a large proportion of drug-possession offenders were diverted into treatment in lieu of incarceration, and the courts were effectively disabled from responding to noncompliance with appreciably more than an extension of probation and relatively toothless demands for more treatment. The results were predictably lackluster. Roughly one-quarter of the offenders never arrived for a treatment session, 50% of those who did arrive for treatment dropped out in less than 3 months, and only one-quarter completed treatment. Worse still, criminal recidivism rates actually increased.

Evidence-based sentencing is a relatively new concept that seeks to avoid this over-reliance on any one disposition for all or most drug-involved offenders. Emphasis is placed, instead, on selecting dispositions that can optimally balance the interests of public safety, cost, and psychosocial impact on offenders. The goal is to choose the disposition in each case that presents the least objectionable risk of recidivism and the greatest likelihood of improving the welfare of the offender, and can do so at the least cost to taxpayers.

RISK AND NEED ASSESSMENT

To be successful, evidence-based sentencing requires drug-involved offenders to be assessed along two dimensions that have been empirically proven to predict success in correctional rehabilitation: (1) prognostic risk and (2) criminogenic needs.

Prognostic Risk

Prognostic risk refers to characteristics of offenders that predict poorer outcomes in standard correctional rehabilitation programs. Among drug-involved offenders, the most reliable and robust prognostic risk factors include a younger age (especially younger than age 25), male gender, early onset of substance abuse or delinquency (especially by early adolescence), prior felony convictions, previously unsuccessful attempts at treatment or rehabilitation, a co-existing diagnosis of anti-social personality disorder (APD), and a preponderance of antisocial peers or associates. Typically, individuals with these high-risk factors must be closely supervised and held accountable for their actions in order to succeed in treatment and desist from substance abuse and crime.

Importantly, in this context, the term “risk” does not necessarily refer to a risk for violence or dangerousness, but rather to a risk of failing to respond to standard interventions, and thus for continuing to engage in the same level of drug abuse or crime as in the past. In other words, it refers to a relatively poorer prognosis for success in standard rehabilitation services. This is why it is most accurately referred to as prognostic risk.

This distinction is crucial because some criminal justice officials may screen high-risk offenders out of more intensive treatment programs because they perceive them as being a threat to others or less worthy of the services. On the contrary, research reveals that the higher the prognostic risk, the more intensive the services should be. Most risk-assessment tools which are administered in routine correctional practice were validated against the likelihood of offenders absconding on bond, violating the terms of their probation or being re-arrested; and not against the likelihood of committing a violent act. Such tools should be used to screen high-risk cases in to more intensive programs rather than screening them out of those programs. Although assessment tools do exist to measure risk of violence, they are most commonly used when treating habitual sex offenders or conducting forensic evaluations in serious felony cases.

Criminogenic Needs

Criminogenic needs refer to clinical disorders or functional impairments that, if ameliorated, significantly

reduce the likelihood of continued engagement in crime. The most common criminogenic needs among offenders include substance dependence or addiction, major psychiatric disorders, and serious functional impairments, such as brain injury or a lack of basic employment or daily living skills. Failing to address these serious deficits or impairments leaves the individual vulnerable to repeated failures and continued involvement in antisocial activities. On the other hand, effectively addressing these deficiencies is associated with improved functioning and the avoidance of crime.

As will be discussed, formal substance abuse treatment is often required for addicted offenders to ameliorate cravings and withdrawal symptoms, teach concrete skills to resist drugs and alcohol, and provide effective coping strategies for dealing with daily stressors and challenges. In some cases, medication or residential services may also be required, at least during the early phases of treatment. Failing to provide an adequate dosage and level of treatment for these high-need individuals is associated with significantly poorer outcomes and higher recidivism rates.

However, an important, but often overlooked, fact is that more than half of drug-involved offenders are *not* clinically addicted to drugs or alcohol. Research indicates that at least 55% of drug-involved offenders are substance *abusers*. These individuals may repeatedly ingest drugs or alcohol under circumstances that are potentially dangerous to themselves and others, but their usage is largely under their voluntary control and they do not suffer from cravings to use the substance or withdrawal symptoms when they attempt to become abstinent.

Substance abusers are best suited to what is called *secondary prevention* – also referred to as *early intervention* according to American Society of Addiction Medicine criteria. Secondary prevention is indicated when clients are engaged in health-risk behaviors, but have not, as yet, developed a clinically significant disorder. Examples of secondary prevention services might include psycho-educational interventions, which teach participants about the dangers of drugs and alcohol; and activity-scheduling exercises, which re-orient participants' daily pursuits away from drug-related peers and events. These services would rarely be sufficient alone to intervene with offenders who are addicted to or dependent on drugs or alcohol.

The important point here is that formal substance abuse treatment services can be contraindicated for nonaddicted offenders. Placing nonaddicted, low-need offenders into intensive treatment programs has been associated with significantly poorer outcomes and higher recidivism rates. Perhaps spending time with addicted peers unduly normalizes the drug-using lifestyle, or perhaps treatment requirements may interfere

with their engagement in productive activities, such as work, school or parenting. Regardless of the rationale, it is clear that providing too much treatment is not only a potential waste of precious resources, it can lead to what are called *iatrogenic effects*, in which outcomes are made worse.

MATCHING DISPOSITIONS BY RISKS AND NEEDS

Research reveals that different sentencing dispositions produce better outcomes for different types of drug-involved offenders. For example, drug courts have been shown to produce the largest effects for offenders who are clinically addicted to drugs or alcohol and also have substantial prognostic risk factors for failure in less intensive programs. The average effect of drug court is estimated to be approximately twice the magnitude for high-risk offenders than for low-risk offenders. This translates into greater cost savings for taxpayers. Drug courts that serve high-risk offenders are estimated to return 50% greater cost benefits to their communities than those serving low-risk offenders. The intensive level of supervision provided by a judge, coupled with weekly drug testing, intensive treatment, and gradually increasing sanctions and incentives, appears to be well suited for this population.

On the other hand, the full menu of services provided in drug courts appears to be unnecessary, or perhaps counterproductive, for low-risk or low-need individuals. For example, several studies have shown that low-risk drug offenders performed at least as well, and sometimes better, when they were not required to appear frequently before a judge in court. The low-risk individuals fared well when they were supervised, instead, by clinical case managers who reported on their progress to the judge and requested court hearings only when needed to address poor compliance in treatment. Not only does this approach reduce the supervisory burden on the court, it also reduces the degree of contact between the high-risk and low-risk participants. Research reveals that mixing high-risk and low-risk participants together can lead to negative effects for the low-risk individuals because they may adopt antisocial attitudes or values. Keeping the populations separate helps to avoid this iatrogenic effect.

Recent studies have reported promising outcomes for what are referred to as *coerced abstinence* programs, such as Project H.O.P.E. (Hawaii Opportunity Probation with Enforcement). In these programs, offenders are closely monitored via weekly drug testing and probation appointments and they receive gradually escalating sanctions for infractions, typically involving brief periods of jail detention. Participants may be referred

to substance abuse treatment if they are not responding adequately to the sanctions regimen or if they request treatment; however, treatment is not ordinarily a core component of the intervention and is not provided to many participants. A substantial proportion of high-risk offenders who had previously been noncompliant on probation or pre-trial supervision were shown to significantly improve their performance after entering these programs.

Although research has not yet addressed this issue, it is reasonable to hypothesize that coerced abstinence programs such as H.O.P.E. may be well suited to high-risk, nonaddicted offenders; whereas programs such as drug courts, which place a central emphasis on substance abuse treatment, may be better suited to high-risk offenders who are also clinically addicted to drugs or alcohol. More research is needed to determine the optimal target population for coerced abstinence programs.

The matching effects that are beginning to emerge in the research literature have not gone unnoticed by the criminal justice system. Recent amendments to sentencing statutes or guidelines in some states are authorizing or requiring judges to at least consider issues of effectiveness and cost-effectiveness when rendering sentencing decisions. In addition to (not instead of) considering other important value-laden issues, such as victims' sentiments, judges, defense counsel, and prosecutors are being encouraged to include information on effectiveness and cost-effectiveness in their calculus of decision-making when advocating for or rendering sentencing dispositions. In a small number of states, information about prognostic risk and criminogenic needs is explicitly referenced in sentencing guidelines or statutes as factors to be considered in sentencing.

These developments are new and considerably more effort will be required before evidence-based sentencing becomes a generally accepted practice in the criminal justice system. Nevertheless, the momentum is beginning to move in this direction. This momentum is influenced in no small part by the fact that the correctional system is overburdened with huge numbers of non-violent drug-involved offenders, and state and federal budgets are buckling under the weight of enormous prison and jail expenditures; yet, crime and substance abuse rates have barely budged or are merely shifting in character. Evidence-based sentencing offers a possible roadmap to address these serious economic and social problems.

EVIDENCE-BASED TREATMENTS

A good deal of research has focused on identifying effective treatment and prevention services for drug-involved offenders. It is no secret that substance abuse

treatment is sparsely available and of notoriously poor quality in the criminal justice system. In many jurisdictions, less than 10% of probationers and 20% of inmates with substance abuse problems have access to substance abuse treatment services on any given day. Where treatment is available, it is often not evidence-based, lacking in a coherent focus or structure, and delivered by inadequately trained staff. The services also tend to be indistinguishable from those that are provided to noncriminal-justice involved populations, and thus might not adequately address the unique needs and risk factors presented by offenders.

Counseling Interventions

The most commonly administered "treatment" in correctional programs is drug education groups, which have been shown to have minimal effects for offenders. Another common form of treatment is what is loosely defined as drug-focused group counseling, which often does not follow a standardized curriculum and thus is of unknown quality and content.

Evidence is clear that the most effective counseling interventions for offenders are highly structured and behavioral or cognitive-behavioral in orientation. Contingency management (CM) programs are one example of a behavioral intervention that has shown substantial promise for drug-abusing offenders. Participants are closely monitored for treatment compliance and substance use via frequent drug testing and careful attendance reporting, and they receive rewards of gradually escalating magnitude for attending sessions or providing drug-negative urine specimens. The rewards are often provided in the form of institutional privileges, reduced program requirements, gift certificates, or payment vouchers that can be exchanged for a limited menu of goods or services. Importantly, CM programs appear to be equally effective for high-risk, antisocial participants who would ordinarily have a poor prognosis for success in standard treatment conditions.

Cognitive-behavioral treatments (CBTs) focus on identifying and correcting clients' irrational or dysfunctional thought patterns. Substance abuse and antisocial behavior are often triggered or exacerbated by offenders' misinterpretations of and overreactions to common events. For example, an offender who has been passed up for a job promotion might overreact and conclude that his supervisor is vindictive or out to get him. Given this interpretation of events, it might seem justified to quit the job, use drugs or get into an altercation with the supervisor. This type of dysfunctional thought pattern is often pervasive and rigid among high-risk, antisocial offenders. Nonaddicted offenders may also benefit from CBT interventions that focus on general

errors in thinking, rather than on substance abuse specifically.

Research is convincing that CBT interventions can significantly reduce crime and substance abuse. Meta-analyses reveal an average reduction in crime of approximately 20–30% for the most commonly administered CBT programs, which include Moral Reconciliation Therapy, Reasoning and Rehabilitation (R & R), and Thinking for a Change. The effects are significantly larger when the programs target high-risk offenders who are most likely to manifest these irrational criminal-thinking patterns. Not surprisingly, the programs are also most effective when treatment providers are well trained on the curriculum, fidelity to the intervention is monitored through integrity checks to be sure it is administered correctly, and treatment providers have graduate-level mental health or substance abuse treatment backgrounds.

In addition, larger effects are reported when the curriculum includes components that focus on anger management and interpersonal problem-solving. Many high-risk offenders get into trouble with the law because they are not adept at finding nonconfrontational solutions to interpersonal conflicts, and they tend to lose their temper quickly before thinking logically and calmly about how to resolve problems. Focusing on these specific deficits is often a key to achieving long-term improvements in their functioning.

As mentioned previously, formal substance abuse treatment is often required for addicted offenders to ameliorate cravings and withdrawal symptoms, teach concrete skills to resist drugs and alcohol, and model effective coping strategies for dealing with daily stressors and challenges without resorting to substance use. Substance abuse treatments that have shown significant improvements for addicted offenders also tend to be highly structured, cognitive-behavioral in orientation, follow a manualized curriculum, are delivered by well-trained staff, and are continuously monitored for fidelity to the model.

One example of a well-studied curriculum is the MATRIX Model, developed by researchers at University of California at Los Angeles, which has shown significant positive effects for offenders addicted to stimulants such as cocaine and methamphetamine. The MATRIX Model includes components that help participants identify and avoid their triggers for substance use, engage in drug-incompatible activities that compete against substance use, and manage their experiences of cravings and negative affects. This intervention has demonstrated particularly beneficial outcomes when it was administered within the context of a drug court program, presumably because the influence of the court helped to retain the offenders in treatment and reinforced their adherence to the curriculum.

For juvenile and young adult offenders, the most effective treatments also tend to be family or systems-based. This means that family members, teachers, and other community role models are included in the intervention and learn how to effectively supervise, interact with and intervene with the offender. For example, Multi-Systemic Therapy (MST), developed by researchers at the Medical University of South Carolina, has demonstrated significant positive effects for drug-abusing juvenile delinquents. Like the MATRIX Model, MST has produced particularly beneficial outcomes when it was delivered within the context of a juvenile drug court program.

Medically Assisted Treatment

Medically assisted treatment (M.A.T.) for addiction is unlikely to be available for most offenders. Less than 5% of offenders on probation or parole have access to effective pharmacological treatments for addiction, such as buprenorphine, methadone, or naltrexone. Only about 12% of state prison inmates and 40% of county jail inmates have access to M.A.T. The reason that a relatively greater percentage of jail inmates has access to M.A.T. is that many of them are being held pending trial or release on bond; therefore, they may be entitled to be continued on medication regimens they were previously receiving in the community. Once they have been convicted and sentenced, however, it is considerably less likely that offenders will be maintained on a pharmacological regimen for addiction while serving their sentence or when released on community correctional supervision.

This is highly unfortunate, because a number of well-controlled, experimental studies have demonstrated that the use of M.A.T. can significantly improve outcomes for addicted offenders. For example, methadone or buprenorphine maintenance initiated prior to and immediately after release from jail or prison has been shown to significantly increase the likelihood that opiate-addicted inmates would enter treatment in the community; reduced illicit opiate use; reduced re-arrests, technical parole violations and re-incarceration rates; and reduced incidences of mortality and hepatitis C infections. Yet, despite these positive results, the use of these medications, which have “agonist” properties, remains rare. Agonist medications stimulate the central nervous system in much the same manner as illicit drugs. Because they have the potential to be addictive themselves, and can produce euphoria in nontolerant individuals, they tend to be fiercely resisted by criminal justice professionals, who may view their usage as like “substituting one drug for another.”

Fortunately, positive outcomes have also been reported for “antagonist” medications, such as naltrexone, which are nonaddictive and nonintoxicating. Naltrexone blocks

the effects of illicit opiates and partially blocks the effects of alcohol, without producing psychoactive effects of its own. At least two experimental studies among opiate-addicted probationers and parolees have reported significant reductions in opiate use and re-arrest rates for offenders receiving naltrexone. The recent introduction of a “depot” form of naltrexone, which can be administered via monthly injections, offers the potential to ensure greater compliance among offenders with the medication regimen.

Despite strong resistance to M.A.T. among some elements of the criminal justice system, its use is clearly endorsed by leading scientific and practitioner organizations. For example, the National Institute on Drug Abuse, in a 2006 publication entitled *Principles of Drug Abuse Treatment for Criminal Justice Populations* [NIH Pub. No. 06-5316], concludes that “[m]edications are an important part of treatment for many drug-abusing offenders” (p. 5), including medications such as methadone and buprenorphine. An important task now is for the scientific community to impress upon criminal justice professionals and policymakers the importance of M.A.T., educate them about the facts concerning these proven treatments, and dispel any myths or misconceptions about their usage.

Correctional Therapeutic Communities

A series of studies of what are called correctional therapeutic community (TC) programs have also reported highly favorable results for drug-involved offenders. TCs are specialized residential programs that isolate participants from drugs, drug paraphernalia, and affiliations with drug-using associates. The peers in TCs utilize a “milieu” therapeutic approach in confronting maladaptive personality traits, discouraging and punishing inappropriate behaviors, rewarding positive behaviors, and providing mentorship and camaraderie. Interventions often include community meetings, process groups, and altruistic volunteer activities. In recent decades, TC programs have also substantially incorporated CBT principles and practices into their curricula.

Because inmates released from jail or prison are often disenfranchised from their families and communities, may not have access to sober living quarters, and may still be under the authority of the correctional system, TC residential programming is often particularly well suited to this group of offenders. However, correctional TC programs are also utilized as an alternative disposition to incarceration.

In the prison system, TC programs are commonly administered on segregated units. Prisoners with long sentences who have previously completed the programs may serve as senior mentors or peer supervisors on the

unit; however, correctional staff always have ultimate authority to determine which inmates are eligible for the program and what consequences should be imposed for accomplishments or transgressions. Following their release from custody, parolees may be transferred to a TC program in a community halfway house or work-release center to complete the therapeutic regimen.

The timing of inmates’ sentences is often a critical factor in determining whether they gain access to TC programs. Inmates must have sufficient time remaining on their sentences to complete the curriculum, but preference is also typically given to inmates who are eligible for release within the next year or two. Because TC slots may not become available at just the right time to thread this needle, many deserving and eligible inmates never gain access to TC programs.

PRISONER REENTRY

Addicted offenders are at heightened risk for relapse to substance abuse, criminal recidivism, and associated health consequences immediately following release from prison or jail. Nearly one-third of inmates resume substance abuse with 2 months of leaving prison and over 95% resume substance use within 3 years. Two-thirds of released inmates are re-arrested for a new crime within 3 years of their release and roughly one half are re-incarcerated. Released inmates are also at significantly elevated risk for drug overdose and mortality or morbidity. One reason for this is that their physiological tolerance to drugs or alcohol may be greatly reduced after a period of enforced abstinence during custody. Therefore, they may be at risk after release for an accidental overdose if they return to their previous level of substance ingestion.

Unfortunately, reentry programs for drug-involved offenders have often been found to produce nonsignificant or even iatrogenic effects, in which crime rates and re-incarceration rates have actually increased. The reasons for this are varied, but at least three basic errors in program implementation have commonly been identified.

First, many reentry programs have administered unstructured and nonevidence-based treatment services which, as discussed earlier, tend not to produce positive gains. Second, many programs have failed to maintain a sufficient dosage of services after the offenders were released from custody. Not surprisingly, a rapid degradation in the quality and intensity of services after release is unlikely to maintain positive effects in community. Finally, many programs have tended to over-rely on revocations and re-incarceration for technical violations, rather than applying gradually escalating sanctions. Technical violations refer to

behaviors that are not, in and of themselves, illegal but violate the conditions of supervision. For example, alcohol consumption is legal for most adults but may violate the terms of an offender's parole. Re-incarcerating offenders for technical violations is apt to be very costly and is unlikely to produce longstanding gains once the offenders have completed the full term of their incarceration and are no longer under the authority of correctional officials.

For example, a program known as Project Greenlight in New York City shortened the R & R curriculum, discussed earlier, to about half its intended length and provided nonstandardized family and pre-vocational services. In addition, the offenders received little if any augmented services after release from custody. The result was significantly higher rates of re-arrests, technical violations, and re-incarceration as compared to matched comparison samples of parolees who did not participate in Project Greenlight.

Similarly, a national project known as the Serious and Violent Offender Reentry Initiative (SVORI) provided \$100 million in federal grants to local communities to enhance treatment services for parolees both pre- and post-release. The results revealed that male offenders did not receive appreciably more treatment services following their release than did matched comparison samples of parolees. Not surprisingly, they also had no better outcomes in terms of re-arrest and re-incarceration rates. Female offenders, on the other hand, did tend to receive more treatment services. Possibly as a result of this, they also had significantly lower re-arrest rates. Notably, however, despite being re-arrested for new crimes significantly less often, the female SVORI participants were re-incarcerated more often, suggesting their parole was more likely to be revoked for technical violations. As a result, SVORI was unlikely to be cost-beneficial for the female offenders.

As discussed earlier, studies of correctional TC programs have reported more favorable outcomes for drug-involved inmates and parolees. Three-year longitudinal evaluations of correctional TC programs in several states, including New York, California, and Delaware, suggest that to be maximally effective, TC services should be provided along the full continuum of reentry, from in-prison treatment through treatment in a work-release or halfway facility to outpatient continuing care. Participants who completed the full continuum of TC programming exhibited substantial reductions of 30–50% points in substance use and crime. Because self-selection may have played a role in some of these findings, the magnitude of the effects might be expected to be somewhat lower in typical correctional practice. Many offenders choose to drop out of TC programs and may achieve relatively poorer outcomes as a result. Nevertheless, the findings are promising

and emerge as an evidence-based practice against a disappointing backdrop of often poor outcomes for this hard-to-treat group of offenders.

More recently, reentry drug courts have emerged as a way of applying the power and authority of the court to keep parolees engaged in treatment and compliant with their supervisory conditions. There have only been a few studies of reentry court programs and the findings are somewhat mixed. A 3-year evaluation in Harlem, NY found that participants in a reentry court were convicted of new crimes significantly less often than matched comparison parolees; however, they were re-incarcerated for technical violations more often. This suggests that reentry courts may be susceptible to making the same mistakes of the past in over-relying on revocations for technical infractions. Faithful application of the drug court model would dictate administering gradually escalating sanctions for infractions, and reserving re-incarceration for repetitive or serious violations.

A more recent study of a Federal reentry court in Boston produced more consistently favorable outcomes. Participants in the C.A.R.E. (Court Assisted Recovery Effort) program satisfactorily completed their supervision requirements and were re-arrested significantly less often than matched comparison offenders on traditional supervised release. Because the C.A.R.E. participants both offended less often and completed the terms of their supervision more often, this suggests that the program did not over-rely on technical violations for infractions, which is more consistent with the drug court model.

In summary, research on effective reentry programming for drug-involved offenders is still very much in its infancy. Evidence has uncovered a number of common errors in practice that are associated with insignificant or poor outcomes, and is beginning to identify programs that appear capable of achieving positive results. Considerably more effort is required to confirm the positive effects of these newer programs and identify the specific interventions and procedures within the programs that may be responsible for improved outcomes.

RACIAL, ETHNIC, AND GENDER RESPONSIVENESS

Research reveals that racial and ethnic minority offenders are less likely than nonminorities to receive the appropriate dose and modality of treatment given their clinical needs. For example, minority offenders who are clinically assessed as requiring residential treatment are more likely to be mismatched to a lower level of outpatient treatment. Minority offenders are also

more likely to receive an incarcerative sentence than a treatment-oriented community disposition for what would appear to be relatively comparable offenses. Not surprisingly, this often translates into poorer outcomes in correctional rehabilitation.

Racial and ethnic minority offenders are also more likely to present with other prognostic risk and criminogenic need factors that may complicate the management of their case when they do enter treatment-oriented diversion programs. For example, studies in drug courts have frequently reported that racial minority participants were less likely than Caucasians to be employed, had significantly lower incomes and were more likely to be addicted to crack cocaine. This, in turn, predicted poorer outcomes in the programs. In other words, racial identity per se did not appear to be responsible for poorer treatment outcomes; rather, other factors that were correlated with race, such as socioeconomic status, appear to have been responsible.

These findings place an onus on the criminal justice and substance abuse treatment systems to do a considerably better job of identifying prognostic risk factors and criminogenic needs among minority offenders, and matching them to appropriate sentencing dispositions and therapeutic regimens. Putting aside the obvious ethical and moral implications of providing disparate treatments for minorities, the criminal justice system is required by the constitutional principles of due process and equal protection to treat all citizens fairly and equivalently. It is therefore legally necessary to develop and evaluate programs that can produce equivalent outcomes for racial and ethnic minority offenders.

At a minimum, researchers should determine whether existing treatment curricula elicit equivalent effects for racial and ethnic minority participants. For example, MST for youthful offenders and the MATRIX Model for adult offenders, discussed previously, appear to produce comparable effects across various racial and ethnic sub-groups. In addition, it is important to develop culturally sensitive and proficient programs that are specifically tailored to the needs of minority participants. Unfortunately, research is still in its relative infancy in terms of proving which culturally tailored programs produce superior outcomes for minorities in controlled studies. Considerably more work is required to develop and evaluate such programs in a rigorous and defensible manner.

Gender issues are also critically important for the treatment of offenders. Research indicates that holding separate treatment groups for male and female offenders tends to produce better outcomes, especially for the women. There are many possible reasons for this. Women and men may have different dynamics or histories related to their addiction, which may make it difficult for them to address their problems in mixed

groups. For example, men are more likely to be introduced to drugs by peers, whereas women are more likely to be introduced to drugs by intimate partners. As a result, men and women might need to employ different strategies for avoiding relapse situations.

In addition, many women in addiction treatment and correctional settings have been the victims of physical abuse, sexual abuse, or domestic violence. Discussing such matters in the presence of male peers may be embarrassing or may make them feel unsafe. Similarly, many males may not want to discuss comparable experiences of victimization in front of women for fear of appearing weak.

Another concern related to mixed-gender treatment is the phenomenon of the "rehab romance." As clients struggle through their early recovery, they may misinterpret intense emotional reactions or attachments that are often triggered in treatment groups for a romantic interest or compatibility. In reality, rehab romances frequently do not work out, often resulting in relapse for one or both parties. Lastly, some drug-involved offenders may be "relationship predators" and treatment groups may offer them an opportunity to seek out emotionally vulnerable or unstable individuals. It is incumbent upon treatment providers, therefore, to take decisive measures to ensure male and female offenders do not spend unsupervised time with each other outside of the treatment program.

CONCLUSION

The substance abuse treatment and criminal justice systems deal with many of the same individuals. Involvement with either system increases the odds many fold of involvement with the other system as well. Unfortunately, for decades neither system adequately recognized the implications of this "comorbidity" or adapted their procedures to accommodate the needs of the large population of drug-involved offenders. Sentencing and correctional supervision practices often failed to address the criminogenic needs of these individuals, and treatment practices often failed to address their prognostic risk factors and the very real threat they may present to community well-being and public safety.

This is beginning to change. Judges, prosecutors, and defense lawyers are becoming better educated on the principles of evidence-based sentencing, which can lead to more effective, safe, and cost-effective dispositions. Treatment providers, on the other hand, are learning to apply structured, evidence-based treatments that are more suitably tailored to the criminal-thinking patterns and other risk factors presented by offenders, which are apt to complicate the clinical picture. The

result has been promising research findings that are beginning to identify the basic principles for effective treatment and supervision of drug-involved offenders. More research is needed to continue this line of work and contribute to better practices and policies that will advance the interests of public health and public safety.

Glossary

Antisocial personality disorder (APD) a psychiatric diagnosis characterized by an adolescent onset and continuous manifestation of criminal or delinquent misconduct, a failure to fulfill basic responsibilities, and a lack of remorse for the misconduct. Individuals with APD typically have a poor prognosis in standard treatment or rehabilitation programs, but respond appreciably better to programs that are highly structured and behavioral or cognitive-behavioral in orientation.

Coerced abstinence programs programs that closely monitor offenders' behaviors, including drug use and treatment attendance, and apply gradually escalating punitive sanctions for infractions, often including brief periods of jail detention.

Correctional halfway house a transitional facility run by the corrections department that houses inmates in community-based living quarters.

Correctional therapeutic community (TC) a residential treatment program that applies milieu principles, community peer interactions, and other therapy techniques to alter the behavior of drug-abusing criminal offenders. TC programs may be located within separate units of prisons or jails, and in community work-release centers or halfway houses.

Correctional work-release program a residential program run by the corrections department that houses inmates in community-based quarters. Inmates typically attend work, school, or treatment in the community during the day and return to the residence in the evenings.

Criminal thinking irrational or maladaptive attitudes or perceptions on the part of some offenders that cause or exacerbate criminal activity.

Criminogenic needs clinical disorders or functional impairments that, if ameliorated, significantly reduce the likelihood of continued engagement in crime. Common examples include substance dependence or addiction, major psychiatric disorders and serious functional impairments, such as brain injury or a lack of basic employment or daily living skills.

Day-reporting centers community programs typically run by the probation, parole, or corrections department, to which offenders are required to report and spend several hours per day on the premises.

Disposition before judgment also known as probation without verdict, an opportunity for diversion after entering a guilty plea or acknowledging factual guilt. Satisfaction of enumerated treatment or supervision conditions leads to the plea being retroactively vacated or withdrawn, and perhaps to the opportunity for record expungement.

Downward departure a decision by a criminal court to impose a shorter or less severe sentence than is indicated by the sentencing statute or guidelines. The sentencing judge must typically base the decision to grant a downward departure on specific mitigating factors, such as demonstrated efforts at rehabilitation or a genuine expression of remorse.

Drug court a special docket or calendar within the traditional criminal court system, in which a judge supervises a diversion program. Participants appear in court frequently for status hearings, during which the judge reviews their progress in treatment and may apply gradually escalating punitive sanctions for infractions or rewards for achievements. Participants must also complete a mandatory regimen of drug abuse treatment and random weekly drug testing.

Drug-involved offender an individual who has been charged with or convicted of a drug offense, was intoxicated at the time of a criminal offense, committed an offense to support a drug habit, or has a documented history of drug abuse.

Drug offender an individual who has been charged with or convicted of drug possession, possession with the intent to distribute drugs, drug dealing, drug manufacturing, or another offense categorized as involving illicit drugs.

Evidence-based sentencing the explicit consideration of effectiveness and cost-effectiveness in rendering criminal sentencing decisions.

Expungement see record expungement.

Halfway house see correctional halfway house.

High-need offender an offender manifesting a clinical disorder or functional impairment that typically requires remediation to ensure future desistance from crime.

High-risk offender an offender with characteristics that tend to predict poorer outcomes in standard rehabilitation or treatment programs. High-risk offenders typically require enhanced supervision and accountability to perform well in treatment.

Iatrogenic effects unintended or unpredicted negative or worse outcomes produced by an intervention.

Intermediate punishment also referred to as intermediate sanctions, a category of criminal sentences imposed in lieu of jail or prison. Examples include military-style boot camps, intensive supervised probation (ISP) programs, correctional halfway houses, day-reporting centers, home detention, and electronic monitoring.

Jail a county or local correctional institution that houses offenders being detained prior to trial or release on bond, or convicted of crimes typically carrying sentences of less than 1 year.

Low-need offender an offender who does not manifest a clinical disorder or functional impairment requiring remediation to ensure future desistance from crime.

Low-risk offender an offender who does not exhibit characteristics that would predict poor outcomes in standard rehabilitation, and

thus who has a good prognosis. These individuals generally do not require intensive supervision and may respond negatively to being treated alongside more serious offenders.

Parole early release from incarceration prior to serving the maximum allowable prison or jail sentence. Parolees are supervised by special officers who enforce the conditions of early release.

Pre-trial supervision supervision by special officers of individuals who have been charged with, but not convicted of, a crime. The court may impose requirements of pre-trial supervision, such as drug testing or treatment, as a condition of being released on bond prior to trial.

Post-adjudication drug court a drug court program in which a final conviction is entered and participants complete the drug court in lieu of a longer or more severe sentence.

Pre-adjudication drug court a drug court program in which successful graduates have their guilty plea withdrawn or vacated and may have the opportunity for record expungement.

Pre-plea diversion a program that permits an individual charged with a relatively minor criminal offense to avoid prosecution by satisfying certain supervision and treatment conditions.

Prison a state correctional institution that houses offenders convicted of crimes typically carrying sentences of longer than 1 year.

Prisoner reentry the process of returning and reintegrating inmates into their communities after release from jail or prison.

Probation a sentence to community supervision instead of incarceration. Probationers are supervised by special officers who enforce conditions set by the sentencing court.

Probation without verdict see disposition before judgment.

Prognostic risk characteristics of offenders that predict relatively poorer outcomes in standard correctional rehabilitation programs. Individuals with prognostic risk factors typically require more intensive monitoring and accountability to perform well in treatment or supervision.

Proposition 36 a voter initiative in California that requires courts to sentence nonviolent drug-possession offenders who do not have a history of another exclusionary offense to probation with treatment conditions. Successful graduates have the plea vacated. Participants are generally entitled to three opportunities for diversion before incarceration may be imposed.

Recidivism any return to criminal activity after the index arrest episode, typically measured by re-arrests or re-convictions for new crimes.

Record expungement a process for removing an arrest or conviction from an individual's criminal record in response to meeting certain requirements, such as completing a treatment or diversion program. Although the record may not be literally erased from criminal justice databases, expungement ordinarily entitles the individual to respond truthfully on an employment application or similar document that the arrest or conviction did not occur.

Reentry see prisoner reentry.

Reentry court a program that applies court supervision to the management of parolees or other inmates conditionally released from prison or jail. Not all participants in a reentry court may have drug-related problems.

Reentry drug court a program that applies the court-supervised drug court model to the management of drug-involved inmates released on parole or other conditional release from prison or jail.

Revocation the removal of an offender from probation or parole for violating the conditions of supervision. Offenders are often, but not always, returned to custody upon a revocation.

Technical violation a behavior, such as alcohol consumption, that is not illegal for most adult citizens, but may violate the conditions of probation, parole, or pre-trial supervision.

Therapeutic community (TC) see correctional therapeutic community (TC).

Upward departure a decision by a criminal court to impose a longer or more serious sentence than is indicated by the sentencing statute or guidelines. The sentencing judge must base the decision to impose an upward departure on specific aggravating factors, such as dealing drugs near a school zone.

War on drugs refers to an Executive Order issued by Former President Ronald Reagan. Federal and state laws enacted pursuant to this Executive Order increased prison penalties and established mandatory minimum sentences for various drug offenses, including some drug-possession offenses.

Work-release program see correctional work-release program.

INTRODUCTION

Road traffic crashes (RTC) lead to approximately 1.3 million deaths and 20–50 million injuries worldwide annually. Human factors (e.g. speeding and other unsafe driving maneuvers, driving while impaired with alcohol or drugs, driver error, distraction, fatigue, neglect of seat belt use) play a contributing role in up to 95% of RTC. This chapter focuses on current efforts to reduce this significant burden on global health with respect to one particularly lethal contributor to RTC, driving while impaired with alcohol and/or drugs (DWI).

DWI is implicated in from 20 to 40% of all RTC. Among the many psychoactive substances that can

impair safe driving ability, alcohol is the one most often detected in DWI-related traffic events. Compared to 0.0 g alcohol/dl blood concentration (i.e. BAC = 0.0%), RTC risk is 4–10 times higher at BAC between 0.05 and 0.07%. Accordingly, the criminal statutory limits for DWI and the administrative thresholds that trigger more severe relicensing sanctions are most frequently set at BAC of 0.05–0.08% and 0.02–0.05%, respectively.

The diversity of licit and illicit drugs with varying degrees of potency, purity, and performance-impairing properties, in addition to their potential synergistic effects when combined with alcohol and/or other substances, makes defining impairment and hence

detection and prosecution of drug-impaired drivers an ongoing challenge. As a result, many jurisdictions have adopted per se laws whereby detection of any illicit drugs in the organism when driving is grounds for a conviction. In addition, courts increasingly recognize a detection of drug-impaired driving executed by Drug Recognition Experts using a highly structured roadside behavioral assessment. These and other measures for dealing with DWI with drugs are receiving growing attention from road traffic administrators and researchers.

DWI is a tenacious problem. Large-scale international efforts to curtail DWI, after realizing significant progress over the past few decades, have stalled since the 1990s, with some jurisdictions more recently showing a slight uptick. Unfortunately, a first conviction for DWI fails to deter many drivers from continuing to commit DWI. Approximately 20% of female and 38% of male DWI first-time offenders are reconvicted within 5 years of their conviction. The transition from first time to repeat offender status (i.e. recidivism) is accompanied by heightened risk, as recidivists contribute disproportionately to traffic-related morbidity compared to other driver groups. Overall, stabilization in the epidemiology of DWI and the risks associated with recidivism make effective prevention and intervention efforts vital to reduce the health burden of DWI.

WHO ARE DWI DRIVERS?

At its core, DWI involves an individual engaging in an episode of excessive alcohol or drug use, the availability of a vehicle, and his/her propensity to drive it. At the same time, the DWI population is a heterogeneous one with a broad continuum of risk, ranging from drivers who may accidentally, rarely, or sporadically drive impaired to a "hardcore" group who frequently drive impaired despite social and legal deterrents. The characteristics possessed by DWI drivers are also markedly heterogeneous.

The sentinel feature of impaired driving is substance misuse. The rate of abuse and dependence among DWI offenders is significantly higher than in the general population. Resolution of substance abuse and dependence will likely reduce DWI risk in many drivers. At the same time, contrary to popular perception, alcohol and drug problems do not explain all DWI risk in the general driving population. The majority of DWI drivers do not possess a substance use disorder diagnosis, but rather sporadically engage in heavy drinking and/or substance use. Consistent with the alcohol preventive paradox, it is the low risk and sporadic heavy drinkers and approximately 20% of the population who consume an average of ≥ 1 ounce of

alcohol per day who are responsible for most DWI-related consequences.

Along with substance misuse, several other characteristics have been consistently correlated to DWI offender status. These include male sex, single marital status, hostility, sensation seeking, psychopathic deviance, poor psychosocial and socioeconomic functioning, legal problems, disrespect for legal authorities and sanctions, family history of alcoholism, and engagement in other risky driving behaviors. In addition to the above, other factors correlated to recidivism status are younger age, early onset of alcohol problems, and high BAC at the time of arrest. At the same time, knowledge of these correlates is inadequate for both disentangling the heterogeneity in the DWI population and accurately discriminating between non-offenders, one-time offenders, and recidivists. Consequently, there is no one feature (e.g. alcohol dependence) that satisfactorily explains all DWI phenomena.

Finally, many individuals in the DWI driver population possess attitudes that challenge efforts to change DWI behavior. These include the tendency to minimize personal concern for their DWI risk by believing that bad outcomes are unlikely and happen to other drivers, by overestimating their control over DWI risks (e.g. intoxication), and by considering that their driving skill are superior compared to other drivers. As counterproductive as these attitudes may be for motivation to change DWI behavior, they are reinforced to some degree by reality: negative consequences associated with DWI (e.g. crashes and arrests) are unlikely events.

The next section briefly highlights a number of methodological challenges that vex both our understanding of DWI and our ability to mount evidence-informed approaches to DWI reduction.

METHODOLOGICAL ISSUES IN EVALUATING DWI INTERVENTION PROGRAMS

A number of methodological and conceptual issues hamper the ability to evaluate DWI program effectiveness. One methodological concern involves sampling. Many intervention evaluation studies recruit samples from among convicted DWI offenders attending remedial programs as part of their sentence or to reacquire their license. Though convenient, this strategy is vulnerable to bias from local, legal, and geographic dispositions regarding DWI and self-selection into study participation. It also fails to sample from two important subgroups who together account for the majority of drivers in the DWI population: namely, those who drive impaired but are not caught and convicted, and those

who, following a conviction, fail to participate in remedial programs. This may positively bias the results by including individuals sufficiently motivated and resourced to participate in such programs (their costs are usually borne by the driver) and who self-select into research studies. In addition, most interventions are embedded within a system of DWI countermeasures. Potential synergistic effects, negative and positive, contributed by systemic factors (e.g. implementation integrity) and other parallel intervention initiatives complicate the appraisal of the unique benefits of a specific program component.

The most obvious outcome of DWI intervention is a reduction in DWI-related crashes and morbidity. Unfortunately, the dependent variables frequently used to gauge program impact, either through study design or availability of data, are indirect and vary across studies. Change in the frequency of documented DWI-related crashes and fatalities, arrests or convictions, self-reported DWI events, and indices of alcohol and drug misuse are common dependent variables for program evaluation. Although documented DWI-related crashes (e.g. postmortem blood assays) are objective measures, they may be susceptible to factors unrelated to prevention program impact, such as reporting fidelity, and seasonal driving patterns and regional fluctuations (e.g. in gas prices) that can reduce driving exposure. As measures of individual intervention outcome, self-reported measures of substance use and DWI behavior are convenient measures yet susceptible to distortion, especially when collected in the often-adversarial environment of DWI assessment and enforcement. Alternatively, biological markers of alcohol dependence (e.g. gamma-glutamyl transferase, carbohydrate-deficient transferrin) are objective alternatives to self-reported substance use. Nevertheless, the level of chronic alcohol misuse the most reliably detect does not appear to be characteristic of the majority of DWI drivers. Moreover, the causal contribution of alcohol use in DWI is likely mediated by multiple additional factors in most offenders. The use of objective biomarkers of acute drug use in DWI is an emerging technology. In addition, linking their detection to DWI is a major administrative and scientific challenge as traces of many substances are detectable in the organism for days and weeks after last use. Finally, individual socioeconomic and environmental factors not directly related to DWI risk can influence the probability of being either arrested by police or successfully prosecuted, including gender, vehicle type, access to competent legal representation, prevailing per se BAC thresholds, traffic density, rural versus urban settings, availability of public transportation, and enforcement vigor.

Given these issues, triangulation using multiple outcome indices is optimal. At the same time, different

indices provide unique information that can at times lead to conflicting inferences about program effectiveness. Changes in DWI-related crash rates are not synonymous with changes in the rate of rearrest or in the severity of alcohol misuse. In sum, in the absence of a "gold standard" for gauging outcome, conclusions about a DWI intervention's effectiveness need to take into account the specific objectives of the program and the indices used to measure their attainment.

CONCEPTUAL FRAMEWORK FOR UNDERSTANDING DWI INTERVENTION EFFECTIVENESS

There is a consensus that the effectiveness of individual intervention components is increased when provided as part of a well-integrated broad-based system. A "system" refers to which strategies and countermeasures are implemented and how they are delivered, as well as the structures and agencies charged with their delivery to a targeted group. In DWI, a system typically involves multiple component programs (e.g. legislation, policy, enforcement, remedial intervention) deployed at multiple levels and by multiple agencies. Given the manifold ways in which traffic safety promotion generally, and DWI prevention specifically, are executed, adoption of a conceptual framework can help to organize the various DWI strategies currently in place and contextualize their appraisal. Several schemas are appropriate for the analysis of DWI. From a public health perspective, DWI can be viewed as the interplay of factors contained in the epidemiological triangle: agent (psychoactive substances and vehicles), environment (e.g. existing laws and enforcement), and host (i.e. the driver and passenger).

Another tripartite model that has been adopted by the US National Institute of Drug Abuse and the European Monitoring Centre for Drug and Drug Addiction is broadly equivalent to the above schema, but is more specific to substance misuse problems. In the DWI context, it involves the following dimensions: (1) universal prevention which targets the general population prior to the occurrence of a DWI event; (2) selective prevention which targets drivers with above average risk for DWI offending relative to the overall population (e.g. first-time offenders); and (3) indicated prevention which targets DWI offenders with more established signs of recidivism risk (e.g. previous DWI convictions, diagnosis of substance dependence, high arrest BAC). Environmental prevention is another element typically considered though it is formally outside this model. In DWI, this could involve micro-level strategies such as installation of an Interlock device that prevents ignition of an vehicle by a driver whose BAC is above 0.02%, or

macro-level community and regulatory level strategies such as roadside sobriety checks and legislation that sets fines and punishments. As such, some environmental prevention initiatives for DWI may be subsumed within one or more of the other prevention levels.

In sections that follow, DWI intervention approaches are summarized and considered broadly in light of the drivers they target (i.e. universal, selective and indicated, environmental prevention) and secondarily the putative contributory factors (i.e. agent, host, environment) they seek to act on. The scope of measures currently deployed to combat DWI is vast. Only some of the better-documented and/or more pervasive approaches in the developed world are surveyed here, with special emphasis given to selective and indicated prevention efforts.

UNIVERSAL PREVENTION APPROACHES FOR DWI

Public Information and Education

One of the most fundamental universal prevention approaches to promote traffic safety is the provision of public information and education. Public information programs involve mass media campaigns whereby information is disseminated using modalities such as television, radio, Internet, and print. Education attempts to provide more information about a problem and may use mass media modalities as well as person-to-person contact. These programs aim to provide information about a health-related issue and encourage healthy individual behavior. Evaluations of public information campaigns with deterrence themes (e.g. awareness of enforcement activities and legal consequences) and social and health consequences themes (e.g. modeled positive behavior alternatives to DWI; fear appeals using graphic depictions of emotional and physical consequences of DWI crashes) have been carried out. While they fail to provide unequivocal evidence for their effectiveness in reducing DWI or alcohol-related crashes, they have been associated with modest but significant reductions ($\approx 13\%$) in alcohol-related RTCs lasting more than 3 years. Importantly, economic analyses suggest that overall, societal benefits from these programs outweigh their costs.

It is noteworthy however that one social theme, the fear appeal, is controversial. Its intuitive appeal contributes to its pervasiveness. Nevertheless, critics have argued that when fear appeals are of insufficient intensity and fail to present positive alternatives, they produce poor outcomes, quickly induce “fear appeal fatigue” and increase maladaptive defensiveness and reactance that could even contribute to increased DWI,

especially in young drivers drawn to risk taking. Finally, their benefit was greatest when they were (1) carefully planned; (2) well executed; (3) attained adequate audience exposure; and (4) embedded as a facet of a comprehensive countermeasure strategy including such measures as visible and rigorous law enforcement.

Host Factors: Young Drivers

Reduction in BAC levels in young drivers is particularly desirable given: (1) their higher crash risk compared to adults; (2) their greater susceptibility to alcohol’s impairing effects on performance; (3) their inexperience in both driving and substance use; and (4) they possess other individual risk factors such as greater sensation seeking, more limited planning capacities, and greater impulsivity that contribute to risk taking. Adolescents are also readily accessible in school settings for participation in educational interventions prior to or at an early stage in their driving careers. Investigation of the effectiveness of school-based instructional programs, peer organizations, and social norming campaigns for reducing DWI-related RTC, deaths and injuries has yielded evidence for their effectiveness in reducing self-reported driving with a drinking driver but more equivocal evidence for effectiveness in reducing drinking and driving. The best results were obtained from programs possessing an interactional component.

Agent Factors: Alcohol Availability

Server intervention training programs provide education and training to the employees of venues where alcohol is served to prevent client intoxication and DWI. Practices acquired in training include providing food with drinks, slowing service to rapid drinkers, refusing to serve intoxicated clients, and discouraging them from driving. There is evidence for the effectiveness of such programs especially when training was of high quality, provided using face-to-face interactions, was accompanied by active support from venue management, targeted cessation of client drinking or a client moving to a safe drinking environment, and was combined with community mobilization and rigorous enforcement of venue rules and licensing laws. Hence, while this approach can be effective when applied under “ideal” conditions, in practice achieving and sustaining the required high level of implementation integrity are major challenges.

Environmental Factors: Alternate Transportation and Designated Driver Programs

A common target for community-based mass media campaigns is to encourage the use of alternative transportation (e.g. public transportation, regular or subsidized low-cost commercial taxi services, or volunteer shuttle

services) or designated driver (e.g. informal arrangements made between friends) strategies when planning or after drinking occasions. While these programs are regularly implemented in some jurisdictions, especially during holiday periods, there is a lack of research in their effectiveness. The available evidence is equivocal concerning their impact. Worryingly, many such programs resulted in flawed application of the approach by many drivers or their companions that could potentially provide a false sense of security, such as no insistence on total abstinence for the designated driver, or failure to designate a driver prior to drinking.

Laws and Policy

Agent Factors: Alcohol Consumption Policy

One public health policy approach to DWI has been to focus on reduction of overall alcohol consumption in the general population. In many jurisdictions, laws specifically target young drivers and their access to alcohol. These include setting a legal drinking age (e.g. 18 years in Canada, 21 years in the United States), zero tolerance for alcohol use during probationary licensing, and administrative license revocation following underage drinking violations. These measures have been found to be associated with reductions in the involvement of underage drivers in fatal crashes and in their BAC levels.

Environmental Factors: BAC Level Specified in Per Se Laws

Consistent evidence indicates that decreases in legal BAC laws from 0.10% to 0.08% have diminished alcohol-related crash fatalities in the United States and Canada. Lowering per se legal BAC levels from 0.08% to 0.05% in European and Australian jurisdictions, and from BAC 0.05% to 0.02% in some jurisdictions such as Sweden, have also been associated with important reductions in DWI-related traffic crashes and fatalities. At the same time, disentangling the impact of adjustments in BAC laws from other initiatives that typically accompany their implementation, such as publicity and enforcement among others, is problematic. Overall, BAC 0.05% seems to represent the level at which most drivers' driving performance deteriorates to a degree where their crash risk increases significantly. Moreover, it is also the level where convergence occurs between public perceptions related to "enough to drink" and acceptance of legal BAC, and police discretion and willingness to enforce DWI laws.

Environment Factors: Enforcement and Sanction Strength

The perceived and actual probability of DWI arrest are pervasively argued to be critical ingredients in the deterrence value of DWI enforcement measures, more

so than increasing the severity of penalties following a conviction alone. Selective or random breath testing carried out in sobriety checkpoints and increased police patrols can increase both the perception and actual risk of arrest. As such enforcement efforts are directed at the general driver population, they are referred to as general deterrence. Evaluations of the impact of sobriety checkpoint programs have produced strong evidence for the effectiveness of both selective and random breath testing checkpoints in reducing alcohol-related crashes, fatalities, and injuries. Exactly how these programs work is uncertain, however, as straightforward relationships between the crash reductions and amount and the type of enforcement activities have not been detected. More importantly, widespread deployment has been mitigated in many jurisdictions by legal obstacles (e.g. probable cause requirements for an arrest), cost, lack of police resources and funding, poor support from community groups, and negative perceptions concerning overall effectiveness and efficiency.

An almost reflexive social and political strategy to deter DWI is to impose increasingly heftier fines and the threat of prison terms for first-time DWI offending. Despite possessing intuitive appeal and relative simplicity of deployment, mandatory fines and jail penalties do not demonstrate either general deterrent effects or effectiveness in deterring re-offending among first-time DWI offenders. This lack of evidence is magnified by the high social cost and inherent risks (e.g. violence, contact with a harder core criminal element, inability to support families) of incarceration.

Similarly, many licensing administrations modulate sanctions following a DWI conviction as a function of a driver's arrest BAC. The premise of this approach is that a high BAC (e.g. 15% in many jurisdictions) reflects a higher risk for RTC, recidivism, and more severe alcohol problems. Hence, individuals seeking to be relicensed following a high BAC arrest face heftier fines, longer license suspensions, mandatory installation of an Interlock device, and participation in more intensive remedial programs. While high BAC is consistently related to RTC risk, its relationship to either DWI recidivism risk or the severity of alcohol problems in first-time offenders is less clear. Thus, though modulating sanction severity to arrest BAC is a popular approach, there is need for systematic evaluation of its implementation and impact to support its effectiveness.

SELECTIVE PREVENTION APPROACHES FOR DWI

Given the rarity of a DWI arrest, many high-risk drivers drive undetected until after dozens or even hundreds of DWI occasions. Identification and

intervention with DWI drivers as early as possible, especially before a catastrophic DWI event has occurred, are clearly advantageous objectives. Two propitious targets for selective prevention initiatives then are injured DWI drivers identified in emergency rooms and trauma centers, and drivers arrested for a first DWI offense.

Host Factors: Alcohol Detection and Brief Intervention Programs

An opportunistic psychosocial intervention approach to DWI reduction in higher-risk individuals, prior to even a first arrest and conviction for a DWI offense, involves screening and brief intervention in emergency rooms and trauma settings. The premise of this approach is that these situations offer a singular opportunity to both detect injured individuals with an elevated risk for alcohol-related injury and provide a brief intervention (i.e. one session lasting several minutes) at a “teachable moment” that potentiates its impact. The format of these programs varies widely, but the more consistent elements include systematic screening using standardized instruments, such as the Alcohol Use Disorders Identification Test, objective feedback about an individual’s substance misuse as a way to rapidly increase problem recognition, clear advice to change, motivational techniques, and provision of information of available resources that can facilitate change in problem behavior.

Screening and brief intervention in emergency rooms and trauma centers have shown consistent benefits in significantly reducing high-risk drinking and readmissions in nondependent drinkers and in individuals admitted for alcohol-related injuries over variable periods of time. Most available studies to date have not focussed specifically on drinking drivers or alcohol-related traffic crashes or fatalities. Nevertheless, the evaluation of emergency room programs for injured and high-risk drivers, offered either alone or in combination with other therapeutic elements, has provided evidence for their effectiveness in reducing DWI arrests, drink-driving incidents, and self-reported problem drinking patterns.

Pragmatic challenges face the deployment of such programs. Trauma centers and emergency rooms are busy and chaotic environments. Moreover, patients in these settings may not be well disposed to answering questions about their substance use or having a discussion with a stranger not directly involved in the treatment of their injuries. In addition, the adoption of systematic screening for substance misuse and brief intervention in front line medical environments, despite being considered a best practice, has been uneven. Reasons for this include lack of time, cost, inadequate training, stigma, and confidentiality concerns. At

the same time, these obstacles are gradually being overcome.

Host Factors: Administrative Relicensing Interventions

In many jurisdictions, a first-time DWI conviction leads to mandated assessment for sanctioning and the setting of relicensing requirements. These assessments often use information from administrative databases on driver socio-demographics, driving history, BAC at time of arrest, and alcohol biomarkers, as well as from self-reported psychometric assessments of alcohol misuse and other DWI-related variables. When judged “high risk,” the offender is mandated to more intensive assessment, monitoring, and preventative intervention, all at his/her expense – which may be in the hundreds or thousands of dollars. Beyond assessment, offenders considered to possess significant substance abuse problems may be prescribed formal rehabilitation, self-help group attendance, and active follow-up and/or monitoring. Offenders deemed low risk are obliged to participate in less intensive remedial procedures. For some of these individuals, merely engaging in assessment and receiving feedback about their results may have a therapeutic value. Participation in such remedial programs is generally considered beneficial in reducing DWI risk, indicated by a modest yet significant 7–9% reduction in DWI recidivism with participation compared to no participation.

There are major shortcomings in the pragmatic operation of these programs. One is that many DWI offenders delay their engagement in remedial relicensing programs beyond the time they are eligible to do so, and sometimes indefinitely. Investigation into this hard-to-reach population reveals that they appear to be a more deviant group who frequently continue to drive unlicensed and are at greater risk for DWI when they do. They also possess severer and more persistent alcohol problems, show lower psychosocial and cognitive functioning, and are reluctant to pay the costs associated with participation in relicensing programs. As relicensing programs involve education, assessment, and substance abuse counseling, robust participation is a requisite for detection of high-risk offenders and provision of the remedial help they require. As with license suspension programs, this has led to calls for adaptations to encourage better and timelier participation, such as lowering the cost of participation.

Another problem stems from the field’s current inability to accurately discriminate between low- and high-risk offenders. Risk assessment procedures rely heavily on self-report instruments that can be falsified by individuals who are motivated to present themselves in an overly positive light. Available objective measures, such as elevated arrest BAC or alcohol biomarkers,

though impervious to falsification, are not always obtainable and have been inconsistent in predicting DWI recidivism risk. Moreover, there is a strong emphasis on detection of severe alcohol and drug use disorders that many risky offenders do not possess, especially young drivers who, though statistically a high-risk subgroup, do not often suffer from severe substance abuse. Perhaps as a result, contemporary assessment protocols have been found to possess no better than 70% sensitivity and 50% specificity, performance that is clinically problematic. This level of uncertainty is troubling because it reduces the effectiveness of a major underpinning of many relicensing programs, namely a graded approach to risk reduction.

There are also other potential consequences of the inability to discriminate between offenders. A high level of false negatives results in failure to identify at high-risk individuals and potentially incapacitate them from the road and/or provide them the remediation (e.g. Interlock devices) they require. False positives can lead to frequent overuse of interventions with offenders who do not require them. This is not only inefficient but can also contribute to the desensitization of offenders to interventions they may require in future. It may also disadvantage undeserving drivers by, for example, prolonging licensing periods or increasing the requirements for relicensing that can result in social and economic hardships. More research and development into valid methods of DWI risk assessment are urgently needed.

Agent Factors: Administrative License Revocation or Suspension

Many jurisdictions have provisions to allow for administrative measures such as car seizure, temporary suspension, or revocation of driver's licenses immediately following a DWI arrest. These provisions serve several functions, including: (1) general deterrence by representing a foreseeable penalty for DWI; (2) specific deterrence by the incapacitation of a DWI driver who may be at risk for further DWI; and (3) celerity by optimizing the deterrence impact of DWI laws through linking immediate consequences to problem behavior. As in the evaluation of any particular component of an overall DWI countermeasure strategy, the impact of this specific tactic is difficult to disentangle from the other countermeasures that inevitably accompany it. Nevertheless, institution of such provisions has been associated with small but significant (i.e. 5%) reductions in fatal crash involvement, irrespective of whether driver BAC was low (i.e. 0.01–0.07%) or higher. Moreover, in line with the celerity principle, license suspensions handed down some time after convictions were less effective as a deterrent of further DWI compared to more immediate suspensions. One factor that diminishes the impact of

administrative license revocation (ALR) and suspension (ALS) programs is that a majority of drivers drive without a license during or after their suspension period. Though these unlicensed drivers tend to drive less, their risk of RTC is elevated when they do.

INDICATED PREVENTION APPROACHES FOR DWI

Indicated prevention approaches aim at reducing DWI in drivers with established risk. The most unequivocal indicator of increased risk is previous DWI arrests and/or convictions. At the same time, the concept of the "hard-core," high-risk, intervention refractory offender subsumes not only recidivists, but also drivers who regularly drive impaired but have not been previously arrested. Features characterizing these hard-core drivers include a high BAC on arrest, a substance use disorder, and history of engaging in multiple high-risk driving behaviors, including previous DWI. The measures that are ordinarily directed at these drivers involve deterrence, removal of the vehicle or the driver from the road, and remediation efforts to decrease substance misuse and dependence. Several of the administrative measures described above for deployment in selective prevention are used in indicated prevention initiatives as well. In high-risk DWI offenders, however, they are more strictly applied through increased sanction and sentence severity, longer duration license suspension and vehicle impoundment, and more intensive remedial program participation as requisites for relicensing. Below, the measures that are commonly applied to recidivists are summarized.

Host Factors: Court-Based DWI Programs

A DWI court is a specific court system that targets the alcohol and drug abuse in DWI recidivists. In most jurisdictions, however, the general court system also plays a key role in the graded legal response for preventing DWI recidivism following a driving-related criminal code violation. Among the DWI court's main objectives are identification of offenders with elevated DWI recidivism risk, referral of high-risk offenders to mandated substance abuse treatment and/or other interventions (e.g. victim impact panels, self-help groups, education sessions, frequent alcohol and drug testing, intensive community monitoring and supervision), and creation of a non-adversarial court environment. Courts can take other legal actions including suspension of licenses, seizure of vehicles, and imposition of mandatory sentences.

The advantage of the court setting is that this is where the majority of DWI offenders can be reached. This is significant, as many DWI drivers do not seek

relicensing, which can trigger a risk evaluation and remediation if appropriate. Moreover, judges are increasingly cognizant of the opportunity their courtrooms provide for not only protecting the public, but also changing problem behaviors associated with DWI. At the same time, DWI courts face significant pragmatic hurdles. Assessment of DWI risk in the court context, like in relicensing settings, is problematic. This shortcoming could challenge a court's ability to modulate mandated intervention content and intensity based on valid risk assessment. Finally, there is little evidence of the effectiveness of mandated treatment in lowering DWI risk or RTC.

Given the multiplicity of ways in which courts may intervene in DWI, both generalization of data on outcomes from one program to another and identification of effective individual program components are difficult. Nevertheless, some information is available. Several pilot projects of DWI courts have found that compliance by offenders was good, and that participation was associated with lower rearrest rates compared to nonparticipants or comparison groups. Court programs with intensive monitoring and supervision have also been associated with reduction of recidivism for up to 5 years post conviction. More rigorous evaluation of different court-based approaches to DWI is clearly needed.

Host Factors: Individual Treatments for DWI

There are few therapeutic approaches designed specifically to address DWI. Most DWI treatments overlap in content and methods with substance abuse treatment and focus on reduction of substance misuse. Referral to specialized substance abuse treatment, follow-up, and monitoring by counselors involved in ALS programs, and possibly installation of an Interlock device for a period of time, are typical elements in the intervention plan for high-risk offenders. Substance abuse treatment may involve a combination of different psychosocial therapeutic components, including multimodal treatment, cognitive-behavioral treatment, relapse prevention, 12-step approaches, behavioral couples therapy, contingency management, among other evidence-informed practices. Overall, participation in these programs is likely to reduce the risks of DWI attributable to more severe substance abuse problems.

Many offenders exhibit poor problem recognition of their substance misuse and DWI behavior. This leads to many offenders being unwilling to fully engage in remedial programs or even consider the need for behavioral change. Engaging these offenders in a rehabilitative process represents an important therapeutic challenge. Interest is growing in motivational interventions in DWI settings as a means toward

enhancing problem recognition, commitment to behavioral change, and adherence to the remedial process. These interventions are being deployed in the court and in the hospital settings discussed above, and as stand-alone interventions.

One sophisticated motivational approach, Motivational Interviewing (MI), is a brief intervention lasting from one to four sessions that has been applied to the treatment of various tenacious problem behaviors, including substance use disorders, pathological gambling, and high-risk sexual practices. It incorporates a precise empathic communication style and an assortment of therapeutic tactics to (1) increase intrapersonal dissonance between clients' deeply held values and current problem behaviors, (2) resolve deep seated ambivalence about change, (3) enhance willingness and autonomy to take action, and (4) reinforce self-efficacy. The MI research consistently indicates its ability to efficiently produce outcomes comparable to other longer-duration psychotherapeutics, and to increase engagement and adherence to treatment. Hence, it seems well suited to the challenge of intervening with recalcitrant, treatment-shy DWI offenders.

Studies evaluating MI specifically with criminal offender groups, including DWI, are relatively rare and mostly preliminary in both their objectives and design. Nevertheless, the available evidence indicates that MI provided to DWI offenders resulted in greater adherence to remedial programs, better outcomes when combined with existing DWI interventions such as Interlock and incarceration, and a significant reduction in high-risk drinking days over a 1-year period when offered as a stand-alone intervention to recidivists with alcohol abuse problems. More research to establish its independent impact on DWI and RTC is needed. At the same time, like in most psychotherapeutic methods, effectiveness is contingent on the clinician attaining an adequate degree of mastery. With its nondidactic approach, specific communication style and a complex bouquet of tactics, MI requires highly motivated staff to learn it, and prolonged supervision to elevate and sustain its practice integrity. These conditions may hamper across-the-board implementation of MI in a DWI service context.

A promising specialized approach to DWI recidivism is the Preventing Alcohol-Related Convictions program (PARC). This program differentiates itself from most existing ones by focusing on the driving side of the DWI equation as opposed to the drinking side. Thus, intervention targets the decision-making process involved in controlling vehicle usage before drinking (i.e. when the offender is not intoxicated). This is in contrast to attempting to control drinking and/or driving after drinking has occurred, when rational

decision-making capacities and the ability to resist social and environmental triggers are impaired. A large-scale trial indicated that this approach was superior to usual care in first-time offenders. This result is intriguing by suggesting that the PARC program strikes at the core of why some DWI offenders persist in drinking-driving even in the face of increasingly severe consequences. Recent studies into the neuroscience of problem behaviors such as alcohol abuse, gambling, and risky sexual practices reveal that individuals who persistently engage in these self-destructive behaviors are prone to dysregulation of the paralimbic system involved in decision making. This may lead to a style of decision making that favors greater short-term gains (e.g. the convenience of driving to a drinking venue) even when accompanied by greater potential losses (e.g. an accident or a DWI arrest) versus smaller gains (e.g. a safe ride home) but smaller potential losses (e.g. no DWI risk). DWI recidivists are more likely to be impulsive, and there is emerging evidence that they have executive control and decision-making difficulties similar to the above risk groups when sober as well. More research is needed to evaluate whether the PARC approach works equally well with recidivists, especially those who may suffer from persistent decision-making impairments.

Agent Factors: Vehicle Impoundment

Vehicle impoundment programs seek to incapacitate the DWI offender's vehicle and remove the high-risk offender from the road, and secondarily to act as a deterrent. Duration of impoundment is variable, from days to months depending on the number of previous DWI convictions and possibly other extenuating circumstances. Costs for towing, storing, and ultimately reacquiring the vehicle are borne by the offender. The evidence suggests that impoundment reduces DWI rearrest and crashes in the year following impoundment. To be effective, impoundment must be executed immediately following an arrest to avoid the driver from selling or otherwise disposing of the vehicle. The deterrent impact is weaker on post-impoundment recidivism and not significant for DWI deterrence in the general driver population.

Administration of impoundment programs is complicated in many instances. For example, about half of drivers, usually owners of lower value vehicles, abandon their vehicles rather than pay storage costs and other fines to retrieve their vehicles. The community is left to absorb these costs. There are reports of multiple offenders intentionally driving valueless vehicles for this reason. DWI offenders and offenders who drive with suspended licenses are frequently apprehended in vehicles registered to others, complicating the impoundment and seizure process. This can also result

in adversity for innocent owners of vehicles who depend on them for vocational and transportation purposes. Other concerns relate to the potential for job loss for the offender. Little systematic investigation of these issues has been undertaken.

Agent Factors: Interlock

Interlock devices are usually offered on a voluntary basis to offenders in order to shorten their license suspension period. They are typically offered to first-time offenders as a way to expedite relicensure, but can become mandatory for life for drivers who want to reacquire their licenses after multiple convictions. Once installed in the offender's vehicle, the driver must blow into the device to start and continue operating their vehicle. Readings over 0.02% result in ignition being cut. There is consistent evidence that Interlock devices installed in the vehicles of DWI offenders and recidivists as part of a relicensing program significantly reduce DWI rates in the order of 40–90% during the time of installation. The device's usefulness as a behavioral change strategy for preventing recidivism is weak, however, with recidivism rates returning to preinstallation levels once it is removed.

Despite the proven capability of Interlock program participation to curtail DWI, uptake by offenders has been incremental. The expense of installation and servicing of the device, which can run up to several thousand dollars depending on the duration of installation, is borne by the offender. This cost, coupled with the low socioeconomic status and willingness to drive unlicensed observed in many offenders, may be preventing greater Interlock program participation. Future investigation into Interlock uptake could appraise the impact of reducing program cost and/or providing other positive incentives for voluntary participation. At the same time, such strategies for increasing participation in Interlock programs, or any other effective DWI remedial programs for that matter, are controversial because they may be perceived as rewarding offenders for their delinquent behavior.

Ongoing research is investigating the predictive and adaptive utility of Interlock data. Strands of evidence suggest that individuals who continue to blow positive after a learning period are more likely to recidivate once the device is removed. This finding, if sufficiently validated, could help administrators adjust the length of time the device must remain installed in the vehicle to ensure maximum public safety. In some jurisdictions, indications of continued positive blows are grounds for expulsion from the Interlock program. The resulting prolongation of the license suspension period is used as punishment to encourage an alteration of drinking behavior. More study of the

comparative impact of these different modalities of Interlock use is needed. Finally, there have been attempts to couple installation of Interlock with other therapeutic elements that target more enduring behavioral change beyond removal of the device. The available evidence suggests that adding a brief, therapeutic motivational component to the Interlock approach can help to maintain gains reliably observed while the device is installed. Further research is needed to understand how to extend the benefits of Interlock device installation in preventing DWI by also achieving more persistent behavioral change.

CONCLUSION

DWI is a major preventable public health concern. Significant strides have been made in the last decades in reducing RTCs related to DWI. More recently, these declines have stalled in much of the developed world. Moreover, rates of DWI-related RTCs are climbing in developing countries as individual access to private transportation grows. Ongoing efforts are needed to develop theory and evidence-based approaches to DWI risk assessment protocols and prevention approaches, and to rigorously evaluate their practical effectiveness in the field. In some instances, better reconciliation and integration of apparently conflicting responses to DWI, namely punishment, deterrence and intervention, are also deserving of continued attention.

Glossary

BAC blood alcohol concentration measured in g alcohol/dl blood and expressed in % (i.e. BAC of 0.05 g alcohol per dl blood = 0.05%).

Brief intervention brief intervention is typically one or more sessions of intervention that lasts 5–60 min. Common elements include the detection of substance use problems using standardized screening instruments, and interventions that involve the provision of feedback concerning the extent of an individual's use relative to his/her normative group and its risks, provokes increased problem recognition and cognitive reappraisal concerning substance misuse, and delivers clear advice to change.

Designated driver a driver who has been appointed to remain sober and be the driver after a drinking event. These are typically informal arrangements made between friends and colleagues.

Interlock device a device that is installed in a vehicle that prevents ignition of an vehicle by a driver whose BAC is typically above 0.02%.

Motivational interviewing a brief intervention lasting from one to four sessions. It incorporates a precise empathic communication style and an assortment of therapeutic tactics to: (1) increase intrapersonal dissonance between clients' values and current problem behaviors, (2) resolve ambivalence, (3) enhance willingness and autonomy to take action, and (4) their self-efficacy to do so.

Per se drunk driving law a law that states that someone is guilty of driving under the influence if their blood alcohol content is at or above a certain level (e.g. BAC \geq 0.08%).

Preventing Alcohol-Related Convictions program (PARC) this approach focuses on the driving side of the DWI equation as opposed to the drinking side. This intervention targets the decision-making process involved for controlling vehicle usage before driving to a drinking venue (when the offender is sober), in contrast to attempting to control their drinking and/or driving after arrival when the driver is more vulnerable to the effect of alcohol on rational decision-making and the social and environmental triggers for drinking.

Recidivists repeated DWI offenders.

Sobriety checkpoints a roadblock conducted by law enforcement officials who stop vehicles in order to establish whether the driver might be legally impaired to drive.

Victim impact panels under court order, DWI offenders must witness the impact of drunk driving on the lives of its victims through panel presentations from a victim of DWI, a rescue professional and/or from another DWI offender.

Zero tolerance law a law that makes it illegal for individuals to be driving with a BAC greater than 0.00%.

INTRODUCTION

Among Buddhist teachings on classical mindfulness that are recognized by all Buddhist traditions, two major types of meditative practice have been described in considerable detail: concentration meditation and insight meditation. While different Buddhist traditions may emphasize either insight or concentration practices, mindfulness meditation typically combines both. The mindfulness (*sati* in Pali, *smṛti* in Sanskrit) is commonly translated as the recollection or recall of the present moment. As a means of recall, remembrance, or recollection (of the present moment), it is a valuable technique or strategy for combating the tendency toward ruminative distraction during meditative practice. This meaning of mindfulness emphasizes the recollection of the present moment by shifting attention away from mental objects other than the one that is the meditative focus (e.g. breath, sound, image) in the present moment.

Traditionally, concentration practices sustain bare attention on the breath as the primary meditation object

while remaining simultaneously aware of the body and mind. Such bare attention permits the awareness of subjective experience but devoid of the projections and associations with which we automatically perceive such experience. Effort is made to maintain attention on the meditative object without distraction. When any cognitive event distracts attention away from the breath, introspective awareness is applied to label the distraction and the act of mindfulness serves to return the attention once again to the breath. Through such repeated labeling, the arising of subjectivity is separated from the specific content of that subjectivity. Only when the mind can hold an object stably for a sustained period can the contents of mind be fully and vividly experienced. Understood in this way, the *concentrative* aspect of mindfulness meditation is stressed and can be described as focused (on a meditative object), microscopic (free of distraction), and narrow in its scope (less aware of other mental activities).

However, mindfulness is also described as a form of attention and introspective awareness directed toward

subjective experience itself in order to discern its intrinsic or “authentic” nature. Rather than viewed as a distraction or obstacle to the tranquility associated with concentration meditation, mental content is directly observed in insight meditation. Through the moment-to-moment experience of subjective events within the context of the mental stability and tranquility induced by concentration practices, the transitory of all subjective experience, their ephemeral and constructed nature, is directly observed or cognized. As a result, mindfulness helps to increase the awareness of the habitual patterns of preoccupation with maladaptive mental content. Understood this way, the *insight* aspect of mindfulness is stressed. Mindfulness (insight) meditation, in contrast to concentration meditation, is less focused, macroscopic, and broad.

Thus, the assumptions underlying insight meditation locate emotional and behavioral distress in dysfunctional attitudes about cognition, rather than in the content of dysfunctional cognitions, per se. According to Buddhist psychology, the type of insight that sustained bare attention facilitates differs from the insights that are derived from content-focused therapeutic interventions such as psychotherapy or cognitive-behavior therapy. For this reason, mindfulness approaches are often considered to be metacognitive in nature, emphasizing that the beliefs that are held about cognition itself can be the source of significant emotional distress. Through repeated labeling of mental process rather than actively engaging with mental content, habitual, reflexive reaction patterns diminish and attenuate, and skillful responses are more likely to occur.

When the cultivation of sustained and increasingly extended periods of attention on an object through concentration practices (bare attention) train is integrated with introspective insight awareness, a deeper understanding of the moment-to-moment arising of subjectivity is achieved. This understanding facilitates a novel, deconstructed experience of self and the phenomenal world.

Sustained mindfulness practice also facilitates perceptual and cognitive regulation, the repeated switching between attention to, and introspective awareness of, subjective experience. Such cognitive and perceptual fluidity helps increase mental flexibility through an attitude of nonidentification with cognitive experience. Such mental suppleness or flexibility is often considered a feature of optimal mental health. Unlike cognitive-behavioral therapy, which deliberately requires the active exposure to undesirable mental events and targeted efforts to restructure or otherwise modify subjectivity, mindfulness is a natural process of experiencing subjective events without interruption, rejection, judgment, or manipulation

regardless of content. Mindfulness encourages an attitude of tolerance or acceptance (but not indulgence) of subjective experience and facilitates adaptive, flexible, nonautomatic response to such experiences through the cultivation of moment-to-moment awareness and observation of mental events as they naturally arise, briefly abide, and subside.

Buddhist-based meditation described above and secular mindfulness meditation that is of great scientific interest currently differ in several important ways. In traditional Buddhist meditation, the goal of mindfulness practice is to realize specific insights (or wisdom) into the nature of consciousness culminating in the experience of enlightenment or nirvana. Such insights are considered radically transformative of the personality, influencing the experience of oneself, others, and one's own internal and external environment. Secular mindfulness, in contrast, stresses the impermanence of thoughts and emotions related to self and the dis-identification with the habitual, reflexive qualities of maladaptive mental patterns with the goal of increasing mental and behavioral flexibility and thereby reducing psychological distress.

The core skill defining secular mindfulness has been described as the capacity to respond to cognitive events (which can include thoughts, beliefs, images, feelings, perceptions, sensations, memories) with an attitude of acceptance, nonjudgment, and present-focused awareness. This capacity is thought to assist the individual to decenter from negative mental states.

MINDFULNESS-BASED INTERVENTIONS

The most popular secular mindfulness program, Mindfulness-Based Stress Reduction (MBSR), has been shown to reduce psychological morbidity associated with chronic illness, emotional dysfunction, and behavioral disorders in several extensive reviews of this literature. In addition to the formal sitting meditation that is at the center of the 8-week MBSR program, there are several additional practices that complete the program (i.e. eating exercise, body scan, yoga, walking, meditation) and a day-long retreat between weeks 6 and 7.

Although the popularity of MBSR has grown in the absence of rigorous empirical evaluation, recent controlled trials have shown impressive reductions in psychological symptomatology associated with medical illness (e.g. chronic pain, cancer, anxiety disorders, rheumatoid arthritis, eating disorders, and fibromyalgia) and enhanced emotional well-being in nonclinical samples. Adaptations of MBSR for preventing depressive relapse (Mindfulness-Based Cognitive Therapy (MBCT)) and addiction relapse (Mindfulness-Based

Relapse Prevention (MBRP)) have also been developed. Moreover, mindfulness-related interventions have been integrated into a number of empirically supported psychotherapies, including Dialectical Behavior Therapy and Acceptance and Commitment Therapy.

MINDFULNESS MEDITATION AND ADDICTION RECOVERY

Although there is no definitive or specific Buddhist psychology of addiction and recovery, the core teachings of this tradition from which mindfulness-based practices originate hold that emotional suffering and distress is caused (or more accurately, conditioned) by “craving.” Craving, distinguished from mere desire, refers to an attributional or projective process in which the object of the craving (for example, a psychoactive substance or associated subjective experiences) is perceived as wholly positive, desirable, or needed (without taking into consideration its negative aspects or consequences). As a result, the object of the craving is obsessively sought after. Or, in contrast, the object of the craving is perceived as wholly negative, undesirable, or unwanted (without taking into consideration its positive aspects or consequences). As a result, the object of the craving is obsessively avoided. Thus, the addict perseverates, repeating actions (i.e. consume a drug) that have produced the desired outcome (i.e. euphoria) or to avoid or escape an unpleasant emotional state based on prior experiences with the psychoactive substance.

Whether it is seeking pleasure or avoiding an uncomfortable situation through, for example, food, entertainment, sex, exercise, or psychoactive substances, craving is a relatively common experience. Addiction to psychoactive substances, according to Buddhist psychology, is thus not fundamentally different from other “cravings” and represents a “false refuge” since the craving for drug-induced experiences ultimately produce the consequences that the individual wishes to avoid and do not actually realize for the individual what they are seeking (e.g. happiness, coping, and health).

Given the highly cognitive nature of the addictive process, there are many reasons why mindfulness meditation can be considered a potentially important component of addiction treatment. Firstly, mindfulness meditation facilitates a detached awareness of subjective experiences (e.g. thoughts, feelings, sensations), an especially useful set of skills for those in early addiction recovery for whom subjective awareness can be unpleasant, overwhelming, and distressful. The natural impulse for addicted individuals is to overidentify with subjective experience and hence seek methods to rapidly

modify (i.e. avoid unpleasant or intensify pleasant) subjective experience using a psychoactive drug. Mindfulness meditation, instead, encourages a radically different approach to subjective experience, especially undesirable ones, focused on observation, description, awareness, and nonjudgment of such experience. Such practice facilitates the addicted individual’s ability to hold or contain the affects they would otherwise wish to regulate through substance use. Through such practice, insight into the impermanent, temporary, and transitory nature of cravings and other addiction-related cognitions is facilitated. The fruit of such practice is an awareness-based response in the presence of substance use triggers rather than one that is impulsive, habitual, or automatic.

Secondly, mindfulness meditation improves coping with cravings, an inevitable and serious threat to recovery. The craving response creates a complex cognitive system consisting of environmental cues, rigid cognitive responding, positive outcome expectancies for the effects of the substance, and motivation to engage in substance consumption to reduce negative effect. Mindfulness may serve to disrupt this system through heightened awareness and acceptance of the craving response within an attitude that defines the essence of mindfulness: nonjudging, analyzing, or reacting. By repeatedly interrupting this system, mindfulness can be construed as a form of counterconditioning in which metacognitive awareness replaces the positive and negative reinforcement associated with consumption of the addictive substance. As a metacognitive skill, mindfulness may enhance the ability of the individual to cope effectively with urges and cravings by modifying how the individual perceives addiction-related beliefs. Thus, mindfulness meditation can weaken the conditioned association between a craving and substance use.

Thirdly, mindfulness meditation can, through concentration on the breath as an anchor for awareness, enhance the ability to concentrate and focus the mind and reduce the tendency toward distraction that can characterize the early phases of recovery. Relying on the meditative object, such as the breath, can help ground one’s awareness in the here-and-now and attenuate ruminative tendencies.

Fourthly, mindfulness interventions are particularly appropriate for addictive disorders given the central role of cognitive distortions, overridealization of sensory experiences, and fear of aversive emotions that have been shown to mediate addictive behavior and relapse. Mindfulness-based interventions have increasingly been shown to be effective in reducing the intensity of variables that are implicated in addiction relapse (e.g. negative affective states, such as depression and anxiety). For example, MBCT, an

intervention that is specifically designed to reduce the rates of depressive relapse following treatment has been shown to assist individuals in decentering from depressogenic cognitive and affective states. Since addiction relapse is also highly associated with cognitive and affective states, training in mindfulness may be effective in reducing addiction relapse as well.

MECHANISMS OF THE CLINICAL EFFECTS OF MINDFULNESS-BASED INTERVENTIONS

The precise mechanisms of action that underlie the action of mindfulness meditation await definitive elucidation. Mindfulness has been described as a metacognitive state of detached awareness of one's thoughts or a form of emotion-focused coping that modifies the response to stress or change rather than reflexively reacting to it. By bringing awareness to a stressful situation rather than automatically or impulsively reacting, the number of choices available to the individual to influence the next moment is increased. Mindfulness meditation may assist the individual to reduce the tendency to respond to negative mental and physical states with a cascade of negative discursive thought (leading to rumination) or maladaptive behaviors (e.g. phobic behavior, avoidance, impulsivity, substance use). Through regular and consistent practice, the mindfulness practitioner may learn to discriminate between the constant stream of cognition that characterizes normal waking consciousness and the "observer" or "cognizer" of such cognition and to lessen the tendency to identify with the content of cognitive processes. This discriminative skill allows the individual to disrupt automatic, conditioned, or impulsive response to such cognitions. Decentering from dysfunctional thinking (i.e. process focus) is a defining feature of mindfulness in contrast to efforts to alter specific beliefs (i.e. content focus) commonly found within psychotherapeutic approaches to psychopathology.

To the degree that one is able to observe one's subjectivity, one is no longer embedded or fused with its content. The result is a profound shift in one's relationships to thoughts and emotions with concomitant clarity, perspective, objectivity, and equanimity. Mindfulness meditation is also believed to reduce cognitive reactivity, the degree to which a mild dysphoric state reactivates negative thinking patterns. While developed within the context of depression relapse, cognitive reactivity has applications to understanding addiction relapse. Previous substance use may condition a link between specific thinking and emotional patterns and

substance use. Even mild reactivation of these mental events may trigger a cycle of ruminative and cognitive activity that exacerbates negative affect trigger urges and cravings for substance and increases the likelihood of ingesting the psychoactive substances.

Drawing on information-processing theory, a model of addiction in which mindfulness plays a central role posits that mindfulness promotes attention to cognitive, sensory, and affective responses. This attention (1) sensitizes the addicted individual to linkages between emotional distress and drug use that they may have not been aware of and (2) reduces the individual's avoidance of negative affect and cognition, thereby desensitizing the individual to the aversive aspects of these cognitive states and reducing the need to escape using psychoactive substances.

Alternative conceptualizations of mindfulness suggest that mindfulness meditation may exert its beneficial effects by producing a fundamental shift in perspective, re-perceiving. Re-perceiving has been empirically shown to comprise three components: intention, attention, and attitude. Through the simultaneous cultivation of these three components, a shift in perspective occurs (i.e. "re-perceiving") in which the meditator learns to dis-identify from the contents of awareness and perceive moment-by-moment experience with greater clarity and objectivity. Re-perceiving modifies the relationship between the individual and their own subjectivity and resembles other constructs such as decentering, de-automatization, and cognitive defusion.

Conditioning and learning processes such as habituation and desensitization have also been suggested as mechanisms of mindfulness. For example, the process of desensitization as a result of prolonged exposure may lead to symptom relief in patients with chronic pain and anxiety as the individual becomes more adept at tolerating, holding, or containing negative affect.

Meditation has often been confused with relaxation. While relaxation is often a welcome outcome of sustained concentration meditation, this is not the intent of such practices. Concentrative meditative practices are intended to create the ideal internal environment to allow the accurate discernment into the nature of subjectivity (i.e. insight). In addition, neurophysiological research suggests that mindfulness meditation is a unique form of consciousness and not reducible to mere relaxation. A randomized trial comparing mindfulness meditation to relaxation found that both interventions produced lower overall psychological distress compared to the control group, but only the mindfulness group also reduced rumination and distraction, an outcome consistent with the goals of mindfulness meditation, but not necessarily associated with relaxation practice.

REVIEW OF THE MINDFULNESS MEDITATION AND ADDICTION TREATMENT LITERATURE

The efficacy of meditative practices as an intervention in both substance abuse treatment and mental health treatment has supportive evidence dating several decades. Early research showed positive results for the effects of Transcendental Meditation (TM), a Hindu-based spiritual practice, as a substance abuse intervention. However, this research will not be reviewed here since the key TM technique is the repetition of a unique mantra syllable believed to be endowed with spiritual and magical potency rather than the development of mindfulness, insight, or meditative skills, *per se*.

To date, relatively few studies have investigated the efficacy of mindfulness-based interventions for the treatment of addictive behavior. In a recent review of mindfulness meditation for psychoactive substance abuse, 17 studies were identified that integrated mindfulness-related approaches into addiction treatment:

Classical Vipassana Meditation (VM; 1 study): this meditative practice adheres most closely to classical Buddhist teachings and typically consists of 10 consecutive days of 10–11 h of intensive daily meditative practice, conducted in silence.

MBSR (8 studies): tested the efficacy of MBSR or some variant of MBSR that modified some of its core techniques. For example, the duration of the interventions ranged from five, 90-min sessions over 7 weeks with less than 50% of the session content devoted to mindfulness meditation in some studies to eight, 2–2.5-h sessions over 8 weeks, with the majority of each session devoted to mindfulness meditation. Only two studies included the full-day retreat that is recommended as part of the traditional MBSR program and which serves to strengthen the mindfulness skills through intensive practice.

Spiritual Self-Schema therapy (3-S therapy; 3 studies): spiritual self-schema therapy has been developed for the treatment of addiction and HIV-risk behavior and consists of an 8- or 12-week-long course synthesizing a lifestyle-based psychotherapy based on the Eight-Fold Path, a central component of Buddhist psychology, with cognitive self-schema theory. All three studies used manualized 3-S therapy delivered in an individual and/or group format, during 1- to 2-h-long sessions per week.

Acceptance and Commitment Therapy (ACT, 3 studies): with its roots in behaviorism and behavioral analysis, integrates mindfulness among a number of other cognitive-behavioral interventions including exercises to reduce cognitive fusion, undermine experiential avoidance, clarify life values, development of a transcendental self, and several other explicitly psychotherapeutic interventions.

Dialectical behavior therapy (DBT, 2 studies): initially developed for the treatment of chronically suicidal clients with borderline personality disorder has been adapted for addictive disorders. DBT consists of strategies from cognitive and behavioral therapies (with a problem-solving focus) and acceptance strategies (i.e. mindfulness) adapted from Zen theory. DBT also includes techniques specifically formulated to assist individuals with severe self-regulatory deficits such as training in dialectic thinking, treatment strategies that balance change versus acceptance, interpersonal effectiveness, and emotion-regulation skills.

This chapter will explicitly exclude the DBT and ACT studies since both are comprehensive and multimodal treatments that integrate mindfulness in nontraditional formats (e.g. eschewing sitting meditation), but are not primarily mindfulness-based treatments. In addition, the understanding of mindfulness differs somewhat in both ACT and DBT from the description provided in the introduction. These treatments are also explicitly psychotherapeutic in nature with the goal of directly modifying cognitive and behavioral psychopathology. As a result, it is impossible to infer from the results of these interventions the unique impact of mindfulness meditation and are thus not of direct relevance for understanding mindfulness-based interventions for addiction. These treatments are better considered cognitive-behavioral treatments in which mindfulness plays a significant but subsidiary role. In addition, Self-Schema Therapy will not be reviewed, as this treatment is a lifestyle-focused, comprehensive, spiritual psychotherapy that is closely tied to Buddhist concepts. As with DBT and ACT, mindfulness is included as one of eight specific interventions based on the Buddhist eightfold path but cannot be described as mindfulness-based. Thus, only the nine studies that specifically evaluated mindfulness-based interventions will be briefly reviewed.

Residential Populations

Four studies, none of which employed randomization, focused specifically on residentially treated substance abusers in which mindfulness meditation formed a component of a multimodal treatment program for addiction. In a nonrandomized study of residents of an addiction recovery house, study participants self-selected into the mindfulness group and received 2-h mindfulness sessions once weekly for 8 weeks in addition to their standard treatment program. On days in between mindfulness sessions subjects listened to an audio-guided mindfulness instructions. Assessments of the effect of the mindfulness intervention were conducted at 8 weeks (post-intervention) and at a 5-month follow-up. No differences

were found between the groups (those who chose the mindfulness treatment versus those who did not) on measures of substance use, interpersonal problems, and measures of psychological health (e.g. spirituality, optimism). Several methodological concerns (e.g. small sample size, self-selection, no control for the mindfulness intervention) tempered any conclusion about the efficacy of mindfulness for addiction. However, the authors suggested that the benefits of mindfulness practice may not have been readily detectable by the assessment measures adopted in their study. Objective measures of mindfulness were not included.

A quasi-experimental evaluation of the MBSR as an adjunctive treatment of substance abuse in a therapeutic community compared to treatment as usual (TAU) found no significant group differences on any measure (e.g. anger control, self-control, social support seeking, hostility). The effect of mindfulness on substance use patterns specifically was not reported nor was mindfulness objectively assessed.

In an uncontrolled study of residents of a therapeutic community, the MBSR decreased salivary cortisol levels indicating reduced stress but found no change on a psychometric measure of perceived stress. Changes in substance use behavior were not assessed. The absence of a control group precludes any inference about the mechanism producing the changes in cortisol levels. Mindfulness was not objectively assessed.

More recently, a mindfulness-based therapeutic community (MBTC) intervention was compared to TAU (historical control) in a therapeutic community of DSM-IV diagnosed substance dependence. Both the MBTC and control groups showed a decrease on a psychometric measure of stress over time with significant reduction by the MBTC group in muscle tension and emotional irritability. However, these benefits did not extend beyond 3 months with both groups showing similar results. Again, the uncontrolled nature of this research precludes any firm conclusions. Mindfulness was not objectively assessed.

Incarcerated Populations

The benefit of the VM in a medium-security incarcerated population was evaluated in a nonrandomized study. Those uninterested in participating in the VM course were assigned to a case-matched "treatment as usual" group who were allowed to attend other rehabilitation courses of their choice (e.g. Alcoholics Anonymous, social skills training). The VM course consisted of several hours of daily meditation, held in silence, except for oral instructions that emphasized acceptance, nonjudgment, and nonreaction to thoughts and feelings. Teachings on basic Buddhist principles, including the Four Noble Truths and meditation, were provided.

Compared to the control group, the VM participants reported significant reductions in substance use (alcohol, marijuana, crack cocaine), fewer alcohol-related negative consequences, lower levels of psychiatric symptoms, higher levels of optimism, and higher levels of internal alcohol-related locus of control. At 3 months after release from prison, those who had participated in the VM group had significant decreases in thought avoidance, which was shown to partially mediate the reduction in alcohol use post release and suggesting that thought acceptance could be a possible mechanism of therapeutic action. Adherence to mindfulness practice was not assessed during or following the mindfulness course, so it is not possible to assess whether participants understood and correctly practiced mindfulness meditation, and therefore it is not clear whether the effects of course participation were due to mindfulness training or other confounding course characteristics. In addition, no objective measures of mindfulness were administered.

Outpatient Populations

Several either uncontrolled or nonrandomized studies on outpatient populations have been conducted. A randomized, controlled trial compared an 8-week outpatient MBRP program to TAU in individuals with substance use disorders who had first completed intensive inpatient or outpatient treatment. While the relation between depressive symptoms and substance use was significantly mediated by craving in the TAU, it was not found to be significant in the MBRP group supporting the hypothesis that mindfulness meditation attenuated the association between negative affect and self-regulation through substance use. However, no group differences in several aspects of mindfulness (observing, describing, nonjudgment of inner experience, and nonreactivity to inner experience) or substance-related problems were found. The intervention (MBRP or TAU) did not predict days of alcohol or drug used 4 months post-intervention.

Individuals with alcohol and/or cocaine use disorders randomly assigned to a mindfulness training or cognitive-behavioral treatment found no group differences in drug use, which was assessed weekly. Response to a personalized, imaginably administered, stress provocation test was assessed posttreatment. The provocation test showed a reduced response on psychological and physiological indices of stress in the mindfulness training group compared to cognitive-behavioral therapy. An objective measure of mindfulness, the Five Facet Mindfulness Questionnaire, did not show a significant change as a result of the mindfulness intervention. Attrition of over 50% reduced the generality of these findings.

An uncontrolled pilot study of MBSR on smoking cessation required subjects to quit smoking during

week 7 of the 8-week MBSR program. Six weeks later, about half of the sample was confirmed as abstinent from smoking for the prior week. Smoking abstinence was correlated with meditation compliance. Mindfulness was neither formally assessed at baseline nor at the end of treatment. Lack of a control group precludes a definitive interpretation of these results.

The MBRP, in an uncontrolled study of 15 alcohol-dependent, outpatient-treated subjects, showed no significant change in alcohol consumption (% days abstinent, heavy drinking days, total number of drinks), craving, liver enzymes, serum interleukin, or salivary cortisol 2 months following the meditation intervention. However, reduction on measures of psychometric measures of depression, anxiety, and stress were found post-meditation. This study was one of the few to actually measure levels of mindfulness prior to and post-intervention using the Mindfulness Attention and Awareness Scale, which showed significant but modest increases in mindful awareness.

SUMMARY OF MINDFULNESS-BASED INTERVENTIONS

Mindfulness-based interventions cannot at the present time be described as demonstrating empirical effectiveness. The outcomes that were reported are generally quite disappointing with the mindfulness intervention not bestowing any decided benefit in modifying substance use in the short-term or the long-term. Surprisingly, the specific impact of mindfulness mediation on patterns of substance use behavior was infrequently assessed or reported, ostensibly the most important variable in evaluating the efficacy of mindfulness-based interventions. Studies that showed mindfulness to have some benefit are difficult to interpret since the studies were not properly controlled, and the outcomes could be explained by a host of confounding variables.

Mindfulness meditation research has been criticized for their lack of scientific rigor. A major criticism concerns the lack of high-quality, randomized control studies (e.g. active or plausible controls where the key element of mindfulness-based approaches, sitting meditation and related practices, is excluded). No study combined both randomization and a credible control group. Indeed, uncontrolled or case series were the most common research design. In addition, small sample sizes, high rates of attrition, infrequent follow-up, absence of psychometric measures of mindfulness meditation also characterized this body of research.

Particularly noteworthy was the general neglect of objective measures of mindfulness such as the Mindful Attention and Awareness Scale or the Five Facet Mindfulness Scale, which were administered in only a very

small number of the studies reviewed. This is an especially glaring weakness of the mindfulness literature since it is simply assumed that those who receive this intervention will practice it properly (e.g. skill in perceiving subjective experience as impermanent, de-identifying with cognition, allowing mental events to arise and subside within a context of nonjudgment, accepting, tolerance). Yet, not one of the research studies reviewed measured any of these key constructs. Thus, outcome measures did not permit assessment of variables that could be specifically related to mindfulness meditation, but instead tended to focus on variables that reflected the outcome of mindfulness (e.g. hostility, depression, and social support). Instruction in mindfulness meditation does not ensure that mindfulness skills have been acquired or even practiced. Only through formal or objective assessment using psychometrically validated instruments of which there are several available can the impact of meditative practice be empirically demonstrated. Thus, it is not possible at this time to evaluate whether the mindfulness intervention even had an impact on mindfulness skills in most of the studies reviewed.

Measures of the process of mindfulness meditation were entirely lacking. Very little is known about what the participants in the reviewed studies are actually doing when they are practicing mindfulness. No study assessed what subjects actually did while they practiced mindfulness meditation. Not one study was able to verify that the participants were even practicing mindfulness meditation rather than engaged in some other activity such as fantasizing, sleeping, reverie, daydreaming, etc. While some studies did inquire as to whether the participants practiced mindfulness or the basic frequency of practice such assessments are far from an adequate evaluation of this core construct. As with all mindfulness meditation studies, it is not possible to determine whether subjects actually meditated at all and what they were actually doing while they meditated.

Furthermore, there appears to be an absence of consensus about an operational definition of "mindfulness," reflecting the ongoing debate about such practices in the general meditation literature. Mindfulness meditation interventions fail to distinguish between attention and awareness as two distinct components of meditation, raising doubts about what exactly practitioners are doing when they are practicing modern mindfulness-based interventions and what instructors are teaching. This distinction often escapes the attention of the mindfulness-researchers themselves.

Thus, the absence of methodologically rigorous research precludes a definitive statement about the future potential of mindfulness meditation for the treatment of addiction. The current evidence is not supportive of this approach at the present time.

FUTURE DIRECTIONS FOR RESEARCH

The most important objective for future research on mindfulness meditation is to clearly define mindfulness practice and to develop psychometrically robust measures of actual meditative practice (rather than outcomes of practice such as a decrease in dysphoric affect or increase in coping skills). Of course, the methodological quality of the research requires the adoption of study designs that can lead to valid inferences and attend to threats to internal validity. Several other reviews have spoken to this issue, and their conclusions will not be repeated here in detail other than to emphasize that sample size, follow-up, attrition etc., must all be seriously attended to if this modality is to receive a fair evaluation of its efficacy. While randomized control trials are the most common approach to achieve this, other methodologies should be explored such as applied behavioral analysis or intensive case studies in which the assessment of what subjects are actually doing when their practice can be assessed and monitored. One might raise the question of whether randomized controlled trial (RCT) methodology is most appropriate for evaluating mindfulness given the requirement of a positive attitude toward this modality in order to practice it properly and to realize its benefits.

The following recommendations that would improve the quality of mindfulness meditation research and the treatment of addiction can be suggested: (1) continuing to manualize mindfulness meditation therapies especially when they have been modified in individual studies to facilitate study replication and pooling of data; (2) assessment of subjects' mindfulness meditation practice intensity and changes in the degree of mindfulness; (3) mechanism of mindfulness meditation should be a component of the clinical assessment; (4) "dismantling" studies to determine necessary and sufficient elements of mindfulness meditation will assist in developing effective interventions; (5) inclusion of credible control therapies in order to conclusively establish treatment efficacy; (6) inclusion of objective measures of mindfulness where possible (e.g. biomarkers, imaging studies) to elucidate a mechanism of action.

In conclusion, existing data do not permit any particular type of mindfulness meditation to be recommended for any substance use-related condition at the present time. While many of the studies showed some positive effects of mindfulness meditation interventions compared to baseline, these effects were not always found, often short-term, and tended to apply to nonsubstance-related variables. While the promise of mindfulness meditation as an efficacious treatment

for psychoactive substance use disorders remains unfulfilled at the present time, there is sufficient evidence to recommend continued investigation of this modality.

PATHOLOGICAL GAMBLING NOSOLOGY, PREVALENCE, AND DEMOGRAPHIC CORRELATES

The *Diagnostic and Statistical Manual of Mental Disorders – Fourth Edition (DSM-IV)* defines pathological gambling (PG) as an impulse-control disorder that involves persistent and recurrent gambling that is disruptive to one's personal, familial, or vocational life. To meet criteria for a diagnosis of PG, 5 out of 10 diagnostic criteria must be endorsed. These symptoms include preoccupation with gambling; tolerance; repeated unsuccessful efforts to stop or control gambling; withdrawal symptoms (restlessness, irritability) when attempting to reduce or stop gambling; gambling as a method of escaping from problems or relieving dysphoric mood; chasing losses; lying to others about the extent of gambling; committing illegal acts to finance gambling; impaired relationship, career, or education due to gambling; and relying on others for

money to relieve a desperate financial situation caused by gambling.

Much of the diagnostic criteria for PG are based on the substance use disorder (SUD) literature, as five of the above symptoms are adapted from criteria for substance dependence. There is a debate in the empirical literature regarding the classification for PG. Future versions of the DSM are considering the inclusion of PG within a class of addictive behaviors, which would include traditional SUDs.

PG has also been called compulsive gambling and a gambling addiction. Although not a formal diagnosis, problem gambling is a term commonly used for individuals who meet some of the diagnostic criteria for PG, but who do not meet full criteria for a diagnosis. Disordered gambling is a commonly used term to summarize PG and problem gambling.

The overall prevalence of PG has been studied in several epidemiological investigations. Results appear somewhat dependent upon the methodology used to

assess PG. Recent large-scale epidemiological surveys in the United States suggest that the rate of PG ranges from 0.4 to 2.0% of the general population. Rates of problem gambling are higher, and may comprise as much as an additional 4% of the population.

Higher rates of PG have been detected in certain populations. Individuals with psychiatric disorders and SUDs are significantly more likely to meet criteria for PG than those without. Higher rates of PG have also been associated with certain demographic characteristics, including adolescents and young adults, individuals of non-white ethnicity, lower socio-economic status, people who are divorced or separated, and males. Recent data also indicate that rates of problem and PG are disproportionately higher among patients being seen for treatment in primary care medical settings, individuals with chronic illnesses, and among people who are medically disabled.

DIAGNOSTIC ISSUES AND ASSESSMENT OF GAMBLING SEVERITY

The most commonly administered measure for assessing gambling severity is the South Oaks Gambling Screen (SOGS). The SOGS is a 20-item self-report questionnaire with scores ranging from 0 to 20. Scores of 3–4 indicate problem gambling, although some studies have used lower cut-off scores. Scores of 5 or higher indicate probable PG.

The SOGS has good reliability and validity in clinical samples and has been translated into more than 20 languages. Advantages of the SOGS include its extensive use in research studies, which provides large empirical databases to compare results. The SOGS is easy to administer and score, and the questions have high face validity. Disadvantages of the SOGS include the following: it has not been updated for DSM-IV criteria, it was not developed as a diagnostic measure, it places an over-emphasis on financial problems, and it has a high false-positive rate. Within clinical settings, the SOGS may best be used as a screening method to detect problem gambling. When the screen is positive, measures with better sensitivity and specificity may be used for diagnostic purposes.

The National Opinion Research Center DSM Screen for Gambling Problems (NODS) is a 17-item interviewer-administered questionnaire. The NODS assesses past-year and lifetime gambling problems. Questions are consistent with DSM-IV criteria for PG. Scores of 5 or higher on the NODS suggests PG, with scores of 3 or 4 indicating problem gambling. Initial psychometric studies evaluating the utility of the NODS indicate that it has good reliability and validity.

The Structured Clinical Interview for DSM-IV (SCID) was developed specifically to assess for psychological disorders. Although the SCID as a whole has demonstrated utility in clinical and research settings, the psychometric properties of the gambling subscale have not been rigorously evaluated. One structured interview that may aid in assessing PG is the Gambling Behavior Interview (GBI). The GBI includes items that measure the 10 diagnostic criteria for PG as well as other questions of gambling severity.

In research settings, where a goal may be to obtain data on the frequency and severity of gambling and gambling-related problems, other measures may be used to supplement traditional diagnostic tools. The Timeline Followback (TLFB) is a commonly used assessment method that uses calendar prompts to elicit frequency and intensity of specific behaviors. The TLFB is frequently used in studies examining SUDs and has been adapted for use with PG. For gambling assessment, the TLFB provides a validated measure of the frequency and financial costs of gambling. The Addiction Severity Index (ASI) is the most widely used measure for evaluating the severity of substance use problems. Given the high comorbidity between PG and other SUDs, a gambling scale for the ASI was developed (ASI-G). The ASI-G has demonstrated adequate internal consistency and convergent validity with other measures of gambling severity, including a collateral informant and clinician-rated scales. Although the ASI-G may not be used to diagnose PG, the measure provides a score of gambling severity and impairment due to gambling.

In summary, there have been a variety of self-report and clinician-administered measures that have been developed for diagnostic issues and problem severity. Within clinical settings, there may be several screening questions that could be used to quickly evaluate whether more intense assessment is indicated. One question may relate to frequency, such as “Have you ever placed five or more bets in a year?” The most commonly endorsed DSM-IV symptoms by pathological gamblers include preoccupation with gambling, chasing losses, and lying to others about the frequency or severity of gambling. If any of these symptoms are endorsed, it may warrant more intensive follow-up assessment. Validated psychological measures are available to provide measures of severity and clinical diagnoses.

PSYCHOLOGICAL TREATMENT OPTIONS FOR PG

Psychosocial treatment options remain in a relatively early stage, but have been evolving over time. Early

investigations were conducted with traditional behavioral therapy methods, but studies were limited in terms of research methodology and statistical power. Studies have emerged in recent years that are driven by psychological theory and include sophisticated research designs and adequate sample sizes. Results from these studies are promising and suggest that there are effective ways to treat PG. Psychological interventions for PG have primarily been based on treatment approaches for traditional SUDs, and adapted for use in this unique population.

Natural Recovery

There are compelling data to suggest that a significant proportion of problem and pathological gamblers recover without treatment. A summary of epidemiological studies found that approximately one-third to one-half of pathological gamblers are in recovery. A recent analysis by Slutske that examined data from two very large US epidemiological surveys, which were stratified to resemble the US population, found that over one-third of individuals with lifetime PG did not experience any problems with gambling in the past year. This occurred despite only a small proportion of individuals having ever sought formal treatment for gambling.

Gamblers Anonymous (GA)

Among pathological gamblers who seek treatment, GA is the most commonly utilized approach. GA is modeled after the 12-step approach of Alcoholics Anonymous and is available throughout the United States. Despite its comparatively wide-spread use, few empirical studies have evaluated the effectiveness of this approach. Studies that have evaluated enrollment in GA yield mixed results. In an early report of 232 individuals who attended at least one GA meeting, Stewart & Brown found that only 8% of participants maintained gambling abstinence for 1 year. Approximately 20% of participants did not return to GA after their first meeting and 70% of participants stopped attending meetings prior to their 10th meeting.

More positive outcomes for GA have been detected when this modality was used in conjunction with professional gambling treatment. In a study by Petry of 342 pathological gamblers enrolled in professional treatment, 48% of patients who also attended GA meetings maintained abstinence from gambling 2 months into treatment. This rate was significantly higher than the patients who did not attend GA, 36% of whom reported abstinence in the same time period. The findings suggest that participation in GA in conjunction with professional gambling treatment may help to promote and maintain

abstinence from gambling. However, the findings should not be considered causal, as external factors such as treatment motivation may have led patients to also participate in GA. Patients who are more motivated for change may work harder in treatment and may be more likely to have successful outcomes.

Brief Advice

In a recent study by Petry and colleagues that included 180 disordered gamblers, researchers demonstrated efficacy for brief advice in helping individuals who were not specifically seeking gambling treatment to help reduce the frequency and severity of their gambling behavior. Participants were randomly assigned to a no treatment control condition, 10 min of brief advice about gambling that included personal feedback and concrete suggestions for reducing gambling, one 50-min motivational enhancement therapy (MET) session, or one session of MET plus three additional sessions of cognitive-behavioral therapy (CBT). In the post-treatment assessment session, those in the brief advice condition had significantly decreased their gambling relative to the no treatment control condition. Treatment gains remained at the 9-month follow-up evaluation. Individuals randomly assigned to brief advice evidenced greater reductions in the frequency and severity of gambling relative to those assigned to the control condition.

Given the brevity with which it occurred, this brief advice approach may be well-suited for individuals with less severe forms of gambling problems, such as problem gamblers, in primary care settings where providers must quickly evaluate and treat a range of concerns, as well as in traditional mental health settings. The advice offered in this intervention included the following recommendations: (1) gamble to have fun, not to make money; (2) only gamble what you can afford to lose (pay monthly bills first); (3) set a dollar limit for each gambling session and stick to the limit; (4) set a time limit for each gambling session; (5) leave checks, credit cards, and ATM cards at home; (6) take your winnings home; and (7) casinos/video lottery machines/state run lotteries set the odds and they are not in the business to lose money. These recommendations are consistent with a harm reduction approach to gambling problems and may be particularly palatable for patients who do not wish to entirely abstain from gambling.

MET

MET was originally developed to treat alcohol and SUDs, and has been adapted to treat PG with some

success. In the first comprehensive evaluation of the utility to treat gambling problems with MET, Hodgins and colleagues randomly assigned 102 disordered gamblers to one of three conditions: a wait-list control, a workbook containing cognitive-behavioral exercises, or a MET session with the self-help workbook. The self-help workbook alone did not lead to greater reductions in gambling compared with the wait-list group. However, the self-help workbook combined with the MET session resulted in the greatest reductions in PG symptoms. Follow-up assessments of patients in the active conditions found that MET was associated with greater reductions in gambling days, money lost, and gambling severity scores, and that some benefits of the MET were apparent 24 months after the intervention. Follow-up studies by this research team and others have yielded similar results, that brief MET sessions alone or in combination with self-help materials are effective in reducing the frequency and severity of problem and PG.

A recent study by Petry and colleagues randomized 117 disordered gambling college students to one of four conditions: an assessment-only control, 10 minutes of brief advice, one session of MET, or one session of MET plus three sessions of CBT (the study design is similar to that reported above, in the Brief Advice section). Gambling was assessed at baseline, week 6, and month 9 using validated outcome measures. Compared to the control condition, those individuals who received any of the active interventions displayed significant decreases in gambling frequency. The MET condition significantly increased the odds of a clinically significant reduction in gambling at the 9-month follow-up, relative to the control condition. Participants assigned to other conditions had benefits on some, but not all measures of gambling. The results indicate that brief interventions, and MET in particular, are efficacious in reducing gambling problems among college students.

In the above study by Petry and colleagues, participants randomized to MET received a 50-min individual therapy session, which took place immediately after the baseline assessment. Participants received personalized feedback about their gambling, which placed the severity of their behavior in comparison with national data. With the therapist, participants explored positive and negative consequences of gambling and discussed how gambling fit with their life goals and personal values. Participants also completed a change plan worksheet, which involved discussing the changes that could be made, reasons to make the change, steps to be taken in making the change, a review of support persons available to assist, and problem-solving obstacles that could interfere with the change plan.

CBT

Cognitive and CBT approaches have been the most widely studied treatment for PG. Initial behavioral therapy studies were met with mixed results. Early studies included aversive therapy, systematic desensitization, and imaginal desensitization. These included case reports, descriptive studies, and several randomized trials, though these were largely underpowered. More recently, a greater emphasis has been placed on cognitive processes that impact gambling (e.g. automatic thoughts, cognitive distortions). Most CBTs now include a focus on building skills toward relapse prevention, problem solving, and development of alternative behaviors.

In the largest randomized trial evaluating the efficacy of psychological interventions to treat PG conducted to date, Petry and colleagues randomized 231 pathological gamblers to one of three treatment conditions: referral to GA, GA referral plus a CBT-based self-help manual, or GA referral plus individual CBT. The CBT self-help manual and individual sessions both consisted of eight chapters or sessions, which covered identification of triggers, functional analysis of triggers and consequences of gambling, engaging in alternative activities, self-management of triggers, coping with urges to gamble, gambling-refusal skills, cognitive distortions related to gambling, and relapse prevention. Gambling was assessed at baseline, 1 month, 2 months, 6 months, and 12 months after the baseline assessment. Collateral informants also provided independent assessments of participants' gambling. Outcomes included reductions in gambling disorder symptoms, number of days of gambling, and amount of money gambled. Using an intent-to-treat analysis, participants assigned to the individual CBT plus GA referral group had significantly greater improvements than participants assigned to GA referral only on all outcome measures. Individual CBT participants also had longer-term benefits of therapy that did not occur in the other two conditions. A secondary analysis of the outcome data found that short-term treatment benefits were mediated by the development of new coping skills.

A recent randomized trial by Carlbring & Smit examined the efficacy of receiving CBT-based materials, designed to reduce the frequency, and severity of gambling, via the Internet. Participants were randomized to a self-guided CBT or to a wait-list control group. The treatment was guided, as participants had exposure to a professional therapist, which included e-mail and weekly telephone calls. A total of 66 participants with PG, and without severe symptoms of depression, were assigned to one of the two conditions. The Internet-based self-guided CBT intervention resulted in significant improvements in PG, anxiety, depression, and

scores on quality of life. Results were significant at the end of treatment and maintained at the 36-month follow-up session. The results from this study suggest that professionally developed CBT materials, delivered in conjunction with minimal therapist contact, may be effective in helping patients reduce their gambling. This finding is particularly important given that only about 10% of pathological gamblers ever seek formal professional treatment.

Other studies have found support for CBT-based treatments to address PG. There are mixed data regarding the best modality of treatment, as recent studies suggest that participants assigned to group therapy may not improve to the same degree as individuals assigned to individual therapy.

Summary

Although CBT and brief interventions have support for treating PG, work remains in optimizing treatment outcomes. Two recent studies have been conducted that modify traditional interventions in hopes of improving upon treatment outcomes. Grant and colleagues adapted Petry's traditional CBT treatment model to include imaginal desensitization and MET techniques in 68 pathological gamblers. They found that the combined intervention was superior to referral to GA, and that participants who failed to respond to GA had significant improvement following later treatment with the new intervention. A study conducted by Korman and colleagues evaluated an integrated 14-week CBT treatment for problem gambling and anger management in 42 problem gamblers with anger problems. Participants randomly assigned to the integrated CBT and anger management treatment demonstrated significant improvements in gambling behavior, as well as decreased anger and substance abuse.

These studies are just two examples of some of the different ways researchers are beginning to modify existing treatments in order to improve participant outcomes. Given the high rates of psychological comorbidity with PG, future investigations may also integrate treatments for PG with empirically supported interventions for mood, anxiety, and SUDs.

IDENTIFYING THE MOST IMPORTANT FACTORS TO ADDRESS IN CBT FOR PG

In a recent report, Morasco and colleagues reviewed the individual CBT sessions among pathological gamblers enrolled in a randomized clinical trial. The goal was to describe the content of participants' responses to individual CBT exercises. All participants

($n = 84$) met criteria for PG and received an 8-session manualized CBT delivered in individual therapy. The following is a summary of the 8-session CBT model, which includes participants responses to each session.

Session 1 focuses on developing a better understanding of the context in which the participant gambles. This focuses on identifying triggers to gambling, and includes certain events, days and times, people, and emotions that have been associated with gambling. Using a structured hand-out, the therapist reviews triggers for gambling with each client. The most commonly reported triggers to gamble among this sample of treatment-seeking pathological gamblers were lack of structured time (reported by 51% of the entire sample), negative emotional state (45% of the sample), encountering reminders of gambling such as an advertisement for a casino or watching sports on TV (37%), and having readily available access to money (33%).

In Session 2, participants are introduced to the concept of a functional analysis. This consists of reviewing the precipitants, behaviors, and consequences (both positive and negative) of gambling. In therapy sessions after conducting several functional analyses, the cyclical nature of gambling is highlighted, as the negative effects of gambling lead directly to the triggers for gambling, which often results in additional gambling episodes. The most commonly reported positive consequences of gambling, which are highlighted as being relatively short-term and transitory, include enhancement of a positive emotional state (endorsed by 80% of participants), having an escape (53%), the opportunity to win money (26%), and companionship (26%). The most commonly reported negative consequences of gambling, which are highlighted as being more long-term and enduring, were inducement or exacerbation of a negative emotional state (reported by 62% of participants) and losing money (47%), or more generalized financial problems (42%).

The focus of Session 3 is on increasing positive events. For many pathological gamblers, gambling has become the recreational activity of choice, to the detriment of other social and leisurely activities. After having a detailed discussion of recreational activities that could be incorporated into daily life, the therapist focuses on high-risk times for gambling. These high-risk times may be similar to the triggers that were reported in Session 1 (e.g. home alone and bored with nothing to do, when feeling depressed or angry). In the subsequent week, clients are encouraged to proactively participate in a new activity during high-risk times. The most common high-risk times reported by treatment-seeking pathological gamblers included specific days of the week (such as payday or weekends; reported by 33% of participants), when having a significant negative fluctuation in mood (reported by 30% of participants), and a lack of structured time (22%).

Session 4 is explicitly focused on the development of new coping methods for managing gambling urges or cravings. In session, participants were primarily taught a variety of short-term coping methods, while higher-level cognitive coping strategies were introduced in later sessions. The most common coping strategies that were reported by participants were distraction (45% of participants endorsed this) and avoidance (40%). Seeking support from professionals or friends was rarely endorsed (4% of participants).

Methods for handling cravings and urges to gamble were introduced in Session 5. Participants were encouraged to focus on the ways in which they experience cravings. They were taught to urge surf as a method for observing how they focus on gambling urges and the therapist highlighted the ways in which physical sensations and thoughts become paired with gambling urges. In session, participants summarized the most common ways in which they experienced cravings. The most frequently endorsed categories for the way in which gambling cravings are experienced were a specific body or physical reaction (e.g. heart pounding, tightness in stomach; reported by 36% of participants), non-specific physical sensation (e.g. feeling antsy or flushed; 30%), or having specific thoughts (e.g. dreams of winning big; 25%) or emotions (such as being stressed out; 25%).

Assertiveness training is introduced in Session 6. The initial focus of the session is on gambling-refusal skills, but treatment also includes general assertiveness training. Three interpersonal styles are described (passive, aggressive, assertive), participants are coached on alternative methods for dealing with others, and role-play is utilized to cement new skills. When participants were asked the most common situation in which assertiveness skills were needed, the most common response was not applicable (48%), as respondents indicated that they primarily gamble alone. Other participants indicated that social pressure (39%) and environmental cues (20%) are situations in which gambling-related assertiveness skills would be useful. For those individuals who indicated that they did not feel pressure to gamble from others, the focus of the session was on general assertiveness training, as passive or aggressive responding often has unanticipated effects, including increased gambling in many instances.

In Session 7, participants were introduced to cognitive distortions and the way these are associated with the maintenance or exacerbation of gambling. Several gambling-specific cognitive distortions were described, including the tendency to over-estimate the odds of winning, the gambler's fallacy, availability heuristic, and illusory correlation. The most common self-deceptions endorsed by participants included specific betting strategies (reported by 48% of participants) and

luck-based approaches (38%). Participants were taught cognitive restructuring methods, ways to develop alternative thoughts, and encouraged to accurately evaluate the effectiveness of their betting strategies.

In Session 8, the final treatment session, the therapist and participant review the coping methods that have been most helpful for the client thus far. They also identify alternative coping methods that may be useful in the future. Relapse prevention strategies are emphasized and participants are encouraged to problem-solve methods for dealing with high-risk situations in the future. In this final session, participants were asked to identify the most common coping strategies they currently utilize when confronted with a gambling urge or trigger. These are potentially the same coping methods that were queried in Session 4. In contrast to Session 4, when participants reported primarily relying on avoidance and distraction, these same participants now reported utilizing more sophisticated and enduring coping methods, such as seeking social support (endorsed by 67% of participants), seeking professional or para-professional support (43%), and implementing cognitive coping skills (31%).

These data highlight specific cognitive and behavioral strategies that may be useful in the treatment of PG. Data suggest that the coping strategies utilized by patients change over time, focusing less on short-term avoidance and distraction, and more on proactive methods for dealing with the trigger. Empirical data indicate that developing and practicing new coping skills are associated with improvement in symptoms of PG.

SUMMARY

Problem and PG impact a significant proportion of the population and are associated with decreased health and quality of life. Disordered gambling occurs at higher rates among certain subgroups in the community, such as individuals with SUDs, psychiatric disorders, among medical populations, and adolescents. Initial treatments for PG have been developed and tested. Studies suggest brief MET and CBT approaches are efficacious in reducing the frequency and severity of gambling. Additional research is needed to evaluate whether these approaches are appropriate for the majority of potential clients, or if specific interventions need to be developed for certain high-risk or difficult to treat groups.

INTRODUCTION

The spread of the human immunodeficiency virus (HIV) is as much a psychological and sociological phenomenon as it is a biological one. Although biology details how the virus is transmitted from specific body fluids of a host to the bloodstream of recipient, human behavior and social cultures and mores influence the ways in which the virus spreads from one person to another and within and across different subpopulations of people. The two most common mechanisms for transmission are sexual behaviors and injection drug use. Substance use of course plays a central role in the spread of HIV through injection drug use. Substance use also plays a major role in the spread of HIV through sexual behaviors for several important reasons. First, injection drug users (IDUs) can transmit HIV to their non-injecting sexual partners. Second, some forms of drug use are associated with increased sexual appetite which can lead to an increase in sex risk behaviors, and third,

substance use can lead to poor decision making and result in engaging in risky sexual behaviors while under the influence of drugs that the person may not have engaged in when not using drugs.

This chapter will describe some of the important elements of the HIV/AIDS substance use relationships. We will start with a brief history of the Acquired Immune Deficiency Syndrome (AIDS) epidemic and current trends in infection rates, then discuss transmission of HIV, injection and sex risk behaviors that can lead to transmission, the role of substance use in HIV risk, HIV in criminal justice settings, and multifaceted approaches for HIV prevention.

HISTORY OF AIDS EPIDEMIC

HIV is believed to have entered the United States as early as the 1970s; however, its impact was not fully realized until the 1980s. In 1981, two infectious diseases

began emerging among male homosexuals in the San Francisco and New York metropolitan areas: Kaposi's sarcoma (KS) and *Pneumocystis carinii* pneumonia (PCP). Treatment in non-immunosuppressed people usually was positive and nonlife threatening, however, the opposite proved true in this population. In June 1981, five cases of PCP were formally reported by the Centers for Disease Control (CDC). Two of the five people identified in this group had died from PCP. Shortly after the announcement from CDC, it was clear that there was a significant public health threat. By the end of 1981, there were over 700 confirmed cases of AIDS in the United States.

Until the end of November 1981, the CDC, scientific and medical communities believed that the syndrome was being transmitted through males having sex with males (MSM), though it could not definitively prove this was the mode of transmission. In December 1981, cases of AIDS among IDUs, both male and female, were being reported. Two months later, in January 1982, the disease began showing up in hemophiliacs and Haitians. AIDS was not limited to North America. By the end of 1982, there were reports of AIDS in South America, Europe, Africa, and Australia. In 1983, the disease was being reported in children and non-IDU women, suggesting mother-to-infant and heterosexual transmission. Every region in the world had been affected by 1985, when China identified its first cases of AIDS.

Scientists, clinicians, and public health professionals scrambled to understand how to prevent the spread of this new deadly disease whose etiology was yet to be determined. There was no known treatment and no known test for the virus for several years. Prevention efforts were complicated further as it was believed that there was a significant latency between the times of viral exposure until clinical symptoms began appearing in individuals. It was clear that the disease targeted the immune system making individuals susceptible to various opportunistic infections and these infections were resistant to standard therapy. It was likely transmitted through either sexual contact, sharing of needles between IDUs, and tainted blood products. The prognosis of AIDS was dismal, as more than 1/3 of all cases died from the disease.

Then in 1984, huge advances were made in the discovery of the virus suspected of causing AIDS. Researchers identified lymphadenopathy-associated virus (LAV) and human T-lymphotropic virus type III (HTLV III). It eventually was established that the two viruses were very similar, and the scientific community agreed on the name HIV and accepted that it was the virus that caused AIDS. Less than 2 years later, in early 1985, the Federal Drug Administration (FDA) approved the first enzyme linked immunosorbant assay (ELISA)

test kit to screen for antibodies to HIV. The first FDA approved medication, Azidothymidine (AZT), was introduced for treatment of HIV in 1987. Vaccines and other drugs were subsequently invented for the prevention of PCP, treatment for KS, and cytomegalovirus (CMV).

By 1996, there were 11 Antiretroviral Treatments available, and the age of highly active antiretroviral therapy (HAART) emerged. HAART is a combination of three or more antiretroviral drugs in combination and has led to significant decreases in morbidity and mortality. AIDS death rates declined by 89% from 1990 to 2003. AIDS was changed from a near universal fatal disease to a generally manageable, chronic illness as long as HAART therapy is continued. HAART has the ability to reduce viral loads in infected patients to undetectable levels in the blood, which also has important implications for reducing transmission to non-infected partners.

TRENDS IN THE HIV/AIDS EPIDEMIC

At the peak of the HIV/AIDS epidemic in 1985, there were over 130,000 cases of HIV/AIDS reported in the United States. Whites accounted for the largest proportion of cases of HIV/AIDS, representing more than 60% of cases reported. This trend has shifted dramatically over the years, and beginning in 1992, African Americans accounted for more than 50% of newly diagnosed HIV infections. This reflects a highly disproportionate distribution of the disease among African Americans because they comprise only 13% of the overall US population. The Hispanic population also has a disproportionate number of HIV infections, representing 20% of newly diagnosed HIV cases and 16% of the US population. Estimates have shown between 2006 and 2009, approximately 40,000 new HIV infections are diagnosed in the United States each year.

AIDS diagnoses peaked between 1991 and 1993 with 80,000 new cases reported each year. There was a dramatic decline in the number of AIDS cases between 1994 and 1999 when it dropped to 40,000 cases per year, and has remained steady at this rate through 2009. Deaths from AIDS peaked at the end of 1995, with 50,000 deaths, and have stabilized at approximately 18,000 deaths per year in the United States. Between 1985 and 2008, the trend for AIDS diagnoses follows that of HIV diagnoses. In 1985, whites represented 60% of AIDS cases, and steadily declined to 38% in 1995, and currently are at around 28% of cases. African Americans showed a steady increase in AIDS diagnoses, going from approximately 25% of cases in 1985 and now represent over 50% of newly diagnosed AIDS cases. Hispanics have also steadily increased in AIDS diagnoses, increasing from 15% in 1985 to over 20% of cases in 2008.

Recent global estimates show that 2.6 million new HIV cases were diagnosed and there were approximately 1.8 million deaths from AIDS. Sub-Saharan Africa has the highest rate of new HIV infections with 1.8 million new cases per year. The mode of transmission is different from other countries where the highest incidence is in MSM. In Sub-Saharan Africa, over 80% of cases are transmitted through heterosexual contact. There are over 22 million people living with HIV in that region, and approximately 1.3 million deaths per year. South and South-East Asia have the second highest rate and account for 4.1 million people living with HIV. North America has 1.5 million cases, Central and South America and Eastern Europe and Central Asia each account for 1.4 million people infected with HIV.

Global estimates have shown that between 1998 and 2003, 13.2 million people worldwide were IDUs. HIV prevalence among IDUs of over 20% was reported in centralized pockets in over 25 countries. The 25 countries include USA, Canada, Ukraine, Russia, Netherlands, Argentina, Brazil, Uruguay, Puerto Rico, India, Malaysia, Myanmar, Nepal, Thailand, Serbia, China, Viet Nam, Nepal, Portugal, Italy, and Montenegro. IDUs posed a significant threat to the epidemic since the 1980s in the United States. The risks associated with IDUs include sharing needles and also other injection paraphernalia, including cotton swabs, rinse water, and cookers. In addition, using drugs impairs judgment and can lead to risky sexual behavior. Between 1984 and 1985, there were over 30,000 new cases of HIV among IDUs. It remained steady in this group until 1990, when it dropped to around 10,000 new cases per year and has stabilized at this rate through 2009. This represents around 12.5% of HIV cases in the United States.

This group is a major carrier of the infection into the general population, as estimates show that heterosexual transmission by IDUs is as high as 70% of new infections in this population. The heterosexual transmission of HIV has shown an upward trend and is the second largest growing group of HIV infections in the United States. In 1985, heterosexual transmission represented less than 10% of new HIV infections. It steadily increased between 1992 and 2000, when it exceeded the number of new cases due to IDUs. Heterosexual transmission currently accounts for more than 30% of new HIV infections in the United States. The transmission rate among IDUs has shown a downward trend since 1981. The estimated transmission rate among IDUs has decreased dramatically over the years from 92 transmissions per 100 cases in 1981 to 5 transmissions per 100 cases in 2006.

There are differences between ethnic groups and gender in the incidence of HIV in IDUs as reported in 2009. More specifically, 50.4% of all cases of HIV

associated with IDU occurred among African American males and 54.4% among African American IDU females, compared to 17.4 and 25.5% in their white counterparts, respectively. Heterosexual transmission in African Americans was much higher than whites, with males accounting for 66.7% and females at 66.5% of new infections, compared to 11.1% in white males and 15% in white females.

Significant preventive efforts have been targeted at the IDU population by the CDC, National Institutes of Drug Abuse, World Health Organization, United Nations, State and County Health Departments, Department of Corrections, Syringe Exchange Programs, and Substance Abuse Programs. Success in the efforts of each of these programs is evidenced by the dramatic decrease in the incidence of HIV and AIDS cases among IDUs. They decreased from 30% of all HIV/AIDS cases in the early 1980s, down to 12% of all HIV cases by 2009. African American IDUs account for a disproportionate amount of cases of HIV and AIDS and efforts should continue to be targeted to this population. The other group that deserves continued preventive efforts is heterosexual cases of HIV associated with IDU since this group has shown a steady increase in HIV cases since the epidemic began in the early 1980s.

TRANSMISSION OF HIV

HIV can reside in several different body fluids, and can be transmitted when there is an exchange of fluids from an infected person to an uninfected person. Body fluids that can carry HIV include blood, semen (including pre-seminal fluid or pre-cum), vaginal fluid, and breast milk. Although HIV is rarely detected in the saliva of HIV+ people and in the rare cases it has been detected, it is at much lower levels than in other more suitable body fluids. However, blood mixed in the saliva from sores or cuts in the mouth can carry the virus.

HIV can be transmitted any time the virus has a chance for entering the bloodstream of a noninfected person. Skin that does not have cuts, abrasions, or sores provides a very reliable barrier against HIV, which cannot enter the bloodstream through unbroken skin. HIV can enter the bloodstream through a number of different venues, however. These include the lining of the anus or rectum, the lining of the vagina or cervix, the opening of the penis, the mouth if there are sores, cuts, or bleeding gums, other cuts or sores on the skin, and through contaminated needles or syringes.

Sexual Transmission of HIV

AIDS.gov, an official US Department of Health and Human Services website, lists different sex behaviors in

order of level of risk for transmission. Sexual behaviors, in order of risk, go from anal sex to vaginal sex to oral sex.

The riskiest form of unprotected sex is receptive anal sex. HIV is present in male sperm and seminal fluid and during anal sex this gets deposited in the rectum. The lining of the rectum is thinner and less pliable than the lining of the vagina and thus is more prone to damage during sex such as tears, cuts, or abrasions. Damage to the rectal lining may be present even when there is no visible bleeding. Insertive anal sex is also considered very risky because the partner may have sores in the rectum that are not visible and small, even unnoticeable tears or cuts on the penis can allow easy entry of the virus. In addition, fluids containing HIV can enter the urethra of the penis allowing infection.

Vaginal sex is also considered a high-risk activity, although it is considered much more risky for the woman than for the man. During unprotected vaginal sex, semen is deposited in the vagina which can enter the vaginal walls through the lining or through tiny cuts or abrasions. Risk is increased if the woman has a sexually transmitted disease or other vaginal infection. Although risks for men during vaginal sex is less than for women, as HIV in infected vaginal fluid or blood can enter the penis through the urethra or small tears or cuts.

Oral sex carries risk of transmission that is somewhat lower than for anal and vaginal sex. Saliva is not a suitable medium for HIV and HIV is rarely detectable in saliva of infected persons. However, performing oral sex on an infected man who ejaculates into the mouth carries risk of infection because the semen carries HIV and it can enter the bloodstream of the recipient through bleeding gums or sores or tears in the lining of the mouth. An uninfected man who is receiving oral sex from an infected person is at much lower risk of infection but there is some risk of virus transmission if blood from sores or cuts is present in the mouth of the person performing oral sex. Because the HIV virus can be present in vaginal secretions of an infected woman, performing oral sex on a woman can result in infection if the virus has a pathway to the bloodstream of the person performing the oral sex through cuts or sores in the mouth. But because the virus is generally not present in the saliva, a woman receiving oral sex from an infected person is at relatively low risk of infection unless the partner has cuts or sores in the mouth or lips.

Sexually Transmitted Diseases and HIV

The presence of a sexually transmitted disease (STD) increases the probability of HIV transmission. According to CDC estimates, people who have an STD are 2–5 times as likely as uninfected persons to acquire HIV if they are exposed to the virus through sexual contact. HIV+ persons who also have an STD are more

likely than HIV+ persons who do not have an STD to transmit the virus to uninfected persons.

Persons who do not have HIV but have an STD appear to be more susceptible to HIV infection due to genital ulcers that provide an easier pathway for HIV to enter the bloodstream, and inflammation from genital ulcers or from non-ulcerative STDs (e.g. chlamydia, gonorrhea, and trichomoniasis) can increase the concentration of cells in genital secretions, such as CD4+ cells, that provide hosts for HIV. STDs also increase the infectiousness of HIV+ persons by increasing shedding of HIV in genital secretions. Men who have HIV and gonorrhea are more likely than those who are infected only with HIV to have HIV in genital secretions and can have much higher concentrations of HIV in their semen, which increases infectiousness.

Condom Use and Sexual Transmission

There are two primary methods of preventing sexual transmission of HIV. The first is to not engage in risky sexual activities. These risky activities include having sex with multiple partners, having sex while under the influence of drugs or alcohol, having sex with strangers, and having sex with HIV+ partners or with partners where HIV status is unknown. Of course, the only true risky sexual activity for contracting HIV is having sex with an HIV+ partner. However, the other activities such as multiple partners, having sex under the influence, having sex with strangers, trading sex for drugs or money, increases the likelihood of having sex with an HIV+ partner.

Throughout human history, limiting sexual activity between humans has been fraught with failure. The CDC reports that latex condoms, when used consistently and correctly, are highly effective at preventing transmission of HIV. Large numbers of both laboratory and epidemiological studies have shown conclusively that consistent use of latex condoms provides a high degree of protection from infection. However, latex condoms do not provide 100% protection as there may still be some exposure to blood or other fluids containing HIV through cuts or sores in areas not protected by the condom, or condoms may fail or come off during sex. Polyurethane condoms are available from several manufacturers as an alternative to people who are allergic to latex. Advantages of polyurethane is that it conducts heat better and is thinner than most latex condoms and has very little odor. However, the material does not stretch as well as latex and, thus slippage and breakage is more common. The effectiveness of polyurethane condoms in preventing STDs is still being studied. Another non-latex alternative is a condom made of polyisoprene. It is considered as strong and safe as latex, is thicker than latex but it stretches well and has lower

slippage and breakage rates than latex. Polyisoprene condoms are FDA approved and considered an effective barrier to HIV and STD pathogens. A third alternative are condoms made of natural animal membranes, such as lambskin. These condoms are not considered to provide any protection against HIV or other STDs.

The CDC recommends that the only 100% effective method is to avoid having sex with HIV+ partners or be in a long-term monogamous relationship with a partner who has been tested and is known to be uninfected.

Transmission Among IDUs

Injection drug use often takes place in social settings where users gather to inject their drugs. These social settings, often called “shooting galleries,” provide social support, a relatively safe place to inject drugs that have been recently purchased, and often, a source of injecting equipment if the users do not have their own. The shooting galleries are often located near the place where the user can purchase drugs so the drugs can be consumed almost immediately after purchase.

A common activity in shooting galleries is the sharing of equipment. This sharing serves several purposes. First, users do not have to obtain their own equipment and carry it with them increasing risk of arrest. Sharing of equipment also serves a social purpose in which the user shares the act of injecting in a supportive environment in which they are not considered outcasts. For new IDUs, the shooting gallery helps the naive user learn the injection process.

The injection process often involves multiple steps. First, the powdered drug is mixed with water to dissolve it. This often takes place in a “cooker”, which can be a metal spoon or bottle cap. The solution is heated in the cooker to dissolve the drug. This solution is then drawn into a syringe, often through a wad of cotton which is used to strain the solution. The combination of cooker, cotton, and needle/syringe are often referred to as “works.”

When this process occurs in a social setting using shared works, there are a variety of points in the process that can contribute to transmission of HIV. First, when an HIV+ user injects drugs into a vein, small traces of blood remain on the needle. After inserting the needle into a vein, the user will first draw blood into the syringe to insure that they have properly hit the vein. After injecting the drug, they will sometimes draw blood into the syringe multiple times in a process called “booting” to make sure that all traces of the drug are used. If the user is HIV+, the needle and syringe contain contaminated blood that can then be passed to the next and subsequent users who inject with that syringe.

Virus transmission can occur, however, even if the user does not share needles or syringes. Sometimes,

when a drug solution is cooked, several users will draw the drug into their syringes from the same solution. If an earlier user uses a needle that has traces of contaminated blood on it, this blood can be transmitted to the drug solution and passed on to other users who draw from that solution. Other times, the solution might be all drawn into one syringe and then injected into the barrels of syringes for other users, in a process referred to as “backloading.” This process allows addicts to share the drug supply equally. A process called “frontloading” is when the drug solution is drawn with the needle from the back of another syringe. So even though needles and syringes are not being shared in this process, blood traces containing HIV can still be transmitted from one user to another.

HIV can also be transmitted when multiple users share the same cooker, the cotton used to strain the solution, or the water used to rinse syringes. Users will sometimes “beat” the cotton by shooting a small amount of water from the syringe into the cotton in an attempt to wash out as much of the drug as possible. If the syringe is contaminated with HIV, the cotton and cooker can then become contaminated. Rinse water is used to rinse syringes between users, not in an attempt to sterilize them as much as to keep them from clotting. In many places where IDUs gather to inject drugs, clean rinse water is not available and is reused and shared. When any of these steps of the process are shared by multiple users, one of which is HIV+, the virus can be transmitted to others even when needles or syringes are not shared.

Disinfecting Syringes with Bleach

Several steps can be taken to reduce risks of HIV transmission in social settings where drugs and equipment are shared. Users who carry their own equipment and works and who do not share it with others can virtually eliminate their risks for HIV infection. However, in many locales, possession of injection equipment is illegal and puts the user at risk for arrest. Even users who provide their own equipment may find themselves in occasional situations where they need to borrow syringes and share works to inject. When needles or syringes are shared between users, the CDC recommends disinfecting the syringe with full-strength household bleach, using a three-step flush, disinfect, rinse process. In the first step, clean water is drawn into the syringe in order to flush out blood, drugs, and other matter from the syringe. The syringe is tapped or shaken to dislodge particles and then the water squirted out and discarded. This step is repeated until no more blood can be seen. Water alone does not disinfect the syringe and does not kill virus particles that might remain in the syringe even after flushing. Filling the syringe with full-strength household bleach (5.25% sodium

hypochlorite) and leaving the bleach in the syringe for at least 30 s will kill virus particles remaining in the syringe. This bleach is then squirted out and discarded and finally the syringe is rinsed by filling with water again to rinse out the bleach. The rinse water is then discarded.

Although laboratory studies have shown undiluted household bleach to be effective at killing the HIV virus, actual practice by IDUs may not be as effective for several reasons. First, users may not follow all of the necessary steps or follow procedures correctly. Fresh, clean water may not be available. Users often do not want to carry bleach because it can identify them as drug users. Bleach is weakened when exposed to warm temperatures, sunlight or air so bleach actually used to clean syringes in practice may not be as strong as fresh bleach. In addition, although disinfecting syringes with bleach can help prevent HIV transmission, it does not sterilize the needle and thus users can get other infections from sharing needles.

Drug Use and HIV Risk

Non-injection drug use of course does not involve the sharing of needles, syringes or works that can lead to transmission of HIV between users. However, there are still important relationships between non-injection drug use and risk for HIV infection. Sexual transmission of HIV is by far the most common means of infection, and as the CDC has pointed out, two primary means of avoiding infection through sex is (1) to avoid having sex with HIV+ partners by abstinence or a long-term monogamous relationship with a person who has been tested and known to be HIV negative, or (2) using a condom correctly and consistently (100% of time when having sex). However, sexuality is a central part of personal identity and sex is a very powerful drive in humans. Even when people have the knowledge they need to identify and avoid risky situations, they often continue to make poor decisions and engage in risky behaviors.

Drug use affects judgment and lowers inhibitions. According to the National Institute on Drug Abuse (NIDA), drug and alcohol intoxication increases brain dopamine in limbic regions of the brain and lowers the threshold for reward stimulation and also lowers sensitivity to stimuli that predict delayed negative outcomes. People with substance use disorders often value immediate, smaller rewards more than delayed but often larger rewards and are often insensitive to the negative consequences of HIV-risk behaviors. People under the influence of drugs will often take more risks than when sober and engage in riskier sexual activities. This can include having multiple partners, having sex with partners who are considered higher risk (e.g. sex with

strangers, sex with partners who also have multiple partners, sex with IDUs), and having unprotected sex.

CRIMINAL JUSTICE SETTINGS

HIV infection is particularly prevalent in criminal justice populations, due in part to the large number of drug-involved offenders in jails and prisons. The Bureau of Justice Statistics reported that in 2008, a total of 21,987 state or federal inmates, or 1.5% of the total prisoners, were HIV+ or had confirmed AIDS. This prevalence rate is more than three times the rate of HIV cases in the US population reported by the CDC in 2006 (0.45%). HIV+ cases were more prevalent among state inmates (1.6%) than among federal inmates (0.8%). Female inmates were more likely to be HIV+ (1.9%) than were male inmates (1.5%). The three largest states in terms of number of HIV+ inmates were Florida, New York, and Texas, which combined accounted for 46% of all state inmates who were HIV+ or had confirmed AIDS, even though the three states account for only 24% of all state inmates. New York reported that more than 5% of male and more than 10% of female inmates were either HIV+ or had confirmed AIDS. There were also significant regional differences in HIV prevalence, with 3.2% of inmates in the Northeast, 1.9% of inmates in the South, 0.8% in the Midwest, and 0.7% in the West. The Bureau of Justice Statistics also reported that 24 states tested all of their inmates either at admission or some time during custody. All states and the federal system tested inmates if they had clinical indications of HIV or if the inmate requested a test, 42 states and the federal system tested after incidents where an inmate might have been exposed, and 18 states and the federal system tested inmates in specific high-risk groups.

Data have shown that HIV-infected inmates have high testing and treatment rates in prison. The prison setting offers opportunities for systematic testing of a high-risk population, as well as the provision of effective HIV care. However, continuation of care upon release back to the community is often poor as a result of inconsistent linkage to care and disruption of ART – with consequent loss of viral suppression and increased risk of HIV transmission. Many inmates released from prison perceive their infection as a secondary priority to other needs, such as housing, family reconciliation and avoidance of substance abuse relapse, and thus a large proportion of released individuals fail to maintain viral suppression. In addition, many released inmates return to high-risk behaviors after release, and coupled with loss of viral suppression, create a significant public health concern. A 4-year study of HIV+ inmates released from Texas state prisons found that

only 5% of released inmates filled a prescription for HAART within 10 days, only 18% did so within 30 days of release, and 30% did so within 60 days. However, inmates who received formal assistance in completing application forms to obtain medications post-release had higher rates of filling prescriptions than those who did not receive assistance.

PREVENTION AND INTERVENTION PROGRAMS

The CDC recommends a comprehensive approach to preventing blood-borne infection among IDUs, HIV as well as Hepatitis B and C and others. These include substance abuse treatment, community outreach, increasing access to sterile syringes, interventions in the criminal justice system, strategies to prevent sexual transmission, HIV counseling and testing and partner counseling and referral services, services for IDUs living with HIV/AIDS, and primarily drug prevention.

Substance Abuse Treatment

NIDA reports that drug abuse treatment has been an effective HIV prevention method. Effective treatment helps users stop or reduce their drug use which leads to reductions in risk behaviors, including reducing or stopping frequency of injecting drugs, reducing risky injection practices, and reducing participation in risky sex. In addition to the direct effects of reductions of drug use on these behaviors, drug treatment services also play important roles in providing current education about HIV/AIDS, counseling and testing services, referrals for medical services, education, and training on less risky injection practices and sex behaviors.

Injection Risk Prevention

Although substance abuse treatment is an effective method for reducing injection and sex risk behaviors, many IDUs are not in treatment for various reasons, including waiting lists for treatment slots, lack of accessible treatment services, or users not being ready for or wanting to receive treatment. These groups of out-of-treatment users, however, maintain risky practices that increase their own risk of contracting and/or spreading HIV and of acting as conduits of HIV spread to nondrug using populations. Harm reduction programs have been developed to reduce risks in these populations. Two important approaches have included needle exchange programs and community outreach.

Syringe Exchange Programs

Another method used to reduce the spread of HIV among IDUs is through syringe exchange programs (SEPs, sometimes referred to as needle exchange programs). In these programs, users can either exchange their used syringes for an equal number of new, sterile syringes, or receive new syringes without the requirement of an exchange. SEPs have been used in a large number of countries, most prominently in Western Europe and in Australia.

The first SEPs in the United States were established in Tacoma, Washington; Portland, Oregon; San Francisco; and New York City in the late 1980s. Programs operated in a variety of settings including storefronts, vans, sidewalk tables, health clinics, and other places convenient to IDUs. Some programs also offered a variety of other services in addition to syringe exchange, including HIV/AIDS education and counseling, condom distribution, substance abuse, medical treatment referrals, or other social service referrals, distribution of alcohol swabs, on-site HIV testing and counseling, screening for other infections, and some primary medical services.

Needle exchange programs have long been controversial in the United States. Critics argue that such programs do not reduce the spread of HIV among drug users, that providing needles to drug addicts encourages, or at minimum, condones illegal drug use, can lead to increases in needle use, and send the wrong message about the dangers of drug use. Use of federal funds for SEPs was banned in 1988 and the ban was renewed annually by Congress. However, the ban was lifted in December 2009, as part of an appropriations bill for labor, health, and education. Although the bill did not provide any new federal monies for SEPs, it allowed programs to use federal funds to provide clean needles.

The CDC reports that there is a large amount of literature showing that SEPs have had significant positive effects on preventing adverse health consequences of injection drug use and that they were not associated with increases in drug use or promoting initiation of injection use. SEPs have also been shown to increase use of substance abuse treatment and other services that can reduce HIV infection. A recent report of several major reviews published in the online version of the journal *Addiction* in 2010 concluded that there was tentative evidence to support the effectiveness of SEPs in preventing HIV transmission. There is sufficient evidence to support the effectiveness of SEPs in reducing self-reported injection risk behaviors, but insufficient evidence to support the impact of SEPs on preventing Hepatitis C transmission. The conclusions argued that the evidence for effectiveness was weaker than given credit in the extant literature but that the lack of evidence was primarily a function of limitations of the studies and

research methods and the tentative evidence should not be interpreted to mean evidence for ineffectiveness.

Community Outreach

Another component of the comprehensive approach advocated by the CDC is community outreach. Many drug users are not involved in substance abuse treatment or do not access other traditional venues providing prevention, medical, mental health, or social services. Community outreach programs are often designed to go to the drug users in the community and reach them where they congregate. Outreach is typically conducted face-to-face by outreach workers who are often former users themselves. Outreach workers attempt to develop trust with drug users in their environment and typically work from a harm-reduction model, working to get them to change their high-risk injection and/or sex behaviors. Services offered involve distributing substance abuse and HIV literature, training on safer injection and sex practices, distribution of condoms and bleach kits, and information about available services (e.g. substance abuse treatment, medical and mental health services, housing, and others). Outreach can be extended by working with social and drug-using networks of IDUs. For example, network leaders are recruited and trained on risk-reduction and prevention techniques and using social learning methods. They are also trained to be mentors, to model safer techniques to others and to motivate their network members to reduce risk behaviors.

The CDC reports that studies of outreach programs have regularly reported reductions in stopping drug injection or reducing frequency of injection, reducing sharing of syringes and works, and reducing crack use. Follow-up outcomes of community outreach programs have also shown increases in needle disinfection, condom use, and entry into substance abuse treatment. Studies have also shown that peer-driven interventions conducted by trained out-of-treatment drug users can extend the reach of harm-reduction programs to social and drug-using networks and can be effective at getting network members to reduce risky practices although they have not been as effective at getting network members to change sexual practices.

Highly Active Antiretroviral Therapy

HAART is a customized combination of several different medications that control viral load, helps to delay the onset of AIDS symptoms in HIV+ persons and helps delay progression of AIDS. HAART, when used as directed, can reduce viral loads to undetectable plasma levels. This does not mean that the virus is eliminated from the body, but that it is reduced to levels that

cannot be detected by available tests. However, less is known about viral loads in other fluids such as seminal or vaginal fluid, as these are typically not measured. Although antiretrovirals (ARVs) are associated with lowered viral loads in seminal and vaginal fluids, the virus has been shown to persist in cells in seminal fluid and breakthrough shedding of the virus in vaginal fluid has been observed during HAART therapy. In addition, some studies have observed that some people on HAART who have demonstrated undetectable viral loads have temporary small increases of viral load. Thus, undetectable plasma viral loads do not necessarily indicate that transmission of the virus cannot occur.

Use of HAART can be problematic for some drug users as the medications in HAART can interact with medications often used to treat drug addicts, which can have the effect of decreasing the effectiveness of both treatments. Some of the medications used in HAART can reduce methadone levels in the blood, making the treatment less effective. Substance use can also interfere with adherence to HAART because of conflicting needs and unstable lifestyles that can make it difficult to maintain a consistent treatment regimen. Noncompliance with the HAART regimen can result in increased viral loads and increased infectiousness.

A study reported in 2011 followed 1,763 heterosexual, serodiscordant couples (i.e. one member of a couple was HIV+ and the other member was not) from cities in nine different countries. Couples were randomly assigned to immediately begin antiretroviral treatment therapy or to wait until their immune system was compromised to a specified level or they experienced an AIDS-related symptom. From 2005 until 2011, when results were reported, 28 cases of seroconversion were reported in which the infected partner was the source of the infection. Of these, 27 were in the group that deferred ARV therapy, and only 1 was in the group that began ARV treatment immediately. These results indicate that early ARV therapy can act as a significant preventive effort for sexual transmission of HIV.

SUMMARY

The face of HIV and AIDS has changed dramatically since the early days of the epidemic in 1981. The development of HAART has changed the disease from an almost certain death sentence to a manageable, chronic condition and is proving to be an essential part of a comprehensive prevention protocol. In spite of advancements made in treatment and prevention, HIV and AIDS still infect large numbers of people and more progress needs to be made. Increases in HIV infections among African Americans are troubling, as are increases in heterosexual transmission, and the high

prevalence in criminal justice populations. The role of substance abuse in HIV infection through injection drug use, sexual partners of IDUs, and the role of alcohol and other drugs in poor decision making and participation in high-risk sexual behaviors should also continue to be a focus in any comprehensive HIV program.

Glossary

Acquired Immunodeficiency Syndrome (AIDS) AIDS is the actual disease that is caused by HIV and is defined as having a CD4 cell count of below 200 or experiencing at least one AIDS-defining complication.

Highly active antiretroviral therapy (HAART) a medication used to treat HIV and AIDS that consists of three or more antiretroviral drugs customized for each individual patient. The advent of HAART has led to a very substantial decrease in HIV-associated morbidity and mortality.

Human immunodeficiency virus (HIV) a retrovirus that infects humans and interferes with the immune system by destroying CD4 cells, a type of white blood cell that plays a significant role in fighting disease. It can reside in blood, seminal fluid, vaginal fluid, and breast milk.

Treatment Practices of Community Providers Based on Independent Evaluation	247	Conclusion and Future Directions	252

WHAT IS COMMUNITY-BASED TREATMENT?

According to the US Institute of Medicine's Committee on Community-Based Drug Treatment report, community-based agencies are the "backbone" of the US treatment system. Their history can be traced back to the 1970s and 1980s, around the time when a host of community-based programs for alcohol and drug dependence emerged. The nature and structure of these community programs varied widely, as they were designed to meet the specific treatment needs of individuals within their respective communities, giving rise to a unique or alternative system of addiction treatment at the public, private, and individual levels. For example, public facilities providing housing and food services for the needy began creating addiction treatment programs, as well as private not-for-profit community mental health centers. Similarly, churches implemented their own drug addiction treatment services. Individuals in recovery elected to start community treatment programs, such as Alcoholics Anonymous and other 12-step programs. While these facilities varied in their

specific ideology regarding the nature and treatment of addiction, they shared a mutual goal of providing alcohol and drug treatment to individuals residing in their local communities.

At that time, community-based treatment was segregated from mainstream medical and mental health services, and treatment practices were based on the "folk wisdom" of individuals in recovery. Educational lectures or films, confrontational interventions, mandated Alcoholics Anonymous, and milieu therapies were among the most commonly used interventions. Treatment practices consisted of a miscellany of techniques, many of which were adopted from the disease model of alcoholism, Alcoholics Anonymous, or other 12-step related programs.

Today the US substance abuse treatment system remains primarily community-based and many clinicians continue to practice strategies with which they are familiar as well as comfortable. However, the standard of care has been evolving in parallel with state and third-party reimbursement mandating that community treatment programs deliver evidence-based treatments (i.e. treatments that possess scientific evidence

for their efficacy). Similarly, there is an increased demand from the public sector and from the courts for substance abuse treatment specialists to provide scientifically valid interventions to their clients. Moreover, greater integration of substance abuse treatment with mainstream health care requires that evidence-based treatment become the standard of treatment in the field.

Given this change in the health care system, the Institute of Medicine (IOM) issued a landmark report in 1998 promulgating their recommendations for bridging the gap with the goal of forging partnerships and fostering communication between researchers, treatment professionals, policymakers, and the public sector. The recommendations made by the IOM committee were directed toward increasing research activities between investigators working in university settings and health care providers working in community treatment programs. A major development in response to this report was the establishment of the National Institute on Drug Abuse (NIDA) Clinical Trials Network (CTN; <http://drugabuse.gov/CTN/>) in 1999. The primary goal of the NIDA-CTN was to initiate a research infrastructure between the research community and community treatment programs for evaluating behavioral, pharmacological, and integrated treatment interventions in rigorous, multisite clinical trials. These trials involve “real world” therapists working with a diverse patient population across a broad range of community treatment settings. Similarly, the Substance Abuse and Mental Health Services Administration (SAMHSA) “Blending Initiative” was implemented in 2001 in order to promote the adoption and implementation of research findings from the NIDA-CTN trials into community-based practice. This initiative is a wide ranging network of partnerships between addiction researchers, community treatment program providers, policymakers, and technology dissemination agencies.

The success of this and similar initiatives, however, is largely contingent upon first acquiring an accurate understanding of what essentially constitutes treatment-as-usual (TAU) within community settings primarily because without this information it is difficult to determine the elements of empirically supported treatments (ESTs) that may already be in broad clinical use and the extent to which clinicians are already delivering efficacious interventions. Unfortunately, identifying the standard practices that occur in community treatment programs has proven to be difficult due largely to very limited information. Moreover, the information that does exist is derived primarily from self-report surveys completed by program directors and agency clinicians working within these settings; therefore, reliance on subjective methods of data collection introduces experimental problems (e.g. demand characteristics) that raise concerns about the accuracy of survey responses.

This chapter will explore the information that is currently available regarding current treatment practices and services delivered in community-based substance abuse treatment programs providing primarily psychosocial interventions and not clinics that provide exclusively methadone treatment services. We discuss the degree to which community treatment agencies are using practices that are “empirically supported” or “evidence-based.”

TAU BASED ON NATIONAL SURVEY DATA

The SAMHSA publishes an annual survey, referred to as the National Survey of Substance Abuse Treatment Services (N-SSATS), which is the most comprehensive survey examining the nature of TAU provided in substance abuse treatment facilities in the United States. The most recently published data (2009) from this survey demonstrated that 13 513 substance abuse treatment facilities actively served over 1.18 million clients seeking treatment throughout the United States. Of these treatment facilities, 58% were operated by community-based private nonprofit agencies, 29% were owned by private for profit agencies, and 13% were publicly operated by federal, state, or local government. The majority (81%) of all treatment agencies provided outpatient treatment (i.e. intensive, day treatment/partial hospitalization, and/or less frequent aftercare services), while 26% offered residential treatment either in addition to outpatient care or alone. Only 12% of outpatient treatment facilities offered methadone or buprenorphine treatment services. With regard to the substance abuse problem treated, approximately 92% of treatment facilities reported treating clients with both alcohol and drug dependence, 81% reported treating clients with drug abuse only, and 79% reported treating clients with alcohol abuse only (Note: facilities may be included in more than one category such that figures exceed 100%).

With regard to the types of services provided, the majority of treatment facilities (98%) provided assessment and pretreatment services, including screening for substance abuse and mental health disorders, community outreach, and interim services for clients in need of services when immediate admission was not available. Almost all of the treatment agencies (99%) provided ancillary services, with substance abuse education (95%), case management (77%), social skills development (68%), and mental health services (56%) being the most common types of ancillary services offered. Pharmacotherapies were administered in 47% of treatment agencies. The nicotine replacement therapy was provided by 19%, acamprosate by 17%, buprenorphine by 17%, naltrexone by 16%, disulfiram by 16%, and

methadone by 11% of treatment agencies (Note: Facilities providing medication for substance dependence tended to provide more than one type of medication so that figures exceed 47%). Nearly all the treatment agencies (99%) provide individual or group substance abuse counseling.

In terms of the types of clinical or therapeutic approaches provided among agencies, substance abuse counseling (96%) and relapse prevention (87%) were identified as approaches that were used "always" by nearly all facilities. Cognitive-behavioral therapy (91%), motivational interviewing (85%), anger management (83%), brief intervention (80%), and 12-step facilitation (79%) were reportedly used "often" or "sometimes" by more than half of treatment agencies. Trauma-related counseling (65%) and contingency management (60%) were identified as used "at least sometimes (e.g. always, often, or sometimes)." The least often utilized approaches (i.e. those approaches used "rarely" or "never") for more than half of all agencies, including those agencies unfamiliar with the approach, were rational-emotive therapy (51%), the matrix model (63%), and community reinforcement-plus-vouchers (86%).

TREATMENT PRACTICES OF COMMUNITY PROVIDERS BASED ON INDEPENDENT EVALUATION

Although the latter information provides insight into the types of counseling services offered at community-based clinics, these data do not speak to the integrity to which these approaches are utilized. To date, only a few systematic and independent evaluations (e.g. assessment of audio, digital, or video recordings) of the types of techniques used by clinicians working in community-based treatment programs have been conducted. In one study, Santa Ana and colleagues provided a description of the "usual care" therapeutic strategies delivered by clinicians to their clients in the early phase of treatment within nine community treatment programs. These clinicians were participating in two National Institute on Drug Abuse Clinical Trial Network effectiveness protocols headed by Carroll and colleagues at the Yale University School of Medicine. The first protocol involved the delivery of a usual care "one-session" standard intake assessment in sites that offered a single-assessment appointment to their patients followed by assignment to group counseling; the second protocol provided TAU across three counseling sessions delivered during the first 4 weeks of treatment, referred to as the "three-session" protocol. Counseling time in the one-session protocol was approximately 2 h in duration, whereas counseling time in the three-session protocol was approximately 45–55 min. The investigators were

primarily interested in describing the primary counseling strategies that characterized TAU in the one- and three-session protocols, and whether interventions from these sessions were associated with ESTs. To verify the latter both the one- and three-session protocols were compared to a one-session motivational interviewing assessment and a three-session adaptation of motivational enhancement therapy.

The patients in these protocols (one-session protocol, $n = 423$; three-session protocol, $n = 461$) were primarily in their early to mid-1930s seeking outpatient treatment for mixed primary substance abuse problems (e.g. alcohol, cocaine, marijuana, opiates, methamphetamines, benzodiazepines), with the majority of patients in both protocols diagnosed as alcohol dependent. The clinicians, consisting of addiction counselors, social workers, psychologists, and marriage and family therapists, had approximately 6 years of substance abuse counseling experience and were predominantly Caucasian women in their late 1930s. Approximately 40% of these therapists endorsed a history of a previous substance abuse problem.

Prior to the start of the NIDA-CTN trials, the investigators surveyed the clinicians, senior clinicians, and site directors from the participating community treatment programs about their use of various treatment strategies. A wide range of practice orientations were endorsed. Most indicated that they were using an eclectic approach, but that they were primarily adhering to the 12-step disease model (e.g. emphasizing total abstinence, discussing concepts such as spirituality, powerlessness, and loss of control), relapse prevention/cognitive-behavioral therapy (e.g. skills training, cognitive restructuring, focus on cognitions), motivational interviewing or motivational enhancement therapy, and providing some counseling regarding HIV risk behavior reduction. Based on these reports, the investigators anticipated that TAU would be characterized by interventions derived from these types of treatment practices. The investigators also hypothesized that counselors would use a broader range of EST-based interventions (e.g. relapse prevention/cognitive behavioral or "skills training" strategies) in the three-session protocol compared to the one-session protocol due to the more extended length of counseling time that the three-session protocol afforded.

To test these hypotheses, the investigators conducted blind independent ratings of 379 randomly selected audio tapes ($n = 160$ tapes in the one-session protocol; $n = 219$ tapes in the three-session protocol) derived from 25 clinicians who implemented TAU. Using a reliable and valid rating system for evaluating therapist adherence (i.e. the extent to which a range of counseling interventions were delivered) across several types of ESTs and commonly used interventions in addiction

treatment, clinicians were rated on their adherence to 31 types of counseling strategies. Ten of these counseling strategies were consistent with motivational interviewing, five of which included basic motivational interviewing skills (e.g. open-ended questions, reflective statements, fostering a collaborative atmosphere), while the remaining five items included advanced motivational interviewing skills, such as heightening discrepancies and change planning. The other 21 counseling strategies assessed two categories of drug counseling interventions. The first category included items “antithetical” to motivational interviewing, referred to as “motivational interviewing (MI) inconsistent” strategies, such as confrontation of denial, unsolicited advice, and emphasis on abstinence. The second category included items representing approaches “other than” motivational interviewing (i.e. “general drug counseling strategies”), such as skills training, disease model, and psychodynamic interventions. Table 26.1 presents the means and standard deviations for the independent adherence ratings and item frequencies in the one- and three-session protocol TAU sessions.

In the one-session protocol, the clinician interventions that dominated TAU were assessing and monitoring substance use and social functioning (e.g. work, family, partner, social network), followed by asking open-ended questions, discussing the client’s medical problems including use of medications for substance use or psychiatric problems, reviewing symptoms related to psychopathology, discussing the problems for which the client entered treatment, reflective listening, and orienting the client to the program. The next most common counseling strategies were therapist disclosures unrelated to the problems of the client (e.g. informal discussions such as personal information, current events, shopping), giving unsolicited advice, asserting therapeutic authority, behaviors associated with an MI style such as rolling with resistance and empathic listening, case management, and psychoeducation.

In the three-session protocol, TAU consisted of high levels of assessment of social functioning, use of open-ended questions and reflections, inquiries about problems for which the client entered treatment, and giving unsolicited advice. The next most common interventions were assessing and monitoring substance use, asserting therapeutic authority, self-help group involvement, and therapist disclosures unrelated to the problems of the client. The only skills that were consistently present and associated with a specific ESTs were motivational interviewing skills, although these were generally limited to the use of basic MI skills (e.g. open-ended questions, reflections) as opposed to advanced MI skills such as heightening discrepancies and change planning.

Most notable, however, were either very low levels or the absence of the types of interventions that the

clinicians indicated they used frequently prior to the initiation of the protocol, such as cognitive-behavioral therapy (skills training, cognitive restructuring, focus on cognitions), HIV risk behavior reduction, and skills associated with the 12-step/disease model, such as emphasizing abstinence, spirituality, powerlessness, and loss of control. As mentioned previously, the authors of this study anticipated that there would be more opportunities in the three-session protocol for clinicians to use an increased variety of interventions associated with ESTs, but the frequency and range of types of specific counseling strategies did not increase across the three sessions. These data were largely inconsistent with the descriptions provided by site directors who reported using “moderate to high” levels of ESTs in their standard practice as well as with the therapeutic strategies clinicians stated they were delivering. Overall, independent ratings of audio-taped sessions from the one- and three-session protocols indicated that TAU was characterized primarily by assessment of substance use and social functioning as well as a variety of other nonspecific counseling skills (e.g. problem discussion, assessing medical issues and medications, informal discussions, basic MI skills), but that ESTs on the whole were rarely implemented in the early phase of individual substance abuse treatment in community treatment programs.

Of interest was the finding that “therapist disclosures unrelated to the problems of the client” (i.e. therapist informal discussions and topics irrelevant to the client’s treatment needs) occurred more often than specific drug counseling strategies (e.g. relapse prevention skill building). This was a surprising finding that occurred in 60% of sessions in the one-session protocol and 48% of sessions in the three-session protocol. Referred to as “chat,” these particular discussions may be potentially disruptive to treatment, as they involve therapist personal disclosures that are unrelated to the clients’ treatment, which may, in turn, detract from the client’s presenting problem.

These data were further examined by Martino and colleagues to explore which types of informal discussions were used by clinicians in community treatment programs as they were delivering TAU and to investigate whether such discussions enhanced or hindered the treatment process. These investigators examined the relationship between therapist informal discussions and client motivation, treatment outcome, and therapeutic alliance. Independent raters coded audio recorded sessions of 60 counselors totaling 736 counseling sessions. Results from the independent ratings indicated that a large proportion (88%) of counselors engaged in informal discussions and that these discussions occurred in 42% of sessions. Informal discussions primarily consisted of personal information

* Treatment-as-usual delivered within a single intake assessment session.

** Treatment-as-usual delivered across three sessions within a 28-day period.

*** Adherence ratings are on a 7-point Likert scale: 1 = not at all, 2 = a little (once), 3 = infrequently (twice), 4 = somewhat (3–4 times), 5 = quite a bit (5–6 times), 6 = considerably (>6 times/more depth in interventions), 7 = extensively (high-frequency/characterizes entire session).

Mean adherence ratings are based on the following sample sizes within each protocol for each condition: One-session protocol ($n = 160$); Three-session protocol ($n = 219$).

Santa Ana, E.J., Martino, S., Ball, S., Nich, C., Frankforter, T., Carroll, K.M., 2008. What is usual about treatment-as-usual: Independent audiotape ratings drawn from two multisite effectiveness trials. *Journal of Substance Abuse Treatment* 35, 369–379.

(e.g. pets, vacation preferences), addiction problems of the therapists' significant others, the therapist's health problems, the therapist's personal opinions, current events (e.g. the news), and the therapist's personal feelings about the client. On average, therapists were found to engage in such informal discussions once or twice per session. While a higher frequency of informal discussion was not related to client treatment retention or substance use outcome, it was associated with a stronger therapeutic alliance, particularly in the three-session protocol.

The authors speculated that "a little informal discussion" may have enhanced the client's perception of the therapist as "warm and genuine." Therapists who give information about themselves, particularly when they share with their clients that they have experienced similar problems, may be viewed by their clients as authentic. Other therapist statements, such as expressing positive opinions toward the patient, may result in enhancing the therapeutic bond. Indeed, this notion of sharing personal information with the client has been described in previous literature as potentially beneficial toward the therapeutic relationship between the therapist and patient. However, the findings reveal that there is a fine line, as the authors also found that a high frequency of informal discussion was negatively associated with client motivation; the more a therapist

engaged in "chat," the greater likelihood the client was less motivated to change his or her substance use. Overall, these data suggest that too much therapist informal discussion can impede the therapeutic process and may result in thwarting client motivation. Thus, it appears that the type of therapist informal statements may have an impact on the therapeutic relationship. For example, unhelpful therapist comments, such as talking about current events at length or disclosing work-related problems, appear to be distracting to the therapeutic relationship.

THERAPEUTIC ALLIANCE AND CLIENT OUTCOME

A growing body of literature has demonstrated that therapeutic alliance and interpersonal skills, including therapist factors such as warmth, genuineness, empathy, affirmation, and support, are associated with improved client retention and outcome. In contrast, evidence suggests that negative therapist behaviors, such as depression, hostility, controlling, and blaming produce the opposite effect (i.e. negative client outcome). Therapist effects may also explain why some standard (i.e. non-empirically supported) substance abuse counseling approaches are as effective as evidence-based approaches.

In a study that highlights this finding, Morgenstern and colleagues examined the effectiveness of cognitive-behavioral treatment (CBT) compared to TAU for 252 clients seeking treatment for a substance abuse problem in a community treatment program located in the US North East. CBT was provided in two levels: a *high-standardization* CBT condition that relied on a therapist manual including review of session tapes and supervisory feedback; and a *low-standardization* CBT condition without adherence constraints where therapists were encouraged to use their own clinical judgment and could integrate 12-step interventions as they deemed appropriate. Both CBT conditions were compared to TAU, which consisted of the delivery of substance abuse counseling that was typical of what counselors normally provided, including reliance on self-help supports. Contrary to the investigator's expectation that the two CBT conditions would improve intermediate (3-month) and posttreatment (9-month) substance abuse outcomes compared to the TAU condition, no significant differences between any of the three treatment conditions were found with regard to the percent of days of which alcohol and drugs were consumed. Therapeutic alliance, a factor common across treatment conditions, explained a significant proportion of the variance, suggesting that standard substance abuse counseling that includes the therapeutic alliance factor may be more effective than previously thought.

These results are consistent with evidence showing that nonspecific factors (e.g. feeling understood, being respected, having someone be interested) are not exclusive to any one approach and can have a significant impact on client outcome. The authors of this study speculated that the relatively good outcomes in their TAU condition raise further questions regarding the "necessary and sufficient" components of effective substance abuse treatment, although their findings may be associated with overlapping patient treatment goals. It may be that few differences in outcome between treatment conditions were associated with clients who were committed to behavior change or to a shared abstinence goal. More studies are needed that elucidate the impact of ESTs relative to standard substance abuse counseling on nonoverlapping differences in patient and agency factors, such as variations in desire for abstinence, failure to achieve abstinence by the end of standard treatment, and reliance on group versus individual therapy as well as other differences in settings and clients.

While treatment alliance and other nonspecific factors (being accepted, being encouraged to face difficulties) appear to account for a significant amount of variance in treatment outcome, these factors do not account for all of the variance. Indeed, there is substantial evidence in the field showing that specific treatments are consistently more effective relative to others in the

treatment of drug and alcohol dependence. Likewise, clinicians vary widely in their effectiveness in working with clients and in their delivery of specific treatments. Given these differences in outcomes based on the type of treatment provided, and the individual therapist who delivers the intervention, optimal outcomes should be realized when treatments with the greatest potential for making the most beneficial impact are provided by therapists who are able to foster strong therapeutic alliances.

In a NIDA-CTN multisite randomized clinical trial conducted by Ball and colleagues who evaluated the effectiveness of motivational enhancement therapy (MET) consisting of MI strategies compared to care-as-usual among 461 participants seeking treatment for substance use problems, participants assigned to both conditions exhibited reductions in substance use through the 1-month treatment phase. However, participants in MET were more likely to maintain their reduced level of substance use over the 3-month follow-up period, whereas participants in the standard care condition increased their level of substance use. Martino and colleagues, examining data derived from this study, found that counselors trained in motivational interviewing were less likely to engage in therapist informal discussions (i.e. "chat") than counselors without such training and that, in turn, the therapists who tended to engage in informal discussions were less likely to provide basic and advanced motivational interviewing skills. Rather, they were more likely to rely on strategies inconsistent with MI or they delivered MI with less proficiency. This finding indicates that therapists trained in an evidence-based intervention such as motivational interviewing may be more likely to deliver the intervention with greater skill and may be less likely to engage in distracting or unhelpful informal discussions that may serve to reduce client motivation.

LIMITATIONS

The data presented in this chapter provide some important insights into the nature of substance abuse treatment in community-based treatment settings. Nevertheless, there are several limitations with which to be mindful. To date, very few studies have attempted to independently evaluate the nature and process of TAU in community treatment programs. These studies have focused exclusively on the early sessions in treatment, and as such, data based on these studies may not be representative of the types of counseling skills that occurred in the later stages of treatment, particularly where clinicians may have been given the opportunity to shift their focus toward providing more direct substance abuse interventions involving ESTs. For

example, the types of interventions that occur in the early sessions of treatment may be associated with customary agency practices emphasizing extensive patient evaluation, assessment, and completion of agency paperwork that serves to limit opportunities for engaging in other interventions. Thus, we have only a limited glimpse of what actually occurs during the course of TAU in community treatment programs. Nevertheless, as discussed previously, data from the three-session protocol indicated that when clinicians were afforded more time and opportunity to shift focus, they did not increase their level of general counseling or interventions associated ESTs across sessions when opportunities for doing so became available.

Another limitation is that clinician behaviors may differ when sessions are audio recorded relative to when they are not, and hence different use of treatment strategies may occur in the natural setting. Finally, the data that describe TAU taken from existing surveys and independent ratings were derived from collaborations between community treatment organizations and major medical school research centers and, as such, these clinical treatment programs may not be representative of all community treatment programs that do not partner with universities.

CONCLUSION AND FUTURE DIRECTIONS

The dissemination and implementation of ESTs in community settings have many far-reaching implications, most notably the potential to enhance the overall quality of substance abuse treatment and improve the nation's public health. In recognition of this important undertaking, the goal of the Institute of Medicine's (1998) landmark report is for community treatment programs to adopt evidence-based treatment practices. For that goal to be realized, researchers must deliver their findings into the hands of clinicians and other treatment professionals. Maintaining accurate identification of the standard treatment practices that occur in community treatment programs will allow investigators to determine the degree to which dissemination efforts are effective over time. The objective data reported in this chapter provide a picture of standard treatment practices in the early phase of treatment and its objective assessment represents an initial step that must continue to evolve in community-based programs, particularly for evaluating the usual care practices in later stages of treatment. If ESTs are indeed making headway in community treatment programs, investigators should observe greater integration of ESTs in therapy sessions based on objective ratings compared to the current status of the data.

Efforts to identify standard practice, in turn, may assist in identifying current barriers for the adoption of ESTs in community treatment programs as investigators seek ways to improve these. Researchers will also be in a better position to elucidate the impact of scientifically based treatments as well as measure their incremental benefit relative to nonspecific factors so that these areas may be combined for enhanced treatment outcome. With that regard, the discrepancy between self-reported standard treatment practices to that of objective data is problematic, and future studies should seek to investigate methods for narrowing this discrepancy. Several innovative strategies discussed in the dissemination literature for bridging the gap between standard practices in community settings and evidence-based treatments include dissemination of manual-guided therapies, providing workshops and providing ongoing supervision for delivering ESTs, and providing clinician incentives for the delivery of ESTs (e.g. leave time for training with pay, bonuses, promotions, and pay raises). Further research is needed to determine whether these strategies could be effective at enhancing the rate at which ESTs are delivered.

INTRODUCTION

Differences in the incidence and prevalence of substance use disorders (SUDs) in various segments of the population are the basis for considering *health disparities*. Health disparities (which can be viewed as objective facts or subjective perceptions) are defined here as cross-group variations in relevant biological traits or in exposures to agents in the environment that lead to differential rates of disease among segments of the population. Similarly, a 2000 definition promulgated by the National Institutes of Health (NIH) states: "A population is a health disparity population if there is a significant disparity in the overall rate of disease incidence, prevalence, morbidity, mortality, or survival rates in the population as compared to the health status of the general population." In other words, "health

disparities" refer to persistent differences between groups in one or more measurable dimensions of health status. A subjective element is commonly assumed, namely that these differences represent social injustice and are "wrong," avoidable and correctable, and/or that resources can/should be brought to bear to alleviate these impacts.

A closely intertwined issue is the subject of this chapter *health care disparities* within the delivery of treatment services for SUDs. A widely used summary definition supported by NIH includes health care disparities related to race, ethnicity, socioeconomic status (SES), and markers of social disadvantage result from a complex confluence of patient, clinician, and system levels factors. From this definition, the variables involved make for what is definitely a complex topic.

This chapter is limited in its focus to the United States, although many of the principles enunciated here have universal application. Cross-national discussions of health care disparities are beyond the present scope since each involves consideration of the values of a given culture and the health care system provided to address SUDs in that setting. While international organizations such as the United Nations has promulgated definitions of adequate health care that attempt to transcend a variety of forms of age, gender and ethnic discrimination at the national level, these "ideals" are neither consensual nor accurate in reflecting the range of values that guide decisions about resource allocation around the world. Thus, sweeping international generalizations rarely go beyond catalogs of one or another's perception of unmet needs.

The design and organization of health care systems essentially define health care disparities. The source of payment for health care is fundamental in structuring these disparities. Where a high level of access to health care is seen as a right of citizenship in a nation, health is usually sponsored by the state and paid for directly or indirectly by taxation. While all nations have some form of publicly provided health care, the scope of its availability and the "depth" of access are highly variable. Thus, in the United States, publicly funded health care is theoretically available to all who are defined as in poverty, health care for the remainder of the population has been, largely by default, the combined responsibility of employers and employees since the post-World War II period. This has left gaps in coverage for those not fully employed and those not in poverty, such as the elderly, whose needs have been largely addressed by Federal health programs, and the "working poor," who are presently the target for enhanced coverage under Federal legislation presently under court challenge. Nations throughout the world vary in the mixtures of employer involvement and publicly provided health care, with no two nations being exactly the same. Thus, health care disparities abound throughout the world but their scope and depth is a combined function of national values that define such disparities (or not) and which provide health care through structures driven by highly variable economic streams.

Considering disparities of care in relation to SUDs adds further complications in attempting an internationally focused discussion. Nations vary in the extent to which SUDs are viewed as a medical problem in contrast to an issue that is the primary responsibility of the criminal justice system. The manner in which the medical/criminal justice responsibilities are divided varies across nations. In nations such as the United States, a much higher proportion of services for the treatment of SUDs is provided under government auspices that is true for many other disorders but at the same

time, there is a public controversy about the extent to which such care actually should be regarded as health care. In other nations, the treatment of SUDs is fully integrated into the medical care system while in some settings, there is substantially more investment in care than in the United States, but the treatment system remains largely segregated. Thus to maintain some control over the subject matter, this discussion is largely limited to the United States.

OVERALL LOW UTILIZATION OF TREATMENT FOR SUDs

Differences in the *nature, availability, and utilization* of treatment for SUDs are the basis for research and policy interest in health care disparities. For those with SUDs and those organizations providing treatment for SUDs, this is not a trivial or minor issue. At present, a single fact dominates any consideration of the utilization of treatment services for SUDs in the United States. This is the gross underutilization of this care by those who are defined to need it, coupled with a common pattern of treatment entry following many years of individuals' evident symptomatology. From this latter point, it can be concluded that in general, patients arrive for treatment much sicker than they might need to be, making greater demands on the providers of care. Typical estimates indicate that the average entering patient has suffered from a SUD from 8 to 10 years.

Common estimates based on nationally representative surveys suggest that as few as 15% of those who need treatment (as defined primarily by their patterns of use of one or more psychoactive substances without in-depth information on social functioning) at a given point of time are actually utilizing treatment for their SUDs. This, however, is both a flexible and controversial definition, regarded by many as an exaggeration to increase attention and resource allocation for SUDs. The "on-the-ground" reality which drives actual diagnoses of SUDs guided by the American Psychiatric Association's *Diagnostic and Statistical Manual* is highly dependent on social reactions and definitions held by "significant others." The formal diagnoses center on impairment in the target individuals' ability to perform expected social roles, and the extent of perceived danger that the individual presents to herself or himself and others.

Observers easily overlook the extent to which social interaction and social role performance are the pivot for SUD diagnoses, recognizing of course that such behavior which is primarily "alcoholic" must be accompanied by excessive use of alcohol but diagnosis of "drug dependence" may only require what some regard as modest or "normal" use of other psychoactive drugs.

This suggests that many persons dependent on drugs and/or alcohol may be socially integrated on the point that their role performances or relation with others is not significantly impacted. It is clearly the case that such integration may be a function of different levels of material, social, and cultural capital that are distributed unevenly across the social structure, correlated in complicated ways with health care disparities.

The assumption that some people with SUDs simply “fit in” to their role expectations does not explain the very low utilization of SUD treatment. Other factors such as the availability of treatment, routes to treatment, perceptions of treatment, and the manner in which treatment is provided are part of this explanation as well. But the pattern of nonuse of apparently needed SUD treatment in the United States is dramatic. Across the range of medical disorders, it is indeed one of the largest, most notable, and least understood of all health care disparities.

THE HISTORICAL AND CONTEMPORARY POLICY CONTEXT

Explanation of the discrepancy lies in the fact that SUD treatment is a relative newcomer to the world of medical care, and it is neither completely welcome nor integrated as of yet. The integration of SUD treatment into the broader medical care system is a major concern of this decade and is being addressed by increasing the involvement of primary care medicine on several fronts, such as screening all patients for evidence of SUDs and direct delivery of medically assisted drug treatment.

While implementation of these steps, to say nothing of a broader implementation plan for complete integration, is a distinct challenge, the change that has occurred over the last 90 years is remarkable. Alcohol distribution and consumption was officially, from 1920 to 1933, a moral issue commanding massive societal attention through National Prohibition. Patterns of apparent alcohol dependence are now in many ways couched in medical definitions and concepts. Likewise, the nonmedical use of many psychoactive substances was fully criminalized from the 1920s until the 1960s when change began to occur. Extensive societal investment in massive international machinery to support “drug prohibition” remains very active today. But in the midst of many anomalies, the medicalization of both alcohol and drug problems continues. Social, political, and organizational forces at present and into the immediate future bode for increased integration of SUDs treatment into the broader realm of medical care, with this specialty interest definitely to be reshaped in yet-unknown ways by these new interactions.

Another contextual fact that accounts for disparities in the delivery of SUD treatment is the overall nature of delivery of health care in the United States from both public and private providers. Disparities of all sorts and varieties constitute the engine that is driving health care reform in the United States. The overall “system” within which SUD treatment delivery is now partially embedded involves an inchoate complex of responsibilities for financing treatment that includes individuals, the federal government, all state governments, independent private for-profit insurers, not-for-profit systems of insurance, and employers, who pay (with a high level of discretion in coverage) a massive proportion of both direct health care costs and insurance premiums. These sources lead to wildly complex differences, contingencies, and exigencies when comparisons are made across a random group of patients being treated for the same SUD but “covered” by different sources paying for some portion of their treatment.

All of the different sources of financing listed above are involved in determining reimbursement for different types of SUD treatment. In addition, and in contrast to nearly all other medical care, SUD treatment financing is heavily influenced by state- and territorial-level “authorities” which make policy decisions about the use of public reimbursement funds, treatment quality standards, and licensing requirements for personnel working in the treatment of SUDs in a given state. These officials are frequently political appointees. Whether politically appointed or not, the national profile of these authorities is that credentials vary widely and their tenure is very unstable, as is their organizational location in state government and consequent reporting relationships. It should be obvious that this unique ingredient of the SUD policy structure adds complexity and confusion to an already muddled reimbursement apparatus. This inadvertent design for reimbursement (and thus access to treatment) is indeed “a perfect storm” for assuring widespread disparities in health care delivery for patients with SUDs.

NEW POLICY INITIATIVES AFFECTING DISPARITIES IN THE DELIVERY OF SUD TREATMENT

Federal legislation has addressed the treatment of SUDs as a national health care disparity by proscribing wholesale discrimination by health insurers and providers of health in sharply limiting the needed treatments for SUDs (and psychiatric disorders). The mechanism is the Wellstone–Domenici Act of 2009, providing for *parity* of SUDs and psychiatric disorders with other medical disorders in third-party reimbursement for treatment. The results of this legislation are not yet

visible in large-scale increases in either the numbers of new patients entering treatment for SUDs or in an increase in the average “dosages” of treatment received by SUDs patients. Some cynics argue that without rigorous enforcement, insurers will find legal loopholes to effectively evade the parity provisions of this Act. Such a conclusion is premature what is known from research about the time required for diffusion and implementation of policy innovations.

This Act may be seen as significantly bolstered by a second and later mechanism, the Federal Affordable Care Act of 2010 (ACA), or health care reform. In this legislation, the ACA has throughout provisions for a strong orientation toward reducing health care disparities. There is another mechanism beyond parity that will potentially lead to a direct increase in patient utilization of SUD treatment, the expansion of Medicaid eligibility and coverage to many in the “working class” who have been particularly shortchanged in health insurance coverage for SUD treatment that may have been provided by their employers. Perhaps of greater significance, the ACA specifically aims at a greater integration of SUD treatment into primary and general medical care through the establishment of “medical homes.”

This will potentially reduce disparities in SUD treatment “across the board” from a demographic perspective by earlier identification of SUD problems before these behaviors impact social, psychological, and organic functioning. This will be accomplished not only by reducing the segregation of SUD care in a specialty network “outside” the medical mainstream, but by educating and motivating all medical care professionals to become involved in SUD treatment as a vital and legitimate component of overall medical care.

There is a massive literature documenting differences across different demographic groups in the rates of SUDs, the rates of different SUDs, and the rates of utilization of treatment for SUDs. Differences in access to high-quality services have also been documented for mental and behavioral health conditions. Focusing more specifically on the content of treatment, recent research has revealed significant racial and ethnic differences in the likelihood that patients receive psychotropic medications. Research on disparities related to physical and mental health has generally focused on the experiences of individual patients, with ample evidence that these disparities persist even after controlling for factors such as income and health insurance. The relationship between physicians and patients has also been studied as a mechanism for producing disparities.

The contention of “disparity” can be made with a wide variety of criteria. The intent here is not to review the statistical findings of studies such as those cited (that document SUD treatment disparities in great

abundance) but focus instead upon the conceptual, methodological, and policy issues that make this both a matter of importance and a conundrum.

SOCIOCULTURAL VECTORS AFFECTING DISPARITIES IN SUD TREATMENT

The topics of health disparities and treatment disparities have been explored from different perspectives for many decades, and have foundations in social epidemiology and health services research. Concerns about these differences in the context of social justice and social policy are, however, of more recent origin. As the sociologist Robin Williams described in his classic text, *American Society*, there are deeply ingrained value orientations in the United States emphasizing racism and racial superiority. Enslavement of American Indians and Africans marked American history from its beginnings up until the Emancipation Proclamation, and many features of segregation and prejudice persist through the present day. Repeated waves of immigration follow the course of American history, each accompanied by prejudice and discriminatory action toward newcomers, including often-exaggerated claims that different immigrant groups are responsible for introducing routine alcohol consumption in the nineteenth century that fostered the growth of the urban saloon, and more recently, that newcomers brought new and dangerous psychoactive drugs into American culture. Likewise, within the culture of inequality, women were subordinated within the US constitution and gender equality is still incomplete despite substantial legislation and cultural change.

Thus, the statistical confirmation indicating that the US patients would be treated differently on the basis of their demographic characteristics is no surprise. Blatant denial of health care on the basis of race was once the norm. In the realm of treatment for SUDs, rare documentation of the denial of alcoholism treatment (“because they did not need it”) in 1967 to African Americans in North Carolina has recently been provided by the British psychiatrist, Griffith Edwards. More recently, there is strong evidence of young African American adult males’ drug-linked criminal activity leading to exceptionally high rates of imprisonment.

Health care disparities may directly reflect health disparities other than the actual availability and delivery of treatment for SUDs, for example a demographic group that is more heavily exposed to the availability of illegal drugs may receive a lower quality of health care for SUDs. A different example is partly independent of disease prevalence, namely where the planning of health service availability fails to provide equal geographic coverage for different populations to access

services relative to actual need, or fails to take into account the link between treatment availability and access to transportation in sparsely populated rural areas. An even different perspective is reflected where services are apparently of reasonable quality and of adequate accessibility, but utilization varies inexplicably across different population subgroups. These utilization differences can often be broken down further into differences in treatment entry, treatment engagement, treatment completion, and participation in long-term follow-up.

Health disparities within SUD treatment that contains a number of ironies easily become conundrums. The fact that certain subgroups apparently are resistant to use services made conveniently available to them in apparently attractive venues is among these ironies but another is that in terms of service development and availability, "more is not necessarily better." This may be demonstrated by the possibility that the provision of either more specialized health care or less of this health care to distinctive social and demographic groups may be viewed both positively and negatively. More care for SUDs may be viewed as deliberately stigmatizing and disabling certain subgroups or creating indirect forms of social control directed toward a particular group.

Thus, increased SUD care of a particular type may be perceived by some portions of a socially marginalized group as undesirable control while others representing the interests of this same group see a relative deficit of particular health care as social neglect. An example is found in apparent higher rates of attention-deficit disorder among African American youth as compared to other ethnic groups but a lower rate of pharmacological treatment of African Americans as compared to other ethnic groups. Others view pharmacological treatment of youth in any form as subtle social control without informed consent, particularly when consenting parents are convinced that their child has a disease or disorder that must be treated. Depending on the perspective of the observer, opposing views of the appropriateness or the intention of the same observed pattern of treatment could coexist.

Epidemiological data can be the source of these dilemmas. One of the goals of epidemiology is to identify correlates of factors that cause disease. When these factors are linked to social and demographic characteristics, the next step is to design interventions that effectively alter or neutralize the etiological vectors. This often results in one or more specific demographic groups being targeted for the intervention because epidemiological studies have revealed that they are both afflicted by the disease and exposed to the particular etiological vector, leading to the further assumption that their vulnerability to the vector leads to the disease,

and that reducing or eliminating their exposure to it will eliminate the disease.

It is very common to assume that the demographic characteristics of the patients who are treated for a given disease potentially represent factors that may play a role in the etiology of the disease. Such an assumption could be true if all of the afflicted patients are in the treated population, and that any deficiencies in data collection are spread randomly across this "totally treated" population. This problem may come to be reflected in a very recent application of epidemiological methods to treatment utilization where patterns of high use are identified as "hot spots" within which delivery systems may be redesigned.

In summary, health care disparities exist, to a degree, in the eye of the beholder. There are indeed linkages between any form of medical treatment and social control. Diagnosis and treatment (in that order) label individuals and may alter their eligibility to participate in certain roles, such as marriage or employment. This is particularly problematic with treatments for SUDs that have low "success rates" where the patient may be doubly labeled as having the disease and having failed at completing or responding appropriately to the treatment regimen. To the extent that such experiences are linked with marginalized social statuses, a tripled labeling process occurs that can lead to further marginalization, loss of social capital, and social exclusion.

At the same time, treatment of SUDs are usually intended to be liberating, to increase opportunities for social integration and participation, and to enhance the patient's social capital. The manner in which the perceived outcomes of treatment lead in these negative or positive directions is likely a strong determinant of subcultural norms on the utilization of treatment for SUDs.

DEFINITIONAL CONTEXTS FOR HEALTH CARE DISPARITIES IN TREATMENT DELIVERY FOR SUDs

The patterns of delivery of services for SUDs result in multiple definitions that can be used to define the existence of disparities in the delivery of health care. Paramount among these is the rigid definitions of long-term unbroken patterns of abstinence from drug and alcohol use that are used to define treatment success. Specifically, the use of this outcome criterion may generate artificial estimates of health care disparities in the delivery of SUD treatment services. These behaviors occur in the uncontrolled environments outside treatment, and typically without significant ongoing contact with treatment. Thus, whatever vectors may have differentially affecting the drinking and drug use behavior of

demographic groups prior to treatment will do so following treatment, when these measures are taken.

Such definitions are a direct heritage from the 12-step programs that were the foundation for much SUD treatment in the United States, and these definitions are not shared by treatment systems in many other nations. Within Alcoholics Anonymous (AA) and Narcotics Anonymous (NA), the goal of affiliation is long-term "sobriety" (a pattern of positive and constructive living characterized by participation in normative social roles of family, work, and community), central to which is abstinence from drugs and alcohol. A form of "keeping score" within these groups is counting the number of days, weeks, months, or years from the last use of drugs, which is the basis for recognition and support from fellow members, but not necessarily the reward of status or prestige. 12-step group members may count their last drink or "use" day as a "birthday," and "chips" which mark distance from these anniversaries are commonly handed out. Perhaps surprisingly, a "slip" or relapse back to drinking or drugging by a member is not viewed with disdain, degradation, or even disappointment in that such events are regarded as a natural part of the recovery process within the programs. Indeed, such events, very often leading to loss of control, serve to be key reinforcements and confirmations of the assertions that one cannot "use" drugs or alcohol in a manner similar to "normal" individuals.

Such an oddly flexible norm does not translate very effectively into the bureaucratic organization of treatment. Instead, in-treatment or posttreatment outcome has typically been defined in terms of "time from last drug/drug use." Standards vary, but many SUD treatment programs regard a 1-year period of abstinence as a sound measure of a successful treatment outcome, with 6 months seen as significant progress.

Using these criteria results in notably poor records of treatment success, with an outcome of 25% reporting 12-month abstinence being "very good." It should be noted that most of the data for posttreatment outcome are based on self-report, which may lead to overestimates of success. Many programs use urine testing to measure drug use during treatment, and while it is often used during posttreatment, particularly in criminal justice-linked treatment, it is expensive. Treatment programs and researchers have struggled with "the criterion problem" for decades, but programs' deviation toward reporting "softer" standards of "improvement" are acceptable only if they are accompanied by the "hard" data on abstinence.

While the potentially self-defeating nature of these abstinence-based outcome criteria are recognized by most working in SUD treatment, the measures are very attractive to government officials representing structures of rules in that they are countable, unambiguous, and

certainly easy to understand in contrast to alternative measures involving mystifying terminology and clinical "mumbo-jumbo" describing improvement of the patient following treatment. Complicating the issue further is the apparent widespread public acceptance of this criterion, coupled with very positive public attitudes toward the principles of 12-step programs and ironic agreement with one of AA's own informal acronyms, KISS (Keep It Simple, Stupid). The long-term abstinence criterion for treatment success is, without doubt, simple. The final irony is that while 12-step programs acknowledge respect but do not award significant status and prestige to their members on the basis of the length of their abstinence, broader American society has come to do so.

Perhaps the rigid use of these rigid criteria will fade with integration of SUD treatment into the broader health care system. As such integration moves forward, perhaps there will be greater recognition that this broader system has no parallel to the outcome criteria used in SUD treatment. The practice of medicine is based upon a harm reduction model, administering interventions with a goal of improving patient functioning, not moving patient functioning to some absolute standard. Treatment success in medical care is not marked by the total disappearance of symptoms, although in diseases such as cancer this may be desired. More to the point is the extent to which criteria reflect on the quality of the service itself. Within broader medical care, conformity to recommended posttreatment regimens are patients' responsibilities, not those of the professionals who delivered the interventions. Thus, a diabetic or cardiac patient who deviates from dietary proscriptions and relapses as a consequence is not viewed as a failure of medical care but as a failure of personal self-control. By contrast, the SUD patient who resumes using drugs or alcohol is seen as behaving in a manner reflecting ineffective treatment. And in some circumstances, the treatment provider's responsibility for this aspect of patient behavior is inferred to persist for years!

The "criterion problem" definitely contributes to confusing, erroneous, and misleading information about health care disparities in SUD treatment because so many persons are "lost" in the treatment process. Creating new measures of improvement during and following treatment, followed by the universal adoption of such standards, would greatly improve the quality of this information, and would also provide data of much greater utility to comprehensive delivery systems such as the "medical home" that is envisioned as the centerpiece of future American health care.

Beyond the outcome criterion issue and the way it may blur data on health disparities in the delivery of SUD treatment, other dimensions of the process of treatment delivery for SUDs may distort information on differential use of treatment. First is the matter of

identification of SUDs and the manner in which social visibility may play a role. Specifically, many SUDs are identified indirectly through the criminal justice system in that persons charged with criminal offenses are found to have SUD disorders. Given the known pattern of higher visibility to police and other agents of social control in urban areas, among minority groups, among youth, among males, among African Americans and Hispanics, in urban neighborhoods with high levels but varying combinations of these demographic characteristics, it is clear that to the extent that SUDs are identified through mechanisms of formal social control, apparent differences in rates of SUDs may become evident and added to other “counts” that suggest health disparities.

One specific mechanism that plays an increasingly important role at the intersection between the criminal justice system and the SUD treatment system is the drug court. Drug courts process a selected (but nonrandom) subgroup of persons who come to be identified with SUDs through criminal justice system identification processes. These persons are, in various contexts, given choices about entry into treatment versus entry into incarceration, with these choices introducing another nonrandom selection. To an extent, members of the next level of subgroup perceive themselves as “coerced” into SUD treatment through this mechanism, leading to different treatment outcomes. With the exception of psychiatric treatment, no other component of the health care system has coerced patients. It is evident that all of these selection and sub-selection events add demographic information to repositories ultimately used to calculate health disparities, creating uncontrollable biases in the data.

Beyond identification and the largely unknown processes leading to the decision to enter SUD treatment (other than criminal justice identification) is the problem of treatment entry and engagement, which again has some sharp differences from other components of the health care system, and generates data that can be used misleadingly to calculate health care disparities. When data have been collected on the topic, substantial portion of persons who contact a SUD treatment center for an appointment never show up. Often, this is linked to overcrowded schedules and delay in appointments, both of which are well known throughout the US medical care system, but are more pronounced, overall, in SUD treatment. During the next two steps, actual induction into the treatment system and engagement in care, there is a very high degree of loss among SUD patients. Investigations have yielded multiple explanations, including simple confusion by patients about what they are expected to do next, rudeness and alienation of patients, unusual long waits, and inaccurate information. Some patients leave treatment by being

“put off” by the overall environment and other patients, becoming unwilling to give up their substance use, and seeing the expectations of treatment as overwhelming. Others attend one or two sessions of treatment and believe that they know the expectations and do not need to attend further sessions, and/or that they have learned what is necessary to achieve abstinence/sobriety and may proceed to do so.

In any event, virtually all research on SUD treatment finds the flow of patients to follow the pattern of a funnel, with loss of significant numbers of patients at each phase of the treatment process, including from session to session, and clearly into the posttreatment phase where patients are commonly contacted for follow-up support and to collect posttreatment information. This attrition clearly has substantial effects on the generation of data about health care disparities, but few studies have systematically reconstructed the “demographics of loss” such that we know little about the selectivity of subgroup membership in these processes.

PROBLEMATIC SUBGROUPS WITH DISPARITIES IN THE TREATMENT OF SUDs

There is a very extensive literature describing a multitude of health care disparities linked to either SUD treatment generally, to specific components of treatment that appear differentially employed with different demographic groups, and variations in access to what is defined in several different ways as “quality” treatment. This may refer to the degree of utilization of “evidence-based practices,” the variation in the treatment regimens that are accessible in a particular program, or the presence of “treatment tracks” designed for specific demographic categories such as the elderly, women, specific ethnic minorities, or those with varying sexual orientations. The following overview is not exhaustive in any respect, but provides a flavor for the types of issues that arise in considering health care disparities in SUD treatment.

Ethnic minorities are prominent in these studies, illustrating several issues. Entry into treatment is governed by a wide range of different cultural and subcultural traditions and norms, representing in some instances careful concern about the human body while in others describing weakness and an inability to meet expected demands. Treatment entry and engagement needs to be appropriately designed to address these considerations.

The elderly, a very rapidly growing subgroup in American society, have been recently discovered to sharply underutilize SUD treatment that is apparently needed. Among the issues here are accessibility to

SUD treatment through transportation and physical accessibility issues for entry and movement around a facility, the multiple disabilities and medications used by the elderly that may be affected by SUD treatment regimens, and the lack of role expectations which make the definition of a "problem" difficult for people who may have little or nothing to do. Again, it is clear that effective treatment needs to be specifically adjusted to accommodate this group.

As with the elderly, special issues arise in providing SUD treatment to youth. By definition, the SUD experience of youth is relatively brief and occurs before engrained role relationships of work, family, and friendship have developed, and thus should offer greater opportunity for minimizing long-term effects. Youth often enter treatment under what would be labeled coercion except that by definition they have few rights, and treatment entry is rarely seen as their decision right. This may, however, create basic reluctances and resistances, reflecting their fluid life stage characterized by developmental challenges in the physical, psychological, and social realms. This clearly suggests the need for expertise in developmental psychology in the counseling process, with an ability to teach out the abnormal consequences of SUDs and the normal patterns of developmental conflict and rebellion before diagnosing serious co-occurring disorders. Youth are subject to exploitation in programs with adults, and thus must be segregated to some degree, yet the pressures of peer influence can generate further problems associated with segregation.

Persons dwelling in sparsely populated rural areas may simply have no access to SUD treatment. Facilities are always designed on the basis of expected utilization, regardless of public or private support, and the presence of comprehensive facilities in remote areas simply cannot be justified. When treatment appears to be reasonably accessible, transportation is nearly always a problem outside urban areas and is not the type of concern that accompanies expertise in counseling and treatment delivery. The accessibility issue is exacerbated when considering the needs for a continuum of care that includes long-term follow-up. One of the exciting uses of current technology is the increased employment of the computer and the Internet for access to counseling in rural areas.

Gender is a major concern in considering health disparities in SUD delivery. From the earliest days of treatment delivery, it has been designed as if SUDs exclusively afflicted males. At one point there were doubts that 12-step programs, which began as exclusively male, could effectively accommodate women, but this issue seems to have diminished somewhat with greater similarity in the social role structures of men and women. There are at least two care-related issues affecting women almost exclusively. These are

the common problems of victimization through male violence, which can be at least a threefold issue in treatment: protection against further violence, treatment of the physical consequences of violence, and treatment of the psychological consequences. Further, many women with SUDs are responsible for dependent children, and accommodation of children during SUD treatment can be a massive challenge, particularly when the children also need treatment attention and/or sustained schooling activity.

DILEMMAS IN CONSIDERING DISPARITIES IN TREATMENT FOR SUDs

Research that systematically considers the life-careers of persons with SUDs is at its early stages, but nearly all such studies seem to offer surprises. A common finding is that a large proportion of patients go "in and out" of recovery at different points in their life cycles. On the one hand, this observation seems to affirm the stigmatizing "chronic relapsing brain disease" model of addiction, yet the evidence also demonstrates remarkable patterns of "comebacks" rather than typical downward spirals to early death that would be implied by the chronic disease model. This type of life-career investigation is not typical of other medical research where treatment episodes rather than personal trajectories are the more common model for long-term studies.

In contrast to other disorders, an unknown and essentially unmeasurable amount of treatment occurs in 12-step programs and other social support structures where records are not kept and data are not entered into systems of evaluation. AA is ironically the cornerstone of treatment for alcohol use disorders in the United States, yet its organizational and programmatic nature precludes its participation in community of care delivery. This is perhaps even more problematic in the case of NA where the target behavior is much less prevalent and the policy needs for accurate counting of treatment episodes are more acute. Hence, health care disparities in SUD treatment evident from treatment censuses may have a different profile if participation in the anonymous 12-step and social support programs could be counted.

Another contrast to the treatment of other disorders in the medical care system is the occurrence of recovery without formal intervention. While there are occasional records of miraculous cures and other recoveries from disease or disorder in general medical care, "spontaneous remission" from a SUD is not newsworthy; estimates indicate that as many as one-third of persons who develop SUDs recover "on their own" without any treatment intervention or involvement in a 12-step or social support program. The few studies that have

examined this phenomenon have found that personal religious experiences rank as the most common denominator of experience across such groups, but it is clearly difficult to generate good representative sampling to conduct such research, as well as to construct useful retrospective measures of who among the spontaneously remitted “really” had a SUD.

The existence of this phenomenon is a conundrum for the entire network of professionals and organizations involved in SUD treatment, since it seems to imply that some kind of effective “folk” activity creates outcomes similar to those generated by relatively expensive treatment, that the estimates of treatment needs are actually largely overestimated because evidence of spontaneous remission indicates that a large proportion of the untreated population with SUDs will recover without treatment, and it may suggest that some proportion of patients undergo expensive treatment unnecessarily since they would have recovered on their own. These intriguing questions, which are completely outside the paradigms of most medical care, rarely are addressed and are in fact excluded from most summary discussions about SUD treatment needs or policy considerations. The unknown demographics and understudied experiences of spontaneous remitters are problematic for the study of health care disparities in the need for and utilization of SUD treatment.

SPECIFIC POLICIES THAT HAVE ADDRESSED DISPARITIES IN TREATMENT FOR SUDs

A rich area for considering the anomalies and contradictions in the definition of health disparities is the development of social policy. Several brief examples illustrate these issues. A first example shows policy change reflecting demographic change. Reaching back into the nineteenth century, David Courtwright has alluded to how in 1880, middle class women using both medications and over-the-counter remedies that contained opiates and cocaine were the typical addicts in the United States, and there was little concern should their addictions be maintained on morphine by their family physicians. When the profile of the opiate addict slowly morphed into that of the working and lower class (often foreign-born) men by 1920, maintenance with opiates became outlawed.

More than 50 years later, leadership of the new National Institute on Alcohol Abuse and Alcoholism (NIAAA) in 1971 sought to differentiate its identity from that of its predecessor organizations by focusing on a “new” socioeconomic category of alcohol-dependent people, the majority of adult Americans who are employed. In so doing, a multifaceted campaign made

exaggerated assertions that prior intervention efforts had focused almost exclusively on Skid Row public inebriates. The new NIAAA focus was to be on the “95%” of the alcohol-dependent population that was respectable, employed but whose alcohol-related behaviors were “hidden” through a complex system of naivete, denial, and cover-up that marked both employment settings and middle class culture. Through deploying consultants to every state, “Project 95” endeavored to create workplace-based identification and referral programs for these “hidden” patients, an effort that eventuated in the rapid growth of employee assistance programs and semi-privatized treatment centers to serve the resulting referrals. The ultimate goal, achievement which remains relatively undocumented, was to reduce the health disparity in alcohol-related treatment for the working, middle, and upper social classes.

In the mid-1970s, a relatively small set of scientific findings, the conclusions of which remain controversial, formed the core of a movement that led to a policy change that had health disparity implications. This was the rediscovery that heavy drinking by mothers (coupled with poor pre-natal care) created the risk for fetal alcohol syndrome among offspring, marked by permanent forms of retardation and physical malformations. The idea of the linkage between maternal behavior and this presumably preventable outcome soon was translated into the broader concern with fetal alcohol effects, and the asserted need for all pregnant women to avoid all alcohol during pregnancy. The spin-off effects of this campaign were to create a health disparity in alleging previously undetected problems in children, and by identifying an equivocal etiological vector, namely drinking in any amount by pregnant women. The most visible resulting actions were eventual inclusion of this concern on warning labels included on all packaged alcoholic beverages (but not on alcohol decanted into other containers in commercial settings) to alert pregnant women, as well as prominent signs in many drinking venues which served as further possible education for pregnant women as well as stigmatizing devices should pregnant women choose to drink in those settings.

A very different type of disparity was highlighted by the Federal Drug Addiction Treatment Amendment (DATA) of 2000 that restricted the administration of buprenorphine for the treatment of opiate addiction to specially certified primary care physicians. These physicians were in turn limited to no more than 30 opiate-dependent patients at one time, a limit later raised to 100 such patients.

The disparities being addressed by this policy were threefold. The essential context is that the only maintenance that had been available to opiate addicts since the 1960s was methadone, distributed primarily through

highly regulated clinics that had over time become stigmatized, provided services in a demeaning context, and operated in what are often perceived as dangerous neighborhoods. Methadone is also available in some comprehensive SUD treatment centers, but this source accounts for only a small amount of use, and requires passage through a different set of perceived “social barriers” for many prospective patients.

The first goal of the DATA policy was to address a neglected group of potential patients, namely to provide treatment access to working and middle class people who were opiate dependent and who were perceived as unlikely to utilize methadone clinics but who regularly sought the services of a family doctor or primary care physician.

Second, the disparity of the existing service was directly addressed. Some policy advocates wanted to revamp the methadone system generally, and offer all addicted patients seeking opiate maintenance to be able to obtain it in a medicalized, clean, safe setting where they were treated with the respect that is supposed to be part of the culture of medical care. Presumably, they would not be bound to utilize only expensive buprenorphine since DATA allowed for certified physicians to also distribute methadone if they chose and adopted proper procedures.

The third target was to mainstream SUD treatment into general medical care via the utilization of the primary care setting. This would presumably have multiple impacts in reducing health care disparities through a degree of destigmatization of SUD treatment, through greater participation of the primary care physician in the identification and treatment of other SUDs within the broader practice setting. This integration could also serve to meet other medical care needs of SUD patients in a “one-stop” fashion, and likely have a dampening effect on longer health care cost utilization.

This ambitious innovation has met with limited success. A substantial proportion of the physicians who have been certified to provide treatment for these SUDs have not begun to do so, and this reluctance has not been systematically investigated. A perceived shortfall of this treatment regimen, again not well documented by research, is that counseling and psychosocial therapy that is supposed to accompany the medication delivery is not adequately provided in these settings, or are adequate linkages developed for coordinating its provision in another setting. A positive and partially unexpected outcome of providing this service delivery platform is its apparent utilization by those affected in the apparently rising epidemic of prescription opiate dependence, many of whom are from middle class settings.

A final example has already been described, namely the outcome of the very popular social policies

implemented through drug courts. Through their higher surveillance in neighborhoods with high crime rates, police identify through arrest-accused perpetrators who have SUDs, generating higher SUD prevalence rates. Selecting from this population for participation in drug court, the process offers a somewhat “loaded” choice between prison and treatment, with those accepting the latter contributing to what might be regarded as artificially inflated data about SUD treatment use by lower SES young African American males.

RESEARCH ARTIFACTS AFFECTING THE MEASUREMENT OF HEALTH DISPARITIES

In creating assumptions about health disparities in SUD treatment, several issues in research design come to the fore as potentially problematic. First is a version of what is called the “ecological fallacy” in several different types of social science research.

The problem develops in this manner. Survey or epidemiological research may find a higher-than-normative prevalence of a certain attribute or experience among a racial, ethnic, gender, or age group. Examples might be a high rate of employment problems or a high rate of reported childhood abuse in the home committed by various family members. These findings are seen as “keys” to increasing treatment impact within a particular demographic group, and addressing these issues becomes part of a specialized treatment track designed for patients who are members of this group.

It is, however, extremely unlikely that all patients sharing a certain demographic category also share the subject attribute or experience. Indeed, it may be found in a majority of members of a given group, but sometimes the reported difference is only a statistically significant difference, which may be minimal, highlighting the importance of distinguishing between substantive and statistically significant differences. In any event, the particular version of the “ecological fallacy” occurs when it is assumed that because a person is a member of this demographic category, they have the subject attribute when in fact it is only the case that they have a higher likelihood of possessing the attribute or having the experience. A further assumption here is that patients are randomly selected into SUD treatment from a given demographic group, that is that they enter treatment with representation of the etiological traits or experiences at identical rates that they appear in the entire population of the demographic group.

When this reasoning is used to construct a treatment track or particular regimen for a demographic group, it is likely that particular interventions may be assumed to be relevant or important for people who in actuality

have not had the subject experience or possess the subject attribute, despite their membership in the higher prevalence group. This leads to either useless administrations of the particular intervention, or possibly to damaging or insulting interventions where the patients have no connection with the problem that is being addressed.

This version of the ecological fallacy may be an argument against treatment tracks intended to address disparities. If assignment to the track is made with awareness that the design of its components may be differentially relevant to each patient and that treatment should take these differences into consideration, it may be argued that the utility of the track fades into a more effective and medically sound approach of a carefully designed individual treatment plan for each patient, regardless of their demographic memberships.

Closely related and part of this research problem is the issue of adequate sampling that is used in research. At present, there are several well-designed US national samples that include good representation of the general population but relatively few studies that provide good representation of persons in treatment for SUDs. None of these national samples is, however, adequately comprehensive to include good subsamples of all of the demographic subgroups that are believed to have inadequate access to the SUD treatment that they need. Further, the time and contact limits of data collection from individuals within large national samples prevent opportunities to conduct in-depth data collection necessary for clinical use. Thus studies with top quality clinical data often preclude adequate sampling to make generalizations that are scientifically defensible. The dilemma of in-depth data versus sound sampling is a classic double bind.

Two other problems worthy of mention are relevant to generating quality data related to health disparities are difficult for researchers to avoid. First, in the conduct of clinical trials, it is necessary to generate the "cleanest" possible data without compromising scientific quality. While it is assumed that top quality data are always generated by a randomized clinical trial (RCT) where all the scientific rules are followed, nearly all clinical trials exclude patients whose characteristics are difficult to randomize and whose presence may add hopeless contamination to the analysis of the effects of the intervention. Such characteristics often include very young or very old age, presence of psychosis, co-occurring physical illnesses, or (on occasion) having exhibited the target SUD for a very long time. As critics have pointed out, the research designs that succeed in removing these potential contaminants also succeed in removing characteristics of the real world. The end result is placing unknown limitations on the clinical utility of data since SUD treatment organizations cannot

refuse to treat the patients who present themselves with the contaminants that were removed from the RCT.

Second is the manner in which culture and demographic characteristics affect the data collection processes themselves, which in the case of research on SUDs almost always involve some aspect of self-report or use of various types of agency records. Self-reports are social behaviors that have been studied extensively. Ideally, these reports are coupled with physiological measures that independently verify substance use behaviors, but this is obviously expansive, evasive, and rarely accomplished with large, representative samples. Cultural norms guide individual decisions about reporting deviant use of legal substances or uses of illegal substances. Such admissions may be seen as humiliating and shameful. Otherwise, subpopulations likely to be characterized by disparity in utilization of SUD treatment may view surveys as efforts at identification, despite repeated assurances of confidentiality. Despite explanations, respondents may not understand the purpose of surveys as anything other than surveillance. Thus, coupled with disparities in exposure to causal factors and use of treatment, the factor of disparities in reporting evidence of SUDs needs to be considered in making generalizations.

CONCLUSION

Health care disparities in the delivery of treatment for SUDs embed many complex issues that relate to overall social policy about responsibility for SUDs. While there is frustration in many quarters about the evident disparities in care for SUDs, the era in which these issues have been addressed with rationality and with an aim toward maximizing the use of scientific knowledge is actually very brief. Perhaps the starkest contrasts are found in National Prohibition about 90 years ago, and the unquestioned imprisonment of drug addicts under Federal auspices as recently as 60 years ago. Treatment for SUDs is novel to much of the public, encouraging suspicion, confusion, and doubt. Thus, while some groups urge for greater access to treatment for SUDs, others see it as unwelcome social control. It is a particularly challenging arena for research, for these health disparities are a "braid" of social facts, social values, and social policies.

Glossary

Epidemiology the science concerned with the study of the factors determining and influencing the frequency and distribution of disease, injury, and other health-related events and their causes in a defined human population.

Health care disparities persistent differences between groups in one or more measurable dimensions of accessing, receiving, or utilization of a certain type of health care service.

Health disparities persistent differences between groups in one or more measurable dimensions of health status.

Medication-assisted treatment addiction treatment involving a combination of medications designed to curb target substance use coupled with ongoing counseling focused on psychosocial adjustment.

Randomized clinical trial a clinical study where volunteer participants with comparable characteristics are randomly assigned to different test groups to compare the efficacy of therapies.

MANAGING ADDICTION AS A CHRONIC CONDITION

There is now consensus among substance abuse treatment researchers that addiction to alcohol and drugs constitute a chronic condition. Moreover, there is increasing agreement that if substance abuse treatment is to be practical and effective, health care policymakers and professionals must manage addiction with a clear understanding of its chronicity. Numerous retrospective and prospective treatment studies make a strong case for a shift in perspective and protocols. For example, Dennis, Scott, and colleagues recently found that the median time from first use to a year of abstinence was 27 years, and the median time from first treatment to a year of abstinence was 9 years with 3–4 treatment episodes.

To enhance understanding on the issues facing the treatment community as well as the concerns of the larger community of health care policymakers, Scott and colleagues looked at the frequency and direction of transitions between points in the relapse, treatment

reentry, and the recovery cycle over 2 years. They found that approximately 33% of individuals moved from one point in the cycle to another during each quarter; 82% transitioned at least once and 62% transitioned multiple times. In addition, it was clear that prolonged, complex service histories were especially prevalent when addiction was accompanied by one or more psychiatric or social pathologies. The remaining key question then is: what new and innovative treatment protocols are needed to manage drug and alcohol addiction, a clearly chronic condition?

Addiction is protracted like other chronic conditions such as mental illness, hypertension, diabetes, and congestive heart failure. And like these conditions, addiction can also be arrested, but, when relapse occurs, it is frequently severe despite acute episodes of stabilization. How can a health care system intelligently accommodate these often dramatic ebbs and flow cycles of addiction? Or perhaps more to the point, have those responsible for national health care policy faced the realities of addiction as a chronic condition? Have they

accepted the fact that the majority of persons leaving treatment will resume alcohol and drug use in the first year following treatment, most within the first 30–90 days? Have they admitted that a single episode of treatment will not likely result in immediate and long lasting positive outcomes? And have they acknowledged that by all practical measures, the widely used acute care model of treatment for individuals suffering from chronic substance use is inadequate?

Not only is acceptance of the chronicity of addiction vital for substance abuse treatment to evolve effectively, the institutionalization of new protocols is logical and necessary. Managing chronic conditions as such has reduced their severity and progression. In a recent review of 22 continuing care studies (conducted in Hong Kong, Sweden, Taiwan, and the United States), only 38% of these studies lasting for 3 months or less produced positive findings. In contrast, 100% of the studies lasting for more than 12 months produced positive results. Effective interventions were also characterized as being more “assertive” with regard to (1) contacting patients, (2) flexible scheduling/placement to accommodate patient choice, and (3) including recovery support services (including self-help). Kristenson and colleagues experimented with the use of quarterly checkups for up to 4 years as part of physician visits in Sweden. Participants who received such checkups reported fewer days of being sick and fewer hospital days in the first 6 years and had lower mortality rates over the 10–16 years.

EVOLUTION OF THE RECOVERY MANAGEMENT CHECKUP MODEL

Building on both general chronic care models and addiction specific studies, Scott and Dennis developed a recovery management checkup model (RMC) to effectively support the management of addiction as a chronic condition marked by cycles of recovery, relapse, and repeated treatments. The core assumption underlying this work is that long-term monitoring through regular checkups and early re-intervention will facilitate early detection of relapse, reduce the time to treatment reentry, and consequently improve long-term participant outcomes. The original objectives of the RMC manual-guided protocol were to (1) provide ongoing monitoring, (2) identify individuals who had relapsed or were at risk of relapsing, (3) link them to treatment, and, consequently, (4) reduce substance use and substance-related problems.

Over the past decade this model has been modified and tested in three clinical trials involving 1355 men and women. In all three trials, participants were randomly assigned to either a control group (assessment

only) or the RMC condition. In the first two trials, men and women were recruited at the largest substance abuse treatment provider in Illinois, and in the third trial, women offenders were recruited at the largest single site country jail in the United States. The evolution over the past decade of each of the major components of the RMC model and related outcomes is discussed in the upcoming sections.

Monitoring

When considering ways to implement monitoring and early re-intervention as a mechanism for managing addiction, characteristics of the condition posed significant and unique challenges. For example, the transient, chaotic, and clandestine lifestyle that accompanies addiction often results in physical and social mobility, which often leads to residential instability and, thus, makes it difficult to provide ongoing monitoring. Furthermore, the nature of substance-abusing lifestyles contributes not only to unstable living arrangements, but also often to alienation from friends and family members. A common feature of programs designed to help manage other chronic medical conditions is to garner the support of friends and family to help manage the patient’s condition; however, the social isolation that often accompanies years of substance use may prohibit this approach. The high rates of multimorbidity such as homelessness, acute psychiatric illness, and criminal justice involvement concomitant with substance abuse also presented significant barriers to successful monitoring of the condition over time. Through the mid-1990s, studies in the addiction field suffered from such high attrition rates that the feasibility of providing ongoing monitoring with this population was questionable.

In the mid-1990s, as part of two earlier studies, Scott developed and demonstrated a proactive method to address the challenges of monitoring individuals with substance use disorders; indeed, this work ushered in the feasibility of a new approach that would reliably achieve 90%, or higher, follow-up, regardless of client characteristics and level of care. This standardized proactive set of procedures was used to (1) maintain contact with participants regardless of high rates of mobility, (2) quickly detect when locating information was no longer accurate, and (3) provide adequate time to relocate participants prior to the interview date. At the same time these procedures relied on the most efficient and cost-effective strategies.

Participants were interviewed quarterly for 2 years in the first study and quarterly for 4 years in the second study. In the third study, women offenders were interviewed upon admission and release from jail, 30, 60, and 90 days post release and quarterly thereafter for 3 years. As shown in [Table 28.1](#), quarterly follow-up rates

** Follow-up still in progress at the time of this chapter; follow-up rates here and results in the next table are based on the 262 interviewed at 24 months by July 12, 2011 (129 assigned to RMCWO).

*** Saliva and/or urine only attempted for interviews done in research offices; they were completed on over 90% of those (which is over 80% of all interviews).

for all waves across all three studies exceeded 90%, clearly demonstrating the feasibility of providing quarterly monitoring with individuals who have chronic substance use disorders.

Assessment and Linkage to Substance Abuse Treatment

A modified version of the GAIN was administered quarterly to identify individuals who had relapsed or felt they needed treatment. For those individuals who were also assigned to the RMC condition, a linkage manager used motivational interviewing (MI) techniques to provide personalized feedback to participants on the status of their condition and related problems, help participants resolve their ambivalence about their dependence and move toward a commitment to change

by accessing additional care, address existing barriers to treatment, and schedule an assessment and facilitate reentry (reminder calls, transportation). MI is an effective evidence-based method for resolving the ambivalence that prevents many individuals from making desired changes in their lives. For individuals who refused treatment, an “alternative plan” was developed that included various activities that the individuals agreed to engage in to reduce or stop substance use. Some of the activities included in the “alternative plans” are attending 12-step meetings, going to church, and reconnecting with former friends and family in recovery.

Results from the first clinical trial indicated that RMC participants were significantly more likely than those in the control condition to return to treatment, to return to treatment sooner, and to spend more subsequent days in treatment. RMC participants also experienced

significantly fewer total quarters in need of substance abuse treatment and were less likely to still be in need of treatment 2 years after intake.

While the intervention was successful in the first clinical trial, it required quarterly checkups over 12 months to significantly improve treatment participation and quarterly checkups over 24 months to improve subsequent participant outcomes. In an effort to reduce this timeline and expedite the impact of the intervention for participants, implementation data from the first clinical trial were used to identify modifications to the original RMC protocol. Data indicated that providing transportation to clients for their treatment intake appointment increased show rates. Therefore, offering transportation was incorporated as a required component for the second and third studies. Treatment intake completion rates increased to 42% in the second clinical trial. In the third clinical trial, which is only at the midpoint of data collection, the rate averaged 28% over 24 months, but varied from 54% at the time of release to 37% at 3 months post release to 21% at 24 months.

Another challenge identified in the first study was the low treatment retention rate; in the first trial, only 39% of the people who accessed treatment stayed 14 days or more, and participants who stayed 14 days or more demonstrated better outcomes. To address this low rate, a highly specified treatment engagement and

retention protocol was implemented in studies 2 and 3. The protocol included a specific telephone and face-to-face contact schedule, and an agreement between treatment and research staff that the linkage manager would have the opportunity to intervene with participants who wanted to leave treatment or that staff wanted to ask to leave treatment prematurely. Treatment retention rates increased in the next two trials.

Average Effect on Treatment Utilization and Substance Use

Table 28.2 shows the average effect of RMC compared to the control group in the first two clinical trials after 24 months. RMC participants were significantly more likely than those in the control group to return to treatment sooner and there were increases in the percentage of individuals who ever reentered treatment and the number of days of treatment they received over 2 years. Results are similar in the third clinical trial at 24 months, but data collection is less than half completed at this writing and, therefore, results are considered preliminary.

Table 28.2 also summarizes the impact of RMC on substance use. In the first two studies, RMC was associated with more days of abstinence than the control over 24 months and at the 24-month observation, though it

TABLE 28.2 Outcomes by Experiment

Outcome variable	Good is	ERI-1 (months 4–24)			ERI-2 (months 4–24)		
		Control	RMC	<i>d</i>	Control	RMC	<i>d</i>

At 24-month interview							
Days of abstinence (out of 90)	Up	72	71	(0.05)	61	68	0.23*
In need of treatment at last wave	Down	44%	34%	(0.21)*	57%	46%	(0.24)*

* Based on those completed through December 7, 2011.

** Control based on maximum months over follow-up time at 24-month observation (between 3 and 24 months for ERI 1 and 2); RMC based on how long it took the experimental group to get to the same place.

Bold = $d \geq 2$, * $P < 0.05$.

only reached significance in the second clinical trial. As noted above, the theory behind RMC is that proactive monitoring and early re-intervention will reduce the time someone stays in the community in need of treatment. As shown in Table 28.2, RMC was associated with significantly reducing the successive number of quarters used in the community in the first clinical trial ($2.31 - 1.86 = 0.44$ quarters) and in the second clinical trial ($3.41 - 2.59 = 0.82$ quarters) RMC participants were also significantly less likely to be in need of treatment at 24 months. Once again, preliminary data from the third trial demonstrate a similar trend for each of these measures.

HIV and Crime Assessment and Intervention

As discussed earlier, the core assumption underlying the model tested in these studies is that long-term monitoring through regular checkups and early re-intervention will facilitate early detection of relapse to substance use, reduce the time to substance abuse treatment reentry, and consequently reduce long-term substance use. These were primary outcomes for studies 1, 2, and 3. However, the third clinical trial involved women offenders with not only substance use disorders but also high rates of HIV risk behavior and high risk for recidivism to the criminal justice system. In order to address these challenges, the RMC model was accordingly expanded to include an intervention designed to reduce HIV risk behavior and criminal justice involvement. To that end, as part of the monthly (30, 60, and 90 days post release) linkage meetings, linkage managers provided a modified women-focused HIV risk reduction intervention, which comprised (1) assessment and feedback on HIV behavior, HIV knowledge, and condom self-efficacy, (2) assistance in understanding related health conditions, (3) health promotion skills (assertiveness and communications, self-empowerment, avoiding violence), and (4) HIV risk reduction materials (HIV treatment referrals, male and female condoms). Thereafter, a booster session was provided quarterly on an "as needed" basis. The booster session provided the same information as the monthly sessions and was conducted when any unprotected sex, multiple sex partners, sex trading, or needle use was reported.

In order to reduce recidivism to the criminal justice system, RMC linkage managers discussed any illegal activity reported in the previous 30 days. Furthermore, a risk reduction plan was developed that outlined several techniques to avoid future illegal activity (i.e. avoiding certain neighborhoods, avoiding persons committing crimes, and thinking through the consequences).

After the first 90 days post release meeting, preliminary data indicate that the RMC condition was

associated with significantly more accurate answers on a test of HIV knowledge. At 24 months women in the RMC condition were significantly more likely to use condoms and demonstrated a trend toward fewer sexual partners. At 24 months women in the RMC condition also reported significantly lower scores on the GAIN's illegal activity scale, which is a measure based on the days of illegal activity, illegal activity for money, and illegal activity to secure alcohol or other drugs. It also measures whether or not these activities took place under the influence of alcohol or other drugs. These preliminary results show that RMC may be effective in addressing not only substance use disorders in women offenders but may also be helpful in reducing rates of HIV risk behavior and illegal activity.

DISCUSSION

Over the past decade, the RMC model has been modified and tested in three clinical trials. Components of the RMC model were designed to address the duration and cyclical nature of dependence via quarterly monitoring and linkage to treatment. These regular checkups provided a proactive approach to help participants learn to identify symptoms and resolve their ambivalence about their substance use, to offer the opportunity for multiple episodes of care in the context of chronic care management, and to include an engagement and retention component to retain participants in treatment. Results from each of these three clinical trials demonstrate the feasibility of using ongoing monitoring and early intervention as a mechanism for addressing the cyclical nature of addiction.

These studies demonstrated the feasibility of implementing quarterly monitoring and recovery management checkups as well as determining the impact on participant outcomes 2 years after the initial treatment episode. However, while the intervention was successful, it required 24 months to impact participant outcomes, and only 39% of those who accessed treatment stayed for 14 days or more. The second clinical trial improved upon the first by adding two important modifications to the original design: transportation to treatment assessments was incorporated as a required component and an engagement and retention protocol was implemented. Data from second clinical trial provided evidence regarding the feasibility of replicating the RMC model and improving its implementation. Data from the third clinical trial, while preliminary provides evidence regarding the feasibility of replicating the RMC model in a very different population and context, as well as expanding its focus to include the consideration of HIV risk behaviors and criminal activity. In all three clinical trials, high

follow-up rates and high participant agreement to return to treatment were achieved.

Relative to the first clinical trial, participants in the second clinical trial were more likely to attend the linkage meetings, complete the assessment, access treatment, and remain in treatment for at least 14 days. In the third clinical trial, the preliminary findings are promising and also show an increase in condom use and a decrease in the reported number of sexual partners, as well as less involvement in illegal activity.

Results also indicate that the modifications to the RMC model likely contributed to more participants returning to treatment sooner and staying in treatment longer, thus improving participant outcomes. It is also consistent with continuing care research that longer term and more assertive monitoring can improve outcomes. Thus, the clinically significant reduction in the successive quarters of unmet need for treatment shown in these clinical trials demonstrates the effectiveness of RMC for managing dependence over time. Preliminary finding also suggest that RMC can be effective at addressing other areas such as HIV risk behaviors and involvement in criminal activity.

STRENGTHS AND LIMITATIONS

These three studies have numerous strengths: random assignment, sample sizes, repeated observations, high follow-up rates, detailed measurement, randomization, and replication across three cohorts. However, it is also important to note the limitations. First, comparisons between studies are based on cohorts that differ in setting (treatment versus jail) and years of recruitment (recruited in 2000–2004 versus 2008–2010) and are hence quasi-experimental at their best in nature. Second, for logistical reasons, recruitment for each study was limited to a single site, with predominately African American inner city participants who had high rates of co-occurring mental disorders, homelessness, and criminal justice system involvement. In the future, it would be useful to replicate this work with a more representative sample of the US public treatment and/or justice system, in other countries and/or less severe clinical samples.

IMPLICATIONS

Addiction like other chronic conditions is often marked by cycles of relapse, multiple treatment episodes, and intermittent periods of abstinence over many years before reaching sustained recovery. Results from the three RMC clinical trials provide evidence that ongoing monitoring, feedback, and early re-

intervention can be effective methods of managing recovery over time. Ideally, such services would be paid for and become a requirement for treatment program licensure, accreditation, and funding. Those requirements would be best linked to a larger strategy of reorienting addiction treatment from a predominantly acute care model of intervention to a service model that provides services ranging from a brief intervention to long-term recovery management. However, the implications of shifting to a chronic care model are significant. That shift will require a radical redefinition of the continuum of care, new service philosophies, new service delivery technologies, and a fundamental rethinking of systems of reimbursement for addiction treatment and recovery support services.

The shift will also require various stakeholders to address a number of critical issues. The first relates to the manner in which posttreatment monitoring, support, and early re-intervention services can be integrated into the current continuum of care. A second issue is how to make these services accessible to all participants who enter treatment with high problem severity, complexity, and chronicity.

Another critical issue is where (organizationally speaking) and by whom these posttreatment recovery support services will be best delivered. The data supporting RMC have been generated by services provided by clinical and nonclinical staff employed within a research organization. Additional research is needed to determine if the effectiveness of such services differs across types of organizations, or differs based on whether they are delivered by clinical or nonclinical staff. Regardless of who ultimately delivers posttreatment recovery support services, considerable thought will need to be given to the recruitment, orientation, training, and supervision of individuals performing these functions. Experience to date also suggests the need for a substantial investment in articulating the ethics and etiquette of conducting RMC across diverse clinical populations and cultural contexts.

An important step in moving forward will be to estimate the costs associated with ongoing monitoring and early re-intervention. It may be that RMC will cost more than standard care (significantly more days of treatment by the RMC participants translates into higher costs for this group, at least for treatment provision in the short term). Though the results demonstrate the efficacy of RMC, cost offset (not just cost) data is also important as it is much more likely that a program would choose to adopt RMC if it not only led to better outcomes, but also could be shown to reduce subsequent costs. Other steps might include (1) testing the model with different populations such as pregnant and postpartum women, male and female offenders leaving jail or prison, or adolescents, (2) determining when a participant can be

transitioned from quarterly to biannual checkups based on need, (3) determining whether more frequent or even continuous monitoring would improve outcomes; and (4) testing the impact of linkages to less formalized types of care such as recovery coaches or faith-based interventions.

Whatever direction the treatment system decides to move in implementing posttreatment care, it is clear that RMC, by providing ongoing monitoring, feedback, and early intervention, is an effective way of managing chronic addiction and recovery over time. The second trial improved over the first by adding transportation to treatment and a more proactive approach to maintaining participants in treatment resulting in better outcomes. So far, the third trial has demonstrated the feasibility of providing RMC to a different population (incarcerated women) and also demonstrated that RMC could effectively address other areas of concern such as HIV risk behaviors and criminal activity. The results of these three clinical trials indicate that the RMC model contributes to participants returning to treatment sooner and staying in treatment longer, thus having better outcomes.

Acknowledgments

This work was done with support provided by the United States National Institute on Drug Abuse (NIDA) Grant No. DA11323 and DA021174. INTRODUCTION

A technology-delivered treatment is any intervention based on or assisted by a technological “media that enables users to access information and services of interest, control how the information is presented, and respond to information and messages in the mediated environment (e.g. answer questions, send a message, take an action in a game, receive feedback, or make a response to previous actions)” (Street and Rimal, 1997, p. 2). In this chapter, we review the current status and postulate future directions of technology-delivered treatments for substance use disorders. In our view, at least three contextual factors enhance the opportunity, importance, and timeliness of the use of such interventions for substance use disorders.

First, the revolution underway in information technology (e.g. computer and telecommunications technology) is expanding in scope and reach. Wireless technologies including smartphones, tablet computers, and wireless local areas networks are making computer and Internet use much more accessible and affordable. Increasingly, information technology is weaving its way into the daily lives of many and influencing everything from commerce to international policy. Information technology is also bringing about great changes in the health care system through the use of distance medicine approaches. Indeed, telemedicine renders distance an irrelevant feature of the health care experience by permitting the utilization of medical expertise at a central site to address a variety of health care challenges at remote locations. These advances are highly

welcome, given that difficulty in accessing state of the art or specialty care can result in failure to obtain effective treatment for disease processes while they are still tractable. In the field of addiction, however, opportunities for optimally utilizing technology have only begun to be explored and are a long way from being fully realized.

Second, an important ongoing context for the field of addiction treatment is the current worldwide recession. Indeed, at the time of the writing of this chapter, the world is reeling from the worst recession since the Great Depression. As a consequence of the economic downturn, various communities throughout the United States are making decisions to limit or decrease various services, taking actions ranging from closing schools to not illuminating streetlights. At the same time, the demand for drug abuse treatment remains high and may be increasing, partly as a result of the recession, while only a fraction of those with substance use disorders are able to access treatment. Thus, if we wish to have a large impact on access to treatment, we will have to reconsider our current treatment models and explore innovative approaches to increase treatment access in a cost-effective manner.

Third, the health of the drug abuse treatment system is less than optimal and faces many challenges. These challenges, in addition to insufficient services to meet demand, include difficulty in recruiting and retaining providers of service, limited treatment financing, and a slow adoption of research-based innovations. And even with optimal interventions, treatment response remains limited, with many clinical studies resulting in only a small percentage of patients showing consistent improvements. Moreover, treatment staff turnover may result from a variety of conditions that produce 'burnout,' including the limited therapeutic outcome among their patients and the repetitive nature of much of the therapy offered in such settings. Lastly, the therapies provided by counselors and therapists often are not evidence-based, and when evidenced-based treatment is provided, more recent scientific advances are not readily integrated into those treatments.

The nexus of these contextual factors, and their associated opportunities and challenges, provides a novel space for reframing and reconsidering how substance abuse treatment is delivered. In that space, we can consider innovative means to deliver treatment in ways that take advantage of the advances in information technology, while recognizing the limitations of resources for, and the challenges associated with, current substance abuse treatment. Exploring that emerging opportunity is fundamentally what this chapter is about. In that exploration, we address five topic areas: (1) the logic of technology-delivered treatment, (2) early efforts to apply information technology

in the field of addiction as well as other fields, (3) the current status of technology-delivered treatment, (4) novel content for technology-delivered treatment, and (5) an extrapolation of the future of new technological developments and the opportunities they afford for treatment delivery.

THE LOGIC AND POTENTIAL BENEFITS OF TECHNOLOGY-DELIVERED TREATMENT (TDT)

The assumptions undergirding the use of technology-delivered treatment (TDT) derive from and are supported by efforts in the substance abuse treatment field to develop instruction manuals for ('manualize') specific evidence-based treatment approaches. These manuals codify the specific content and sequence of content necessary for achieving therapeutic outcomes. The original goal of these manuals was to permit systematic replication of new therapies and facilitate treatment adoption. The specificity of these manuals provides the opportunity to reconsider the means of delivery of these treatments. If they can be manualized, then in principle, they can be computerized and delivered via the Internet or other information technology. Additionally, the use of information technology allows for the incorporation of important methods that can be employed to demonstrate, illustrate, and support the acquisition of therapeutically important skills and knowledge (e.g. fluency training, scenario planning, video clips to model specific behavior).

The benefits of TDT are severalfold. Some of these benefits are of greatest importance to the providers or payers of care, some are most applicable for patients, while still others are relevant for both groups.

Starting with the providers and/or payers of treatment, technology-delivered treatment provide several substantial benefits. First, the most expensive components of delivering substance abuse treatment result from the cost associated with the personnel who deliver the treatment. Delivery of treatment via informational technologies has the potential to dramatically lower costs even in hybrid models where therapists also participate and monitor the use of technology-based treatment.

Second, another concern for the payer of treatment is the extent to which evidence-based treatments are being conducted and delivered with fidelity. Treatments provided without being faithful to intended procedures render the treatment as not evidence-based and likely less efficacious. The use of these technologies to deliver treatment ensures that treatment delivery is consistent and conducted with fidelity.

Third, in our current system, retooling treatment delivery to incorporate recent advances in the science of treatment can be a long and expensive task, requiring treatment programs to adopt new practices and providers to obtain suitable training and practice. On the other hand, when information technology is used to provide treatment, new information can be incorporated easily and exported quickly. This is particularly true when technology-delivered interventions are web-based, such that updates in program content can be incorporated centrally and made readily and concurrently available to all end users. Thus, technology-based delivery has the potential to rapidly and continuously innovate contemporary treatment models with the latest scientific advances and in essence would permit continual improvement of the treatment system. Indeed, this delivery mechanism may provide a means to enhance provider adoption of science-based interventions.

Fourth, exporting treatments to new, sometimes remote areas remains another challenge for the substance abuse treatment community. Treatment delivered via information technology can be exported easily to the places where it is needed, especially in light of rapidly expanding communication infrastructures.

Next, let us consider the benefits for patients receiving care delivered via information technology. First, one challenge in delivering treatment in any setting is that of ensuring access. Delays to treatment entry can result from either waiting lists or challenges of getting transportation to the treatment facilities. In principle, treatments delivered via a mobile device or a computer can be immediately available and accessible without effortful or long commutes.

Second, discussing sensitive issues of addiction and other topics such as HIV status may render the process of therapy very challenging if not highly threatening to some patients. Several studies have demonstrated that the use of information technology as the means of treatment delivery results in more accurate reporting of sensitive information from the patient and may be perceived as less threatening. In one study regarding HIV education, a significantly greater percent of opioid-dependent patients were interested in receiving additional HIV services after receiving a computer-based HIV education intervention compared to patients enrolled in a therapist-delivered HIV education intervention (Marsch and Bickel, 2004).

Third, the typical provision of treatment is restricted by the counselor's schedule (during fixed office hours, typically on week days) and therefore may not correspond with the availability of potential patients, who may be engaged in other activities such as employment. The use of information technology to deliver treatments provides the opportunity for patients to receive therapy

at times that are convenient for them regardless of the time of day. In principle, treatment via the Internet could be available on a 24-hour/7 days per week basis.

Several benefits of TDT are relevant to all groups: providers/payers of treatment and patients. For example, computerized therapy, when properly delivered, requires active responding by the patient to demonstrate that they are acquiring relevant information. No doubt effective counselors/therapists require patient participation, but technology-based programs will do so consistently, regardless of external demands, and minor or major challenges in life. Therefore, technology-based programs benefit the patient by building their skills and knowledge base and providers as well as payers of treatment who are assured that clinically important information/skills are acquired.

Another joint benefit of TDT is that they can be constructed so as to tailor or customize the treatment (see Current Status section below). Therapy provided via information technology often can be customized based on the current circumstances of the patient. Again, highly skilled therapists can and do customize treatment. However, computerized therapy can serve to provide evidence-based approaches tailored to the individualized needs of patients. In addition, use of computer-generated speech technology can accommodate illiterate patients in a fashion similar to therapists. Finally, computer-based interventions may allow patients to engage in therapeutic activities for a greater period of time than would be possible with a therapist alone, review repetitive but necessary skills training, and complete therapeutic tasks that the therapist may find uninteresting or repetitive.

Early Efforts to Use TDT for Addiction and Other Disorders

The opportunities associated with the use of information technology for behavior change were recognized early on by several innovators. These researchers used information technology across several different platforms or technological devices, including desktop computers, email, hand-held devices, telephone-accessed computer systems, video-disk training, and virtual reality (VR) systems. The disorders for which computers have been employed to provide treatment or promote health behaviors include Alzheimer's, arthritis, asthma, anxiety, depression, diabetes, heart disease, HIV, and hypertension.

We begin here with a brief example of this early work from the anxiety and depression literature that was in large part this start of the TDT approach reviewed here. Early implementation of information technology to target these disorders may have resulted from the early adoption and use of treatment manuals for these

disorders. As noted earlier, manuals that specify the use of certain sequences of procedures are potentially easily adapted via information technology approaches for delivery to the patient. For example, computer programs have successfully implemented certain behavioral therapy techniques consisting of very specific components such as cognitive restructuring, relaxation training, systematic desensitization, and self-exposure treatment.

In these early applications of computerized behavioral treatments, comparable results were generally observed between the computer-delivered and therapist-delivered treatments. For example, in a 1990 study by Selmi et al., depressed patients were randomly assigned to receive either computer-delivered, cognitive behavioral therapy (CBT), therapist-delivered CBT, or were placed on a waiting-list (control). Both active treatments significantly reduced depression relative to the control group at the end of treatment and at a 2-month follow-up. The two treated groups did not differ from each other. Additionally, 50% of the computer group and 42% of the therapist group were improved at the end of treatment, while only 17% of the controls showed improvement. Thus, both active treatments demonstrated efficacy in this study, but the computer- and therapist-delivered treatments were almost equally efficacious.

Although in these early applications computer- and therapist-delivered treatments appear to not differ dramatically in their efficacy, they did differ in terms of the cost of treatment. That is, a computer-based treatment can be used numerous times with most of its expense associated with the one-time purchase of hardware and software, while the cost of the therapist-delivered treatment is a fixed cost per use (i.e. therapist salary). In a 1997 study by Newman et al. examining this issue, the cost of a computer-based treatment for panic disorder was estimated to have saved \$540 per patient or 32% relative to a therapist-delivered treatment for panic disorder.

In summary, the early use of information technology to deliver treatment in anxiety and depressive disorders (the first researched area of computer-delivered therapy) suggests that such technological approaches to therapy are generally as effective as counselor-based treatment while being less costly.

Treatment of Substance Use Disorders

Information technology was used to assess and treat substance abuse disorders in several early efforts. A considerable focus of this research was on the computerized assessment of substance use and the computerization of interviews and questionnaires. Comparisons of these computerized assessments with more traditional methods have found them to be acceptable to patients.

For example, Skinner and Allen (1983) asked substance abusing patients to rate computer-based, face-to-face, and self-report assessments. Patients rated the computer-based assessments more favorably than face-to-face interviews or self-report on several dimensions (i.e. the computer assessment was rated as more relaxing, more interesting, faster, and shorter). No differences in rates of substance abuse were reported across the three methods. Other studies have found increased reporting of sensitive thoughts, symptoms, or behaviors via the use of computer-based assessments. Validation studies conducted with other populations confirm that computer assessment is reliable, valid, and equivalent to clinician-administered scales.

A few trials have been conducted to examine the use of computer-delivered therapy for substance abuse. Studies related to smoking treatment have successfully used computer-generated personalized messages and feedback to promote smoking cessation, encourage movement of smokers along the stages of change, or promote nicotine fading procedures; however, these studies were either not controlled trials or patients in these trials generally did not interact with information technology on a regular basis to receive some aspect of therapy (e.g. patients generally received a computer-generated, personalized letter or report based on their self-reported smoking status).

During this early period of application of information technology, to our knowledge only three controlled clinical trials examined the efficacy of interactive computer-delivered therapy for substance abuse. The first study, by Schneider et al. (1990), used the CompuServe computer network to provide an interactive behavioral smoking cessation program. There were four treatment groups: (1) full computer-based smoking cessation program with a stop-smoking online forum, (2) the full program without the online forum, (3) a sham program with the online forum, and (4) a sham program without the online forum. The 1158 participants were randomly dispersed between treatment groups. The individuals receiving the full program achieved significantly better abstinence rates at 1- and 3-month follow-ups relative to those receiving the control treatment, irrespective of the online forum. However, overall utilization of these resources was poor, and there was no difference between the groups at the 6-month follow-up.

The second controlled study of interactive therapy, referred to as the Drinkers Check-up, was from a line of research conducted by Hester and colleagues. In the first experiment (1997) in the series, 40 heavy drinkers were randomly assigned to receive a computerized version of a behavioral self-control training program either immediately after pretreatment assessment or after a 10-week waiting period. Compared to the

pretreatment drinking levels of both the experimental treatment group (35.2 drinks) and the delayed treatment group (34.3 drinks), patients in the experimental group who received the computer-based intervention reduced their drinking significantly to between 13.8 and 14.5 drinks per week. Importantly, once the delayed treatment group received treatment, they also significantly reduced their drinking from 34 drinks during baseline to 20.8 standard drinks. These effects were long-lasting, with treatment gains maintained over a 12-month follow-up period. These investigators replicated these results using a motivational treatment approach.

In a third controlled study of TDT in the substance abuse population, conducted by Marsch and Bickel (2004), computer-delivered HIV/AIDS education was compared to therapist-delivered HIV/AIDS education among opioid-dependent, injection drug users (IDUs) receiving buprenorphine treatment. Thirty participants were randomly assigned to one of the two conditions (15 per condition). In the computer-based training, IDUs received computer-based HIV/AIDS education using a computer-assisted instruction (CAI) that incorporates a fluency-building engine. Fluency-building technology requires the user to develop a predetermined level of accuracy and speed in responding during an active learning process. As a result, the interactive program can be adjusted based on a given user's level of responding. Indeed, fluency-based programs have been demonstrated to promote mastery of a specific content area and improve both short- and long-term retention of the material. Additionally, the computerized fluency-building program provided performance feedback and remediation for errors. IDUs in the counselor-based training condition received HIV/AIDS education in the context of one or more counseling sessions with a trained, masters-level substance abuse therapist and viewed a videotape on drugs and AIDS. Patients who received computer-based instruction learned significantly more information and retained significantly more of that information at a 3-month follow-up, a finding attributed to the fluency-building component of the computer intervention. Participants in the computer-based training condition liked the teaching medium significantly more than those in the therapist-delivered program. Also, at the end of treatment, patients were asked if they would like to receive more information about AIDS, including HIV/AIDS pamphlets and information on being tested for HIV. Significantly more (approximately 80%) patients receiving the computer-based training requested such information while considerably fewer (approximately 20%) of those receiving the therapist-based training requested that information. Both groups of patients exhibited significant reductions in HIV-risk behavior, with no differences between groups observed on this

outcome measure. This study demonstrated that computer-based HIV/AIDS education may constitute an effective, systematic intervention that is attractive to IDUs and cost-effective.

CURRENT STATUS OF TDT FOR SUBSTANCE ABUSE

The use of technology for treating substance use disorders is increasingly being recognized in the research community and among funders of research as offering great potential, and the number of research projects in this area has been rising in recent years.

Evidence-Based Behavioral Therapies for Treating Substance Use Disorders

At least four evidence-based behavioral therapies for individuals with substance use disorders have recently been computerized and demonstrated to be efficacious.

First, there is the Therapeutic Education System (TES), an interactive, self-directed, web-based version of the evidence-based psychosocial intervention rooted in the community reinforcement approach (CRA). TES includes over 65 interactive, multimedia modules, including some focused on basic cognitive behavioral relapse prevention skills (e.g. drug refusal skills, managing thoughts about drug use, conducting functional analyses, and self-management planning); some related to the prevention of HIV, hepatitis, and sexually transmitted infections; and others that teach skills that may help improve psychosocial functioning (e.g. employment status, family/social relations, financial management, communication skills, decision-making skills, management of negative moods, time management, and recreational activities). The evidence-based content in TES is provided using informational technology. Specifically, TES uses fluency-based CAI, grounded in the fluency teaching approach to continually assess (via interactive quizzes) a patient's grasp of the material and adjust the pace and level of repetition of material in order to promote mastery of the skills and information being taught. TES also creates an experiential learning environment via the use of interactive videos of actors modeling various behaviors in order for the program user to better learn the modeled behavior (e.g. progressive muscle relaxation, drug refusal skills). It employs a variety of interactive exercises to enhance learning (e.g. graphics and animation) and personalize content for participants (e.g. personalized functional analysis). Further, TES can optionally include a flexible system for tracking and reinforcing target behaviors (e.g. abstinence) and monitoring

earnings via evidence-based contingency management procedures. An electronic reporting system within the TES program allows therapists to view summaries of their patients' activity and progress, recommend modules to be covered, and integrate patients' use of TES into their counseling sessions.

In 2008, Bickel et al. initially evaluated TES in a randomized, controlled trial assessing its efficacy with opioid- or cocaine-dependent patients receiving outpatient treatment with buprenorphine ($n = 135$). Participants were randomly assigned to one of three study conditions for 23 weeks: (1) 30 min TES thrice weekly with biweekly counselor contact and incentives for opioid- and cocaine-negative urine samples, (2) 30 min therapist-delivered CRA with incentives for opioid- and cocaine-negative urine samples, or (3) standard counseling. Outcomes as measured by continuous weeks of cocaine and opioid abstinence for the computer-delivered, therapist-delivered, and standard treatments were 7.78 (standard error of the mean (SEM) = 1.17), 7.98 (SEM = 1.09), and 4.69 (SEM = 0.88) mean weeks of abstinence, respectively. The therapist-delivered and computer-assisted therapy did not produce significantly different outcomes on this measure, but both produced significantly better abstinence compared to standard treatment. Participants in the therapist-delivered and computer-assisted interventions achieved comparable results on measures of treatment retention, Addiction Severity Index scores, and therapeutic alliance with their counselor. Importantly, computer-assisted treatment reduced interaction with counselors by 80% and is estimated to have reduced the cost of effective treatment by over 70%. Overall, results from this efficacy research are highly promising and clearly support the efficacy of the computerized package of CRA plus incentives. Due to its strong efficacy data and its considerable potential to promote the widespread dissemination of evidence-based psychosocial treatment for individuals with substance use disorders, TES has been included in a number of other large-scale evaluation projects funded by the National Institute on Drug Abuse (NIDA), including a multi-site study conducted in 10 substance abuse treatment settings on NIDA's Clinical Trials Network platform as well as a multi-site study in 10 criminal justice settings across the United States.

The second technology-based behavioral therapy, which delivers a computerized version of CBT, was developed by Carroll and colleagues (2008). This program, called Computer-based Training in Cognitive Behavioral Therapy or CBT4CBT, is composed of six sessions focussing on (1) understanding and changing patterns of substance use, (2) coping with craving, (3) refusing offers of drugs and alcohol, (4) problem solving skills, (5) identifying and changing thoughts about

drugs and alcohol, and (6) improving decision-making skills. Module content is presented using video-taped vignettes illustrating the various skills taught within the program. In a randomized, controlled trial, 77 individuals entering treatment for substance dependence were randomly assigned to either standard treatment or standard treatment plus access to CBT4CBT for an 8-week intervention period. Participants in the group that received CBT4CBT as an adjunct to standard treatment submitted a lower percent of drug-positive urine samples (34% positive) relative to those in the standard of care condition (53% positive). Treatment involvement and the completion of homework (in between sessions) were strongly related to outcomes from the CBT4CBT intervention.

A third technology-based behavioral therapy, a computerized version of motivational enhancement therapy (MET), was developed by Ondersma et al. (2005). This brief MET-based intervention, called the Motivational Enhancement System, was primarily designed for postpartum women who reported drug use before pregnancy. The intervention has three sections based on principles of motivational interviewing (MI) and brief intervention including: (1) feedback to the user about the negative consequences of drug use, her readiness to change, and her drug use as compared to that of all adult women (based on her responses to questions posed by the program); (2) pros and cons of drug use and related change; and (3) review of the participant's interest in change with the opportunity to set goals regarding drug use. In an initial evaluation of this program, 30 women were randomly assigned to the brief computerized intervention or to a control group. Participants in the intervention group reported that the intervention was highly acceptable and that it significantly increased their motivation to reduce drug use at post-intervention and 1-month follow-up ($d = 0.49$). The promise of this brief intervention was further underscored in a 2007 evaluation with 107 postpartum women randomly assigned to the brief intervention or a control condition. Illicit drug use declined among individuals in the intervention group and slightly increased in the control group.

In the fourth study utilizing a technology-based behavioral therapy program, Kay-Lambkin et al. (2009) evaluated a computer-based intervention for individuals with comorbid depression and alcohol/cannabis problems. This program, which teaches skills found in CBT, while using an MI therapeutic style, includes content underscoring the relationship between substance misuse and depressive symptoms. In a randomized controlled trial, 97 individuals from the target population received a brief intervention for depressive symptoms and substance misuse followed by one of three conditions: (1) no further treatment,

(2) nine sessions of MI and CBT delivered by a psychologist, or (3) nine sessions of MI and CBT delivered by a computer. Results indicated that two MI/CBT groups produced better outcomes than a brief intervention alone on measures of cannabis and other substance use, with the group receiving the computerized intervention showing the largest effects. Additionally, MI/CBT produced better outcomes than the brief intervention on measures of depression, with the in-person treatment producing better short-term outcomes but the computerized intervention producing comparable outcomes at a 12-month follow-up.

Additional Novel TDT for Substance Use Disorders

In addition to technology-based, psychosocial treatment interventions for substance use disorders (as reviewed above), several additional empirically supported technology-delivered interventions have been developed for individuals with substance use disorders.

For example, novel research led by Jesse Dallery (2005, 2007) has focused on promoting smoking cessation using an entirely automated, Internet-based contingency management (abstinence reinforcement) intervention, called *Mōtiv8*, to obtain video-based evidence of smoking behavior and reinforce evidence of behavior change (e.g. smoking reduction or abstinence). *Mōtiv8* is a web-based platform that delivers reinforcement in the form of electronic vouchers (statements of earnings) based on evidence of meeting targeted behavior change goals. A critical feature of *Mōtiv8* is its ability to remotely observe, via a web camera, objective evidence of the presence or absence of behavior (e.g. participants providing carbon monoxide (CO) breath samples—a reliable and valid measure of smoking status—via an at-home monitor with each at-home reading recorded by web camera, and then receiving reinforcers for meeting targeted CO levels). Several studies have shown that the *Mōtiv8* intervention reliably promotes smoking abstinence in heavy smokers, rural smokers, and adolescent smokers. These results demonstrate the powerful early onset of efficacy of the CO intervention and the feasibility of delivering reinforcement for smoking abstinence over the Internet.

Additionally, innovative work led by Kenneth Silverman has focused on the development and evaluation of a novel, web-delivered, employment-based intervention for chronic drug users called the Therapeutic Workplace. The Therapeutic Workplace is designed to address the interrelated problems of poverty and drug addiction. In this model, participants are eligible for employment in a work setting contingent upon the provision of drug-free urine samples, and are then taught skills via

the web-based system that are later applied to various work tasks (via the web-based Therapeutic Workplace system). Incentives (payment for work) are delivered contingent upon the quality of work performance. The Therapeutic Workplace model has reliably produced marked reductions in drug use and has underscored the potential utility of workplaces (that use long-term contingency management interventions) as long-term therapeutic agents in the treatment of substance dependence.

FUTURE DIRECTIONS OF TDT: CONTENT DEVELOPMENT

MET

As previously described, early efforts by Hester and colleagues in 2005 with a computerized tool for assessing alcohol use called the *Drinker's Check-up* began integrating content derived from the principles and procedures of MI. However, with the exception of a few studies such as those cited above with pregnant or postpartum women, little research on computerized MET procedures has appeared in the past decade. To more authentically replicate MET, some interactive programs have incorporated (putatively) important MET components of amplified reflection, summary statements, ambivalence development exercises, expression of empathy, individualized goal setting, and rolling with resistance. A few reports of such programs have appeared and more are likely on the horizon. However, there are limitations to programming that attempts to mimic personal interactions that involve the more sophisticated MET components such as expression of empathy or focused reflections. The strength of computer applications in this arena might stem from the fidelity and consistency of the delivery of other key components; moreover, the inherent impersonal nature of the computer may facilitate more open self-thought and dialogue by removing the interpersonal anxieties that sometimes block contemplation of sensitive topics.

CBT

As reviewed above, most computerized programs for individuals with substance use disorders to date have focused on delivery of CBT skills (e.g. TES programming). Recent research on video modeling of coping skill responses will likely encourage continued development of more comprehensive and sophisticated software programs utilizing this modality. Carroll's recently developed video-based CBT modeling program described above was shown to enhance coping skills used in the real world, which in turn predicted better

substance use treatment outcomes. This mediational finding has rarely been observed with therapist-delivered CBT research. One can envision future adaptations of the content and medium that involve direct practice of coping skills via immersion in VR programming or video gaming participation (see next section), which may further enhance patient learning and utilization. The content of such programming could be related to that currently used in role plays performed during therapy sessions and practice assignments completed outside of therapy sessions.

Web-Based Social Support

The importance of social support to successful recovery from substance use problems is well established. Over the past few years, self-help groups like AA and SMART Recovery have taken advantage of the Internet by establishing live web-based text and voice chat meetings that can be accessed at any time of day as well as forums and postings of educational materials and meeting information. Treatment researchers are likely to explore alternatives for using digital communication to provide therapeutic social support. Highly popular online social networks, such as Facebook or MySpace, could host groups from specific or non-specific treatment programs. Such sites might serve as a source for active or emotional coping support; offer advice or encouragement in addressing urges to use or following a relapse; provide a place for group practice of therapeutic skills; or be a source for information about employment, school, recreation, or social activities. Social networking sites might also provide parents or spouses of substance abusers with social support and coping skill advice or training for dealing effectively with their family member. Use of digital technology can make access to support virtually immediate, a clear advantage over traditional group therapy or self-help meeting modalities. This form of remote social contact may also increase the probability that socially anxious persons will access social support when needed.

FUTURE DIRECTIONS OF TDT: TECHNOLOGICAL DEVELOPMENT

Existing technological platforms and devices such as short message service or texting (SMS), hand-held computer devices or personal digital assistants (PDAs), cell phones/smartphones, global positioning systems (GPS), VR, and video gaming offer a plethora of alternatives for innovative delivery of therapeutic interventions for substance abuse/use problems. Utilizing these mechanisms to address various health or human performance issues is already becoming a reality, as evidenced

by the coining of the terms for these emerging technologies, for example, ubiquitous computing (ubicomp) and ambient intelligence systems, which function as pervasive and intelligent service systems surrounding individuals by anticipating, adapting to, and meeting users' needs; *eHealth* (the use of electronic communication devices to provide health services and information); and *mHealth* (the mobile subset of *eHealth*). Moreover, the use of video games to promote health behaviors and the use of VR programs to assist with the treatment of some mental health disorders are currently being applied and studied. Below we offer a few illustrations of innovations that might be employed to intervene in substance use disorders in the near future. Many of these ideas and examples reflect applications either being contemplated for development and testing or are research projects currently underway.

Programmed SMS (texting) could prompt or remind individuals to use particular relapse prevention coping skills, provide regular educational messages to enhance learning of skills, or simply provide motivational or encouraging messages that might help maintain positive, recovery thoughts and behaviors. Such messages could be programmed by a clinical provider to occur on specific dates, times, and frequencies. The ubiquitous presence of cell phones in today's society would suggest that such use of SMS could be readily integrated into most patients' care.

Smartphones (i.e. mobile phones with computing ability and Internet connectivity) offer a myriad of intervention possibilities in addition to use of SMS. For brevity, we will discuss smartphone capabilities as encompassing that of a combination of a cell phone, a PDA, and a GPS. An important feature of smartphones is that they allow users to download and run complete software applications (apps) that provide opportunities for development and use of unlimited types of programs. Hence, smartphones could be used to deliver the therapeutic software applications including video modeling discussed earlier in the chapter, with the addition of being able to access such programs from anywhere at any time. Detailed active coping plans and strategies could be made readily available for real time use when needed via these devices. Patients could also gain mobile access to social support systems as discussed in the previous section.

A number of current research projects are exploring combined use of GPS and PDA capabilities to develop "warning" systems that would alert the patients when they enter environments that present high risk for drug use and potentially prompt them to engage in specific coping behaviors. GPS technology also would allow increased monitoring by those concerned with the whereabouts of the patient (e.g. concerned parents), which could be integrated into a comprehensive

therapeutic program. Others are seeking to integrate wireless devices that measure behavioral and physiological responses with smartphones to allow therapeutic interventions to automatically be delivered when physiological changes signal risk (e.g. of stress or craving).

Another promising development targeting primarily teens and young adults is the video game platform to promote learning experiences relevant to effective recovery from substance abuse. Games for this platform could provide a medium that includes modeling of coping skills via culturally and gender relevant characters and environments, and reinforcement of mastery and effective use of coping skills. The participant would be challenged with making key decisions and choices followed by realistic consequences (e.g. to win the game you need to achieve sobriety), which requires effective decision making and use of specific skills. The overall goal of these games would be to create an engaging, interactive experience that facilitates learning, plus encourages and motivates behavior change. Games directed at prevention of substance use and other health behaviors have already appeared in the literature.

A final example of nascent use of technology for substance abuse treatment is the employment of VR, i.e. computer-simulated experiences that utilize visual, auditory, tactile, or olfactory sensory features to facilitate active participation in simulated environments. VR has been used to enhance exposure therapies for specific phobias and for post-traumatic stress disorder. Potential applications for substance abuse interventions would include simulating real-life drinking or drug use environments that provide opportunities to practice skills consistent with successfully negotiating the scenes without lapsing to use. Again, culturally relevant environments and situations could be developed that would enhance participation and learning of effective behaviors. Currently, a number of research projects are using VR to facilitate cue exposure-type interventions designed to reduce or extinguish craving linked to environmental cues that might trigger relapse.

In summary, the near future offers a wealth of exciting possibilities for creative use of advanced technologies to better intervene in substance use disorders. The primary focus of these advances are likely to be (1) delivering active treatment components when and where they are needed in real time, perhaps to specific substance-using populations and (2) using digital simulations to create more realistic environments that may enhance participation in therapeutic activities, motivation to change, and learning of coping skills. Other inventive applications will inevitably emerge. For example, we are aware of several new research projects investigating the development and evaluation of web-based interventions for specific sub-populations of substance-using individuals including web-based

MET/CBT for individuals with marijuana use disorders, web-based behavioral therapy for adolescents with substance use disorders, web-based HIV prevention intervention for adolescents in substance abuse treatment, and online programming for opioid-maintained chronic pain patients with aberrant opioid-taking behavior. Additionally, several early stage projects are examining the use of online social networks as well as mobile phones and other mobile devices in the assessment and treatment of substance use disorders.

Barriers to the Adoption of TDT

As reviewed above, technology-based therapeutic tools hold great promise for increasing the likelihood of adoption of science-based behavioral interventions targeting individuals with substance use disorders (among other populations). Despite the wealth of research supporting a number of behavior change interventions targeting substance use disorders and related issues, substance abuse treatment programs have been particularly slow to adopt evidence-based practices. The realities of community-based treatment systems (especially marked limitations in resources) present numerous barriers to effectively transfer evidence-based programs into treatment practice. However, if adopted, technology-delivered behavioral interventions inherently contain many features that may facilitate the likelihood of adoption of innovations. They may function as 'clinician-extenders' that enable rapid and widespread diffusion of evidence-based psychosocial interventions to individuals with substance use disorders in treatment programs in a manner that ensures fidelity of intervention delivery and is cost-effective.

Despite the potential utility of technology-delivered interventions in substance abuse treatment programs, it is important to recognize that the majority (90%) of individuals with substance use disorders are not in substance abuse treatment. Thus, nearly 21 million Americans annually remain untreated for a substance use disorder, suggesting that the current treatment system is either inaccessible or unacceptable to most substance-abusing individuals (SAMHSA, 2009). Thus, in addition to their use in substance abuse treatment settings, evidence-based, technology-delivered interventions targeting substance use disorders could be offered within other systems of care, including an array of medical settings (e.g. emergency rooms, primary care settings, health clinics) and/or criminal justice settings (e.g. probation/parole settings, jails, prisons). However, challenges to delivering technology-based intervention in these nontraditional settings are similar to known challenges in delivering evidence-based care using more traditional approaches in substance abuse treatment settings, and include limited training, time, and

(sometimes) interest among providers to deliver such interventions. Thus, technology-based therapeutic tools may meet a significant but currently unmet need in such nontraditional settings. Technology-delivered approaches may become increasingly important and clinically useful in light of the recently announced 2010 National Drug Control Strategy from the U.S. Office of National Drug Control Policy (ONDCP), which places a strong emphasis on integrating treatment for substance use disorders into other areas of health care (mental health clinics, infectious disease management programs, primary care clinics) where providers may have limited expertise in treating individuals with substance use disorders.

It is important to acknowledge that while technology-based interventions appear to be optimal for adoption in a wide range of service settings as well as direct to users in nonclinical settings, a number of factors will impact actual adoption. In order to effectively translate the science of technology-based interventions for individuals with a substance use disorder to practice, dissemination efforts must reach diverse stakeholders, with meaningful information and support material to optimize the potential of these interventions to have a substantive public health impact. Further research is needed on how to best reach various service system audiences to promote routine use of technology-based interventions in community-based systems of care. Additionally, further study is needed to better understand local, state, and federal policies, as well as reimbursement structures for payment of services within public and private sectors that may impact adoption of technology-delivered interventions in various systems of care. Current considerations regarding payment structures for technology-delivered services within the public health care system may lead to reimbursement structures that further promote the widespread deployment of technology-based therapeutic tools.

CONCLUSION

In the past two decades, the use of information technology to deliver treatments for substance use disorders has transitioned from a potential opportunity to a reality. Research clearly shows that technology-based treatments can be efficacious and are acceptable to patients. This next decade will likely involve a proliferation of innovative applications that promise to increase both access to and effectiveness of substance abuse treatment interventions. An important additional step is to empirically examine how this approach to treatment can be used to expand, extend, and reorganize our approach to the provision of treatment. For example, there may be reason to integrate these approaches into some

hybrid modality with other telemedicine approaches (e.g. holding meetings with counselors via videoconferencing). Another potential opportunity is the use of these lower-cost information technologies to deliver treatment to be used productively for continuity of care following an acute treatment episode. Additionally, the use of smartphones remains an important potential tool to exploit for this type of application.

This next decade may move the study of technology-delivered treatments of substance use disorders from the study of the efficacy of various treatment approaches to an examination of how to deliver them so that they have the broadest reach and greatest opportunity to positively affect the plethora of substance use disorders. The use of interactive information technologies is an important step that may have transformative impact on existing approaches to treatment and permit expansion of treatment, increasing its relevance to patients with the potential to deliver evidence-based treatments in a cost-effective manner.

INTRODUCTION

A number of clinical methods have been developed to detect substance abuse. These include blood tests, urine toxicology screens, self-report measures, structured interviews, and educated guessing based on clinical experience. Blood tests (such as liver function tests) may detect organ damage or malfunction, but only identify those patients with long-term use in whom secondary symptoms have occurred. Early stage substance abuse is rarely identified by this means. In spite of the popularity of urine toxicology (in response to illicit drug use), these screens are able to identify only fairly recent use of a substance and provide no information about frequency or length of use. Urine, blood, and breath tests are all relatively unreliable indicators of alcohol use, as alcohol is metabolized quickly and is unlikely to be detected in body fluids. Educated guessing based on clinical experience may identify some users, but is heavily dependent on the

practitioner's attitudes and experiences. Structured interviewing is time intensive and requires careful training and monitoring that is impractical in most medical settings. Therefore, the most effective method for detecting substance abuse is often via a validated questionnaire-based screening tool. Such screening tools are generally designed to be administered face-to-face, patient to provider. They are not designed to diagnose a substance abuse problem, but are intended to determine if a patient may be at risk or experiencing early stage harm from alcohol or drug use. This earlier detection of problems is generally a precursor to preventive interventions, which aim to avoid the development of serious problems or ameliorate early stage harm (secondary prevention). Thus, this chapter will focus on follow-up, after screening, in the form of brief, preventive interventions rather than treatment per se. However, if screening identifies severe substance use problems it can act as a precursor to assessment and thence specialist treatment.

SCREENING

A current debate concerns the relative merits of two different approaches to screening – universal screening, aimed at all patients attending a medical facility, and targeted screening, aimed at predefined groups of patients such as those attending new patient registrations in general practice, special types of clinic or ward where substance abusers are more likely to be found, and emergency department services where patients present with specific indications for substance abuse. Some research has shown that targeted screening is preferred by both practitioners and patients, but universal screening, if practicable, has the obvious advantage that substance abusers are less likely to be missed. The relative effectiveness, cost-effectiveness, and acceptability of universal versus targeted screening in routine practice are the focus of ongoing research.

Screening for Alcohol

Clinicians are often familiar with laboratory indicators of excessive alcohol consumption, such as mean corpuscular volume, gamma-glutamyl transferase (GGT), and carbohydrate deficient transferrin. However, in medical practice, standardized questionnaires have been found to have a greater sensitivity and specificity than laboratory indicators; they are also far less intrusive and more acceptable to patients. In addition, questionnaire-based screening is less costly than laboratory analysis.

The CAGE questionnaire, named after its four questions, is one such example that may be used to screen patients quickly in a clinical encounter. CAGE is an easy to use, international screening test for identifying patients who are experiencing drinking and potential alcohol problems. The name CAGE is an acronym formed by taking the first letter of key words (cut down, annoyed, guilty, eye opener) from each of the four screening questions:

1. Have you ever felt you should cut down on your drinking?
2. Have people annoyed you by criticizing your drinking?
3. Have you ever felt bad or guilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (eye opener)?

The CAGE questionnaire is best used in a clinical setting as part of a general clinical history taking and should not be preceded by any questions about alcohol intake because its sensitivity is dramatically enhanced by an open-ended introduction. Two Yes responses are considered clinically significant (sensitivity of 93% and

a specificity of 76% for the identification of problem drinking), compared with GGT liver function test that detects only a third of patients having more than 16 standard drinks per day. While the CAGE questionnaire has demonstrated a high effectiveness in detecting alcohol-related problems, it has limitations in people with less severe alcohol-related problems, white women, and college students.

The alcohol use disorders identification test (AUDIT) was the first screening tool designed specifically to detect hazardous and harmful drinking in both primary and secondary health care settings and across a range of different countries and drinking cultures. AUDIT is a 10-item questionnaire that includes items on drinking frequency and intensity (binge drinking), together with experience of alcohol-related problems and dependence (see Fig. 30.1). At a score of 8 or more out of a possible 40, the ability of AUDIT to detect genuine excessive drinkers (sensitivity) and to exclude false cases (specificity) is 92 and 94%, respectively. Thus, AUDIT is a highly accurate tool, which has been validated in a large number of countries with consistently strong psychometric performance. It is now regarded as the “gold standard” screening tool to detect hazardous and harmful drinking in primary care patients. When AUDIT has been applied in routine primary care, approximately one in five patients screen positive for hazardous or harmful alcohol consumption.

Nevertheless, even with just 10 items, the full AUDIT has been considered too lengthy for use in routine practice due to the limited amount of time available to clinicians. Moreover, since four out of every five patients tend to screen negative for hazardous and harmful drinking, clinicians need an efficient detection method of identifying relevant patients needing alcohol intervention. For this reason, several shorter versions of the AUDIT have been developed including the following:

- AUDIT-C – the first three (consumption) items of the full AUDIT. A score of 5+ indicates hazardous or harmful drinking.
- AUDIT-PC – the first two (consumption) questions of the full AUDIT plus items 4, 5, and 10, which focus on alcohol-related problems and possible dependence. A score of 5+ indicates hazardous or harmful drinking.
- Fast alcohol screening test – a two-stage screening procedure based on four of the original AUDIT items. Item 3 is asked first and classifies over half of respondents as either nonhazardous or hazardous drinkers. Only those not classified at the first stage go on to the second stage, which consists of AUDIT items 5, 8, and 10. A response other than “never” to any of these three items classifies the respondent as a hazardous drinker.

Question	Scoring System					Your Score
	0	1	2	3	4	
How often do you have a drink that contains alcohol?	Never	Monthly or less	2–4 times a month	2–3 times a week	4+ times a week	
How many standard alcoholic drinks do you have on a typical day when you are drinking?	1–2	3–4	5–6	7–9	10+	
How often do you have 6 or more standard drinks on one occasion?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
How often in the last year have you found that you were not able to stop drinking once you had started?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
How often in the last year have you failed to do what was expected of you because of drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
How often in the last year have you needed an alcoholic drink in the morning to get you going?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
How often in the last year have you had a feeling of guilt or regret after drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
How often in the last year have you not been able to remember what happened when drinking the night?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
Have you or someone else been injured as a result of your drinking?	No		Yes, but not in the last year		Yes, during the last year	
Has a relative/friend/doctor/health worker been concerned about your drinking or suggested you cut down?	No		Yes, but not in the last year		Yes, during the last year	

Scoring: 0–7 = sensible drinking; 8–15 = hazardous drinking; 16–19 = harmful drinking; 20+ = possible dependence.

FIGURE 30.1 Alcohol use disorders identification test (AUDIT).

- Single alcohol screening questionnaire – “When was the last time you had more than “ x ” drinks in one day?” (where $x = 5$ for men and 4 for women (US values) and 8 for men and 6 for women (UK values)) – Possible responses are never, over 12 months, 3–12 months, and within 3 months. The last response suggests hazardous or harmful drinking.

These short instruments take less time to administer than the full AUDIT but they are generally less accurate than the longer tool. In addition, they do not clearly

differentiate between hazardous, harmful, and dependent drinking. Nevertheless, a recent review of AUDIT and its shorter variants reported that the shorter tools have relatively good psychometric properties and that AUDIT-C in particular was nearly as accurate as the full AUDIT. Thus, a pragmatic approach for primary care clinicians may be to use AUDIT-C as a prescreening tool to quickly filter out negative cases, and then administer the remaining seven AUDIT questions to the smaller pool of positive cases to provide an accurate and differential assessment of alcohol-related risk or harm.

Screening for Tobacco

There are a number of questionnaires that have been designed specifically to measure tobacco dependence. The most commonly used tobacco dependence measures are the Fagerström tolerance questionnaire (FTQ) and the Fagerström test for nicotine dependence (FTND). The scales' brevity and relations with relapse make them valuable clinical tools. The FTND (see Fig. 30.2) is preferred over the FTQ because of its enhanced reliability and equal or better predictive validity.

A 10-item self-report questionnaire, the tobacco dependence screener, has also been developed for screening for tobacco/nicotine dependence. However, tobacco/nicotine dependence is defined as a cluster of cognitive, behavioral, and physiological symptoms for which the individual attributes use of tobacco despite significant tobacco-related problems. Earlier detection of problems is necessary for preventive interventions,

which aim to avoid the development of serious problems or ameliorate early stage harm. Some screening tools are available that include questions about tobacco such as the World Health Organization Alcohol, Smoking and Substance Involvement Screening Test and because *any* current tobacco use places a patient at risk these screening tools only need to include a single question about tobacco use.

Screening for Other Drugs

Because drugs eventually show up in body fluids and hair, in one form or the other, clinicians can detect drug abuse by chemical analysis of a given specimen. The most common forms of analysis are of the hair, blood, saliva, sweat, and urine. As urine analysis is less invasive than blood analysis, it is typically the least expensive and can detect infrequent or recent single use and is the most commonly used drug test. However, these

1. How soon after you wake up do you smoke your first cigarette?

Within 5 minutes	(3 points)
5 to 30 minutes	(2 points)
31 to 60 minutes	(1 point)
After 60 minutes	(0 points)
2. Do you find it difficult not to smoke in places where you shouldn't, such as in church or school, in a movie, at the library, on a bus, in court or in a hospital?

Yes	(1 point)
No	(0 points)
3. Which cigarette would you most hate to give up; which cigarette do you treasure the most?

The first one in the morning	(1 point)
Any other one	(0 points)
4. How many cigarettes do you smoke each day?

10 or fewer	(0 points)
11 to 20	(1 point)
21 to 30	(2 points)
31 or more	(3 points)
5. Do you smoke more during the first few hours after waking up than during the rest of the day?

Yes	(1 point)
No	(0 points)
6. Do you still smoke if you are so sick that you are in bed most of the day or if you have a cold or the flu and have trouble breathing?

Yes	(1 point)
No	(0 points)

Scoring: 7–10 points = highly dependent; 4–6 points = moderately dependent; less than 4 points = minimally dependent.

FIGURE 30.2 Modified Fagerström test for nicotine dependence. Adapted from Heatherton TF, Kozlowski LT, Frecker RC, Fagerström KO. The Fagerström test for nicotine dependence: a revision of the Fagerström Tolerance Questionnaire. *Br J Addict* 1991;86:1119–27

tests provide no information about frequency or length of use and a distinction must be made between testing for drug use (such as random drug testing in the workplace) and screening in order to determine if a patient may be at risk or experiencing early stage harm from drug use and therefore benefit from preventive interventions. Screening tools are available for drug use or abuse.

The drug abuse screening test (DAST) was developed in 1982 and is still an excellent screening tool. It is a 28-item self-report scale that consists of items that parallel those of the Michigan alcoholism screening test (MAST). The DAST includes both the use of prescribed or "over the counter" drugs in excess of the directions and any nonmedical use of drugs. The various classes of drugs may include and are not limited

to cannabis (e.g. marijuana, hash), solvents (e.g. gas, paints etc.), tranquilizers (e.g. Valium), barbiturates, cocaine, and stimulants (e.g. speed), hallucinogens (e.g. LSD) or narcotics (e.g. Heroin). It does not refer to alcohol or tobacco. The DAST is one of the most widely used screening tests for drug abuse and addiction (see Fig. 30.3).

The DAST has exhibited valid psychometric properties and has been found to be a sensitive screening instrument for the abuse of drugs other than alcohol. A score of "1" is given for each Yes response, except for items 4, 5, and 7, for which a No response is given a score of "1." Based on data from a heterogeneous psychiatric patient population, cutoff scores of 6 through 11 are considered to be optimal for screening for

The following questions concern information about your involvement with drugs. Drug abuse refers to (1) the use of prescribed or "over-the-counter" drugs in excess of the directions, and (2) any non-medical use of drugs. Consider the past year (12 months) and carefully read each statement. Then decide whether your answer is YES or NO and check the appropriate space. Please be sure to answer every question.

	YES / NO
1. Have you used drugs other than those required for medical reasons?	___ ___ *
2. Have you abused prescription drugs?	___ ___
3. Do you abuse more than one drug at a time?	___ ___ *
4. Can you get through the week without using drugs (other than those required for medical reasons)?	___ ___
5. Are you always able to stop using drugs when you want to?	___ ___ *
6. Do you abuse drugs on a continuous basis?	___ ___
7. Do you try to limit your drug use to certain situations?	___ ___
8. Have you had "blackouts" or "flashbacks" as a result of drug use?	___ ___ *
9. Do you ever feel bad about your drug abuse?	___ ___ *
10. Does your spouse (or parents) ever complain about your involvement with drugs?	___ ___ *
11. Do your friends or relatives know or suspect you abuse drugs?	___ ___
12. Has drug abuse ever created problems between you and your spouse?	___ ___
13. Has any family member ever sought help for problems related to your drug use?	___ ___
14. Have you ever lost friends because of your use of drugs?	___ ___
15. Have you ever neglected your family or missed work because of your use of drugs?	___ ___ *
16. Have you ever been in trouble at work because of drug abuse?	___ ___
17. Have you ever lost a job because of drug abuse?	___ ___
18. Have you gotten into fights when under the influence of drugs?	___ ___
19. Have you ever been arrested because of unusual behavior while under the influence of drugs?	___ ___
20. Have you ever been arrested for driving while under the influence of drugs?	___ ___
21. Have you engaged in illegal activities in order to obtain drug?	___ ___ *
22. Have you ever been arrested for possession of illegal drugs?	___ ___
23. Have you ever experienced withdrawal symptoms as a result of heavy drug intake?	___ ___ *
24. Have you had medical problems as a result of your drug use (e.g., memory loss, hepatitis, convulsions, bleeding, etc.)?	___ ___ *
25. Have you ever gone to anyone for help for a drug problem?	___ ___
26. Have you ever been in a hospital for medical problems related to your drug use?	___ ___
27. Have you ever been involved in a treatment program specifically related to drug use?	___ ___
28. Have you been treated as an outpatient for problems related to drug abuse?	___ ___

* Denotes questions used for DAST-10

FIGURE 30.3 The drug abuse screening test (DAST). Adapted from Skinner, H.A. The drug abuse screening test. *Addict Behav* 1982; 7(4):363-71.

substance use disorders. Using a cutoff score of 6 has been found to provide excellent sensitivity for identifying patients with substance use disorders as well as satisfactory specificity (i.e. identification of patients who do not have substance use disorders). Using a cutoff score of <11 somewhat reduces the sensitivity for identifying patients with substance use disorders, but more accurately identifies the patients who do not have a substance use disorder. Over 12 is definitely a substance abuse problem. In a heterogeneous psychiatric patient population, most items have been shown to correlate at least moderately well with the total scale scores.

The DAST-10 is a 10-item, Yes/No, self-report instrument that has been shortened from the 28-item DAST taking less than 8 min to complete. The DAST-10 was designed to provide a brief instrument for clinical screening and treatment evaluation and can be used with adults and older youths. It is strongly recommended that the short MAST be used along with the DAST-10 unless there is a clear indication that the patient uses no alcohol at all. For the DAST-10, 0 indicates no problems reported, 1–2 low-level problem, 3–5 moderate problem, 6–8 substantial problem, and 9–10 severe problem (see Fig. 30. 3).

A single screening question “How many times in the past year have you used an illegal drug or used a prescription medication for nonmedical reasons?” has recently been shown to be successful at identifying drug use in primary care. The single screening question was 100% sensitive for identifying a drug use disorder and 74% specific. The single question screen accurately identified a broad spectrum of drug use in a sample of primary care patients. The use of a brief screen is often desirable in identification of drug use in primary care settings, which should in turn facilitate the implementation of brief intervention programs in this setting.

BRIEF INTERVENTIONS

Two basic forms of brief intervention have been identified, simple brief intervention (structured feedback and advice) and extended brief intervention (brief behavioral counseling).

Definition of Simple Brief Interventions

Brief interventions refer to a range of clinical activities focused on the use of a talk-based therapeutic approach aimed at changing certain health-limiting behaviors (usually smoking, heavy drinking, or other drug use) and their associated problems. Brief interventions have been applied opportunistically to nontreatment-seeking populations, with the core aim of secondary prevention, as well as to those undergoing treatment (sometimes referred to as brief treatments). Key components of brief interventions include simple structured advice, written information, behavior change counseling (BCC), and motivational interviewing and each of these elements can either occur alone or in combination with each other.

Brief interventions have also been delivered either in a single appointment or a series of related sessions. Sessions can last between 5 and 60 min, and while brief interventions for nontreatment-seeking populations do not tend to exceed five sessions in total, those in treatment can have many more than five sessions including cognitive-behavioral therapy (CBT) and motivational interviewing. Although there is a wide variation in brief intervention activities, there are a number of essential principles to delivery; brief interventions should obviously be short and should be deliverable by health professionals without specialist training and who are working in busy health care settings. Brief interventions are often based on a fundamental set of ingredients summarized by the acronym FRAMES (see Box 30.1).

BOX 30.1

FRAMES

Feedback	Provides feedback on the client's risk for behavior
Responsibility	The individual is responsible for change
Advice	Advises reduction or gives explicit direction to change
Menu	Provides a variety of options for change
Empathy	Emphasizes a warm, reflective, understanding approach
Self-efficacy	Encourages optimism about changing behavior

Again, given the variability in activity, it is important to explain that brief interventions are *not* merely traditional treatments (psychiatric or psychological) carried out in a short timescale; they have more specific properties than that. Brief interventions are techniques that a variety of health professionals (physicians, nurses, pharmacists, health workers, drug workers, social workers, psychiatrists, etc.) can easily incorporate into their practice in a variety of cultural settings, populations, and health care systems.

Brief interventions, particularly for alcohol and tobacco, are supported by a large literature on their efficacy and cost-effectiveness with a wealth of trials and meta-analyses indicating that both opportunistic brief interventions delivered by generalists and brief treatment delivered by addiction specialists are efficacious as a secondary prevention and as a treatment strategy, respectively.

Opportunistic brief intervention is made up of interventions typically designed for and evaluated among individuals not seeking help for substance abuse problems who are identified by opportunistic screening in primary health care settings. Such individuals often have less severe problems and lower motivation for change. These interventions are typically shorter, less structured, less theoretically based, and delivered by a nonspecialist.

Brief treatment has typically been evaluated among individuals seeking or being persuaded to seek treatment for substance abuse problems. These interventions are usually longer, more structured, theoretically based, and delivered by a specialist. As brief interventions are now increasingly being evaluated in the context of illicit drug use, the distinction between generalist and specialist delivery is becoming increasingly blurred although the evidence for brief interventions in nontreatment seekers is stronger than those in treatment settings. Brief interventions are also highly cost-efficient due to the minimal cost of the intervention and the breadth of scope for prevention of more serious and costly problems. Brief interventions are particularly effective in the field of substance use.

Definition of Extended Brief Interventions

An extended brief intervention typically takes 20–30 min to deliver and can involve a small number of repeat sessions. It is essentially a condensed form of “motivational interviewing” in which an attempt is made to elicit, rather than impose, an increase in motivation to change behavior. More specifically, extended brief intervention is based on generic principles of health behavior change described by Rollnick and colleagues. The level of training required to carry out this form of brief intervention effectively is substantially

greater than that for simple advice and should involve an emphasis on experiential learning.

Brief Interventions Theory

Brief interventions are firmly grounded in theory from the field of psychology, which is concerned with understanding, predicting, and changing human behavior. Different theories are relevant to the context for brief interventions and its content or delivery mode.

In general terms, the principles of brief interventions are broadly based on social cognitive theory, which is drawn from the concept of social learning by Albert Bandura. Consequently, brief interventions address, in a structured format, an individual’s knowledge, attitude, and skills in relation to behavior so as to encourage behavior change for subsequent health benefit.

In terms of therapeutic application, brief interventions in pioneering research were based on principles of CBT, which was itself closely linked to the social learning perspective. CBT is a talk-based treatment designed to make individuals change how they think (cognitive) and what they do (behavior). Unlike some other therapies it focuses on “here and now” problems and difficulties instead of focusing on causes or symptoms in the past.

Recently in brief interventions research and practice there has been a move away from condensed CBT toward adaptations of motivational interviewing (MI). MI is a patient-centered interviewing style with the goal of resolving conflicts regarding the pros and cons of change, enhancing motivation, and encouraging positive changes in behavior. The interviewer style is characterized by empathy and acceptance, with an avoidance of direct confrontation. Any statement associated with positive behavior change that the patient brings up in the discussion are encouraged so as to support self-efficacy and a commitment to take action. Although within the time constraints for brief interventions, particularly in general health and social care settings, it is not possible to carry out MI, the general ethos and some of the techniques of MI can be adapted for this purpose. Adapted or condensed versions of MI are often referred to as BCC or adapted motivational interventions.

The transtheoretical (stages of change) model has been widely used to inform the context for brief intervention activities. Initially developed to describe the stages through which people progress in smoking cessation, this model has since then proved influential in guiding treatment across a range of addictive behaviors. Individuals are characterized as belonging to one of six internal “stages” depending on the individual’s awareness of a problem and their readiness to change behavior to address this problem. The stages consist of

precontemplation (not thinking about change for at least 6 months), contemplation (planning to change in the next 6 months), preparation (planning to change in the next month), action (changing behavior within the last 6 months), maintenance (having changed for more than 6 months), and termination (permanently changed behavior). Individuals progress through these stages sequentially and it may take several cycles around the stages of change (i.e. relapses) before a sustained recovery is achieved. The model also proposed that different self-change strategies or “processes of change” are involved in moving between different stages and that different stages are associated with different beliefs about a problem. It argued that brief interventions to promote change should be designed so that they are appropriate to an individual’s current stage. Although the theory has provided a heuristic model, evaluations to date have not supported its use in improving treatment outcomes.

Interventions for Alcohol

More than a hundred clinical trials have been conducted to evaluate the efficacy and cost-effectiveness of alcohol screening and brief interventions in both nontreatment- and treatment-seeking populations. There is now a very strong evidence base supporting the effectiveness of brief alcohol interventions in reducing alcohol-related problems. Many systematic reviews and meta-analyses have reported beneficial outcomes of brief interventions, compared to control conditions, in terms of reductions in hazardous and harmful drinking. In 2007, a review focusing on primary care identified 29 controlled trials of brief interventions, which included over 7000 patients. This review found that brief interventions produced an average reduction of seven standard drinks (UK = 8 g ethanol) per week and there was no significant benefit of longer (more intensive) interventions compared to shorter input.

Primary Care Settings

In terms of strength of the evidence and relevance to practice, the most obvious setting for early identification of alcohol-related risk and brief intervention to reduce excessive drinking is primary health care. This setting represents most people’s first point of contact with health services in the majority of countries worldwide. Primary care generally refers to general practice-based health care with a relatively large distribution of health centers or doctor’s surgeries across a wide geographical area. However, primary care can be defined as all immediately accessible, general health care facilities that treat a broad range of possible presenting problems, and which can be accessed by a wide range of patients on

demand, and not as the result of a referral for specialist care. Thus, emergency care (accident and emergency departments) can also be considered to be part of primary care.

The most recent review of brief interventions in primary care settings reported a significant reduction in weekly drinking at 1-year follow-up compared to a range of control conditions (such as assessment only, treatment as usual and written information). The magnitude of this effect was an average reduction of 4–5 standard drinks per week. In addition, the review found no significant benefit of increased treatment exposure during brief interventions. Thus, although spending extra time and/or delivering extra sessions did produce some additional reduction in alcohol consumption, this addition was not statistically superior to shorter single-session input. Moreover, there was no significant benefit of extended psychological intervention compared to brief intervention on weekly drinking outcomes. Thus, in primary care contexts, short focused input appears to be the most effective approach to alcohol risk reduction work.

The review considered both the countries that brief intervention trials were based in and the characteristics of patients in these trials. It was clear that the majority of this work had been conducted in the United States and other English-speaking countries, although there was a growing body of work emerging in the Mediterranean countries of Europe and in Scandinavia. However, there was no published research from developing or transitional countries. In addition, the majority of participants in the brief alcohol intervention trials were middle-aged males and there was insufficient work in women, young people, and individuals from black and other minority ethnic backgrounds. Thus, there is a need for more research in the developing world and in different types of drinkers.

Other Medical Care Settings

There is now abundant international evidence that brief interventions delivered in other medical settings are efficacious in leading to reduced alcohol consumption. A comprehensive systematic review of this evidence considered 34 randomized controlled trials carried out in generalist settings among individuals not seeking treatment for alcohol problems. Small to medium aggregate effects were seen consistently across different follow-up points. At follow-ups of between 3 and 6 months inclusive, the effect for brief interventions compared to control conditions was significantly larger when patients showing more severe alcohol problems were excluded from the analysis. Studies conducted in the “real world” conditions of general practice show somewhat less benefit than in those carried out under optimal research

conditions, but they nevertheless support the effectiveness of brief interventions. Equally impressive are the findings of randomized clinical trials carried out in emergency departments, with several large studies in the United States and the United Kingdom showing the positive effects of brief interventions. In general hospital wards, both patients and staff have more time available for screening and brief intervention than in primary care. Research in general hospital wards has been less extensive and evidence for the effectiveness of brief interventions is inconclusive at present, although there seems no good reason in principle why they should not also be effective there.

College Settings

Meta-analyses have consistently reported that students who received brief interventions in educational settings subsequently reduced their drinking behavior compared to control conditions who typically received assessment only. The key elements of the brief interventions were MI approaches and/or personalized feedback on alcohol consumption typically with a normative component. Such brief interventions typically achieved small to medium effect sizes across multiple measures of alcohol consumption including quantity, frequency, and intensity of drinking. The effects of brief interventions seemed to peak in the shorter term and then diminish over time. Indeed, it has been noted that relatively few of the reduced drinking effects seemed to persist beyond 6 months following the intervention. Thus, it is clear that booster or repeated brief intervention sessions may be needed in college populations to help sustain positive changes in drinking behavior. However, while reductions in alcohol-related problems often took longer to emerge, they were reported in longer term follow-up of 1 year to 18 months.

For example, the college drinker's checkup (CDCU) was developed as both a Windows and web-based brief motivational intervention for heavy drinking college students. The CDCU first screens for heavy drinking. Students who screen positive are given personalized feedback and invited to use the rest of the program, which takes about 35 min. The modules include the following:

- A decisional balance exercise to begin the process of considering the "not so good" things they've experienced from their heavy drinking.
- A comprehensive assessment of drinking and drug use, alcohol-related problems, and risk factors for future alcohol-related problems.
- Personalized feedback includes quantity and frequency compared to their gender specific fellow students at their University, blood alcohol content

feedback, and feedback on how their frequency of alcohol-related problems compared to other, same gender students at their school.

- A final module, Consider Your Options, helps students resolve their ambivalence about changing and develop a plan of action to reduce their drinking and risk for alcohol-related problems.

The results of two randomized clinical trials have demonstrated the effectiveness of the CDCU with heavy drinking college students. Heavy drinking students who used the CDCU reduced their drinking by 43–55% at follow-ups to 12 months.

Another example, Brief Alcohol Screening and Intervention of College Students (BASICS) is a preventive alcohol intervention program for college students of 18–24 years old. It is aimed at students who drink alcohol heavily and have either experienced or are at risk for alcohol-related problems such as poor class attendance, missed assignments, accidents, sexual assault, and violence. BASICS is designed to help students make better alcohol-use decisions. The program

- Reduces the adverse effects of alcohol consumption.
- Promotes reduced drinking.
- Promotes healthier choices among young adults.
- Provides important information and coping skills for risk reduction.

BASICS is conducted over the course of only two 50-min interviews, and these brief, limited interventions prompt students to change their drinking patterns. Before or after the first interview, the student receives a self-report questionnaire to complete. From the questionnaire and the first interview, information is gathered about the student's alcohol consumption pattern, personal beliefs about alcohol, understanding of social alcohol norms, and family history. The second interview, which occurs approximately 1 week after the initial interview, provides the student with personalized feedback on myths about alcohol's effects, facts on alcohol norms, ways to reduce future risks associated with alcohol use, and a menu of options to assist in making changes. As a harm reduction approach, BASICS motivates students to reduce risky behaviors. It can be implemented in a variety of settings including university health and mental health centers, residential units, and administrative offices. Students can be identified through routine screening or through referral from medical, housing, or disciplinary services. BASICS has been evaluated and found to be effective with nontreatment-seeking students in large, traditional university settings but may be tailored for use with young adults in other settings such as the military.

Interventions for Tobacco

Brief interventions were first developed in the smoking cessation field. A study carried out by Russell et al. (1979) revealed that a small proportion (5.1%) of patients had stopped smoking 1 year after their general practitioner provided a simple brief intervention. This intervention comprised brief advice to quit smoking plus a leaflet with additional information to help patients to achieve their goals. While the results from this study appeared modest from a clinical perspective, the authors estimated that such a simple intervention could easily be delivered by physicians to all smokers who consulted; if implemented by all physicians in the United Kingdom, this could potentially result in over half a million smokers quitting each year. They claimed that this figure could not be matched even if the number of specialist smoking cessation services were doubled.

This move toward interventions in nontreatment-seeking populations was perhaps the key principle supporting the development of brief interventions. The potential impact of brief interventions from a public health perspective was huge and coincided with a growing interest in secondary prevention around this time. A model for brief interventions, derived from this pioneering study, continued to be used within the field of smoking cessation; however, it was further applied to other areas of public health. In particular, brief interventions were applied to excessive alcohol consumption in 1983 as coincidental research had highlighted that lower intensity interventions were often as effective as more intensive treatments coupled with moderate alcohol consumption being accepted as a valid treatment goal. Brief interventions for excessive alcohol consumption have subsequently proved successful in a wide range of published studies.

There have also been over 41 controlled trials of brief interventions for smoking cessation. Pooled data from 17 trials of brief advice versus no advice or usual care have shown that brief interventions result in significant increase in smoking cessation among patients. Brief interventions are shown to be even more effective if combined with nicotine replacement therapy. It has been concluded that when health practitioners provide brief interventions for smoking it increases the likelihood that the patient will successfully quit and remain a nonsmoker 12 months later.

The 5 A's, developed by the US Public Health Service, represent a set of clinical practice guidelines for treating tobacco use and dependence in patients. Activities can be divided among the clinical staff, for example a receptionist can provide patients with a questionnaire that asks if the patient uses tobacco, a physician can advise the patient to quit and prescribe pharmacotherapy, a nurse can help the patient create

a quit plan, and a case manager can refer the patient to intensive counseling and provide follow-up. Successful intervention begins with identifying users and appropriate interventions based upon the patient's willingness to quit. The five major steps to intervention are the 5 A's: Ask, Advise, Assess, Assist, and Arrange.

Ask: Systematically identify and document tobacco use status (current, former, never) for every patient on his/her first clinical visit. Update tobacco use status at least annually.

Advise: In a clear, strong, and personalized manner, urge every tobacco user to quit.

Assess: Establish if the tobacco user is willing to quit. Provide a motivational intervention to all users unwilling to quit and repeat at each visit. Diagnose and treat underlying disorders.

Assist: For users willing to quit provide counseling, resources, and pharmacotherapy to help them quit.

Arrange: Schedule follow-up, either in person or on the phone. Provide relapse prevention intervention for all former tobacco users.

Interventions in Other Settings

Unlike smoking, excessive alcohol consumption is associated with social as well as health problems, which means that interventions sometime occur outside of the health context. Prevalence of excessive alcohol consumption is higher amongst those in contact with the criminal justice system. It should be possible to implement brief interventions within the criminal justice system – in prisons, probation settings, and even police stations. Evaluation of brief interventions in a variety of criminal justice settings is ongoing.

Electronic forms of brief intervention can modify behavior compared to controls who generally receive screening or assessment only. However, it is not clear whether electronic forms of brief intervention are as effective as those delivered by therapists since there are conflicting accounts across different trials. One potential source of conflicting findings could be the heterogeneous nature of interventions, which often contain multiple components. Hence, it is difficult to ascertain which components are effective.

Other settings where research studies have shown some positive effects of brief intervention include somatic outpatient clinics, general population health screening work, and workplace or occupational settings. However, more research is needed before we could conclude that brief intervention in these settings was robustly evidence based.

Despite less evidence for the effectiveness of interventions for illicit drug use in nonmedical settings, the

evidence for brief alcohol interventions in nonmedical settings may guide the development of brief interventions for illicit drug use.

Interventions for Benzodiazepines

While only six randomized controlled trials have evaluated brief interventions to reduce benzodiazepine use, all six studies produced positive effects. Brief interventions, consisting of a physician's letter, consultation offer, simple advice, and/or self-help booklet, significantly reduced benzodiazepine use compared to control groups. A systematic review with meta-analysis of brief interventions (e.g. giving simple advice in the form of a letter or meeting to a large group of people) and systematic discontinuation (defined as treatment programs led by a physician or psychologist) found both to be significantly more effective than treatment as usual. Using different inclusion and exclusion criteria, a more recent systematic review with meta-analysis assessing the effectiveness of treatment approaches to assist benzodiazepine discontinuation also concluded that brief interventions were more effective than routine care. Brief interventions in this review consisted of a letter outlining the need to reduce benzodiazepine use, sometimes accompanied by a self-help booklet.

CONCLUSIONS

Research on interventions for alcohol and tobacco has accumulated rapidly during the past two decades. There is now a very large literature on the effectiveness of brief interventions including both opportunistic brief interventions delivered by generalists and brief treatment delivered by addiction specialists. Not only are the procedures generally effective with a variety of population groups, they can be delivered by a variety of health care providers. Less evidence is available regarding brief interventions for other drug users, but several studies show positive effects. There is no reason in principle why some of the findings from the alcohol and tobacco field should not be explored. It could possibly be argued that illicit drug use disorders usually show such a high level of dependence, and/or involve such a strong commitment to a deviant lifestyle that brief interventions are unlikely to be successful. Needless to say, however, these assumptions should be tested and there will almost certainly be exceptional subgroups that may well respond to brief intervention. As indicated above, one example of generalization to substances other than alcohol and tobacco is work on the effectiveness of forms of brief interventions directed against long-term benzodiazepine use in primary health care

populations. Research indicates the global efficacy of brief interventions for illicit and licit drugs in the general population.

MI	motivational interviewing

Glossary

- Behavior change counseling** adapted or condensed version of motivational interviewing.
- Binge drinking** episodic excessive drinking. There is currently no worldwide consensus on how many drinks constitute a "binge," but in the United States, the term is often taken to mean consuming five or more standard drinks (male), or four or more drinks (female), in about 2 h for a typical adult. In the United Kingdom, binge drinking is defined as drinking more than twice the daily limit, that is, drinking eight units or more for men or six units or more for women.
- Brief interventions** a range of clinical activities focused on the use of a talk-based therapeutic approach aimed at changing certain health-limiting behaviors (usually smoking, heavy drinking, or other drug use) and their associated problems.
- Cognitive-behavioral therapy** a talk-based treatment designed to make individuals change how they think (cognitive) and what they do (behavior).
- Dependent drinking** when a person meets diagnostic criteria for alcohol dependence.
- Harmful drinking** when a person drinks over the recommended weekly amount and has experienced health problems directly related to alcohol and will typically meet criteria for alcohol abuse.
- Hazardous drinking** when a person drinks over the recommended weekly limit or binge drinks. Individuals may not yet have any health problems directly related to alcohol, but are increasing the risk of experiencing problems in the future.
- Motivational interviewing** a patient-centered interviewing style with the goal of resolving conflicts regarding the pros and cons of

change, enhancing motivation, and encouraging positive changes in behavior.

Primary health care settings all immediately accessible, general health care facilities that treat a broad range of possible presenting problems, and which can be accessed by wide range of patients on demand, and not as the result of a referral for specialist care.

Screening tool to determine if a patient may be at risk or experiencing early stage harm from alcohol, tobacco, or drug use.

Secondary health care settings health care provided by hospital clinicians for a patient whose primary care was provided by the general practitioner or other health professional who first diagnosed or treated the patient.

Standard drinks a simple way of remembering alcohol strengths. One standard drink is one half-pint of ordinary strength beer, larger or cider (284 ml, 3.5% ABV); one pub measure of spirits (25 ml, 40% ABV); one standard glass of wine (125 ml, 8% ABV); one small glass of sherry (50 ml, 20% ABV). Also referred to as alcohol units.

The transtheoretical model developed to describe the stages through which people progress in cessation across a range of addictive behaviors.

Screening for Mental Disorder in People with Addictive Disorders	300		

THE ISSUE OF COMORBIDITY

Comorbidity is a widely used term that refers to the co-occurrence of two or more mental disorders as defined by the Diagnostic and Statistical Manual of the American Psychiatric Association or International Classification of Diseases (ICD-10). There is considerable comorbidity between substance use disorders and other mental health problems. In people with substance use disorders the most common disorders seen are the anxiety and mood disorders (Hides, Diagnostic Dilemmas in Comorbidity). While figures vary across studies, a third to half of people with a substance use disorder would meet diagnostic criteria for another mental disorder in the previous 12 months. Assessing additional co-occurring disorders in people with a substance use disorder is of particular importance given that the presence of two or more disorders is associated with poorer treatment outcome and greater service utilization. Indeed, the more disorders a person has the greater the impact will be on their ability to function. Finally, the likelihood of keeping an individual in treatment for an optimal period is influenced by whether co-occurring disorders are addressed as part of an integrated treatment approach.

However, it is not simply the presence of another disorder that is of concern. For many people, a substance use disorder may be accompanied by feelings of dysphoria and anxiety that impact on quality life and daily functioning. Such symptoms may not meet diagnostic criteria at the point of first contact with a treatment service, but certainly pose a risk of further exacerbation if not recognized and then addressed within a broader treatment plan.

IDENTIFYING HOW DISORDERS ARE RELATED

The time course and associated symptoms of co-occurring disorders need to be carefully assessed when a person presents with an array of symptoms that could be substance related and also influenced by the presence of another disorder. The possibilities that need to be considered are as follows:

1. Are the symptoms due to either withdrawal or intoxication? If so, comorbidity – a second disorder – is not present. For example, “feeling edgy and restless” could be a symptom of amphetamine intoxication,

alcohol withdrawal or of an anxiety disorder; while “low energy and fatigue” could be a sign of withdrawal from amphetamines or a symptom of depression. If symptoms are substance-related, these symptoms should abate relatively quickly following withdrawal. *See Diagnostic Dilemmas in Comorbidity* for a more detailed discussion.

2. Does the substance abuse cause the co-occurring mental disorder/symptoms? If so, the latter are sometimes referred to as substance-induced disorders. Once again, the symptoms of the co-occurring disorder typically cease within a matter of weeks after substance use has stopped.
3. Does the substance abuse occur only when the mental health symptoms are present? For example, a person who has social anxiety may drink alcohol prior to a social event. As time progresses there is greater reliance on alcohol (exacerbating alcohol problems).
4. Do the co-occurring substance use and mental health symptoms have mutually synergistic effects? This mutual determinism can occur regardless of the causal relationship at the start. So, in addition to the examples given, the first episode of disorder may appear substance-induced, but that may increase the risk of a subsequent independent episode.
5. There may be several disorders present that may not be causally related. For example, a person may have a long-standing alcohol problem and then be exposed to a traumatic event. At presentation there would then be two independent disorders, alcohol abuse and posttraumatic stress disorder (PTSD). The former may be exacerbated by the latter.

PURPOSE AND STRUCTURE OF THE CHAPTER

Fundamental to the delivery of effective treatment is the need to identify those who are either at risk of developing a co-occurring disorder or those who have an existing disorder that requires treatment. This chapter provides an overview of the issues surrounding the screening and assessment of a range of co-occurring disorders and describes measures to assess both comorbid mental disorder/s in people with a substance use disorder and comorbid substance use disorders in people with mental disorders. This consists of an overview of: (1) screening measures, i.e. those who are intended to flag that a disorder may be present, (2) diagnostic measures, i.e. those who lead to a formal diagnosis within the current diagnostic nomenclature of the Diagnostic and Statistical Manual (DSM-IV-TR) and the International Classification of Diseases (ICD 10), and (3) symptom measures that allow for the

measurement of particular symptoms that may or may not meet formal diagnostic criteria. Within each of these three categories we review key instruments that measure general mood states such as anxiety and depression, emotional well being or psychological health. We further include instruments that assess PTSD and personality disorders as these distinct disorders are prevalent in people with substance use disorders. Finally, we review instruments that are designed to measure psychotic symptoms.

PSYCHOMETRIC ISSUES TO CONSIDER WHEN SELECTING A MEASURE OF COMORBIDITY

There is considerable “behind the scenes” work undertaken before a measure is considered to be scientifically robust. The field of study concerned with the development and testing of psychological measures is psychometrics and involves a series of steps that first begins by defining the construct or concept that is being measured such as depression. In the case of self-report instruments or structured interviews, questions are developed around these concepts and scored as present or absent, or rated on a scale with end points reflecting extremes such as “never” or “not at all” to “always” or “all of the time.” It is then important to determine whether this measure has predictive validity. In the case of depression, for example, does the reduction in score on this measure predict improvement over the course of treatment such as a decrease in sadness and hopelessness and an increase in energy level and whether the measure converges with other measures of the same construct (convergent validity)? The accuracy of an instrument is assessed by how well it detects the presence of a disorder (sensitivity) and absence of a disorder (specificity). The validity of an instrument is constrained by its reliability. Inter-rater reliability assesses whether two independent raters would reach the same score or diagnosis (and is relevant to instruments requiring interviewers to observe or rate symptoms); internal consistency is the extent an instrument’s items correlate with each other and form a total score (typically measured by Cronbach’s alpha) and its test-retest reliability measures how stable its scores are over time.

SCREENING FOR MENTAL DISORDER IN PEOPLE WITH ADDICTIVE DISORDERS

Screening instruments are best thought of as a way of “flagging” that there are other important problems that

may need either or both (1) further assessment and/or (2) inclusion in a treatment plan. They are brief, easily administered, and scored and developed for use across a range of settings. There are several well validated and widely used measures for general psychological functioning and well being that can be easily administered. The following are some examples.

The *General Health Questionnaire (GHQ)* is one of the most widely used measures and is particularly sensitive to the presence of psychological problems in individuals presenting in primary care settings. The GHQ28 and GHQ12, with 28 and 12 items, respectively, are well validated and found to be sensitive to the presence of mental health problems such as anxiety, depression, somatic complaints, and social withdrawal. The GHQ has been translated into 38 languages. The widespread use of the GHQ enables comparisons to be made across different populations as well as having well established cut-off scores that indicate "caseness."

A similar instrument that was developed by Kessler and colleagues at Harvard Medical School is the *Kessler-10 (K10)* and the shorter 6-item version (*K6*). The *K10* was originally designed to form the mental health component in the annual United States National Health Interview Survey. Since then, it has been included in many other epidemiological surveys including the United States National Health Interview Survey and the American Indian Services Utilization, Psychiatric Epidemiology, Risk and Protective Factors Project. The *K6* was also in the Australian National Indigenous Health Survey in 2004–2005. The Kessler screens for the presence of psychological distress in the preceding 30 days and has items that cover behavioral, emotional, cognitive, and psychological difficulties which fall into four distinct categories: negative affect, nervousness, lethargy, and agitation. The *K10* has strong psychometric properties and is a good predictor of mental illness. Like the GHQ, it has been translated into many different languages, and these versions are available to download from the Internet.

A well-validated screening measure for PTSD is the *Primary Care Posttraumatic Stress Disorder Screen*. This measure consists of four items that measure the main symptom clusters of PTSD in the last month: reexperiencing, numbing, avoidance, and hyperarousal. Each item on the PC-PTSD is administered with the opening statement, "In your life, have you had any experience that was so frightening, horrible, or upsetting that in the past month you..." Items are scored as yes (1) or no (0) and individual scores are summed to provide an overall score ranging from 0 to 4. This measure has been shown to have strong psychometric properties and has cut-off scores that provide important information on the likelihood of a person needing further assessment of trauma-related symptoms.

There are many people with substance use problems who also have long-standing personality problems that have been found to impact on treatment outcome. For those whose substance use meets diagnostic criteria for abuse or dependence, the estimates for concurrent personality disorder fall between a quarter and half the substance use treatment population (compared with an approximately 10% in the general population). There are relatively few screening instruments developed to flag personality disorders. One that shows promise is the *Standard Assessment of Personality – Abbreviated Scale (SAPAS)*. This clinician-administered scale consists of eight items that are scored as present (1) or absent (0). The SAPAS is quick to administer and derives a single score. A score of three or more may need to be followed up with a more detailed structured interview for personality disorders. The SAPAS tends to be more sensitive to the presence of paranoid, dependent, avoidant, and borderline personality disorders, and is less sensitive to antisocial personality disorder. Given the high rates of antisocial diagnoses typically found in substance abuse treatment settings, clinicians within inpatient substance abuse treatment clinics may also use additional screens.

An alternative to the SAPAS is the *Iowa Personality Disorder Screen (IPDS)*. A mini-structured interview, the IPDS consists of 11 items designed to test each of the 11 DSM-IV axis II disorders. A score of 3 from the following suggests further follow-up: (1) marked shifts in mood, (2) actions directed toward immediate satisfaction, (3) reluctance to confide in others, (4) excessive social anxiety, (5) unwillingness to get involved unless certain of being liked, (6) lack of stable image, and (7) prone to overemphasize importance.

In situations in which a self-report measure is desired to screen for possible personality disorders, clinicians may wish to use the *DSM-IV and ICD-10 Personality Questionnaire (DIP-Q)*. Unlike the SAPAS and the IPDS, the DIP-Q is a questionnaire completed by the client. However, this is a lengthy device with 151 yes/no items plus further rating scales of impairment and ratings of global functioning. As with the SAPAS and the IPDS, the DIP-Q has been validated in substance use treatment samples and has been found to correlate highly with treatment staff ratings of personality.

The final diagnostic category that is worth screening for is the schizophrenia spectrum disorders. While psychotic disorders can be considered to be low prevalence disorders, when present they have considerable impact on treatment course and outcome. *The Psychosis Screener* is one of the several instruments that have been developed to screen for the presence of a psychotic illness such as schizophrenia. This measure was originally developed as screening for psychotic disorders in an epidemiological study of mental health and well

being in Australia. It consists of seven items, although three of these are only asked if the previous question is answered “yes.” Its items are drawn, in part, from the *Composite International Diagnostic Interview (CIDI)*. A score of 1 indicates that there may be psychotic symptoms that require further assessment (Table 31.1).

SCREENING FOR ADDICTIVE DISORDER IN PEOPLE WITH MENTAL DISORDER

There have been several reviews of assessment instruments to identify addictive disorder in people who experience a mental disorder – see examples in the further reading. These instruments may be separated into screening instruments (e.g. AUDIT, SDS, MAST, CAGE, DAST), consumption patterns (Timeline Follow-back), level of dependence (SADQ, SODQ), collateral reports and urine screens, and measures of substance related problems (e.g. DrInC).

Most of these are client self-report measures. However, the AUS/DUS are five-item clinician-administered screens, and the Addiction Severity Index is regarded as a gold standard in substance-related interviews. A new self-report measure, the DrugCheck Problem List accurately predicts substance use disorder in people with psychosis. The problem list identifies areas to address in further assessment and in treatment.

DIAGNOSIS OF COMORBIDITY

A mental disorder is diagnosed when a set of clearly specified criteria for the presence of a disorder has been met within the current diagnostic classification systems: The Diagnostic and Statistical Manual of Mental Disorders (currently in its fourth revision, and draft fifth revision – see website listed at the end of the chapter) and Chapter V: Mental and Behavioral Disorders, of the ICD-10. However, diagnosing both substance use problems and other mental disorders is plagued by difficulties in that symptoms frequently overlap. For this reason, diagnostic assessment should ideally occur following a period of abstinence, or at least when the person is not intoxicated or experiencing substance induced withdrawal. A general rule of thumb is to allow 2–4 weeks since cessation of use in order ensure that there are no confounding effects of either intoxication or substance withdrawal. In services that do not provide this time for assessment, multiple assessments over time can be helpful.

The primary purpose of a diagnosis is to provide clear descriptive categories that allow for more effective treatment planning and patient management. When diagnoses are necessary, the use of structured clinical

interviews to differentiate between comorbid substance misuse disorders and other mental disorders is strongly recommended, as structured interviews are both more accurate and have greater inter-rater reliability than the traditional unstructured diagnostic interview. Indeed, structured interviews are generally considered the “gold standard” of diagnostic assessment. However, they do not typically provide an index of symptom severity, which is important for assessment of changes after treatment. In addition, they are considerably more time-intensive than the screening instruments and other self-report measures, and require training in the administration and scoring of the clinical interview.

There are a number of well-validated structured diagnostic interviews that are based on the DSM. *The Psychiatric Research Interview for Substance and Mental Disorders (PRISM)* was developed specifically for the assessment of comorbid psychiatric diagnoses in people with substance abuse, including an assessment of 20 DSM-IV axis I disorders and 2 axis II disorders: antisocial personality disorder and borderline personality disorder. The interview begins with recording heavy drug and alcohol use across the lifetime. In this way, it is possible to plot the course of symptoms that occur within the context of substance use by taking into account the potential effects of intoxication or withdrawal. A disorder is considered to be substance-induced if (1) all DSM criteria are met, (2) the symptoms occur entirely during a period of heavy substance use or within the first 4 weeks of cessation of use, (3) the substance used is related to the nature of the symptoms shown, and (4) the symptoms are greater than the expected effects of intoxication or withdrawal. There is growing evidence that the PRISM is the most reliable diagnostic instrument when there is comorbidity. However, in common with other diagnostic interviews, the PRISM requires training and establishment of reliability, and takes some time to administer.

The Structured Clinical Interview for DSM Diagnosis (SCID-CV) has been widely used in psychiatric research for many years. While it is not as reliable as the PRISM in determining whether the condition is substance induced, it is still considered to be one of the gold standard instruments. The SCID is organized around disorder classes, which allows the researcher or clinician to tailor a diagnostic assessment. An example question for the diagnosis of a depressive episode is: “In the past month, has there been a period of time when you were feeling depressed or down for most of the day nearly everyday?” – where the clinician rates the patient with a “+” or “0,” followed by prompts for further descriptive information as required. The SCID can be administered in pencil and paper form or in computerized form; there are versions for clinicians (SCID-CV) and for researchers (SCID-RV) with an online resource

TABLE 30.1 Screening Measures for Comorbidity

Screening measures: author and date	Description	Cut off scores
<i>(a) General mental health</i>		
General Health Questionnaire (GHQ): Goldberg, 1972	Designed to screen for psychological distress in the general population. Measures depression, anxiety, somatic symptoms, and social withdrawal. Two versions: a short 12-item version and a 28-item version. Translated across a range of languages.	Cut off available for both. "caseness" GHQ28 = 4, GHQ12 = 3.
Kessler 10, K-6: Kessler, 1996; Andrews and Slade, 2001	Designed to screen for depression and anxiety in the previous 30 days. Consists of 10 items on 5-point rating scales. Translated across a range of languages.	K10 10–15 = low; 16–21 = moderate; 22–29 = high; 30–50 = very high psychological distress.
<i>(b) Trauma/PTSD</i>		
Primary Care PTSD screen (PC-PTSD): Prins et al., 2004; Kimerling et al., 2006	PC-PTSD is a four-item yes/no rated scale to detect PTSD: reexperiencing, numbing, avoidance and hyper-arousal in the past month.	Cut off score of 3 indicates further assessment.
<i>(c) Personality disorders</i>		
Standard Assessment of Personality – Abbreviated Scale: (SAPAS): Moran et al., 2003; Hesse and Moran, 2010	Eight yes/no items deriving a single score with a follow-up question. The SAPAS is a general screen for the presence of a personality disorder. This measure is more sensitive to paranoid, dependent, avoidant, and borderline personality and less sensitive to antisocial personality disorders.	Cut off of 3 indicates the probability of a personality disorder.
Iowa Personality Disorder Scale (IPDS): Langbehn et al., 1999; Casillas and Clark, 2002	An alternative to the SAPAS, the IPDS is a 11-item mini-structured interview that screens for each of the 11 personality disorders in the DSM-IV. Items 1–6 are general screening questions, items 4–8 assess social anxiety and instability.	Cut off of 2–3 for items 1–6; cut off of 2 for items 4–8.
DSM-IV and ICD-10 Personality Questionnaire (DIP-Q): Hesse, 2005	A 151-yes/no item self-report questionnaire with an additional five-item impairment and distress scale and a 100-point global functioning scale as used in the DSM-IV. This questionnaire is based on DSM-IV and ICD-10 axis II criteria. Takes approximately 20 min to complete. Computer scoring recommended.	Cut off for diagnosis require the specified number of criteria as per the DSM/ICD plus a score >1 on the distress scale and global functioning <70.
<i>(d) Psychosis</i>		
Psychosis screener: Degenhardt et al., 2005	Derived from the CIDI the psychotic screener has seven items in total with three only asked if previous questions are positively answered. Items cover delusions of control, thought interference, and passivity, delusions of reference or persecution, grandiose delusions, and whether respondent reports ever receiving a diagnosis of schizophrenia.	Cut off of one indicates likely psychotic case.
<i>(e) Substance use in people with a mental illness</i>		
AUDIT: Saunders et al., 1993	The alcohol use disorders identification test is a 10-item self-report measure those screens of drinking at hazardous and harmful use. Rated on a 4-point Likert type scale, the AUDIT provides a possible score of 0–40. The AUDIT has been validated on a wide range of samples from across the world. The AUDIT assesses quantity and frequency of drinking, binge drinking, alcohol dependency symptoms, and negative consequences from drinking.	Scores of 8 or above suggest hazardous drinking. Scores of 13 or above indicate harmful drinking. Lower cut off has been recommended for women and adolescents.

(Continued)

TABLE 30.1 Screening Measures for Comorbidity—cont'd

Screening measures: author and date	Description	Cut off scores
SDS: Gossop et al., 1995	The severity of dependence scale is a five-item self-report measure that assesses the degree of psychological dependence on a range of drugs. The SDS focuses on anxiety regarding use, impaired control over drug use and excessive preoccupation with drug use. Unlike other measures of drug use severity the SDS does not assess physical symptoms such as withdrawal and tolerance.	Cut off differ across drug of use: 4 for amphetamine, 3 for cannabis and 6 for benzodiazepine.
AUS/DUS: Drake et al., 1996	The alcohol use scale (AUS) and drug use scale (DUS) are five-item clinician administered screens with items based on the DSM-IV criteria for alcohol and drug use disorders during the past six months.	Patients are assigned a score from 1 = no use, 2 = use with impairment, 3 = abuse, 4 = dependence, to 5 = dependence with institutionalization.
DrugCheck Problems list: Kavanagh et al., 2011	The drugcheck problem checklist (PL) predicts substance use disorder in people with a psychosis. It has 12 items rated No (0), 1 (A bit) or 2 (A lot); with eight items adapted from the Problem Drinking Questionnaire, and four items assessing psychological impact of substance use. The problem list identifies areas to address in further assessment and in treatment.	A cut off score of 2 indicates the presence of a DSM-IV abuse or dependence with 97% sensitivity and 84% specificity.

site. Although clinically experienced interviewers tend to achieve better inter-rater reliability and overall diagnostic accuracy than novice interviewers, both groups are able to achieve and maintain high levels of reliability and diagnostic accuracy.

A companion interview for diagnosing axis II disorders, the *Structured Clinical Interview for DSM-IV Personality Disorders* has been developed. This measure covers 11 DSM-IV personality disorders in addition to two personality disorders no longer included in the DSM-IV (depressive and passive aggressive). The SCID-II has been validated across a range of client populations including those with drug and alcohol use disorders. The SCID-II also includes a questionnaire for the client to complete prior to the interview. This “brief screen” takes approximately 20 min to complete. The clinician is then able to follow-up with any endorsed items. The SCID-II is regarded as one of the “gold standards” for assessing axis II pathology. However, structured interviews such as the SCID-II are lengthy and require specialist training. In large part, these limitations have led to the development of shorter, brief screens such as those discussed in the previous section, such as the SAPAS and the IPDS.

The *CIDI*, developed by the World Health Organization, is also a structured symptom interview that provides DSM-IV and ICD-10 diagnoses. As with the SCID it can be administered in either paper and pencil or computer-administered forms; the latter can be completed by patients themselves if they are able to understand the nature and purpose of the questions. A

short form of the CIDI (CIDI-SF) has been developed that can be administered as a screener to rule out nondisordered cases rather than as a diagnostic assessment instrument as it tends to overestimate the rate of diagnoses. The CIDI is supported by 10 centers around the world, where standardized training programs are provided. There is a data entry and scoring program to derive diagnoses.

A third brief structured interview is the *The Mini-International Neuropsychiatric Interview – Version 6 (M.I.N.I.6)*. The M.I.N.I. is a short diagnostic structured interview developed in the United States and Europe, with “Yes/No” items designed to generate positive diagnoses for 23 axis I disorders in the Diagnostic and Statistical Manual-III-R and IV. There are clinician-rated (M.I.N.I.-CR) and patient-rated (M.I.N.I.-PR) versions.

The structured interviews provided by the SCID, CIDI and M.I.N.I.6 cover all diagnoses contained in the DSM and ICD, and it is possible to use particular sections of each instrument to check for the presence of one diagnosis only. However, there are a number of other diagnostic schedules for specific disorders. These are often slightly longer instruments, and in some instances provide more accurate diagnostic classification of individual, targeted disorders. *The Clinician Administered PTSD Scale (CAPS)* is a structured clinician-administered interview designed to assess the 17 PTSD symptoms identified in the DSM-IV and associated features such as guilt over acts, survivor guilt, gaps in awareness, depersonalization, and derealization. The CAPS includes standardized questions to determine the

TABLE 30.2 Diagnostic Interviews for Comorbidity

Diagnostic interviews: author and date	Description
PRISM: http://www.columbia.edu/~dsh2/prism/	Extensive structured interview covering axis I and some axis II disorders (antisocial personality and borderline personality disorder). Current gold standard for differentiation of primary psychotic disorder and schizophrenia disorders. Best used in research settings.
Structured Clinical Interview for DSM Disorders (SCID): Spitzer et al., www.scid4.org	Clinician administered structured interview with modules for various disorder classes. Online or hard copy versions available, and SCID-II for personality disorders (see below).
Composite International Diagnostic Interview (CIDI): Andrews and Peters, 1998.	A structured symptom interview that yields diagnoses according to both the DSM-IV and ICD-10 diagnostic criteria. Available in either hard copy or computerized versions.
Mini International Neuropsychiatric Interview: (MINI): Sheehan et al., 1998, Mordal et al., 2010	Interview with yes/no items designed to generate positive diagnoses for 23 axis I disorders in the DSM-IV. There are clinician-rated (MINI-CR) and patient-rated (MINI-PR) versions.

frequency and intensity of each symptom over the past month, using standard prompt questions and explicit, behaviorally anchored rating scales. The CAPS has been found to be both reliable and valid in a number of different populations (Table 31.2).

ASSESSMENT OF SYMPTOMS

Some of the screening measures reviewed above are also used as symptom measures to track progress across time. Other measures that tend to be longer are also available to monitor change across time. One of the most widely used of these in the substance misuse field is *The Addiction Severity Index (ASI)*, which has been in use for over 25 years. The ASI is a semi-structured interview that assesses the frequency of substance use and areas of everyday functioning that are also affected by substance misuse i.e. poor physical health, distress, family/social environment, employment/financial problems, and legal difficulties. Each item is assessed with reference to two time frames: lifetime and current (past 30 days). The instrument is sensitive to treatment effects and can be used to monitor individuals across several admissions. The ASI is the most widely used instrument in US substance abuse clinics, and is used increasingly in other countries. It has been made freely available in the public domain, promoting its use and increasing the rich source of information on cross cultural applicability and validity. There are also shorter versions available which tend to be used by treatment agencies rather than researchers. The ASI-Lite, is made up of 111 items and can be administered in approximately 30–40 min.

Another frequently used measure is the *Health of the Nation Outcome Scale (HoNOS)*. This is a clinician-rated

instrument with 12 items that measure behavior, impairment, symptoms, and social functioning on a five-point scale (0 = no problem, 1–4 = minor problem to very severe problem) in the previous two weeks. There are versions designed for adults, children, and older adults. While the HoNOS appears psychometrically sound, there have been concerns regarding accuracy of symptom description, complexity of social items, and the subjective nature of terminology used. In addition, the measure does not appear to be sufficiently sensitive to cultural differences. As with other clinician-rated instruments, training and ongoing monitoring of inter-rater reliability are needed to ensure ratings are accurate.

There are also many self-report instruments that can be used to track symptom course for the mood and anxiety disorders. Those that are widely used include *The Beck Depression Inventory (BDI)*, a 21-question self-report inventory, the *Spielberger State Trait Anxiety Inventory*, and the *Depression Anxiety and Stress Scale*. All are also well validated and have been shown to be sensitive to treatment gains. The *Adult Wellbeing Scale*, although less well known, has been recommended as a key measure of parental functioning under the framework for the assessment of children, Department of Health, UK. In addition to these measures are a number of instruments developed to assess the severity of psychotic symptoms. One of these is *The Brief Psychiatric Rating Scale*. This is administered by a clinician or researcher to measure psychiatric symptoms such as depression, anxiety, hallucinations, and unusual behavior associated with psychosis. Finally, the *Posttraumatic Stress Symptom Scale Self-Report (PSS-SR)* is a self-report version of the structured interview for PTSD. The 17 items on this scale are identical in content to the interview, but contain simplified wording. The

TABLE 30.3 Description of Symptom Measures

Symptom measures: author and date	Description	Norms and cut-off scores
<i>(a) General mental health</i>		
The Addiction Severity Index: McLellan et al., 1992, 2006; Makela, 2004. http://www.tresearch.org/resources/instruments.htm	A semi-structured interview of frequency of substance use and associated problems, lifetime and current (past 30 days).	Extensive normative data available, accessible through websites and publications (e.g. McLellan et al., 2006)
Health of the Nation Outcome Scale (HoNOS): Wing et al., 1996	A semi-structured interview consisting of 12 items assessing psychosocial functioning of respondents in treatment for a range of disorders. Uses a five point rating scale covering the previous 2 weeks.	Both adult and adolescent/child (Health of the nation outcome scale for children and adolescents; HoNOSCA) norms are available.
<i>(b) Mood disorders</i>		
Beck Depression Inventory-II: Beck et al., 1996	The Beck Depression Inventory (BDI, BDI-IA; BDI-II) is a 21-question multiple choice self-report inventory, with items rated from 0–3 according to frequency in past week.	Cut off score on the BDI-11: 0–13 (minimal depression), 14–19 (mild depression), 20–28 (moderate depression), 29–63 (severe depression)
The Spielberger State Trait Anxiety Inventory: Spielberger, 1983	The STAI comprises two 20-item scales: the state measure assesses how respondents feel “right now, at this moment,” and the Trait measure targets how respondents “generally feel.” The scale has been used in thousands of studies and translated to over 30 languages.	Both percentile ranks and standard (<i>T</i>) scores are available for male and female adults in three age groups (19–39, 40–49, 50–69). Norms also available for high school students.
The Adult Well Being Scale: Snaith, 1978	18 item measure of adult well being with four subscales: depression anxiety, outward irritability, and inward irritability	Scoring available on website framework for the assessment of children, UK.
<i>(c) Psychoses</i>		
Brief Psychiatric Rating Scale: (BPRS) Overall and Gorham, 1962; Leucht et al., 2005	The BPRS is a rating scale in which a clinician or researcher may use to measure psychiatric symptoms such as depression, anxiety, hallucinations, and unusual behavior. Each symptom is rated 1–7 and depending on the version between a total of 18–24 symptoms are scored.	Norms are available for a range of diagnostic samples.
<i>(d) Trauma/PTSD</i>		
Posttraumatic Stress Symptom Scale Self Report (PSS-SR): Foa et al., 1993, 1997, 1999	Is a 17 item self-report version of Foa’s structured interview for PTSD. The questions correspond to DSM-IV symptoms so that the measure permits diagnosis of the disorder. Subscale scores are calculated by summing symptoms in the reexperiencing (four items), avoidance (seven items), and arousal (six items) clusters.	Cut off score of 13 indicates likelihood of PTSD. Norms available for men and women who have suffered a traumatic event.

questions correspond to DSM-IV symptoms so that the measure permits diagnosis of the disorder. The PSS-SR is intended for use with individuals who have a known assault history. If the background information is unknown, the PSS-SR should be used in conjunction with a trauma screen (Table 31.3).

SUMMARY AND CONCLUSIONS

In summary, epidemiological and clinical studies indicate that people with a substance misuse problem typically

also experience a range of other mental disorders or psychological problems. These may be separate diagnoses and may or may not predate the substance misuse problem. However, as there is growing consensus that it is important to treat both problems in an integrated manner, it is necessary to determine the most efficient method for assessing for co-occurring symptoms/disorders. We have presented a range of measures that may be selected to screen for the presence of a disorder, be used to determine if diagnostic criteria are met for the disorder and finally to measure symptom changes over time. Awareness and consideration of the full range of

factors that may contribute to substance use problems is the first important step in treatment planning.

Glossary

- Convergent validity** the extent to which a measure is associated with other measures of the same construct.
- Cronbach's alpha** an index of internal consistency of a questionnaire or scale.
- Cut-off scores** scores on a measure that best identifies correctly between individuals likely to have a disorder and individuals unlikely to have a disorder.
- Inter-rater reliability** the extent of agreement between two or more raters on measures that require a judgmental score/diagnosis.
- Norms** a summary of measure scores including typical means for various clinical and nonclinical populations obtained from large, representative samples.
- Predictive validity** the extent to which scores on a measure are predictive of future behavior and emotions assessed by the measure.
- Psychometrics** the field of study concerned with the development and testing of psychological measures.
- Reliability** the extent to which a measure consistently assesses a disorder or symptoms of a disorder.
- Sensitivity** the accuracy of correctly detecting the presence of a disorder.
- Specificity** the accuracy of correctly identifying the absence of a disorder.
- Test-retest reliability** the extent to which scores on a measure change across time in the absence of treatment.
- Validity** the extent to which a measure accurately assesses the construct that was designed to measure.

Common Comorbid Disorders	309	Alternative Models of Comorbidity	313
Psychiatric Nomenclature and Comorbidity	310	Summary and Conclusions	314
Structured Clinical Interviews	311		

INTRODUCTION

The high rates of comorbid mental health and substance use disorders and the poor clinical, functional, and treatment outcomes associated with them make the accurate diagnosis of comorbid disorders an important clinical priority. However, a number of diagnostic dilemmas associated with the presence of comorbid disorders have hindered our understanding of the etiology of comorbid disorders and our ability to effectively treat them. This chapter begins by discussing the prevalence of common comorbid disorders. The diagnostic dilemmas created by comorbid disorders and issues with the reliability, validity, and clinical utility of current systems of psychiatric nomenclature's approach in diagnosing comorbid disorders will then be briefly reviewed. A number of alternative models for understanding comorbid disorders will be briefly discussed, followed by suggestions for how research can improve our understanding of comorbid disorders.

COMMON COMORBID DISORDERS

Alcohol and cannabis are the most commonly used licit and illicit drugs in the world. Affective and anxiety disorders are also highly prevalent worldwide. Data

from the United States National Comorbidity Survey-Replication indicated that 26.2% met criteria for a mental health disorder in the past 12 months, including anxiety (18.1%), mood (9.5%), impulse control (8.9%), and substance use disorders (3.8%). Similar 12-month prevalence rates of mental health disorders (20%) were reported in the Australian National Survey of Mental Health and Wellbeing (NSMHWB) indicating that 14.4% had an anxiety disorder, 6.2% had an affective disorder, and 5.1% had a substance use disorder. Depression is now the leading global cause of years lost to disability and alcohol and drug use disorders rank in the top 10 most disabling conditions in the developed world. Alcohol is a major risk factor for chronic disease and injury and is responsible for 3.8% of all deaths and 4.6% of global disability-adjusted life-years worldwide.

Epidemiological data consistently indicate that mental health and substance use disorders frequently co-occur. The 2010 Australian National Drug Strategy Survey reported recent drinkers who drank at least once a week (>4 standard drinking units) were more likely to be diagnosed with a mental illness (13.6%) than low risk drinkers (11.1%). Cannabis users in the previous 12 months (18.7%) or in the previous month (20.5%) were also more likely to have been diagnosed with mental illness than nonusers (11.3%).

Comorbidity is not random, and some disorders occur much more frequently than others. Substance use disorders are particularly prevalent among individuals with bipolar disorder, with population estimates of a 12-month prevalence rate of 33%. Large-scale international surveys have found consistently high rates of cannabis use in psychotic populations. For example, the Australian NSMHWB found that cannabis-dependent individuals were 11 times more likely to screen positively for psychosis. Community studies conducted in the United States and Australia found that individuals with alcohol dependence are 3–4 times more likely to have a concurrent anxiety or affective disorder compared to the general population. Cannabis dependence has been associated with between 3 and 6 times the risk of a comorbid mood or anxiety disorder.

Even higher rates of comorbid disorders are found within treatment settings. Between 30 and 50% of individual presenting to alcohol/drug or mental health treatment services meet criteria for comorbid substance use and depression disorders. High rates of comorbid alcohol and anxiety disorders (15–45%) have also been documented, with comorbid alcohol and social anxiety or posttraumatic stress disorder (PTSD) the most common. Of particular concern are the high rates of comorbid cannabis use and psychotic disorders, with recent studies reporting rates ranging from 40 to 74%.

PSYCHIATRIC NOMENCLATURE AND COMORBIDITY

Such high levels of comorbid disorders pose a significant challenge to diagnostic systems such as the *Diagnostic and Statistical Manual* (DSM) and the *International Classification of Diseases* (ICD). These diagnostic systems were developed to improve the reliability of clinical diagnoses and enhance treatment planning and outcomes. However, clinical diagnoses may be unreliable due to five sources of error variance. This includes subject variance, in which individuals have different diagnoses at different times, occasion variance in which individuals may be in different stages of the same condition at different times, and observation variance due to clinicians noticing different things about the same patient. The two largest sources of unreliable diagnoses are information variance, which occurs when clinicians have different sources of information, and criterion variance, when clinicians vary diagnostic criteria. These sources of diagnostic variance are even more pronounced among individuals with comorbid disorders, as clinicians need to identify two or more comorbid disorders, based on a complex history, typically provided by an acutely unwell patient over a short time-frame, with little collateral information available.

The diagnosis of comorbid mental health and substance use issues is further complicated by variability in the nature of the relationship between the disorders (*see* Models of Relationships between Substance Use and Mental Disorders). First, comorbid mental health and substance use disorders may represent two or more independent conditions with their own clinical course, treatment needs, and outcomes. Second, there may be an interaction between mental health and substance use disorders. Substance use may contribute to the onset, course, and relapse of mental health problems, such as the growing evidence for the influence of cannabis use on the onset, course, and relapse of psychosis. Third, substance use may develop secondary to a mental health condition in an attempt to alleviate the symptoms of the disorder or the side effects of psychiatric medications. For example, the relief of depression and anxiety symptoms are the commonly reported reasons for substance use among a range of comorbid populations. Finally, mental health symptoms may develop as a consequence of substance use. For example, substance users often present with a depressed mood as well as a number of other symptoms of major depressive disorder (MDD) including anhedonia, poor sleep, and feelings of hopelessness, suicidal ideation, and intent. The relationship between mental health and substance use disorders may also be bidirectional, where the disorders interact to mutually influence the course and outcomes of each disorder. For example, while cannabis use has been strongly associated with psychotic symptom severity and relapse, there is also evidence that individuals may increase their cannabis use in response to exacerbations in psychotic symptoms. Thus, after identifying the presence of comorbid disorders, clinicians must develop an understanding of the relationship between the mental health and substance use disorders in order to develop a case formulation and treatment plan.

The multiaxial format of both the ICD and the DSM allows for the recording of comorbid disorders as well as other presenting problems on multiple domains. Traditionally, comorbidity was defined according to primary and secondary disorders, in which the primary disorder was usually defined by chronology. However, this approach provides little information on the relationship between the comorbid disorders. While several suggestions for improving the recording of comorbid disorders have been made, including the use of asterisks and arrows, or the use special axes (as in the Chinese classification of mental disorders) to denote the potential relationship between comorbid disorders, there has been little uptake of these ideas.

The role of substance-induced disorders (SID) in the high prevalence of comorbid disorders also requires

consideration, as some of the observed relationships between mental health and substance use disorders may be the result of drug intoxication and withdrawal. For example, the resemblance of the intoxication and withdrawal effects of substances such as cannabis and stimulants to the symptoms of psychosis (e.g. persecutory ideas) make it difficult to differentiate substance induced from primary psychotic symptoms. Cannabis-induced psychotic disorder is characterized by the presence of persecutory delusions, anxiety, emotional variability, and depersonalization, while the common symptoms of stimulant-induced psychosis include persecutory delusions, distorted body image, misperception of people's faces and tactile hallucinations (bugs under skin). Substance-induced depression disorders may also develop during alcohol intoxication or withdrawal, or during withdrawal from cannabis, sedatives, and anxiolytics. The presence of SID has also been associated with intoxication with cocaine, hallucinogens, inhalants, opiates, PCP, sedatives, hypnotics, and anxiolytics.

The prevalence of SID varies across different categories of substances and mental health disorders. For example, up to 40% of alcohol-dependent and 65% of stimulant-dependent individuals will develop SID. Forty-four percent of 386 psychotic patients were found to have a substance-induced psychosis (SIP), while the remaining 56% had primary psychotic disorder (PPD) with concurrent substance use. Cannabis-induced psychosis (19%) was the most common type of SIP, followed by alcohol- (17%) and cocaine-induced psychosis. Similarly, another study found 30% of 1193 alcohol-dependent adults diagnosed with MDD had an SID. A comparatively lower rate (2.4%) of 320 alcohol-dependent adults with anxiety disorders in the same study had a SID, but this is likely to be an underestimate as generalized anxiety disorder and PTSD were not assessed.

The addition of diagnostic criteria for SID to DSM-IV sought to improve the diagnostic reliability of comorbid disorders, by providing information on the specific timeframes and conditions necessary to distinguish substance-induced from primary disorders among individuals with substance use. For example, a DSM-IV diagnosis of SIP is made when psychotic symptoms only occur during periods of heavy substance use, and exceed the expected effects of intoxication or withdrawal. In contrast, a PPD is diagnosed if a full psychotic syndrome (including schizophreniform, schizophrenia, schizoaffective disorder, etc.) is established before substance use onset, if the symptoms are in excess of what would be expected for the type or amount of substance used, or if symptoms persist for more than 4 weeks after the cessation of acute intoxication or withdrawal.

However, the DSM criterion for SID is difficult to apply in clinical practice. The accurate diagnosis of substance induced from primary disorders in the context of substance use relies on clinicians being able to reliably differentiate (1) the expected effects of drug intoxication and withdrawal, (2) mental health disorders occurring during period of active substance use, and (3) mental health disorders that are independent from substance abuse. Clinicians rarely have the opportunity to observe patients during sufficient periods of abstinence (>4 weeks) to accurately differentiate these three conditions. The criteria offer little guidance on the frequency, severity, and duration of psychotic symptoms or substance use required to meet the criteria for an SID. The 4-week timeline also contradicts data relating to the clearance of substances such as cannabis in urine (46–77 days after last consumption). It is also unclear how clinicians are supposed to establish the independence of mental health symptoms from substance use, among substance users. Finally, the term substance-induced is also misleading, as it implies causation, whereas DSM specifies that a diagnosis of SID be used when it is not possible to establish the independence of the psychotic symptoms from substance use.

STRUCTURED CLINICAL INTERVIEWS

A number of structured diagnostic interviews have been developed to improve the reliability of psychiatric diagnoses. However, many of these instruments were not developed specifically to assess comorbid mental health and substance use disorders.

For example, the Structured Clinical Interview for DSM (SCID) differentiates primary from SID by determining (1) if the onset of mental health symptoms preceded alcohol or drugs use and (2) if the mental health symptoms are greater than the extent expected from the effects of the substance itself. This process can be problematic, however, as guidelines on the expected effects of the substances are not provided, nor are specific questions to determine the temporal relationship between mental health symptoms and substance use. These diagnostic issues are highlighted by the results of several studies finding that the SCID has poor levels of inter-rater reliability among substance users. Other diagnostic instruments, such as the Composite International Diagnostic Interview (CIDI), suffer from the same definitional limitations as the SCID and have only moderate levels of reliability among substance users.

Several diagnostic instruments have been designed specifically to differentiate substance induced from primary disorders and improve the reliability of comorbid diagnoses. The Semi-structured Assessment for the

Genetics of Alcoholism (SSAGA), developed for use in population-based studies, provides current and lifetime diagnoses of mental health and substance use disorders, classified as independent, completely co-occurring, or a mixture between the two. The SSAGA takes between 45 min and 4 h to administer and uses a timeline approach to gather detailed information on the chronology of mental health and substance use disorders. A final diagnosis is determined by a clinician following a diagnostic review of all available data sources. The SSAGA has high levels of inter-rater reliability for diagnosing substance use and mental health disorders, but its ability to differentiate substance induced from primary mental health disorders is yet to be determined.

The Psychiatric Research Interview for DSM-IV Substance and Mental Disorders (PRISM) is a valid and reliable measure of current and lifetime DSM-IV substance use, affective (including depressive and bipolar disorders), anxiety, and psychotic disorders, as well as antisocial personality disorder. The PRISM differentiates SID from primary disorders by (1) obtaining a lifetime timeline of periods of heavy substance use and abstinence, (2) determining the temporal relationship of psychotic symptoms and substance use, and (3) providing guidelines for differentiating primary disorders from SID and from the expected effects of intoxication and withdrawal. The PRISM has shown good to excellent test-retest reliability for diagnosing mental health and substance use disorders, as well as differentiating PPD from SIP in two studies of substance-abusing patients. PRISM diagnoses for SIP and schizophrenia have also been shown to have significantly better concordance with diagnoses derived using longitudinal, expert, all data (LEAD) criteria and the SCID. However, the PRISM requires intensive clinical training to administer and takes approximately 2 h.

Thus, structured clinical interviews such as the SSAGA and PRISM can assist with the accurate diagnosis of comorbid disorders by differentiating substance induced from primary mental health disorders. However, these measures are lengthy, and require considerable clinical judgment and intensive training to administer. They also provide little assistance with determining the nature and direction of the relationship between primary mental health and substance use disorders.

Nevertheless, structured clinical interviews like the PRISM can provide a number of hints for improving the reliability of comorbid diagnoses. The development of a timeline of the onset, course and patterns of drug and alcohol use, and psychiatric symptoms over time can facilitate understanding of comorbid disorders. This is particularly effective if the timeline assessment of drug and alcohol use is conducted prior to the timeline assessment of mental health symptoms. The

substance use assessment should include information on the age of onset of regular (weekly) use, patterns of heavy or binge use (at least 4 days a week for a month or 3 days straight), as well as periods of abstinence or minimal use of at least a months duration.

Several indicators of an SIP have been identified in the clinical research literature, which may assist clinician's with the differentiation of substance induced from primary psychotic disorders (with concurrent substance use). Individuals with an SIPD are more likely to have a concurrent substance use disorder and a parental history of substance use, but are less likely to have a family history of psychosis than those with a PPD. SIPD have also been associated with less severe positive and negative symptoms, the presence of visual hallucinations in particular.

Consideration should also be given to the timing of the initial psychiatric assessment, as SID will be most prevalent during drug intoxication or withdrawal. This requires clinicians to be aware of the common signs and length of intoxication and withdrawal from a range of substances. It is also important to note that the first few weeks of abstinence are likely to be associated with the experience of a range of depression-related symptoms.

The assessment of comorbid disorders requires clinicians to take a longitudinal perspective to develop an understanding of the relationships between these disorders over time. The collection of collateral information from multiple sources can also assist with this process. The results of the assessment should be used to develop a biopsychosocial case formulation and treatment plan to ensure the individual receives the most appropriate and effective treatment available.

VALIDITY OF COMORBID DIAGNOSES

A number of the diagnostic issues associated with comorbid disorders may be associated with the validity of the diagnostic categories themselves. Diagnostic validity is demonstrated if one of the two conditions is met. First, if the defining characteristic of the category is a syndrome, then this syndrome needs to be an entity with distinct boundaries that clearly separate it from normality as well as other disorders. Second, if the defining characteristic of the category has a biological basis, this must be clearly differentiated from other disorders that may indeed be conditions with a similar syndrome. Psychiatry is especially prone to problems with diagnostic validity, as most diagnoses are based on a combination of symptoms and there is rarely a genuine discontinuity between the threshold symptoms of a disorder and normality (e.g. most people experience an occasional depressed mood). In addition, there are few (if any) biological tests that are sensitive and

specific enough to establish a psychiatric diagnosis. The presence of comorbid mental health and substance use disorders makes diagnostic validity a particularly challenging issue to address.

Problems with the validity of the diagnostic criteria do not necessarily threaten their value. In psychiatry, there has been an increasing emphasis on the clinical utility of a diagnostic category in recent years, defined as the extent to which it provides distinct information about the etiology, risk factors, course, treatment, and outcomes of a diagnosis, compared to other diagnoses. Research evidence has consistently demonstrated the negative prognostic value of comorbid disorders. For example, comorbid substance use and depression disorders have been associated with more severe depressive symptoms, suicidal ideation, poorer social functioning, and increased service utilization. Relapses and remissions in depressive and substance use disorders among individuals with both disorders have been found to adversely influence the course of the other disorder. Cannabis use has been associated with higher rates of psychotic relapse among individuals with first episode and established psychoses, as well as poorer treatment attendance and medication adherence. There is also preliminary evidence for the clinical utility of SIP, as it is characterized by a higher level of substance use, less severe positive, negative, and general symptoms at initial presentation as well as higher rates of symptom remission over a 12-month follow-up period. Thus, while comorbid diagnoses have been associated with a range of negative outcomes the extent to which different combinations of comorbid disorders have a distinct etiology, clinical course, and outcomes is yet to be determined.

ALTERNATIVE MODELS OF COMORBIDITY

If comorbid diagnoses lack clinical utility and do not have a distinct clinical course and outcomes compared to other disorders, alternative approaches to comorbid mental health and substance use disorders would need to be considered. One approach argues that comorbid disorders are an artifactual by-product of the overlap between the symptoms of several disorders in the current DSM and ICD diagnostic systems. Two potential solutions have been proposed. One involves increasing the specificity of current diagnostic criteria. Another involves “lumping” diagnostic categories together into fewer more broadly defined categories. However, the current diagnostic classification systems were developed to be as simple and broadly applicable as possible to facilitate communication between clinicians and researchers. It is unclear whether redefining or reclassifying diagnostic criteria for mental health and substance

use disorders will overcome the diagnostic issues associated with comorbid disorders, or just create diagnostic issues of their own. It may also be premature to change current diagnostic criteria at a stage when we are only just beginning to understand the genetic, neurobiological, environmental, and psychological etiology of many mental health and substance use disorders.

A number of alternative models for understanding comorbid mental health and substance use disorders have been provided. One approach involves the development of more dimensional models of psychiatric nosology, in which variation in symptoms is considered to be continuous. This model is based on increasing evidence that psychotic symptoms are continuously distributed between the general population and individuals with psychotic disorders. There is also increasing evidence for the clinical utility of dimensional models of depression over categorical models. Substance use disorders are also better represented as a single dimension of dependence rather than separate diagnoses of substance abuse and dependence.

While dimensional models of comorbid disorders are yet to be developed, a number of dimensional models of mental health and substance use disorders have been proposed. One option retains the current categorical diagnoses of mental health and substance use disorders, and examines the size and the direction of the relationship between the comorbid disorders. “Symptom network models,” which conceptualize comorbidity as a network of symptoms of distinct disorders, which are directly (possibly causally) related to one another, could also be applied to the development of dimensional models of comorbidity. It has been argued that such a network approach more accurately reflects the reality of comorbidity, as it allows for (1) multiple etiological processes that interact in causing symptoms, (2) interindividual differences in the manner in which a constellation of symptoms is contracted, (3) direct relations between overlapping symptoms, and (4) inequality of symptoms. However, the reliability, validity, and clinical utility of any of these alternative models of comorbidity are yet to be tested.

A number of advances in statistical modeling including latent class analysis (for categorical data), latent class factor analysis (for both dimensional and categorical measures), and factor mixture analysis have made it possible to quantitatively develop new dimensional models of comorbidity as well as compare these to categorical DSM and ICD diagnoses. These statistical approaches focus on identifying variability both within the individual as well as interindividual differences in the trajectories of mental health symptoms and substance use over predefined periods of time. Mapping changes in the trajectories of both substance use and mental health symptoms (i.e. modeling the

association between latent growth curves for substance use and symptoms) will help us to ascertain the clinical validity of current DSM diagnosis, as well as develop alternative categorical diagnostic and/or dimensional models of comorbidity.

SUMMARY AND CONCLUSIONS

Clinicians are faced with the reality of the diagnostic dilemmas created by comorbid mental health and substance use disorders everyday. The presence of comorbidity requires a comprehensive assessment aimed at developing a biopsychosocial formulation of the comorbid disorders. This requires an understanding of the relationship between the comorbid disorders in terms of whether they are independent entities or interactive. If an interaction between the comorbid disorders is identified, it is important to determine both the nature and direction of the relationship between them. This is complicated by the fact that comorbid relationships may be bidirectional and vary over time.

Increased concerns about the validity of the DSM and ICD diagnostic systems have resulted in an increased focus on the clinical utility of diagnostic categories. While comorbid disorders have consistently been associated with a range of negative outcomes, the extent to which different combinations of comorbid disorders have distinct outcomes is yet to be determined.

A number of alternative models for understanding comorbid disorders have been proposed. The first involves the development of dimensional models of psychiatric nosology in which variation in symptoms is considered to be continuous. The second retains the diagnosis of mental health and substance use disorders, and examines the size and the direction of the relationship between them, while the third proposes the development of new symptom network models of comorbidity, which focus on the direct relationships between the symptoms of comorbid disorders. However, these alternative models of comorbid mental health and substance use disorders are yet to be developed or tested.

There is much to learn about comorbid disorders. Future research aimed at developing alternative models for understanding comorbid disorders is urgently required to determine if these new approaches overcome the diagnostic dilemmas of the current systems of psychiatric nosology. Studies comparing the reliability, validity, and clinical utility of categorical and/or dimensional approaches to comorbid disorders would be most useful at this time. This will require large prospective studies, which systematically map the course of substance use and mental health symptoms, using a combination of structured clinical interviews

(e.g. PRISM) and dimensional measures (e.g. Brief Psychiatric Rating Scale, Timeline Followback Method) and frequent follow-up (at least monthly).

HISTORICAL TREATMENT OF CO-OCCURRING DISORDERS

The historical division in the training of clinicians and the treatment of people with substance use or psychiatric disorders resulted in two approaches to the treatment of co-occurring disorders that predominated until recent years. These two approaches, *parallel treatment* and *sequential treatment*, each have their own significant limitations, as described below. Traditional treatment approaches to treating co-occurring disorders are becoming increasingly obsolete as they are gradually replaced by more nuanced and effective interventions that integrate the treatment of both disorders.

Parallel treatment is when the substance use and psychiatric disorder are treated at the same time by different clinicians who are usually working for different agencies. There are several problems associated with this approach. Although in theory people should be receiving treatment for both their disorders in parallel

treatment approaches, in practice this often fails to occur, for a number of reasons. First, some North American health insurance policies make it difficult or impossible for people to obtain both psychiatric and substance use disorder services provided by different agencies at the same time. Second, people with co-occurring disorders who are receiving treatment from one provider often fail to follow through on referrals for treatment for their other disorder. For example, people with a substance use disorder may not pursue a treatment referral for their psychiatric disorder because of the stigma of mental illness, and either denial or minimization of the effects of this disorder on their life and well-being. Similarly, people receiving treatment for a psychiatric disorder often do not follow through on referrals for treatment of their substance use problems because they lack motivation to seek such treatment, or are unaware of the effects of their substance use on their psychiatric disorder and life. Third, even when people do receive both types of treatment, the services are often poorly

integrated, and sometimes addiction and mental health professionals give inconsistent or even contradictory messages.

In the *sequential treatment* approach, first one disorder is treated or stabilized followed by the treatment of the second disorder. Sequential treatment approaches are often predicated on the assumption that a “primary” disorder can be identified, and the treatment of that disorder may obviate the need to treat the other, or “secondary” disorder. There are several problems with this approach. It is often difficult or impossible to identify which disorder is primary and which is secondary. Co-occurring disorders frequently develop within a relatively narrow time period, making it difficult to accurately determine which came first. Furthermore, delaying treatment in order to attempt to distinguish which disorder is primary often does not yield more conclusive evidence, and can lead to further deterioration in functioning. However, the most significant limitation of sequential treatment is that it fails to take into account the fact that each disorder tends to worsen the other, making it difficult to successfully treat either one alone. For example, it can be difficult or impossible to pharmacologically stabilize a person with bipolar disorder who is actively abusing substances without attending to their substance use. Similarly, addressing substance use problems in a person with poorly controlled symptoms of schizophrenia can also pose a major challenge.

INTEGRATED TREATMENT

The limitations of parallel and sequential treatment approaches to co-occurring disorders have led to the development and growing adoption of integrated treatment approaches. Integrated treatment is defined as when both the psychiatric and substance use disorders are treated at the same time, by the same clinician or same team of clinicians, who assume responsibility for integrating the treatment of both disorders. In addition to the integration of mental health and substance abuse services, effective programs also share several other common characteristics, including comprehensiveness, motivational enhancement, harm-reduction orientation, low stress treatment environment, and pharmacological treatment. These components are briefly described below.

Comprehensive Assessment and Treatment

Substance use disorders in people receiving treatment for a major mental illness are frequently not detected, and hence treatment is often not provided. Similarly, psychiatric disorders are frequently not detected in people receiving treatment for substance use disorders.

Effective integrated treatment requires routine screening for substance use disorders in people receiving psychiatric services, and screening for mental illness in people receiving addiction treatment services. Psychometrically valid assessment instruments have been developed for detecting psychiatric and substance use disorders in these populations.

When a co-occurring disorder has been detected, comprehensive assessment is necessary in order to better understand the nature of each disorder and how the disorders interact with one another. Comprehensive assessment of substance use disorders includes obtaining information about the types of substance used, routes of administration, the situations in which use is most common, the pattern of use over time, and the consequences of substance use. Comprehensive assessment of psychiatric disorders involves the identification of characteristic symptoms and specific psychiatric diagnoses, the individual’s awareness and involvement in the management of the disorder, and its functional consequences in areas such as work, school, social relationships, and independent living. Understanding the individual’s socio-environmental context is also a critical feature of comprehensive assessment, including social support, housing, legal problems, and medical illnesses and related treatment needs.

Developing an understanding of how psychiatric and substance use disorders interact can lead to more effective treatments. For example, an individual with schizophrenia may use alcohol in social situations to feel more comfortable and facilitate contacts with others, suggesting that social skills training may help the individual learn more effective skills for meeting and getting closer to people, and resisting offers to use substances from other people. Similarly, someone with posttraumatic stress disorder (PTSD) may use alcohol in an attempt to cope with the hyperarousal symptoms and sleep difficulties related to their PTSD, suggesting that in addition to overall treatment of their PTSD the person may benefit from learning relaxation and sleep hygiene skills to reduce their susceptibility to using alcohol to cope with these symptoms.

Individuals with co-occurring disorders often experience complex problems, and integrated treatment programs need to have services that address the broad range of needs. For example, common problems in people with co-occurring disorders include housing instability, family conflict, unemployment, health problems, legal problems, and an exploitive social network. Comprehensive treatment requires attention to all of these problem areas if sobriety is to be successfully achieved and maintained, and if psychiatric symptoms are to be stabilized or remission of symptoms sustained. Interventions such as supported housing, family psychoeducation, medical and legal services, supported

employment, and skills training may be critical to addressing these needs.

Motivation-Based Treatment

People with co-occurring disorders often lack motivation to pursue and follow-up on treatment for one, if not both, of their disorders. Integrated treatment needs to enhance and harness motivation to work on these problems. In order to gear treatment to the individual's level of motivation, their motivation to change must be understood.

One useful concept for understanding the role of motivation in behavior change is the stages of change. The *stages of change* concept posits that changes in health behavior (such as substance abuse) occur over a period of discrete stages, with each stage reflecting a different degree of motivation and readiness to change. At the *pre-contemplation stage*, the individual is not even thinking about changing. At the *contemplation stage*, the individual is considering the possible advantages and disadvantages of change. In the *preparation stage*, the person has made a decision to change and is undertaking preparatory steps. During the *action stage*, the person is actually making desired changes. In the *maintenance stage*, change has successfully been made, and efforts focus on maintaining the behavior change.

The stages of change concept has been adapted to provide a clinical heuristic for treating substance use disorders in people with major mental illness—*stages of treatment*. This framework may also be useful for harnessing motivation to work on psychiatric illness in people receiving treatment for their substance use disorder. Each stage is characterized by a different level of motivation to change, and a different treatment goal, with multiple options available for achieving each treatment goal. Matching the treatment goal and interventions to the individual's level of motivation to change, or stage of treatment, optimizes treatment effectiveness and minimizes dropout from treatment. Each of the four stages of treatment is described below, including the goal of each stage and examples of treatment options.

Engagement Stage

In the engagement stage of treatment, the client is not involved in treatment with the clinician or treatment team who can provide integrated care for their disorders. Therefore, the goal of this stage is to develop a therapeutic relationship with the client, defined as meeting with the individual on a regular basis. This goal can be achieved through strategies such as assertive outreach into the community, practical assistance to address basic living needs (e.g. housing and food),

assistance in resolving the crisis (e.g. social network support and medical problem), or legal constraints (e.g. court mandated treatment).

Persuasion Stage

The client enters the persuasion stage when he or she has been successfully engaged in treatment, but continues to actively abuse substances. The goal of this stage is to help the individual understand that he or she has problems related to substance abuse, and to instill motivation for working on these problems. A wide range of strategies can be helpful in increasing insight and motivation for working on substance abuse. Effective *pharmacological treatment* can reduce severe symptoms that may contribute to substance use in some individuals and facilitate awareness of the effects of substance use. *Motivational interviewing*, which involves helping people articulate personal goals and values, and then exploring the effects of substance use on those priorities in order to draw attention to the problem can often instill motivation to work on substance abuse in order to make personally desired changes in one's life. *Psychiatric rehabilitation* methods such as social skills training, supported employment, and teaching skills for coping with symptoms can address common motives for using substances, such as socialization, having something interesting to do, and coping with symptoms, thereby reducing reliance on substances for getting basic needs met and increasing willingness to work on substance abuse.

Active Treatment Stage

When the client is motivated to reduce his or her use of substances or to become abstinent, as indicated by repeated attempts to cut down, successful reduction in use, or abstinence, they enter the active stage of treatment. The goal of this stage is to help the individual further reduce the use of substances and to prolong the periods of abstinence. A wide range of interventions can be helpful at this stage. Individuals often benefit from *cognitive-behavioral therapy* groups aimed at increasing coping skills and social skills related to urges to use and situations involving substance use. *Self-help programs* such as Alcoholics Anonymous, or special self-help programs designed for people with co-occurring disorders such as Dual Recovery Anonymous, may be useful in providing support and inspiration about the benefits of long-term sobriety. *Social network interventions*, such as family work, may facilitate garnering support for sobriety, and helping individuals change substance use habits that may be inadvertently or deliberately reinforced by family members. *Pharmacological interventions* such as naltrexone or acamprosate may be useful in reducing cravings to use substances.

Relapse Prevention Stage

When an individual's substance use has not been problematic for an extended period of time (e.g. 6 months), he or she begins the relapse prevention stage of treatment. The goals of this stage are to prevent relapses and to extend the recovery to other areas of functioning. Developing a *relapse prevention plan* for dealing with high-risk situations for using substances can be provided in this stage. Extending the recovery to other areas of functioning involves focusing greater attention on important domains such as work, social relationships, school, and health, which in the long run may protect the individual from relapses back into substance use.

Harm-Reduction Philosophy

Many people with co-occurring disorders have limited motivation for treatment and are not willing to set abstinence as a goal regarding their substance use. Despite this, the numerous negative consequences of co-occurring disorders make it incumbent upon professionals to take steps toward engaging and initiating treatment with these individuals. A harm-reduction philosophy focuses first on efforts to reducing the most harmful consequences of substance use on an individual's health, safety, well-being, or living situation. Successfully addressing some of these consequences can be crucial to establishing a therapeutic relationship with the individual, which can then be used to instill motivation to work on substance use reduction and abstinence, as described above in the persuasion stage of treatment. Common harm-reduction strategies include helping people obtain clean needles, providing vaccinations to protect them against hepatitis B, teaching safe sex practices to individuals who trade sex for drugs or money, and identifying places where substances can be used that have reduced risks of victimization.

Low Stress Treatment

Individuals with co-occurring disorders are often highly sensitive to the effects of interpersonal stress, which can precipitate symptom relapses, and contribute to exacerbations of substance abuse. Therefore, maintaining a low stress treatment environment is a common feature of integrated treatment programs for co-occurring disorders. Low stress treatment involves minimizing heated interpersonal exchanges and face-to-face confrontations that historically have been a common feature of substance abuse treatment approaches. Maintaining a low stress treatment environment does not mean that individuals are not confronted with the self-defeating aspects of their own behavior. However, insight into these contradictions, and

motivation to change, is instilled by gentle probing and prompting of the individual in an empathic and understanding manner. In the context of a good working relationship with the clinician, the exploration of apparent contradictions or ambivalent feelings regarding substance use, mental illness, and their interactions, and combined with identifying and increasing self-efficacy for achieving personal goals, is often sufficient for motivation to change to take root.

Pharmacological Treatment

Following the principles of integrated treatment, pharmacological treatment should also focus on managing both the psychiatric and substance use disorders simultaneously. This approach primarily involves engaging the person with co-occurring disorders in a collaboration on identifying the most useful treatments for managing each disorder, while remaining mindful of potential effects on the other disorder. While many evidence-based treatments for psychiatric and substance use disorders tend to have little direct impact on the other disorder, stabilizing each disorder facilitates global stability and improved treatment outcomes. There are some risks of destabilization to be aware of, such as prescribing potentially addictive medications (e.g. benzodiazepines and opiates), or medications that may exacerbate psychotic, mood, or cognitive symptoms (e.g. amphetamines, benzodiazepines and anticholinergics). There is also some potential for medications prescribed for one disorder to be somewhat helpful in managing the other.

Numerous psychotropic agents have been studied for their potential to help reduce substance use. This evidence base is limited by methodological factors such as small sample sizes and naturalistic designs. The few randomized, controlled trials generally show weaker effects. For example, desipramine had been suggested to suppress cocaine use, but a well-controlled study failed to demonstrate a significant effect. Selective serotonin reuptake inhibitors have been suggested to help reduce substance craving, but have not demonstrated substantial impact on substance use outcomes. There is some evidence that lithium might help reduce alcohol use, but a controlled trial failed to demonstrate significant benefit. On the other hand, bupropion has been clearly demonstrated to help reduce tobacco use, and this finding is well replicated among people with schizophrenia. Valproate treatment has been associated with significant reduction in alcohol use among people with bipolar disorder. Numerous small studies have also suggested that various second-generation antipsychotic medications may be associated with reduction in substance use among individuals with schizophrenia. The strongest evidence involves clozapine, and a recent

controlled trial demonstrated some advantages of clozapine over antipsychotic treatment as usual among people with schizophrenia.

Research on the neurobiology of addiction among people with psychiatric disorders has implications for pharmacotherapy. There is growing evidence that the altered activity in the mesocorticolimbic circuitry associated with schizophrenia impairs brain reward responsiveness, creating vulnerability to addiction to substances that can activate brain reward responses exogenously. Brain reward responses, which stimulate repetition of behavior, are mediated by dopaminergic neurons in this circuit. Consistent with this model, psychotropic agents that produce potent dopamine blockade appear to be associated with poorer reward responses, greater substance self-administration in animals, and poorer substance use outcomes among people with schizophrenia. On the other hand, some agents with modest dopamine antagonistic effects (e.g. clozapine) have been associated with reduction in substance use. Antagonism of the norepinephrine alpha 2 receptor, which facilitates greater norepinephrine output, appears to improve signal detection in the mesocorticolimbic circuit as well. This may help to explain why clozapine, which has the highest ratio of alpha 2 to dopamine 2 receptor antagonism of currently available antipsychotics, appears to have the most appreciable effects on substance use behavior. Pharmacologic enhancement of brain reward response among people with mental illness may also facilitate their engagement in inherently reinforcing recovery activities such as physical exercise or work. While further work is needed to confirm this model, it could help to inform future directions in medication development.

Most medications that have demonstrated efficacy in the treatment of people with substance use disorders have had at least limited study among people with co-occurring disorders. This body of work generally finds that these agents are safe and well tolerated and have similar effects among people with co-occurring disorders, although the magnitude of these effects is often attenuated. A recent study failed to find beneficial effects of acamprosate on drinking outcomes among people with schizophrenia and alcohol use disorders, but this is consistent with a large trial among people with primary alcohol use disorders. Disulfiram inhibits dopamine-beta-hydroxylase, an enzyme responsible for the metabolism of dopamine. While higher dopamine levels might be helpful for brain reward response, there are several case reports of psychotic symptoms among individuals treated with disulfiram. Studies of disulfiram among people with co-occurring disorders treated with antipsychotic medications have shown good tolerability, suggesting that antipsychotic

treatment may adequately protect against this potential risk. On the other hand, bupropion has been demonstrated to improve negative symptoms among people with schizophrenia in controlled trials. Methadone has been associated with some improvements in negative symptoms in case reports among people with schizophrenia. Improvements in anxiety among some individuals treated with naltrexone have also been observed.

Pharmacologic management of anxiety is a particular challenge among people with co-occurring disorders. People with co-occurring disorders who are prescribed benzodiazepines are more likely to abuse them than individuals who are not prescribed these medications. Medications with low abuse potential, such as the serotonergic antidepressants, buspirone, and some antipsychotics, may be helpful with anxiety without exacerbating substance use disorders. Psychotherapy, skills training, and physical exercise may also be effective interventions for anxiety management.

Finally, prescribers should be aware of potential drug interactions between psychotropic medications and substances of abuse, and engage people with co-occurring disorders in an informed discussion about these risks. Cocaine use may stimulate cardiac arrhythmias, which might be facilitated by medications that prolong the cardiac QTc interval. Sedating medications that have potential to suppress level of consciousness and respiratory drive could interact additively with alcohol, opiates, or barbiturates. Alcohol use during disulfiram treatment results in adverse reactions. Using a shared decision-making approach and documenting clear informed consent for medication treatment despite the potential for interaction with substances that the individual may use may help to reassure clinicians about their liability risks, and highlight the individual's responsibility for managing their health risks. The decision-making discussion can highlight the importance of prioritizing effective treatment for the co-occurring disorders, and the role that stabilization can play in achieving desired outcomes.

RESEARCH

Research on the treatment of people with co-occurring disorders has progressed rapidly over the last 20 years. People with these disorders value several recovery outcomes: managing their mental illnesses and addictions, avoiding institutionalization (i.e. hospitalization, incarceration, homelessness, and nursing homes), living in independent housing, having a job, and having friends who support their recovery. Many people do achieve recovery goals within each of these outcome domains. Recovery often takes years, and these

outcome domains are only weakly associated with one another over time, suggesting that people take different pathways to recovery, pursuing different goals, paces, and sequences.

Effective interventions involve integrating mental health and addiction treatments with needed psychosocial services and supports. The optimal vehicle for delivering integrated treatments is the multidisciplinary team, typically including care managers, addiction specialists, medical professionals, supported employment specialists, and peers in recovery.

Treatment research has established effective interventions for each of the domains. Supported housing models, such as housing first, and care management models, such as assertive community treatment, especially when combined, help people to avoid institutionalization and to maintain independent housing in the community. Supported employment (often combined with supported education for younger clients) helps people to find and succeed in competitive employment (and schooling). Professionally led dual recovery groups and attending peer support groups in the community help people to establish new social networks of people who support abstinence and recovery. Research shows that these basic outcomes – housing, employment, and friends who support recovery – often precede recovery from addiction and, for many people, are necessary steps in the process.

Learning to manage psychiatric symptoms is also possible and often precedes recovery from addiction. A large number of interventions are effective in symptom management. For most people, symptom management via a combination of pharmacological and psychosocial strategies is optimal, and may generate synergistic interactions between treatment modalities. People learn to use medications effectively and develop strategies to avoid relapses and to cope with residual symptoms. Specific interventions address specific types of symptoms, for example, antipsychotic medications for psychotic symptoms and cognitive-behavioral or exposure-based treatments for posttraumatic stress disorder symptoms. The illness management and recovery program draw together many of these interventions in a coherent package.

Recovery from addiction also can be speeded or enhanced by evidence-based interventions. The strongest evidence (controlled trials) supports three types of interventions: professionally led dual recovery groups, residential treatments, and contingency management. Different models of group interventions and residential programs are effective, but all effective programs integrate mental health and addiction interventions. Contingency management, the systematic use of rewards to reinforce abstinence, is largely a research-based intervention at this point.

Research-based interventions must of course be delivered in the context of trusting therapeutic relationships, often termed *working alliances*. The art of co-occurring disorder treatment entails engaging the client in such a relationship, understanding the client's individual needs (i.e. specific problems, goals, strengths, stage of recovery, and so on), blending appropriate interventions into a coherent plan through a process of shared decision making, and supporting the client over months and years while he or she is working toward recovery. Interventions can only be effectively delivered within such an interpersonal context.

CONCLUSIONS

Co-occurring psychiatric and substance use disorders are the norm rather than the exception, and clinicians need to be prepared to assess and treat both disorders. Traditional approaches to treating co-occurring disorders, including parallel and sequential models, have proved ineffective due to either the inability to engage people in treatments for both disorders or the failure to address the interactions between the disorders. Integrated treatment, characterized by the concurrent treatment of both disorders, by the same clinician or team of clinicians, is widely accepted as the treatment of choice, and is supported by a growing research literature. In addition to combining treatments for both psychiatric and substance use disorders and addressing their interactive nature, effective integrated treatment programs share a number of other common features, including comprehensive assessment and treatment, motivation-based treatment, a harm-reduction philosophy, minimization of treatment-related stress, and pharmacological treatment. Until recently, the outlook for people with co-occurring disorders was bleak, with one or both disorders insufficiently treated, and individuals suffering frequent relapses, functional impairment, and premature mortality. There is now good reason for hope and optimism, as integrated approaches to the treatment of mental health and substance use problems are rapidly becoming the standard in the field, improving the quality of life of most individuals, and making their recovery from both disorders a true possibility.

Glossary

Co-occurring disorders the co-occurrence of a substance use disorder and a psychiatric disorder.

Parallel treatment the concurrent treatment of co-occurring disorders by different treatment providers addressing the psychiatric and substance use disorder, usually working for different agencies and systems.

PTSD posttraumatic stress disorder

Sequential treatment the treatment of co-occurring disorders by first treating either the psychiatric or the substance use disorder, followed by the treatment of the other disorder.

Integrated treatment the concurrent treatment of co-occurring disorders by the same clinician or clinical team, who assume responsibility for integrating the treatment for both disorders.

<i>Treatments Should Address the Multiple Issues of Concern</i>	329	Conclusion	333

In the past, co-occurring substance use and mental health problems have often been missed, because related screening and assessment has not been routine. When co-occurrence has been identified, affected people have often been excluded from services, or were referred to other agencies without assistance to ensure that they arrived and received help. If they did receive treatment, it was often focused on a single problem domain, or was offered by different agencies, which frequently were in

different locations, had differing priorities, policies and procedures, and did not share record systems or communicate effectively in other ways. As a result, treatment plans often missed key elements or had conflicting goals and demands. Practitioner training typically focused on either addictive disorders or other mental health problems, and graduates lacked skills and confidence in dealing with problems outside their focal domain. Despite international attempts to improve services for people with

co-occurring problems, many of the issues remain. However, we now have more information on comorbidity and its management, and on ways to disseminate sound, evidence-based care. This knowledge can guide our development of services that are more responsive to these co-occurring problems. Principles or observations about co-occurring disorders and their implications for practice are summarized in Table 34.1.

PEOPLE WITH CO-OCCURRING DISORDERS HAVE A RIGHT TO EQUAL ACCESS TO QUALITY CARE

The historical situation described above clearly violated the basic right of people with co-occurring

TABLE 34.1 Principles and Observations on Comorbidity Practice and Their Implications for Services

Principle or observation	Implications for services
People with co-occurring disorders have a right to equal access to quality care	Underpins all the implications that follow
Co-occurring disorders are common and often have a profound impact	Screening for co-occurring problems should be routine A boutique service is impractical: existing agencies must address the issue Universal interventions must be capable of large-scale implementation
Tobacco smoking is endemic and affects morbidity, mortality, and functioning	Assessment and interventions should include tobacco smoking
Co-occurring problems are often multiple and closely interlinked	Treatments should address the multiple issues of concern Closely interrelated problems require integrated treatments A single health agency to assist an individual is typically needed Strengths, resources, and functional sources of pleasure should be included in assessment and intervention
Better policies and practices for co-occurring disorders require organizational change	Co-occurring disorders must be core business for the organization and practitioners Effective comorbidity practice should be recognized and rewarded Required skills must be present or taught, and cues to use them provided A culture supporting the use of the intervention should be fostered

Note: These estimates are based on the results from Kavanagh, D. J., & Connolly, J. M. (2009). Interventions for co-occurring addictive and other mental disorders (AMDs). *Addictive Behaviors*, 34, 838-845.

disorders to an equal access to the same quality of care as if they had a single problem. The moral imperative presented by this right of access is the guiding assumption underpinning all the recommendations that follow.

CO-OCCURRING DISORDERS ARE COMMON AND OFTEN HAVE A PROFOUND IMPACT

In Western countries, 25–30% of people with a mental disorder also have a substance use disorder at some time in their lives. In the landmark US Epidemiologic Catchment Area (ECA) study in 1980–84, this corresponded to 2.7 times the risk of a substance use disorder if the person had a mental disorder. In antisocial personality disorder (84%, OR = 29.6), bipolar I disorder (61%, OR = 5.3), and schizophrenia (47%, OR = 4.6), the lifetime prevalence and increased risks were particularly high. Mental disorders are also common in people with substance use disorders. In the ECA study, the lifetime rate of a mental disorder in people with an alcohol use disorder was 37% (OR = 2.3) or 53% (OR = 4.5) in people with another substance use disorder.

Since rates of substance use disorders in the community as a whole are higher among men, and depression and anxiety are more common in women, there are gender differences in risk that reflect these overall trends. Generally, problematic substance use is also more common in younger people. Exact proportions of affected people change across countries, over time, and in specific religious or ethnic groups, with many indigenous groups at particularly high risk of both substance misuse and mental disorder or distress. Community rates of both substance-related and other mental health problems increase even further when subclinical conditions are included.

Treatment settings have greater rates of comorbidity than the general community, especially where crisis care is delivered. This is partly because co-occurring issues have synergistic effects on functioning and distress, and crises that trigger demands for treatment can occur from either problem. In many agencies, this means that a substantial majority currently has a co-occurring substance-related problem.

Not only are co-occurring disorders common tragically, but they also pose substantially increased risks of morbidity and mortality. Substance use increases the risk of illness and fatality from a variety of causes, some directly related to the substance and its metabolism (e.g. overdose, withdrawal, and vitamin depletion), some as a consequence of psychological or lifestyle impacts (e.g. suicide, injury, being a victim of assault, and hyperthermia), and some related to illegal supply (e.g. toxic additives).

Co-occurring disorders also tend to have profound and widespread impact on the functioning and quality of life of the individual and their family. Even mild forms of co-occurring disorders can have a powerful functional impact: for example, any substance use at all by someone with severe mental disorder who is unemployed can entail missing meals, going into debt, having housing problems, or foregoing highly valued opportunities for rehabilitation or employment. If cognition, impulse control, motivation, and social skills are substantially impaired, adding intoxication can take the person from marginally appropriate to dysfunctional behavior, with significant and lasting consequences. Families experience economic impacts (e.g. financial burdens of housing, medical care and other support, lost work time, and property stolen to support substance use), as well as emotional hardship and disruption to their social and recreational activities.

While the functional impacts of co-occurring disorders are often substantial, the companion disorders are often of mild or moderate severity, partly, because less severe problems are much more common in the general community. So, although the relative risk of bipolar disorder or schizophrenia increases to a greater extent than anxiety disorders in people with addictive disorders, anxiety and unipolar depression are most commonly seen. This observation offers some optimism in approaching co-occurring disorders. For example, a study by Green and colleagues showed that some people with even very severe mental disorders spontaneously reduce consumption of cannabis use in the month after they experience a negative effect from it. This suggests that even this group may often have existing skills in self-control that they can exercise if sufficiently motivated.

Together with the moral imperative to provide equal access to service, these observations have important implications for agencies addressing mental health or substance use.

Screening for Co-Occurring Problems Should Be Routine

In assessments and reviews of mental health problems, protocols should include questions about all substance use, with brief screening for associated problems, followed by more detailed assessment of affected areas. Similarly, assessments and progress reviews of people with substance use problems should routinely include screening for psychological distress and disorder, with a full symptomatic assessment being conducted where indicated. Universal screening needs to be brief and easily implemented within the agency's standard assessment protocol if it is to be feasibly

undertaken without significantly increasing costs per patient. Fortunately, brief screening tests are available to assist (*see* Screening and Assessment of Comorbidity).

A Boutique Service Is Impractical: Existing Agencies Must Address the Issue

Some agencies have nominated a staff member or group of staff to deal with co-occurring disorders. However, if specialist practitioners have to assess and provide ongoing management for patients with co-occurring disorders, the high incidence of these problems either means that they will soon be swamped with referrals (preventing others from receiving treatment), or selecting only some for special attention. There is some merit in devoting specialist time to a subgroup that presents greater challenges for care, as long as that does result in better outcomes. However, a consequence is that a large group would then miss out on that attention, unless the specialist staff became the primary practitioner group. Given the moral imperative of equity of access to care, agencies may be better advised to give specialists in co-occurring disorders the roles of consultants or trainers rather than case managers, so their expertise becomes spread throughout the organization and all affected people can receive appropriate treatment.

Universal Interventions Must Be Capable of Large-Scale Implementation

The most readily implemented minimum standard for a universal intervention to address co-occurring disorders is a treatment that is effective for many affected people, but minimizes additional contact time. There are several potential forms this treatment can take: one to two focused sessions, brief segments within case management sessions, or computerized or web-based intervention with or without therapist coaching. A recent trial of treatments for alcohol and depression by Baker and colleagues found that 10-session interventions had greater impact on outcomes at some points of time, but effects from a single, integrated session were also strong. A small number of sessions are particularly well suited to contexts where ongoing treatment may be impractical – for example, in emergency rooms. Within ongoing, case management short segments about co-occurring problems can be included within routine sessions. Brief segments over several sessions are particularly suited to people who have problems with attention and memory, such as people with psychosis.

Efficiencies in delivery may also be increased by supporting the use of computer- or Internet-based interventions. These programs can be applied in various

ways – for example, as stand-alone adjunctive or primary treatments (where staff may just encourage their use and monitor progress), or with varying degrees of staff support as required. These approaches allow high-fidelity, multicomponent interventions to be delivered inexpensively. When used within treatment sessions, they also build practitioners' skills and confidence in delivering treatment for co-occurring problems – a training strategy that incurs little or no cost to the agency. Both computerized and web-based treatments have shown strong results in co-occurring depression and substance use problems. In fact, one study by Kay-Lambkin and colleagues found that a computerized treatment for substance use and depression (“SHADE”), which had a few minutes of therapist contact at the start and end of each session, was as effective as giving the same treatment strategies in a face-to-face format. Increased availability of smart phones and of phone-based applications is progressively allowing additional ways to practice skills, cue their application, and monitor changes in the natural environment, while minimizing service costs.

Brief treatments are typically preceded by a triage, so that more severely affected people are streamed to more intensive treatment (e.g. people with severe cognitive deficits and risk of self-harm or people with severe substance dependence). Agencies may also offer a form of “stepped care,” where more intensive skills training or supportive treatment is offered in cases where brief interventions do not produce optimal results.

TOBACCO SMOKING IS ENDEMIC AND AFFECTS MORBIDITY, MORTALITY, AND FUNCTIONING

The frequencies of substance use in mental disorders that were quoted earlier in this chapter do not include smoking, which is endemic in serious mental disorder: For example, a 1997 Australian community survey of people with psychosis found that 74% currently smoked tobacco (over three times the community prevalence at the time). After suicide, tobacco smoking is the most important contributor to the increased morbidity and early mortality seen in people with serious mental disorders. Smoking also has important impacts in the shorter term: when people are on low incomes, its cost has a substantial impact on money available for both leisure and for essentials such as housing and food.

There are also pragmatic reasons to address smoking in conjunction with other substance use. Almost all people with serious mental disorder who smoke cannabis also smoke tobacco, and users with limited money often cut cannabis with tobacco. Where

community-wide campaigns to stop smoking have been implemented, patients can often be more easily engaged initially in an attempt to quit tobacco than to stop using cannabis. Attempts to become more healthy by stopping smoking can sometimes then be generalized to cannabis and other substance use.

Despite the cogency of these arguments, we have found it easier to convince staff of mental health services that they should address illegal drug use or problematic drinking than to convince them of the need to assess and manage tobacco smoking. Cannabis, amphetamines, hallucinogens, cocaine, and excessive drinking have obvious mental health impacts, and are also readily seen as important foci by substance use services. Tobacco smoking is commonly seen as the province of the family doctor. However, people with severe mental disorder or with multiple substance use are less likely to attend a family physician regularly, and may need more support to stop smoking than others. Omission of smoking from issues to be assessed and addressed by specialist services is, therefore, particularly problematic.

Assessment and Interventions Should Include Tobacco Smoking

Routine screening should include whether the person smokes, and how many cigarettes they smoke each week. Motivational interventions for smoking should be offered, and reengagement after lapses encouraged. Because many people with co-occurring disorders are on very low incomes, financial subsidies for nicotine replacement therapy will often be needed.

CO-OCCURRING PROBLEMS ARE OFTEN MULTIPLE AND CLOSELY INTERLINKED

Co-occurring disorders are often referred to as a dual diagnosis. However, multiple substances are commonly used, and the psychological problems often include more than one type of mental disorder – including personality disorders, or subclinical features of other problems (e.g. social anxiety). Physical problems are also commonly experienced, including poor oral health (which is exacerbated by smoking). More than one situational problem is often present (e.g. social, forensic, housing, and employment issues).

Some problems can be secondary to others, so that someone only has psychotic symptoms when they are using substances. When the companion problem is truly secondary, there may really be only one disorder. However, the relationship is often more complex: While two or more problems may seem to resolve when one

problem is addressed, if an untreated problem becomes worse, it may still increase the risk of relapse in the treated one. So, depression often resolves after treatment for alcohol dependence, but if the person becomes depressed once more, they tend to be at greater risk of relapse in alcohol misuse. Furthermore, a problem may initially be triggered by substance use, but then develops a momentum of its own (e.g. amphetamine use may trigger psychosis, but later psychotic episodes may occur even when the person is abstinent). Indirect associations can also be seen: For example, one study found that the mechanism by which cannabis use triggered a later psychotic episode in that sample appeared to be conflict within the family (which was greater in people with more cannabis use).

Interlinkage between problems is often present, so that exacerbations of each problem may exacerbate the other(s). Close mutual associations between mental health status and substance use appear especially common in people with psychosis; substance use by this group is often triggered by worsening symptoms, but more consumption also puts them at greater risk of psychotic symptoms. These observations also have important implications.

Treatments Should Address the Multiple Issues of Concern

Close interlinkage of problems implies that the interventions that are used should impact on all that are required to obtain and maintain change. If as in the example above, conflict with the person's immediate family is a trigger for later symptomatic relapse, it is important to monitor whether the relationships improve as cannabis use comes under greater control, or whether family intervention for that issue is needed. Furthermore, the vulnerability to conflict suggests that care should also be taken to avoid generating distress within the therapeutic relationship (e.g. by using confrontation). If exacerbations of depression appear to have triggered alcohol use by an individual in the past, even if depression improves after the alcohol treatment, then vulnerability may need to be addressed.

Closely Interrelated Problems Require Integrated Treatments

Comparisons of outcomes from integrated treatment of co-occurring problems by a single agent and parallel or sequential treatment of problems clearly favor integrated treatment for people with psychosis. In the case of depression and anxiety, the evidence is less clear-cut. Sustained long-term outcomes appear to require

that treatment of the substance-related problem(s) is provided.

One trial on people with both excessive alcohol use and depression demonstrated substantial recovery in depression at 12 months, regardless of whether treatment comprised a single integrated session, gave additional treatment focused on alcohol or depression, or provided extended integrated treatment for both problems. Women had faster short-term recovery in alcohol and depression if they received either integrated or depression-focused treatment, but the latter gave weaker alcohol outcomes for them at 12 months. Men had stronger short-term alcohol-related outcomes from extended treatment that focused on alcohol or on both problems. The central importance of the substance-related treatment is consistent with other research showing that the alcohol-related treatment is often equally effective in people with and without depression. However, the differential response of women suggests that it may also be important to address depression to maximize the speed of recovery.

Having multiple treatment goals does not necessarily mean that the treatment is more complex for the patient, or requires more sessions. A sensitive treatment for co-occurring disorders often involves negotiating targets that address both problems at once rather than burdening the person with a complex set of concurrent behavioral goals. Creative interweaving of treatment elements can then offer positive outcomes for each area. Examples include increasing pleasurable time with non-substance-using friends to improve the person's mood and reduce their substance use, and helping the person find highly valued housing or employment that precludes heavy substance use. Even when one issue is the primary focus of current treatment (e.g. substance control), relationships with others are explicitly addressed (e.g. negative mood as a trigger for drinking and as an outcome of binges).

A Single Health Agency to Assist an Individual Is Typically Needed

Integrated treatment is difficult to achieve in practice. As noted at the start of this chapter, mental health and substance use are commonly addressed by different agencies, whose staff have correspondingly different training and expertise. In consequence, a common service model for co-occurring disorders involves multiple agencies, each of which treats a different aspect of the person's problem in parallel or sequentially. As already mentioned above, these models potentially result in inconsistent treatment or treatment that is insufficiently sensitive to the co-occurring problem. Affected people may miss treatment for one or more

problems altogether, partly because the low severity of the most common co-occurring problems means that people who need help often do not meet priority criteria for the companion agency (e.g. severe mental disorder or severe substance dependence).

Where multiple agencies duplicate assessments, interventions, or monitoring regimes, also waste staffing resources and unnecessarily increase costs for affected people and their families. More people may be effectively treated within a particular budget if fewer agencies are involved, overlaps in functions or duties are minimized, and interagency communication is effective and efficient. Ideally, this would include sharing of patient records. Since these features are difficult to attain, a single agency with primary responsibility for integrated care provides the greatest assurance that required treatment will be received; delays minimized; harmful treatment interactions; duplication, or miscommunication avoided; and costs contained.

Which agency should therefore take responsibility in an individual case? There is a risk that uncertainty about this issue could result in each agency consigning the person to the other, resulting in exclusion from service. A heuristic is provided by the 2×2 "quadrant" model proposed by Ries and Miller in 1993 and further explicated by the US Substance Abuse and Mental Health Administration in a 2002 report to Congress. The model describes the severity of the psychiatric disorder and substance use disorder on two dimensions, categorized as low versus high. People with low-severity problems in both domains are seen as being best treated by the general health system (e.g. in primary care). Those with severe psychiatric problems and low-severity problems with substance use are typically seen as being the responsibility of mental health services, and those with severe substance misuse and relatively mild mental health problems are seen as being best managed by alcohol and other drug services. This would leave just one quadrant with a potential need for multiple services: those with high-severity problems in both areas. Health service organizations need to negotiate which agency will have the lead responsibility for this group, calling in assistance from other agencies when needed. In most cases, we suggest that the lead agency will need to be mental health, since that agency is usually better able to provide the level of assertive follow-up, supported care, and engagement of multiple other agencies that this group often requires.

The quadrant model clearly needs operationalization (i.e. with clear guidelines on what diagnosis, measure, or dimensional cutoffs are used), if it is to have practical use in agency decision making. Also, it is based on a conceptualization of the problems as dual disorders, and omits consideration of agencies apart from primary care, substance use, and mental health ones. As already

stated, these restrictions frequently oversimplify the true situation. The task of clarifying decision rules still requires negotiation between agencies and is likely to differ across jurisdictions, depending on the roles that particular agencies have. The quadrant model also needs further testing, to show that its application does improve treatment access and outcomes.

Strengths, Resources, Functional Sources of Pleasure Should Be in Assessment and Treatment

The number and severity of problems in this group sometimes capture attention of practitioners, and both assessment and treatment often focus exclusively on behaviors that need to be controlled or problems that require solution. The emphasis on symptoms and deficits potentially leaves people demoralized, and the complex array of needs can be overwhelming for all parties.

We know that negative mood undermines confidence in being able to make changes, and that sustained changes need to be rewarded, yet much of what we are trying to achieve has at best, a delayed net benefit, and at worst, can leave the person feeling worse off. Assessing and building the strengths, resources, and capabilities of the person increase confidence, which encourages the person to start and persist in their attempt in the face of difficulties. Assessments need to seek out areas that are unaffected or represent significant achievements, summarizing them, showing their relevance to the current challenges, and encouraging the person to rehearse them. Of special importance are ones that show an ability to delay or forego short-term comfort for the sake of greater long-term benefits – for example, maintaining attendance at work or school, practicing a musical instrument, looking after pets, paying rent, and paying off debts. These islands of achievement highlight resources, sources of social support and personal skills, and often give strategies to address current problems.

A focus on behaviors that need to be controlled means that some current sources of pleasure or relief (at least in the short term) may be lost (e.g. positive effects of intoxication, a leisure activity that relieves boredom or distracts from negative rumination, or contact with substance using friends – who in some cases are the only people outside the family and other patients who accept them as they are). To maintain change, new sources of pleasure and reward may be needed: highly valued relationships, opportunities for training or employment, and new housing options. While addressing problems sometimes allows these positive changes to occur, they may not do so without therapeutic

support. For example, the person may be highly socially anxious or lack skills in forming relationships. A focus on improving quality of life and inclusion of its measurement in monitoring of outcomes will help ensure that practitioners and patients address goals that both see as central.

BETTER POLICIES AND PRACTICES FOR CO-OCCURRING DISORDERS REQUIRE ORGANIZATIONAL CHANGE

Even if we continue to have separate agencies for substance misuse and other mental disorders, as well as ones to deal with other health or social problems, there is much that can be done to improve services and make them more integrated and easier to access. However, this typically requires changes to organizations and the way practitioners work. There is now a substantial body of research and theory about the effective diffusion of innovations throughout organizations, and we can also be guided by what we know about individual's behavior change. Some of these principles are applied to co-occurring disorders below. Overall, the evidence shows that both top-down and bottom-up supports of the change through the organization are needed for optimal uptake.

Co-Occurring Disorders Must Be Core Business for the Organization and Practitioners

A corollary of the need for existing agencies to take responsibility for co-occurring disorders is that they must acknowledge that co-occurring disorders represent core business. That in turn requires that this principle is captured by the agency's mission, addressed in its policies, and reflected in the duty statements of individual staff. Policies need to be translated into procedures or guidelines that clearly communicate how they are translated into routine practice, are publicly supported by senior managers, and are widely promulgated throughout the organization. The organization's budget must also reflect this priority, providing sufficient staffing for it, including after-hours coverage where required, and consultants with specialist expertise to support use of the interventions by other staff. In some cases, additional prescribers will be needed to ensure that appropriate pharmacological interventions are available. Other resources for specific intervention components may also be required (e.g. space for support groups, cars for assertive follow-up of vulnerable patients, supported housing, computers and fast Internet links for electronic interventions within clinics, facilities to send text messages to remind about

appointments, cue coping strategies, etc.). Resources to cue high-fidelity use of the practices (e.g. forms, electronic record systems, charts, or computerized tools to use in sessions, brochures, cue cards, etc.) are typically also needed, which in turn involves investment in their development, organizational approval, production, and regular updating (e.g. including new drugs or slang terms, and adapting to new technologies).

Similarly, individual practitioners need to view the assessment and management of co-occurring disorders as being core to their role. Where specialist mental health services have a history of being split from services for alcohol and other drug use, staff have tended to see their role only through the narrow lens of their subspecialty. We have found it useful to describe co-occurring disorders as a subtype of "complex presentations": Practitioners are used to dealing with complexity, and more easily acknowledge it as core business than if the discourse is framed in terms of problems they initially see as the province of another agency.

Effective Comorbidity Practice Should Be Recognized and Rewarded

Just as patients need to see a clear net benefit from changing their behavior, the incentive balance for practitioners needs to favor implementation of sound procedures to address co-occurring disorders. If the procedures are seen as incurring cost for little benefit (e.g. effort, time, or financial cost to learn new skills, extra duties, more time for consultations, perceived restriction of practitioner choice, etc.), they are unlikely to be implemented. One aspect of ensuring a high level of implementation is to minimize these costs (e.g. by showing how existing skills can be applied to co-occurring disorders).

Positive incentives for uptake are also needed. A strong motivator of uptake of the required practices is to systematically collect data on their use, and then give individuals and teams information comparing their own performance with the performance target (or the average or top performance of the overall group). An incentive for uptake by individual staff is provided by routinely including co-occurring problems in case review meetings, and praising attempts to assess and address them. Inclusion of work on co-occurring disorders in performance reviews of staff at all levels is also highly motivating.

Ultimately, both practitioners and organizations are motivated by demonstrably better patient outcomes. Tracking and summarizing positive changes in a patient's admissions, substance use, symptoms, functioning, or quality of life can help to keep motivation high, even when some other patients appear to have

gained limited benefit or (as commonly is the case) their outcomes are at least initially unstable. A corollary is that outcomes should be systematically monitored, so that staff are aware of positive changes, and organizations can report on improved outcomes across their serviced population. Reductions in use of high-cost services by individual patients (e.g. inpatient or after-hours interventions) can be especially motivating for managers, since that can substantially impact on organizational costs and on numbers who can be treated within existing budgets.

Incentives should not exclusively rely on external rewards for optimal uptake. Individual staff should be encouraged to develop goals for learning and using assessments and interventions for co-occurring problems, to solve problems with their application, and notice their own achievements. Effective self-regulation makes them less reliant on the continued integrity of organizational monitoring and reward systems.

Required Skills Must Be Present or Taught, and Cues to Use Them Provided

If co-occurring disorders are adequately covered in the initial training of practitioners in addiction, mental and general health, additional training to assess and manage comorbidity may be able to focus just on local procedures and on advances in practice. In the meantime, other strategies are needed to increase the knowledge, skills, and confidence of front-line staff.

In both mental health and substance use agencies, some effective strategies that are amenable for use on a large scale are already in the skills repertoire of staff. Examples related to assessment are the ability to establish trust and rapport, to take a detailed history, examine triggers and effects of exacerbations, and review contexts, coping strategies, and supports that were associated with periods of better status. Intervention examples include development and maintenance of motivation for agency attendance and behavioral change, and effective goal setting, planning, and problem solving.

Some other strategies are relatively easy to communicate, for example the need to use multiple methods to accurately determine consumption (e.g. daily frequency and amount, frequency and amount of purchases, and weekly cost); the use of a "Timeline Followback" (a day-by-day review of recent events to cue recalled consumption); or helping the person identify pleasurable, non-substance-using activities that can help to boost their mood. Some more demanding areas of knowledge and skills can be supported by other resources (e.g. information on the effects and management of withdrawal from a specific drug, or information

about potential drug interactions can be provided) or given by other specialist staff on the team (e.g. pharmacotherapy for mental health symptoms, management of withdrawal, or long-term support of abstinence).

Low-intensity interventions for co-occurring substance misuse typically involve motivational interviewing or brief advice, plus goal setting, planning, and problem solving for issues that are likely to arise in early phases of initiating behavior change. In addition to pharmacotherapy for depression, several brief psychological strategies have significant impact, including behavioral activation (to increase pleasurable activity and daily achievements). Problem solving, goal setting, and planning (e.g. to address situational stressors) are applicable to both depression and anxiety. Longer treatments with application to both addictive and mental disorders include mindful meditation, which assists users to reduce rumination and related distress.

Where additional skills are needed, one-off workshops by themselves appear to have limited impact: while short-term increases in knowledge and skill can often be demonstrated, unless they are then consolidated in everyday practice, the gains may then be lost. In order for that consolidation to occur, the context must allow it – for example, the new practice may initially take a little longer until it is mastered, and this additional time must be able to be accommodated. Mentoring or supervision may be needed to assist the practitioner to use it effectively and solve problems with its use, and practitioners may need to be cued so they remember to use it (e.g. by items to be checked in patient records of assessment and treatment). Strategies to increase ongoing fidelity may also be required – for example, checklists for key steps in the assessment or intervention.

A Culture Supporting the Use of the Intervention Should Be Fostered

"Champions" can develop enthusiasm for comorbidity practice in the organization. Whether they are within management or among practitioners, they model the use of skills in dealing with co-occurring disorders, provide incidental learning, and reward use of the practices by others. However, excessive reliance on champions in the longer term is dangerous, as their loss can mean that use of the intervention collapses.

A focus on staff who are already keen to use the intervention ("early adopters") appears useful; it avoids unproductive conflict with staff who are initially resistant to comorbidity practices, and allows a critical mass of mutually reinforcing users to develop. We have found that provision of mentoring to this group results in

significantly improved rates of screening and intervention for co-occurring disorders being recorded in patient files. Active engagement of staff in development and updating of support materials is another useful strategy; it both increases commitment to their use and helps to consolidate their understanding of the strategies.

CONCLUSION

There is no “silver bullet” to meeting the complex needs of people with co-occurring disorders, and ensuring stable positive outcomes. However, adopting sound practices that ensure detection of co-occurring problems and access to the best-known treatments is both an excellent start and a moral necessity.

List of Abbreviations

ECA Epidemiologic Catchment Area

OR odds ratio

Glossary

Antisocial personality disorder a disorder that produces pervasive disruptions in interpersonal functioning and is characterized by features such as aggression, deceitfulness, impulsivity, reckless disregard for others, and a lack of remorse.

Bipolar disorder a disorder with mania (elevated or irritable mood, often with increased activity and impulsivity), or alternating mania and depression – which may have psychotic features that are consistent with that mood (e.g. grandiose delusions in mania).

Incentives these are expected and valued benefits from engaging in a behavior. They increase the likelihood of that behavior occurring.

Integrated treatment this treatment is adjusted to take account of the presence of co-occurring problems, and addresses them all. It is typically conducted by a single practitioner or team, and is contrasted with parallel or sequential treatment for different problems, usually by different agencies.

Odds ratio the increased chance that a person from a particular group shows a feature (in this case a disorder) in comparison with other people.

Psychosis a type of disorder that affects brain processes and is marked by features such as attentional difficulties, delusional beliefs, disorganized speech, and disturbances in perception (e.g. hallucinations). Speech may be disorganized, or be limited in amount or content, and motivation may also be affected.

Schizophrenia a psychotic disorder (see above), which is not dominated by mood features. Emotional expression, speech, and motivation may be significantly impaired, and disorganized behavior or immobility seen. It cannot be due to another disorder (e.g. intoxication), causes significant functional disruption, and is

distinguished from similar disorders by its duration (in the *Diagnostic and Statistical Manual* of the American Psychiatric Association, persisting disturbance for at least 6 months, including at least a month of acute symptoms).

Quadrant model of substance misuse and psychiatric problems a guide for decisions on which service should lead the management of an individual with co-occurring disorders. It is a 2 × 2 matrix, based on the severity of the psychiatric and addictive problems.

Timeline Followback a day-by-day review of events or activities over recent weeks or months to cue recall of consumption.

INTRODUCTION

Cigarette smoking is the leading cause of preventable death in the developed world. Cigarette smoking results in 435 000 premature deaths in the United States and 5 million deaths worldwide. Half of cigarette smokers die as a result of smoking related diseases, including lung cancer, coronary heart disease, stroke, and chronic obstructive pulmonary disease. The economic cost of cigarette smoking is enormous: over \$158 billion annually in the United States alone. Approximately 80% of smokers wish to quit and 40% attempt to quit each year. Unfortunately, without treatment, less than 5% of smokers are able to achieve abstinence lasting more

than 1 year. These data appear daunting and discouraging; however, longitudinal epidemiological data are more optimistic. In the United States, smoking rates have steadily dropped during the past four decades from 42.4% in 1965 to 19.8% in 2009. The decline in smoking prevalence is largely the result of a massive anti-smoking campaign targeting both smoking initiation as well as smoking cessation. While the prevention of smoking initiation is vital for long-term reduction of tobacco-related illnesses and deaths, there will be a delay of several decades before the prevention strategies bear fruit. Thus, current efforts to improve smoking cessation rates will likely provide more immediate results. Currently, there are effective medications to aid smokers

in quitting smoking including nicotine replacement therapy (NRT), bupropion, and varenicline. These pharmacological treatments increase the success rate of smoking cessation by two- to threefold compared to quit attempts without any treatments. In this section, we review the first pharmacotherapy developed for the treatment of tobacco addiction, NRTs. First, we overview nicotine's role in tobacco addiction. Then a brief history of NRTs will be provided, followed by their clinical use. We will also review the use of NRTs in special populations of smokers and genetic factors influencing the efficacy of NRTs.

ROLE OF NICOTINE IN TOBACCO ADDICTION

Nicotine is thought to be the main addictive chemical in tobacco smoke. After inhalation of a cigarette puff, nicotine in smoke particles diffuses readily into pulmonary veins. Nicotine is then carried to the arterial circulation and rapidly enters the brain tissue in less than a minute after its delivery. In the brain, nicotine binds to nicotinic cholinergic receptors (nAChRs). The nAChRs are ligand-gated ion channels that facilitate the release of several neurotransmitters in the brain, including dopamine (DA), serotonin, noradrenaline, acetylcholine, γ -aminobutyric acid (GABA), and glutamate. Increased release of these neurotransmitters mediates multiple effects of nicotine on mood, cognition, and the neuroendocrine and cardiovascular systems. Following a rapid delivery of nicotine to smokers, as with smoking or intravenous route, nicotine induces subjective effects of euphoria and drug liking, and increases blood pressure, heart rate, and plasma levels of cortisol, ACTH, and norepinephrine. Nicotine, especially in abstinent smokers, increases level of arousal and performance on attention tasks. With repeated nicotine exposure, as in light to heavy smoking, nAChRs desensitize, thereby resulting in diminished effects of nicotine (i.e. tolerance). At the same time, the number of nAChRs increase (upregulation). This nAChR desensitization and upregulation lead to tolerance development, which is thought to be crucial in nicotine dependence as well as tobacco withdrawal upon cessation of nicotine intake.

The nAChRs are pentameric combinations of 12 subunits ($\alpha 2$ – $\alpha 10$ and $\beta 2$ – $\beta 4$). The two most commonly expressed nAChRs in the brain are $\alpha 4\beta 2$ nAChR and $\alpha 7$ nAChR types. The $\alpha 4\beta 2$ nAChRs have a high affinity for nicotine and desensitize at low concentrations of nicotine, within the range of those found in the blood of smokers. Stimulation of $\alpha 4\beta 2$ nAChRs that are found in dopamine cell bodies and presynaptic terminals increases dopamine release both in the nucleus

accumbens and prefrontal cortex. For the addictive effects of nicotine, dopamine release in the nucleus accumbens, mediated by $\alpha 4\beta 2$ nAChRs, is especially critical. Dopamine release in the prefrontal cortex contributes to cognitive-enhancing effects of nicotine.

The $\alpha 7$ nAChRs, similar to NMDA type glutamate receptors, are highly permeable to calcium, which allows them to enhance neurotransmitter release (e.g. glutamate) and modulate synaptic plasticity. The $\alpha 7$ nAChRs located in the hippocampus and the prefrontal cortex have been studied in relation to cognitive processes including attention and memory tasks. Compared to the $\alpha 4\beta 2$ nAChRs, $\alpha 7$ nAChRs have low affinity for nicotine and do not desensitize at low nicotine concentrations. This delayed desensitization of $\alpha 7$ nAChRs has been suggested to maintain dopaminergic activity after the $\alpha 4\beta 2$ nAChRs are desensitized, thereby contributing to nicotine reward and addiction.

Nicotine is extensively metabolized in the liver to cotinine largely by CYP2A6 enzyme. Cotinine is widely used as a marker for exposure to nicotine. Because of its long half-life (about 16 h), cotinine is useful to verify abstinence in cigarette smokers. For smokers who are receiving NRTs, cotinine is not useful to verify abstinence, which is generally assessed with exhaled carbon monoxide levels.

HISTORY OF NRT

The idea for using NRT for treatment purposes was conceived based on the findings that nicotine administered intravenously or orally reduced the number of cigarettes smoked by smokers. In the 1960s, Dr Claes Lundgren observed that Swedish submariners were able to cope when unable to smoke cigarettes by using smokeless tobacco. In 1973, two Swedish researchers, Ohlin and Westling, hypothesized that pure nicotine could be used for the purpose of tobacco withdrawal. Ohlin and Westling reasoned that using NRT is feasible and appropriate "if it is accepted that the tar and carbon monoxide are the most noxious components of tobacco smoke (Ohlin and Westling, p. 191)." The difficulty that the researchers encountered was that a suitable nicotine delivery system was not available. Fernö, Liehtneekert, and Lundgren developed a chewing gum that released nicotine at a slow rate when chewed. In a seminal paper in 1973, Ohlin and Westling reported that during a 1-week double-blind study smokers receiving nicotine gum smoked less cigarettes than those receiving a placebo gum. During the 6-month follow-up phase all subjects were offered nicotine-containing chewing gum. The researchers reported that the number of nonsmokers then remained fairly constant in the "initial-nicotine group" while it increased in the

“initial-placebo group.” These pioneering studies began a cascade of research studying whether nicotine administration in a variety of delivery systems could aid as potential smoking cessation treatments.

MECHANISM OF ACTION

Though a definitive mechanism of action has not been identified, several possible mechanisms have been proposed to explain the therapeutic efficacy of NRTs as pharmacological aids for smoking cessation. Initially, NRTs were thought to be a “substitution” treatment, similar to methadone treatment for opioid addiction. Opioid dependent individuals on methadone treatment display significantly reduced opioid reinforcement as a result of tolerance to opioid effects. Unlike methadone treatment, NRTs have limited efficacy in reducing nicotine reinforcement and smoking behavior changes minimally in unmotivated smokers who are treated with clinically used doses of NRTs. A likely mechanism is the attenuation of tobacco withdrawal severity by NRT treatment. Following cessation of cigarette smoking, smokers experience a range of withdrawal signs and symptoms including anger, anxiety, dysphoric mood, difficulty in concentrating, impatience, insomnia, weight gain, and restlessness. These symptoms start within hours and last up to 2–4 weeks following abstinence from smoking. Smokers also experience powerful cravings for smoking, sometimes precipitated by cues related to smoking. Cigarette smoking rapidly relieves these symptoms. It is important to emphasize that the relationship between withdrawal severity and relapse to smoking is not straightforward. Smokers may relapse to smoking without experiencing severe withdrawal and some smokers may not relapse in spite of experiencing withdrawal symptoms. However, withdrawal severity during early abstinence predicts relapse to smoking. It has been suggested that the NRTs’ effectiveness in relieving tobacco withdrawal makes it easier to abstain from smoking, improving the success rate of smokers trying to quit.

NRT FORMULATIONS

Five NRT products have been marketed in the United States: nicotine patch, nicotine chewing gum, nicotine lozenge, nicotine nasal spray, and nicotine vapor inhaler. While the vapor inhaler and nasal spray are only available by prescription, nicotine gum, patch, and lozenge can be purchased over-the-counter (OTC). The NRTs are classified as short-acting (gum, lozenge, inhaler, and spray) and longer-acting (patch) products. The short-acting NRTs are especially effective in acute

management of tobacco withdrawal and cigarette craving. For NRT treatment, an important consideration is titration of the dose of longer-acting products based on the smoker’s nicotine intake. In clinical practice, this is roughly determined by the number of cigarettes smoked per day (CPD).

Nicotine Patch

The nicotine patch is currently available OTC in 16- or 24-h delivery systems. The nicotine patch delivers nicotine at a relatively steady rate transdermally. The steady-state blood nicotine levels with patch treatment are about half those found in an average smoker. The 24-h delivery system is available in 7-, 14-, or 21-mg doses. Smokers who smoke more than 10 CPD begin with a 21-mg/day nicotine patch for the first 4 weeks and switch to 14 mg/day on weeks 5 and 6, and to 7 mg/day on weeks 7 and 8. Neither longer term (>8 weeks) nor a higher dose (>21 mg day⁻¹) of nicotine patch improves efficacy over the standard treatment. Some evidence suggests that highly dependent smokers may benefit from higher nicotine doses and longer treatment duration. The nicotine patch has many advantages including ease of administration, few side effects (skin irritation, nausea, vomiting, sweating, mood, and sleep disturbances), and once-daily dosing, all of which may lead to better compliance. For nicotine patch use, smokers are instructed to place a new patch on a relatively hairless location, typically between the neck and waist at the start of each day. It is recommended to rotate the site of application to reduce local skin irritation. Smokers who experience sleep disturbances are recommended to remove the 24-h patch before bedtime or use the 16-h patch, which is designed for use while the smoker is awake. Nicotine patches, however, do not alleviate craving episodes for smoking.

Nicotine Gum

Nicotine polacrilex gum is available OTC in 2- or 4-mg doses. With nicotine gum administration, nicotine is absorbed through buccal mucosa, reaching peak plasma nicotine concentrations within 15–30 min, as compared to within 1–2 min after smoking. Smokers who are heavily dependent (>25 CPD) are recommended to start with the 4-mg pieces. The initial recommended dose is one piece every 1–2 h in the first 6 weeks, one piece every 2–4 h between weeks 7 and 9, and one piece every 4–8 h between weeks 10 and 12. The gum should be used for up to 12 weeks with no more than 24 pieces to be used per day. Smokers are instructed to chew the gum intermittently for about 30 min or until the taste dissipates. The main side effects of gum include nausea,

burping, hiccups, and jaw fatigue. Acidic beverages such as coffee and juices should be avoided before and after the use of nicotine gum because they decrease the absorption of nicotine.

Nicotine Lozenge

Similar to nicotine gum, the lozenge is available OTC in 2- or 4-mg doses of nicotine. The pharmacokinetic properties of lozenge are similar to nicotine gum, except that lozenge delivers about 25% more nicotine than the same dose of nicotine gum, as some nicotine is retained in the gum, and the lozenge is dissolved completely. The 4-mg dose is preferred for highly dependent smokers (those who smoke their first cigarette <30 min after waking up). Smokers are advised to use at least nine lozenges per day in the first 6 weeks for a total duration of up to 12 weeks. The lozenge use should not exceed 20 lozenges per day. Nicotine lozenges may be particularly well-suited for smokers who wear dentures, have temporomandibular joint pain, or prefer not to chew gum.

Nicotine Nasal Spray

Nicotine nasal spray is available by prescription only. Nicotine nasal spray delivers nicotine faster than the other NRTs, achieving peak plasma levels between 5 and 10 min after delivery, perhaps leading to a better efficacy in relieving acute cravings in comparison to gum or lozenge. The nasal spray comes in a multidose container with a pump that delivers 0.5 mg of nicotine per 50- μ l squirt. The dose of nasal spray varies depending on the individual level of dependence and severity of symptoms. The usual recommended dose is 1–2 doses for 8 weeks, with a minimum of 8 doses per day and a maximum of 40 doses per day. Gradual tapering is recommended between 9 and 14 weeks. Smokers who use nasal spray are more than twice as likely to have long-term abstinence from cigarette smoking as compared with placebo treatment. Nasal spray may cause nasal burning, itching, and irritation, and adherence rates tend to be lower than those for other forms of NRT.

Nicotine Inhaler

The nicotine inhaler contains a vaporized cartridge of nicotine placed in a plastic container with the mouthpiece similar to that used in the treatment of asthma. The nicotine aerosol is inhaled and absorbed through the buccal mucosa rather than through the lungs, as in smoking. Peak levels of nicotine are reached 15 min after delivery. The nicotine comes in individualized 10-mg

cartridges, of which 4 mg are delivered and 2 mg are absorbed. However, puffs are highly variable and dependent on factors such as consistency of delivery between puffs as well as air temperature. Recommended dosage is 6–16 cartridges per day, with a treatment duration up to 6 months. Smokers are instructed to taper dosage during the final 3 months of treatment. The nicotine inhaler can cause local irritation, such as a burning sensation in the throat, coughing, sneezing, dizziness, nausea, and indigestion. These side effects may compromise compliance with heavy use and may reduce the efficacy of an inhaler.

ABUSE LIABILITY OF NRTS

Given the addictiveness of nicotine delivered via cigarette smoking, an important consideration is the abuse liability of NRTs. For drugs of abuse, addictiveness is also influenced by the speed and dose of delivery such that large amounts of the drug delivered rapidly is more addictive than lower doses delivered slowly. This is also true for NRTs. Nicotine gum, lozenge, spray, or vapor inhaler provides faster delivery than nicotine patch. Nicotine delivered via patch does not produce any psychoactive effects. Similarly, nicotine, 1–2 mg, delivered via gum or lozenge produces much lower level of reinforcement than the same amount delivered via smoking. Faster delivery systems, like nicotine vapor inhaler and spray, although much less than cigarette smoking, have greater abuse potential than other NRTs. In clinical practice, only a few smokers continue using NRTs longer than their recommended use. In one prospective study, among smokers trying to quit smoking, those who continue using NRTs at week 15, beyond the 12 weeks of recommended use, were 2% for patch, 7% for gum and inhaler, and 10% for spray. These figures are consistent with the rate of nicotine delivery from these NRT products, those with faster nicotine delivery having a greater abuse liability.

EFFICACY OF NRTS

Overall, the efficacy of NRTs has been tested in more than 100 clinical trials in over 35 000 smokers. The meta-analyses of these clinical trials demonstrate the efficacy of NRTs in helping individuals quit smoking. However, because there are different preparations of NRT, their effectiveness may also vary. In 2008, a large meta-analysis investigating 83 studies was conducted to determine relative efficacies of NRT for smoking cessation. As summarized in [Table 35.1](#), all NRTs, compared to placebo, significantly improve smoking abstinence rates at 6 months following quit date.

TABLE 35.1 Comparison of Nicotine Replacement Therapy (NRT) Preparations

Preparation	Dosage	Schedule	Precautions and adverse effects	OR* (95% CI) versus placebo
Nicotine chewing gum	2 mg (\leq 25 cigarettes per day) 4 (>25 cigarettes per day)	Week 1–6: 1 piece 1–2 h Week 7–9: 1 piece 2–4 h Week 10–12: 1 piece 4–8 h	Dentures, acidic beverages, sore throat, nausea, burping, hiccups, jaw fatigue	1.5 (1.2–1.7)
Nicotine patch	7 mg 14 mg 21 mg	Most smokers Weeks 1–6: 21 mg Weeks 7–9: 14 mg Weeks 10–12: 7 mg	Local skin irritation, contact sensitization, vivid dreams, headache, insomnia	1.9 (1.7–2.2)
Nicotine nasal spray	0.5 mg (1 spray into each nostril = 1 dose)	Weeks 1–8: 8–40 doses per day Weeks 9–14: taper down	Hot peppery spray sensation in back of throat, sneezing, cough, watery eyes, runny nose	2.3 (1.7–3.0)
Nicotine inhaler	4 mg (1 cartridge delivers 4 mg over 80 inhalations)	Months 1–3: 6–16 cartridges per day Months 4–6: taper	Headache, cough, mouth/throat irritation, dizziness, nasal congestion, hiccups, nausea, vomiting	2.1 (1.5–2.9)
Nicotine lozenge	2 mg (>30 min to first cigarette) 4 mg (\leq 30 min to first cigarette)	Weeks 1–6: 21 mg day ⁻¹ Weeks 7–9: 14 mg Weeks 10–12: 7 mg	Hiccups, heartburn, nausea, vomiting, diarrhea	2.1 (1.6–2.6)

* Odds ratio compared with placebo 6 months post-quit.

NRT COMBINATION TREATMENTS

NRT combination strategy entails combining two NRTs to improve the outcomes for smoking cessation. The rationale for this strategy is that the slow nicotine delivery via nicotine patch, while reducing the severity of tobacco withdrawal symptoms, does not relieve episodes of craving for cigarettes. Combining nicotine patch with a faster delivery NRT like gum or spray provides relief from breakthrough cravings. The most commonly studied combination is nicotine patch plus nicotine gum. Several studies support the added benefit of this combination than either treatment alone. Combination of nicotine patch with other rapid delivery NRT products has been less well studied. A recent clinical trial of five smoking cessation pharmacotherapies (nicotine lozenge, nicotine patch, sustained-release bupropion, nicotine patch + nicotine lozenge, or bupropion + nicotine lozenge) found that only the combination of nicotine patch plus nicotine lozenge significantly improved smoking cessation at 6 months post-quit. These findings are consistent with a recent meta-analysis in which nicotine patch (>14 weeks) and one NRT (gum or spray), relative to placebo treatment, increased the success rate of smoking cessation by 3.6 times.

In addition to combination of two NRTs, NRTs can also be combined with other smoking cessation medications. For example, combination of NRT with bupropion increases the success rate of cessation more than either treatment alone. The safety and efficacy of NRT and

varenicline combination remains to be evaluated in controlled studies.

REAL-WORD EFFECTIVENESS OF NRTs

Some questions have been raised about the efficacy of NRT in real-world use, especially for those that are available OTC including nicotine patch and gum. A large survey study from California questioned the effectiveness of NRT in long-term smoking cessation by demonstrating that those who attempted to stop smoking using NRT were no more likely to remain abstinent for 6 months or more than those who did not use NRTs. One particular flaw of this survey was its retrospective nature, which may introduce systemic bias. It is possible that smokers may recall quit attempts if they purchase NRTs, than other short-lived attempts without the use of NRTs. In addition, smokers who purchase NRTs may believe that they may not be able to quit on their own and be more dependent on tobacco. Given these limitations, cross-sectional population-based studies may not be a good way to assess treatment effectiveness of NRTs.

SPECIAL POPULATIONS

One of the difficulties of applying clinical trial data into general treatment settings is that the composition of the sample in clinical trials may not mirror the

diversity of patients seen in clinical settings. Ethnicity, gender, age, medical co-morbidities, presence of other addictions or psychiatric disorders, and level of smoking may influence the efficacy of NRTs.

Ethnicity

Ethnic minorities represent more than one-third of the US population, with Hispanic/Latino Americans and African Americans as the largest minority groups. In a large 1996 California Tobacco Survey, Latino, Asian, and African Americans were more likely to attempt smoking cessation than Caucasian smokers but had equivalent smoking cessation rates. Additionally, smokers from minority racial/ethnic groups reported lower utilization of NRTs, lower rates of physician advice, and physician assistance to quit smoking. These disparities remain even after correcting for sociodemographic factors and smoking history. Overall, NRTs seem to be effective in African Americans and Hispanics, although the relative efficacy of NRT in racial/ethnic groups is less well understood.

Gender

In the United States, the rate of smoking among women is significantly lower than that for men (34.5% versus 22.5%). In general, women maintain their nicotine addiction with lower levels of nicotine intake than men, even after controlling for the number of cigarettes smoked. Evidence also suggests that women may be more sensitive to the behavioral effects of nicotine. Many studies have demonstrated that NRTs are effective in women smokers. Although some studies suggest that NRTs may be less effective in women than in men, gender-specific guidelines for NRT treatment remains to be developed.

Pregnancy

Rates of smoking during pregnancy are about 13%, reflecting the fact that about half of the women are able to quit during pregnancy. Unfortunately, among those who quit smoking during pregnancy, 40–52% relapse within 2 weeks and 70–80% resume smoking within 1 year of childbirth. In addition to the health risk associated with smoking in postpartum women, second-hand exposure is also a significant health risk for newborns. In pregnant smokers, NRTs seem to be safe and increase birth weight. However, the efficacy of NRTs, as well as any other first-line medications, remains to be determined in pregnant and postpartum smokers. Behavioral treatments are preferred for pregnant and postpartum smokers.

Adolescents

Accumulating evidence suggests that adolescence is a period of greater vulnerability to nicotine addiction, with more than 80% of dependent smokers starting smoking before the age of 18. In the United States, every day, about 4000 teenagers smoke their first cigarette, with one-third becoming daily smokers. Unfortunately, only 4% of teenage smokers successfully quit smoking each year. The efficacy of NRTs, or any other smoking cessation pharmacotherapies, has not been demonstrated in adolescent smokers. Clearly, further research is needed to develop effective pharmacotherapies for teenage smokers.

Older Adults

Older adults, age 50 or older, who quit smoking are likely to benefit from smoking cessation by decreasing their likelihood of cancer, coronary heart disease, stroke, and chronic obstructive pulmonary disease. Even smokers who are in poor health can reduce the risk for imminent mortality, reverse respiratory difficulties, decrease disability levels, and increase quality of life through smoking cessation. Studies have demonstrated that nicotine patch is safe and ought to be offered to older smokers who are motivated to quit smoking.

Psychiatric Disorders

Individuals with psychiatric co-morbidity, including those with other addictions, compared with those without co-morbidity, consume more cigarettes, are more dependent on tobacco, and are less likely to quit smoking. High rates of smoking have been observed in individuals with schizophrenia (44–88%), depression (40–60%), bipolar disorder (55–70%), and panic disorder (19–56%). Similarly, smoking rates are high in those with cocaine (80%), methamphetamine (>90%), opioid (>80%), and alcohol use (70–80%) disorders. Smokers who receive treatments for other addictions represent a unique opportunity to target both tobacco and other addictions. The efficacy of NRTs in smokers with psychiatric co-morbidities has not been well studied. For example, preliminary studies suggest that schizophrenic smokers may benefit from NRT combined with bupropion. Further research is needed to establish clinical guidelines for NRT use in smokers with psychiatric disorders.

Medical Comorbidities

Smokers with medical conditions including cancer, diabetes, cardiac disorders, COPD, and asthma particularly benefit from quitting smoking. Unfortunately,

smoking cessation is difficult to achieve in smokers with medical co-morbidities: over 50% of smokers resume smoking within 6 months after having a heart attack and 58% of smokers continue to smoke after a new cancer diagnosis. The safety of NRTs has been demonstrated in smokers with medical co-morbidities including those with coronary artery diseases. Although the efficacy of NRTs needs to be further examined in many of the medial co-morbid conditions, the clinicians should not hesitate to provide smoking cessation treatment in smokers. Evidence suggests that smokers with co-morbidities may require longer treatment with NRTs and may benefit from combination treatments. Further controlled studies will help to develop more effective guidelines for NRTs in smokers with medical co-morbidities.

Light Smokers

Light smokers, those who smoke less than 10 cigarettes day⁻¹, comprise about 25% of smokers in the United States. Light smokers, like heavier smoker, have difficulty in quitting smoking. Since light smokers have traditionally been excluded from clinical trials, there is little information regarding the effectiveness of NRTs in this group. One study suggested that light smokers had better outcomes with nasal spray than placebo, while another study did not find differences between the 2 mg and placebo gum for smoking cessation outcomes. Further research examining the efficacy of NRTs in light smokers is needed. This is especially important given the increasing number of light smokers, perhaps due to increasing cigarette cost and restrictions on smoking.

PERSONALIZED MEDICINE WITH NRTs

In recent years, an active area of research has been to identify individuals who will respond favorably to smoking cessation medication including the NRTs. This approach is especially important for tobacco addiction, where treatment success rates are low and smokers show significant individual differences in their tobacco addiction including amount of use, and severity of tobacco withdrawal and craving. The overall goal of this “personalized medicine” approach is to be able to choose the most effective medication and the dose with least side effects based on the genetic makeup of individual smokers. Most of the pharmacogenetic studies conducted with NRTs have focused on genes related to nicotine reward and nicotine metabolism.

As mentioned before, several neurotransmitters play an essential role in mediating the rewarding effects of nicotine and some have been examined as potential

moderators of NRT responses. Among them are genetic variation in the mu opioid receptor (OPRM1), $\alpha 4$ subunit of nAChR (CHRNA4), dopamine D2 receptor, dopamine and serotonin transporter, catechol-O-methyltransferase (COMT), and dopamine beta-hydroxylase (DBH) enzymes. Although, there have been initial promising findings, they remain inconclusive.

Other studies have focused on the genetic variation in nicotine metabolism. In one study, the rate of nicotine metabolism was predictive of treatment response to nicotine patch but not to nasal spray. Those with slower nicotine metabolism were more likely to quit smoking at the end of the trial and at 6-month follow-up. These examples support the promise of pharmacogenetic approaches to improve the effectiveness for NRT treatment of tobacco addiction.

INTRODUCTION

Cigarette smoking is the leading cause of preventable death in developed countries and it is spreading rapidly throughout the developing world. Currently, an estimated 1.1 billion people smoke cigarettes worldwide and approximately 4 million deaths occur annually due to smoking-related illnesses such as lung cancer and cardiovascular disease. If the prevalence of cigarette smoking continues to climb in developing countries, the annual death toll from smoking-related morbidity will rise to a staggering 10 million by the year 2030. In the United States, smoking-related morbidity accounts for upwards of \$400 billion per year in health-care costs. Furthermore, though the prevalence of smoking in the United States has nearly decreased in half since 1965, mortality rates remain above 400 000 annually without

any observed decline over the past 10 years. This is true despite increased focus on prevention strategies such as the institution of various social policies and educational programs aimed at curbing the initiation of smoking by adolescents. This speaks to the importance of developing effective interventions for treating current smokers – especially those who have not been able to quit with available treatments.

Over 70% of current smokers report the desire to quit; however, the observed long-term (1 year) quit rate is a mere 6%. Nicotine replacement therapies (NRTs), such as the gum, the patch, and the inhaler, which are designed to reduce nicotine withdrawal by delivering nicotine through methods other than smoking, are the most widely accessible pharmacological treatment options available. While NRTs substantially improve quit rates in the short run, more than 85% of individuals

relapse within 6–12 months. This finding highlights the limitations of NRTs and the need for the development of more effective long-term pharmacological treatment strategies for smoking cessation. Over the past decade, non-nicotine medications have shown great effectiveness in treating nicotine dependence and are the focus of this chapter.

NEUROBIOLOGY OF NICOTINE AND TOBACCO

Nicotine

Nicotine is the principal reinforcer found in tobacco smoke and has been strongly implicated in mediating tobacco dependence. Like most other drugs of abuse, nicotine has been shown to stimulate the release of the neurotransmitter dopamine in the mesolimbic reward pathway. The mesolimbic reward pathway comprises midbrain dopaminergic neurons that originate in the ventral tegmental area (VTA) and project to the nucleus accumbens (NAc). Nicotine acts on several neurotransmitter systems including dopamine, norepinephrine, serotonin, glutamate, gamma aminobutyric acid (GABA), and endogenous opioid receptors; and its primary site of action in the central nervous system (CNS) is the nicotinic acetylcholine receptor (nAChR), which is located pre-synaptically on these neuronal types. nAChRs in the CNS are pentameric ligand-gated ion channel complexes composed of two α and three β subunits, forming a pore. There are seven types of α and three types of β subunits found in the CNS that allow for considerable diversity among nAChRs in terms of sites of action and activation response. High-affinity $\beta 2$ -containing nAChRs desensitize to a greater degree than the low-affinity $\alpha 7$ -containing nAChRs in response to treatment with nicotine. While $\beta 2$ -containing nAChRs are located on the GABAergic inputs to VTA dopamine neurons, $\alpha 7$ -containing nAChRs are located on the glutamatergic inputs to the VTA dopamine neurons. Thus, after activation with high concentrations of nicotine, the $\beta 2$ -containing receptors on GABAergic neurons desensitize to a greater extent than the $\alpha 7$ -containing nAChRs on glutamatergic neurons, resulting in reduced inhibition of dopaminergic projections to the NAc. Accordingly, there is relatively more excitation of glutamatergic neurons compared to GABAergic neurons, resulting in increased VTA dopaminergic firing and dopamine release in the NAc. While nAChRs desensitize quickly (i.e. within milliseconds) in response to nicotine activation, they re-sensitize after overnight abstinence. This heightened sensitivity may explain why most smokers report the first cigarette in the morning to be the most satisfying.

The role of nAChRs and related transmitter systems in the psychopharmacologic effects of nicotine/tobacco implicates numerous targets for the development of non-nicotine medications.

NON-NICOTINE PHARMACOTHERAPIES

In this section, we review FDA-approved (i.e. bupropion and varenicline) as well as some nonapproved (e.g. topiramate, baclofen) non-nicotine pharmacotherapies for nicotine dependence.

Bupropion

Sustained-release bupropion (Zyban®), initially used for treating major depression as Wellbutrin®, was the first FDA-approved non-nicotine first-line pharmacological intervention for treating nicotine dependence.

Mechanism of Action

The exact mechanism of action of bupropion in treatment of tobacco dependence is still not clearly understood. However, multiple mechanisms have been proposed as mediating bupropion's anti-smoking effects.

One of the proposed mechanisms is the attenuation of withdrawal symptoms. Dopamine and norepinephrine are the main neurotransmitters that have been implicated in mediating these effects. Bupropion has been found to block the reuptake of dopamine and norepinephrine in the mesolimbic reward pathway, which is believed to contribute to the mitigation of withdrawal symptoms such as irritability and negative affect. Chronic administration of bupropion has been found to increase dopamine release in the NAc. Norepinephrine transmission in the NAc also has an impact on dopamine flow during nicotine withdrawal and bupropion may mitigate the anhedonic effect of nicotine withdrawal through norepinephrine reuptake inhibition. Thus, given that dopamine plays a central role in motivational and reward-related processes, it is likely that bupropion mitigates the unpleasant effects of withdrawal by boosting dopamine release within the NAc. There is also some evidence that the mechanism by which bupropion enhances synaptic availability of norepinephrine may not be the inhibition of reuptake, but the enhancement of the firing rate of noradrenergic neurons. Whichever the precise mechanism of action, norepinephrine is linked to dopamine release in the reward system and bupropion's action on both of these neurotransmitters is thought to be important to attenuating withdrawal symptoms and aiding smoking cessation.

In addition to the blockade of reuptake associated with withdrawal attenuation and reward replacement, bupropion also plays a role in decreasing satisfaction from smoking. Bupropion administration has been associated with reduced smoking satisfaction and psychological reward. Chronic bupropion administration has been shown to decrease smoking, and decreases smoking satisfaction in those who continued to smoke during bupropion treatment. While it may seem counter-intuitive at first glance, acute bupropion administration has been associated with increased ad-lib smoking behavior. However, this unexpected increase in smoking behavior is likely due to decreased satisfaction from smoking, which has been most strongly linked to bupropion's antagonistic properties toward the high-affinity nAChRs. Thus, both acute and chronic bupropion mitigate the rewarding properties of nicotine, likely through the blockade of nAChRs.

In summary, increased dopamine release in the mesolimbic pathway mimics the action of nicotine, thereby reducing nicotine withdrawal. The increase in concentration of norepinephrine is also thought to attenuate withdrawal symptoms. There is also some evidence that bupropion can act as an antagonist for high-affinity nAChRs. This is thought to reduce some of the reinforcing effects of nicotine. However, further research is required to clarify the link between neurobiology of bupropion and the resulting behavioral correlates, in facilitating smoking cessation.

Clinical Studies

Several pivotal studies helped establish bupropion's efficacy as a smoking cessation aid. A double-blind four-arm placebo-controlled trial by Hurt and colleagues was the first large study (N = 615) to demonstrate the efficacy of bupropion in treatment of smoking cessation. This study showed that bupropion as compared to placebo leads to a twofold increase in abstinence rates at 7 weeks of treatment. At the end of the treatment, the abstinence rate for subjects receiving placebo was 19% as compared with 28.8% in the 100 mg group, 38.6% in the 150 mg group, and 44.2% in the 300 mg group. This advantage was maintained 45 weeks following the end of treatment. This study also established the recommended dose of bupropion as 300 mg/day (150 mg bid), since the best smoking cessation outcomes and a favorable side-effect profile were observed in the 300 mg/day group. Subsequent analysis revealed no effect of past history of major depression on treatment response. Additional analyses showed that lower smoking rate, longer periods of previous abstinence, and male gender were among the important predictors of successful outcome. A large (N = 893) multicenter follow-up study by Jorenby and colleagues corroborated these results for 9 weeks of

bupropion treatment and further demonstrated that bupropion is superior to NRT for achieving abstinence.

Bupropion was also evaluated as a means for smoking relapse prevention in abstinent smokers. Hays and colleagues conducted an open-label study (N = 784) investigating the effects of prolonged bupropion administration on relapse prevention. This study showed that treating smokers who had successfully quit by the seventh week of treatment and continued to receive bupropion as opposed to placebo for an additional 45 weeks achieved greater abstinence rates at the end of the 52-week treatment phase of the trial (55.2% versus 42.3%). However, these gains were not present at the 6-month or the 1-year follow-up visits. The study did show, however, that bupropion as compared with placebo delayed the median time to relapse (156 days versus 65 days). Thus, bupropion was shown to be efficacious in short-term cessation and demonstrated some utility in delaying relapse.

Common Adverse Effects

The most common adverse effects associated with bupropion include insomnia, dry mouth, and nausea. These effects are generally well tolerated and usually subside with continual use.

Serious Adverse Events

Seizures are the most common serious adverse events associated with bupropion. While seizures were not commonly reported in clinical trials, a number of cases have been reported in post-marketing surveillance studies. Depression is the most frequently encountered psychiatric effect; however, since nicotine withdrawal is commonly associated with depressive symptoms, the direction of causality is unclear. Other psychiatric side effects include unusual changes in behavior, worsening of depression, and onset of suicidal ideation. In 2009, the Food and Drug Administration requested the manufacturers to add a black box warning on the prescribing information, highlighting the risk of serious psychiatric side effects.

Use in Special Populations

Bupropion has been evaluated for use in a number of special populations, including those with psychiatric co-morbidity, patients with cardiovascular disease, and ethnic minorities.

The prevalence of smoking is elevated in people with a number of co-morbid psychiatric conditions. Rates of smoking are significantly higher in patients with schizophrenia, major depression, and other mood disorders. Given the high prevalence of smoking in psychiatric populations, much attention has been given to establishing the efficacy and safety of bupropion in these populations. Over the past decade, numerous studies have

been conducted to test the efficacy and safety of bupropion in patients with schizophrenia. Evins and colleagues conducted a 12-week double-blind placebo-controlled trial of bupropion added to high-dose NRT (i.e. combination of transdermal nicotine patch and nicotine polacrilex gum) and weekly group cognitive behavioral therapy for smoking cessation in patients with schizophrenia (N=51). They found that compared with patients on placebo+NRT, patients on bupropion+NRT had a higher rate of smoking reduction at week 12 and 24, a lower expired air carbon monoxide during treatment and follow up, and a greater continuous abstinence rate at week 8 prior to NRT tapering. However, abstinence rates were not significantly different between groups at week 12. In a similar study, George and colleagues conducted a 10-week double-blind placebo-controlled trial of bupropion in combination with the transdermal patch for smoking cessation in patients with schizophrenia (N = 58). Findings from this trial corroborated previous findings that short-term continuous abstinence rates were greater for patients on bupropion+NRT than those on placebo+NRT, and long-term abstinence rates were consistent with previous findings. No worsening of psychiatric symptoms was observed in either of these trials for patients on bupropion+NRT. Taken together, these and other trials of bupropion in patients with schizophrenia suggest that bupropion is well tolerated in smokers with schizophrenia and that while it is effective in smoking cessation and reduction during treatment, these effects are not sustained in the long term. Bupropion has also been tested for efficacy in populations with depression. While bupropion appears to have only moderate success in patients with depression, it appears to be a safe treatment option as no significant side effects or drug–drug interactions have been noted to date. Further studies regarding the efficacy and safety of bupropion in other psychiatric populations are warranted.

Since smoking cessation following myocardial infarction significantly reduces the risk of death in patients with cardiovascular disease, bupropion has been evaluated as a treatment option for patients with cardiovascular disease. These studies suggest that similar to the pattern observed in the general population, bupropion increases short-term abstinence rates but is not as successful in sustained long-term abstinence. Bupropion is safe for use in this population.

Bupropion has also been tested for use in ethnic minorities. Not only do smoking rates vary by ethnicity, but abstinence rates are also significantly different among ethnic minorities in North America. For example, while 70% of all smokers express the desire to quit, African Americans who smoke fewer cigarettes and have more frequent quit attempts than Caucasian smokers report

significantly lower abstinence rates. Research into the efficacy of bupropion for smoking cessation suggests that while bupropion is associated with increased abstinence rates among ethnic minorities such as African Americans, Hispanic Americans, and Indian Americans, quit rates are still significantly lower compared with Caucasian samples. Further research is required to determine the relative contribution of metabolic differences and environmental factors to the observed differences in efficacy between different ethnicities.

Bupropion has also been evaluated as an aid to smoking cessation in adolescents. Randomized placebo-controlled trials have shown that while at 150 mg/day bupropion in combination with the patch does not increase abstinence rates relative to placebo in combination with the patch, bupropion treatment at 300 mg/day in combination with individual counseling does improve short-term abstinence. However, short-term abstinence rates are lower than those observed in adults, and adolescents relapse soon after discontinuation of medication.

Varenicline

Varenicline, a synthetic derivative of a naturally occurring nAChR partial agonist cytisine, is the most recently approved pharmacological aid for smoking cessation. It is currently the most effective monotherapy available, as it nearly triples the odds of achieving long-term abstinence at 12 months after the beginning of treatment.

Mechanism of Action

In order to understand varenicline's mechanism of action, a brief review of nicotine's action in the mesolimbic reward system is necessary. The addictive characteristic of nicotine can at least be partly contributed to the stimulation of $\alpha 4\beta 2$ -containing nAChRs, which in turn result in increased stimulation of dopaminergic neurons in the VTA (see above). Varenicline has a high affinity for the $\alpha 4\beta 2$ type of receptor, which results in modulation of dopaminergic neurons of the VTA. It is hypothesized that a partial agonist whose affinity for the $\alpha 4\beta 2$ nAChR is greater than nicotine's would bind them selectively, thereby antagonizing (i.e. reducing the availability of binding sites for) nicotine. The natural nAChR partial agonist cytisine seemed the most promising candidate at the time. However, its low bioavailability and poor ability to cross the blood–brain barrier rendered it only minimally effective for treating smoking cessation. Thus, scientists began making structural changes to cytisine with the aim of arriving at a compound with more suitable biochemical properties.

Studies have shown that the increase in dopamine in response to varenicline exposure ranged from 35 to 60%

of the response to nicotine exposure. That is, due to its partial agonist properties, varenicline stimulates dopamine release at a significantly lower concentration than nicotine, itself a full agonist. It has been suggested that stabilization of dopamine levels in response to varenicline treatment in smokers may help curb craving and withdrawal symptoms associated with smoking cessation or reduction. At the same time, since the dopamine release is significantly reduced, the rewarding effects of nicotine are also attenuated to a large extent. In line with this theory, rates of abstinence increase over the first few weeks of varenicline treatment. This suggests that the reduction in rewarding properties of smoking associated with varenicline may actually facilitate the initiation of abstinence, rather than attenuating withdrawal symptoms after abstinence has already been reached. This reduction in dopamine release also limits varenicline's potential for abuse and dependence.

Clinical Studies

The initial Phase II trials of varenicline aimed to investigate its safety and efficacy as a smoking cessation aid. Taken together these studies identified the optimal dosing regimen as 2.0 mg/day and showed that titration of the medication over the first week improves its tolerability. The Phase III trials aimed to determine the efficacy and safety of varenicline compared to other existing pharmacotherapies. Two identical randomized double-blind placebo-controlled studies by Gonzales and colleagues and Jorenby and colleagues, compared the efficacy of varenicline directly to bupropion and placebo. A total of 2045 smokers were randomized to receive either varenicline, bupropion, or placebo. Both studies yielded almost identical outcomes for continuous abstinence for weeks 9–12. Abstinence rates for varenicline (study 1: 44.4%, study 2: 44.0%) at the end of the 12-week trial were significantly higher compared to bupropion (study 1: 29.5%, study 2: 30%) and both drug treatments were associated with significantly higher abstinence rates compared to placebo (study 1: 17.7%, study 2: 17.7%). Continuous abstinence rates for the follow-up period (weeks 9–52) were lower for all groups. However, participants in the varenicline group continued to show a higher abstinence rate (study 1: 22.1%, study 2: 23.0%) compared to bupropion (study 1: 16.4%, study 2: 15.0%) and placebo (study 1: 8.4%, study 2: 10.3%). The continuous abstinence rate was statistically significant in study 1 ($p < .0001$) but only showed a trend toward significance in study 2 ($p = .064$). These studies established the superiority of varenicline to bupropion after 12 weeks of treatment. The effects of varenicline on long-term abstinence and prevention of smoking relapse were tested by Tonstad and colleagues using a 12-week open-label phase

followed by randomization to an additional 12 weeks of either varenicline or placebo. Only participants who had achieved abstinence for at least the last week of the open-label treatment phase were randomized. Of the 1926 participants, 64.1% achieved 7-day point-prevalence abstinence at the end of the open-label phase and 1206 were randomized. Results showed that participants taking varenicline were 2.5 times more likely to continue abstaining during weeks 13–24 and 1.5 times more likely during weeks 13–52, compared to the placebo group. Taken together, these studies demonstrated that varenicline is an efficacious pharmacotherapy for smoking cessation, that it is more effective than bupropion, and that its long-term use is also effective in reducing relapse.

Common Adverse Events

The most frequent adverse events reported with varenicline use include nausea, abnormal dreams, and insomnia. Phase III trials revealed that nausea mainly occurred in the first week of treatment and its prevalence was highest in week 2.

Serious Adverse Events

Since its approval in 2006, some concerns have emerged regarding the risk of serious neuropsychiatric symptoms in patients using varenicline. As of July 2009, the FDA requires manufacturers of varenicline to add new black box warning highlighting the risk of various neuropsychiatric symptoms to their prescribing information. These symptoms were determined based on post-marketing surveillance data received by the FDA and include changes in behavior, hostility, agitation, depressed mood, suicidal thoughts and behavior, and attempted suicide.

Post-marketing adverse event reports are continuously monitored by the FDA and from May 2006 to December 2007 there were 227 cases of suicidality associated with varenicline, 28 of which were fatal. Fifty percent of these cases were of individuals with pre-existing mental illness whereas approximately 25% had no documented psychiatric history. Gunnell and colleagues conducted a large cohort study in the United Kingdom ($N = 80660$) showing that NRTs were associated with a greater risk of self-harm than both varenicline and bupropion. However, the risk of suicidal thoughts was elevated by 43% in participants treated with varenicline. Contrary to the concerns of FDA, a cause-and-effect relationship cannot be conclusively established as smoking doubles the risk of suicidality. Furthermore, prevalence of smoking is much greater in patients with mental illness, who also have a higher risk of suicidality than the general population. Thus, further research into patients who experience suicidality while taking varenicline is required to identify the risk factors of suicidality for varenicline treatment (Table 36.1).

TABLE 36.1 Approved Smoking Cessation Pharmacological Treatments

Medication	Mechanism of action	Dosing details	Effectiveness rating	Odds ratio of smoking abstinence (in comparison to placebo)
Varenicline	Acts as a partial nAChR agonist, reducing cravings and withdrawal symptoms while also reducing the reinforcing effects of nicotine	1 mg twice daily following a 1-week titration period	1	2.33*
Bupropion	Acts by inhibiting DA and NE reuptake to reduce withdrawal symptoms while its nAChR antagonism reduces reinforcing effects of nicotine	150 mg twice daily following a 3-day titration period	1	2.1*

OTHER NON-NICOTINE PHARMACOTHERAPIES

Other medications have been tested for safety and efficacy in treating smoking cessation. However, none of these medications have yet been approved by the FDA.

Nortriptyline

Nortriptyline is a second-generation tricyclic antidepressant and its main indication is the treatment of major depression. It is currently a second-line treatment for treating smoking cessation due its history of adverse events when used for depression, though smoking cessation trials have not reported serious adverse side effects. Nortriptyline's mechanism of action in aiding smoking cessation does not appear to be related to its antidepressant effects. Its effect on noradrenergic neurons may substitute for the noradrenergic action of nicotine. Another possible mechanism contributing to its anti-smoking effects may be its property as a weak nAChR antagonist. However, its exact mechanism of action for smoking cessation is unclear. A 2004 study by Hall and colleagues investigating the effect of long-term nortriptyline treatment in conjunction with smoking cessation counseling (N = 160) showed that while short-term abstinence rates were higher compared with placebo, short-term treatment (i.e. 8 weeks) with nortriptyline resulted in high relapse rates. By contrast, extended treatment (i.e. 52 weeks) increased long-term abstinence rates significantly for both placebo and nortriptyline groups compared with those receiving nortriptyline or placebo for a shorter duration. All in all, randomized clinical trials of nortriptyline have shown that compared to placebo, nortriptyline

treatment doubles the odds of achieving smoking cessation and results in higher continuous abstinence rates for at least 6 months.

Rimonabant

Rimonabant, a selective endocannabinoid (CB1) receptor antagonist, was initially developed as an anti-obesity drug. However, since the endogenous cannabinoid system (mediated by CB1 receptors) in the brain is known to play a part in nicotine reward, rimonabant was investigated as a potential aid to smoking cessation. Three large clinical trials involving smokers and quitters have been conducted. Rimonabant was found to increase abstinence rates at high dosages only, and in a relapse prevention trial smokers who quit were more likely to stay abstinent in the treatment group relative to placebo. Weight gain was also significantly lower in the rimonabant quitters. Though these results appear promising and the reported adverse events were low, some concern has emerged over the prevalence of depression and suicidal thoughts in people taking this medication for weight control. Rimonabant was withdrawn from the European market in 2007, and was given a letter of nonapproval in the United States.

Topiramate

Topiramate is a synthetic anti-convulsant and is most commonly prescribed for the treatment of migraines, epilepsy, and bipolar disorder. Though the exact mechanism of action of topiramate is unclear, it is known to antagonize AMPA (α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid)/kainate subtype of glutamate receptor. This receptor has been implicated in the

expression of established addiction and this property has been exploited as a means of curbing nicotine addiction. Findings from small pilot studies suggest that topiramate may have some modest effects on facilitating short-term smoking cessation and reduction. However, larger trials are required to determine its efficacy in smoking cessation. Research on patients with alcohol dependence has shown that topiramate treatment is associated with increased smoking reduction and spontaneous abstinence rates. A secondary analysis of topiramate for smoking cessation in patients with schizoaffective disorder found no difference across treatment groups. There is also some evidence that topiramate may in fact increase nicotine craving and reward. Taken together, the evidence suggests that the efficacy of topiramate for smoking cessation is mixed at best, though it may have some utility in smokers with alcohol dependence.

Selegiline

Selegiline hydrochloride is a selective irreversible inhibitor of MAO-B subtype, which is responsible for the metabolism of neurotransmitters such as dopamine involved in the reward pathway. Selegiline may facilitate smoking cessation by inhibition of nicotine metabolism or by mimicking the effects of cigarette smoke on MAO. Selegiline demonstrated moderate success in smoking cessation treatment in preliminary studies and was found to be safe and well tolerated. However, large-scale trials failed to demonstrate an advantage for selegiline as compared with placebo in smoking cessation. For example, Weinberger and colleagues conducted a double-blind placebo-controlled randomized trial to determine the efficacy and safety of selegiline as a smoking cessation aid. Subjects received either selegiline (5 mg twice daily) or placebo in addition to brief smoking cessation counseling. No significant improvements were observed in 7-day point prevalence abstinence rates or continuous 4-week abstinence rates at the end of the trial. Other recent large trials have corroborated these negative results and therefore this medication is no longer being actively pursued as a potential treatment for smoking cessation.

Naltrexone

Naltrexone is an opioid antagonist mainly used for treatment of alcohol and opioid dependence. Findings on the efficacy of naltrexone on treating nicotine dependence have been equivocal. However, naltrexone may augment the effect of NRTs on craving and attenuate weight gain associated with smoking cessation.

Baclofen

Baclofen, an agonist at gamma-amino-butyric acid-B (GABA_B) receptors, reduces the surge in dopamine produced by various drugs in the NAc. Animal studies have shown that Gamma-vinyl GABA, another GABA receptor agonist, reduces both acquisition and expression of nicotine-induced conditioned place preferences and decreases self-administration of nicotine in rats. However, this compound is not well tolerated and baclofen appears to be a safer alternative for clinical treatment of nicotine dependence. Preliminary double-blind placebo-controlled pilot trials of baclofen for smoking reduction in smokers who are contemplating quitting suggest that baclofen may be effective in attenuating cravings and facilitating smoking reduction. Baclofen merits further investigation in larger controlled trials.

Nicotine Vaccine

The latest advance in the search for an effective intervention for smoking cessation involves immunotherapy techniques in the form of nicotine vaccination. The vaccine induces the production of antibodies which bind to the nicotine molecule. These antibodies are too large to cross the blood-brain barrier, reducing the distribution of nicotine in the brain and preventing nicotine from producing its addictive effects. Nicotine vaccine is currently in Phase III clinical trials and preliminary findings are encouraging. These findings suggest that the nicotine vaccine is well tolerated and can be effective in boosting continuous abstinence rates when sufficient levels of antibody concentration are reached (Table 36.2).

CONCLUSION

Our increasing understanding of the neurobiology of tobacco dependence has provided a wide range of pharmacological targets for the development of non-nicotine medications. The prototypes for non-nicotine medications include FDA-approved pharmacotherapies such as sustained-release bupropion and varenicline. Interestingly, the mechanism of action of these approved agents involves at least in part action at the receptors for nicotine. Other promising medication target sites related to the pharmacodynamic actions of nicotine include dopamine, GABA, glutamate, and endogenous opioids. One very promising non-nicotine therapy targets the pharmacokinetics of nicotine (e.g. nicotine vaccines). Over the next few years we can expect to see the development of non-nicotine medications related to the actions of nicotine and its associated neurotransmitter systems.

TABLE 36.2 Nonapproved Smoking Cessation Pharmacological Treatments

Medication	Mechanism of action	Dosing details	Effectiveness rating	Odds ratio of smoking abstinence (in comparison to placebo)
Nortriptyline	Acts as a weak nAChR antagonist and blocks reuptake of NE; exact mechanism of action still unclear. Side effects limit utility	75–100 mg daily following a 10–28-day titration period	1–2	2.1*
Rimonabant	Acts as an endocannabinoid antagonist that may contribute to nicotine reward by affecting dopamine release. Side effects limit utility	Not approved, tested at 5 and 20 mg day ⁻¹ in Phase III studies	2	1.61 [§]
Topiramate	Acts by antagonizing AMPA glutamate receptors, leading to inhibition of dopamine release in the reward system	Dosage used varied from 50–225 mg daily across studies	3	1.14 [†]
Selegiline	Acts as a Monoamine Oxidase Inhibitor, increasing monoamine (e.g. DA, NE) levels	10 mg daily in BID dosing following a 7-day titration period	3	1.17 [†]
Naltrexone	Acts by antagonizing endogenous opioid peptide receptors, augmenting the effect of NRT on craving and attenuate weight gained associated with smoking cessation	50 mg daily	3	0.94 [†]
Baclofen	Acts as a GABA agonist, reducing the surge of DA in the reward system	60 mg daily following a 12-day titration period	2	NA [‡]
Nicotine Vaccine	Acts by inducing the production of nicotine anti-bodies too large to cross the blood-brain barrier	NA [§] 100 µg Nicotine-Qβ	2	1.7 [¶]

CONCEPT

The alcohol withdrawal syndrome (AWS) consists of symptoms and signs arising in alcohol-dependent individuals, typically within 6–48 h of consumption of their last drink (Table 37.1). Although AWS occurs intentionally in those seeking abstinence, it may arise unexpectedly in an alcohol-dependent patient, after an admission to hospital. Although alcohol withdrawal is common and usually mild, the abrupt cessation of alcohol consumption by a patient with alcohol dependence may lead to delirium tremens (DTs) and withdrawal seizures.

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

The prevalence of alcohol withdrawal in the general population is low (<5%). However, in the setting of

medical practice, this figure is higher, with the prevalence of alcohol abuse or dependence reaching 20% of hospital inpatients and up to 40% of patients attending accident and emergency departments.

The spectrum of withdrawal symptoms and the time range for the appearance of these symptoms after cessation of alcohol use are listed in Table 37.2. Generally, the symptoms of alcohol withdrawal relate proportionately to the amount of alcoholic intake and the duration of a patient's recent drinking habit. Most patients have a similar spectrum of symptoms with each episode of alcohol withdrawal.

Uncomplicated AWS

In those patients with physiologic dependence on alcohol, the clinical manifestations of alcohol withdrawal begin within 6–24 h after the last drink, sometimes arising before the blood alcohol level has

Time of appearance of symptoms after cessation of alcohol use (hours)	6–12	12–24 (hallucinations) 24–48 (seizures)	48–72

hyperactive reflexes, sweating, and hyperthermia. A tremor, best brought out by extension of the hands or tongue, may appear. This tremor has a rate of six to eight cycles per second and appears on electromyography to be an exaggeration of normal physiologic tremor. For up to 90% of patients, withdrawal does not progress beyond the mild to moderate symptoms described previously, peaking between 24 and 36 h and gradually subsiding.

Hallucinations

In mild alcohol withdrawal, patients may experience perceptual distortions of a visual, auditory, and tactile nature. Lights may seem too bright or sounds too loud and startling. A sensation of “pins and needles” may be experienced. In more severe cases of withdrawal, these misperceptions may develop into frank hallucinations. Visual hallucinations are most common and frequently involve some type of animal life. Auditory hallucinations may begin as unformed sounds (such as clicks or buzzing) and progress to formed voices. In contrast to the auditory hallucinations of schizophrenia, which may be of religious significance, these voices often are of friends or relatives and frequently are accusatory in nature. Tactile hallucinations may involve a sensation of bugs or insects crawling on the skin. In milder cases of withdrawal, the patient’s sensorium is otherwise clear and the patient retains insight that the hallucinations are not real. In more severe withdrawal, this insight may be lost.

Alcohol Withdrawal Seizures

Grand mal seizures are another manifestation of alcohol withdrawal. Withdrawal seizures occurred in around 11–33% of the patients enrolled in prospective controlled studies. Withdrawal seizures usually begin within 8–24 h after the patient’s last drink and may occur before the blood alcohol level has returned to zero. Most are generalized major motor seizures, occurring singly or in a burst of several seizures over a period of 1–6 h. Although 3% of withdrawal seizures evolve into status epilepticus, alcohol withdrawal has been found to be a contributing cause in up to 15% of status epilepticus patients. Seizures peak 24 h after the last drink, corresponding to the peak of withdrawal-induced electroencephalogram (EEG) abnormalities, which include increased amplitude, a photomyoclonic response, and spontaneous paroxysmal activity. These EEG abnormalities are transient, in keeping with the brevity of the convulsive attacks. Except for this brief period after withdrawal, the incidence of EEG abnormalities in patients with withdrawal seizures is not greater than in the normal population. The risk of withdrawal seizures

appears to be in part genetically determined and is increased in patients with a history of prior withdrawal seizures or in those who are undergoing concurrent withdrawal from benzodiazepines or other sedative-hypnotic drugs. There also is evidence that the risk of seizures increases as an individual undergoes repeated withdrawals. This association has been described as a “kindling effect.”

Alcohol Withdrawal Delirium

DTs is one of the most severe clinical complications of the AWS. In the classic cases of withdrawal delirium, the manifestations of withdrawal steadily worsen and progress into a severe life-threatening delirium accompanied by an autonomic storm.

DTs generally appears within 72–96 h after the last drink. In their classic presentation, DTs is marked by all the signs and symptoms of mild withdrawal but in a much more pronounced form (marked tachycardia, tremor, diaphoresis, and fever). The patient develops global confusion and disorientation to place and time. The patient may become absorbed in a separate psychic reality, often believing himself or herself to be in allocation other than the hospital, and misidentifies staff as personal acquaintances. Hallucinations are frequent, and the patient may have no insight into them. Without this insight, they can be extremely frightening to the patient, who may react in a way that poses a threat to his own or the staff’s safety. Marked psychomotor activity may develop, with severe agitation in some cases or continuous low level motor activity in others. Severe disruption of the normal sleep–wake cycle also is common and may be marked by the absence of clear sleep for several days. The duration of the delirium is variable, but averages 2–3 days in most studies. In some cases the delirium is relatively brief, lasting only a few hours before the patient regains orientation. In other cases, the patient remains delirious for several days or weeks before the confusion clears. It is known that many cases of delirium during alcohol withdrawal occur without the autonomic storm associated with classically described DTs. Although the terms alcohol withdrawal delirium and DTs are often used interchangeably, many cases of delirium in alcohol withdrawal are mild and transient.

Risk Factors for the Development of Complicated AWS

Many clinical findings have shown that severe clinical manifestations early in the course are predictive of the development of seizures and delirium. Other risk factors for complicated withdrawal include a history of prior DTs or withdrawal seizures. Marked autonomic

hyperactivity, commonly measured as elevated heart rate on admission, elevated blood alcohol level of 100 mg dl⁻¹ or higher at the time of admission, serum electrolyte abnormalities, and medical comorbidity, particularly infection, are other clinical findings associated with an increased rate of DTs or severe withdrawal. Characteristics that have not been useful in triaging patients include amount of daily intake, duration of heavy drinking, age, and gender.

ASSESSMENT OF AWS: ALCOHOL WITHDRAWAL SCALES AND BIOMARKERS

Because alcohol withdrawal involves a constellation of nonspecific finding, efforts have been made to develop structured withdrawal severity assessment scales to objectively quantify the severity of withdrawal. The most extensively studied and best known scale is the Clinical Institute Withdrawal Assessment-Alcohol-Revised (CIWA-Ar) (Table 37.3). The CIWA-Ar has well-documented reliability, reproducibility, and validity based on comparisons to ratings of withdrawal severity by experienced clinicians. The CIWA-Ar requires 2–4 min to complete and has proved useful in a variety of settings, including detoxification units, psychiatric units, medical/surgical wards, and intensive care units. The CIWA-Ar allows rapid documentation of the patient’s signs and symptoms and provides a simple summary score that facilitates accurate and objective communication among staff. A score of 9 indicates mild withdrawal, a score of 10–18 moderate withdrawal, and a score of >18 severe withdrawal. A careful analysis of symptoms recorded using withdrawal scales found that patients segregated into distinct clinical groups. Approximately 20% had no significant withdrawal symptoms. Another 20% had only vegetative (physical) signs, such as tremor and sweating, but no psychologic symptoms. The largest group, approximately 40%, had both vegetative and mild to moderate psychologic symptoms, primarily anxiety. The last group, about 20% of patients, had both vegetative and severe psychologic symptoms with either disorientation, delirium, or hallucinations. As indicated previously, relatively few patients in alcohol withdrawal experience the adrenergic and clinical manifestations of DTs. The Luebeck alcohol withdrawal risk scale (LARS) is a rating system developed to predict the severity of withdrawal.

When a history is unobtainable or unreliable, and suspicion is present for alcohol dependence, biochemical markers of heavy alcohol consumption are modestly helpful in clarifying the diagnosis. Gamma glutamyl transferase and carbohydrate-deficient transferrin are both sensitive markers for alcohol overuse, particularly when tested as a combination. Other nonspecific

TABLE 37.3 Clinical Institute Withdrawal Assessment-Alcohol-Revised (CIWA-Ar)—cont'd

AUDITORY DISTURBANCES — Ask “Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?” Observation.

- 0 not present
- 1 very mild harshness or ability to frighten
- 2 mild harshness or ability to frighten
- 3 moderate harshness or ability to frighten
- 4 moderately severe hallucinations
- 5 severe hallucinations
- 6 extremely severe hallucinations
- 7 continuous hallucinations

VISUAL DISTURBANCES — Ask “Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?” Observation.

- 0 not present
- 1 very mild sensitivity
- 2 mild sensitivity
- 3 moderate sensitivity
- 4 moderately severe hallucinations
- 5 severe hallucinations
- 6 extremely severe hallucinations
- 7 continuous hallucinations

HEADACHE, FULLNESS IN HEAD — Ask “Does your head feel different? Does it feel as if there is a band around your head?” Do not rate for dizziness or lightheadedness. Otherwise, rate severity.

- 0 not present
- 1 very mild
- 2 mild
- 3 moderate
- 4 moderately severe
- 5 severe
- 6 very severe
- 7 extremely severe

ORIENTATION AND CLOUDING OF SENSORIUM — Ask “What day is this? Where are you? Who am I?”

- 0 oriented and can do serial additions
- 1 cannot do serial additions or is uncertain about date
- 2 disoriented for date by no more than 2 calendar days
- 3 disoriented for date by more than 2 calendar days
- 4 disoriented for place and/or person

Total CIWA-Ar score: _____

Maximum possible score: 67

biomarkers of alcohol consumption can reflect the effect of alcohol on different body tissues (mean corpuscular volume, alanine aminotransaminase, and aspartate aminotransferase). The measurement of direct ethanol metabolites, such as ethyl sulfate, may serve as biomarkers of recent ethanol intake in the future. Homocysteine levels are elevated in nonabstinent alcoholics and levels are associated with alcohol withdrawal seizures. Homocysteine and a product of its metabolism, homocysteic acid, may overstimulate *N*-methyl-D-

aspartate (NMDA) receptors, leading to a reduction in seizure threshold. In addition, homocysteine levels have been shown to be significantly higher in patients actively drinking with a history of withdrawal seizures than in those actively drinking without a history of seizures, and thus a homocysteine level has been thought to be a useful biomarker of risk for alcohol-withdrawal seizures. However, difficulty in defining a cut-off value that will allow adequate sensitivity and specificity has hampered its clinical usefulness.

PATHOPHYSIOLOGY

Alcohol has an effect on multiple neurotransmitter systems in the brain (see Table 37.4). Acute alcohol ingestion has an inhibitory effect at NMDA receptors, reducing excitatory glutamatergic transmission, and has an agonistic effect at gamma-aminobutyric acid type-A (GABA_A) receptors. During prolonged exposure to alcohol, NMDA receptors are upregulated and GABA_A receptors are downregulated, leading to tolerance. The roles are reversed during abstinence, with enhanced NMDA receptor function, reduced GABAergic transmission and dysregulation of the dopaminergic system, leading to many of the symptoms and signs of AWS. Although GABA levels increase in both plasma and *Cerebrospinal fluid* during withdrawal, symptoms of withdrawal still evolve due to downregulation of GABA_A receptors during prior prolonged alcohol exposure. GABA_A and GABA_B mechanisms are also critical for the development of anxiety symptoms that are induced by repeated ethanol intoxications and withdrawal. Altered numbers and functions of NMDA and GABA_A receptors resulting from chronic alcohol exposure may be partly responsible for alcohol withdrawal seizures.

In addition, voltage-dependent calcium influx modulates neurotransmitter release and expression of genes that regulate production of NMDA and GABA-receptor proteins; the continued presence of alcohol increases voltage-operated calcium channel expression and contributes to alcohol tolerance and AWS. Dopaminergic transmission is enhanced during AWS and may play a role in hallucination formation; increased dopamine receptor-binding density has also been observed. The potential importance of the amygdala and the striatum

in the pathophysiology of alcohol withdrawal has also been suggested by persisting high levels of cyclic guanosine monophosphate in these regions. Neurons in the deep layers of the superior colliculus are also an important part of the neural network that initiates ethanol withdrawal seizures. Increased noradrenergic activity has been observed in early AWS, which contributes to sympathetic overdrive during withdrawal. However, the role of serotonin is less certain, but levels have been noted to be lower than controls at various stages of AWS.

MANAGEMENT OF AWSs

In most patients with mild to moderate withdrawal symptoms, outpatient detoxification is safe and effective and costs less than inpatient treatment. However, certain patients should be considered for inpatient treatment regardless of the severity of their symptoms. Relative indications for *inpatient alcohol detoxification* are as follows: history of severe withdrawal symptoms, history of withdrawal seizures or DTs, multiple previous detoxifications, concomitant psychiatric or medical illness, recent high levels of alcohol consumption, pregnancy, and lack of a reliable support network.

General Principles

The primary goals of the treatment of AWSs are to first assure clinical stability of the patient and secondarily encourage on going treatment (e.g. rehabilitation) of a patient's alcohol consumption. The first step in managing a patient with alcohol withdrawal is to perform an *assessment for the presence of medical and psychiatric problems*. Chronic alcohol intake is associated with the

TABLE 37.4 Neurobiology of Acute Alcohol Actions and Alcohol Withdrawal

	Acute effects		Alcohol withdrawal syndrome	
	Pharmacodynamic action	Clinical effects	Biological effects	Clinical effects
NMDA	–	Sedation, amnesia	+++	Seizures
GABA _A	+	Sedation, activation, euphoria, anxiolysis	---	Anxiety, neuronal irritability
NE	–	Anxiolysis	+++	Anxiety
5-HT-3	+	Anxiolysis, nausea	---	Insomnia, depression
DA	+	Activation, euphoria	++	Psychotic symptoms
Opioids	+	Euphoria	---	Craving
Muscarinic	–	Amnesia	++	Tremor
Adenosine	+	Incoordination/sedation	Lower response	?
Ca ⁺⁺ channels	–	Inhibition	+++	Cell damage

NMDA = N-methyl-D-aspartate; GABA = Gamma aminobutyric acid, NE = Norepinephrine, 5-HT = serotonin, DA = dopamine; (+) = Activation, (–) = Stimulation.

development of many acute and chronic medical problems. The clinician needs to determine whether there are acute conditions that require hospital treatment or chronic conditions that may alter the approach to management of withdrawal because they could be exacerbated significantly by the development of withdrawal or its treatment. Pertinent *laboratory tests* generally include complete blood count, electrolytes, magnesium, calcium, phosphate, liver enzymes, urine drug screen, pregnancy test (when appropriate), and Breathalyzer or blood alcohol level. Others, depending on suspected co-occurring conditions, may include skin test for tuberculosis, chest X-ray, electrocardiogram, and tests for viral hepatitis, other infections, or sexually transmitted diseases.

General management also involves maintaining adequate *fluid balance* correction of electrolyte deficiencies, correction of thiamine deficiency, and attendance to the patient's nutritional needs. Patients in early withdrawal often are overhydrated so that aggressive hydration usually is not necessary unless there have been significant fluid losses from vomiting or diarrhea. Supportive care and reassurance from health care personnel are important elements of comfortable detoxification and help to facilitate continuing treatment. Supportive nonpharmacologic care is an important and useful element in the management of all patients undergoing withdrawal. Simple interventions such as reassurance, reality orientation, monitoring of signs and symptoms of withdrawal, and general nursing care are effective.

Pharmacologic Management of Uncomplicated Withdrawal Syndrome

The medical literature on the pharmacologic management of alcohol withdrawal has been recently reviewed in several meta-analysis. These reviews of the evidence indicate that the cornerstone of pharmacologic management of withdrawal is the use of benzodiazepines.

Benzodiazepines

Benzodiazepines are pharmacologically cross-tolerant with alcohol and have the similar effect of enhancing the effect of GABA-induced sedation. A specific benzodiazepine receptor site has been identified on the GABA-receptor complex. It is believed that the administration of benzodiazepines alleviates the acute deficiency of GABA neurotransmitter activity that occurs with sudden cessation of alcohol intake. Well-designed studies consistently have shown that benzodiazepines are more *effective* than placebo in reducing the signs and symptoms of withdrawal. Meta-analysis of prospective placebo-controlled trials of patients

admitted with symptomatic withdrawal has shown a highly significant reduction in seizures, with a risk reduction of 7.7 seizures per 100 patients treated, as well as in delirium, with a risk reduction of 4.9 cases of delirium per 100 patients treated. Trials comparing different benzodiazepines indicate that all are similarly efficacious in reducing signs and symptoms of withdrawal. However, longer-acting agents such as diazepam and chlordiazepoxide may be more effective in preventing seizures. Longer-acting agents may also contribute to an overall smoother withdrawal course, with a reduction in breakthrough or rebound symptoms. On the other hand, pharmacologic data and clinical experience suggest that longer-acting agents can pose a risk of excess sedation in some patients, including elderly persons and patients with significant liver disease. In such patients, shorter-acting agents such as lorazepam or oxazepam may be preferable. Another consideration in the choice of benzodiazepine is the *rapidity of onset*. Certain agents with rapid onset of action (such as diazepam, alprazolam, and lorazepam) demonstrate greater abuse potential than do agents with a slower onset of action (such as chlordiazepoxide and oxazepam). This consideration may be of relevance in an outpatient setting or for patients with a history of benzodiazepine or other substance abuse. However, when rapid control of symptoms is needed, medications with faster onset offer an advantage. A final consideration in the choice of benzodiazepine is *cost*, as these agents vary considerably in price. Given the evidence of equal efficacy, if a particular agent is available to a practitioner or program at a lower cost, cost is a legitimate factor to consider. Studies have indicated that nonbenzodiazepine sedative-hypnotics are also effective in reducing the signs and symptoms of withdrawal, but non-benzodiazepine agents have not been as extensively studied, and the size of studies with them is not adequate to draw conclusions as to their degree of effectiveness in reducing seizures and delirium. Benzodiazepines have a greater margin of safety, with a lower risk of respiratory depression, as well as overall lower abuse potential than do the nonbenzodiazepine agents. Phenobarbital, a long-acting barbiturate, is still used by some programs, as it is long-acting, has well-documented anticonvulsant activity, is inexpensive, and has low abuse liability.

Determining the Dosing Schedule

Three treatment schedules have been used on AWS: a fixed dose, symptom-triggered, and a front-loaded regimen (see Fig. 37.1).

FIXED DOSE

In general, these regimens start with a standard dose (such as chlordiazepoxide 50 mg every 6 h), which is

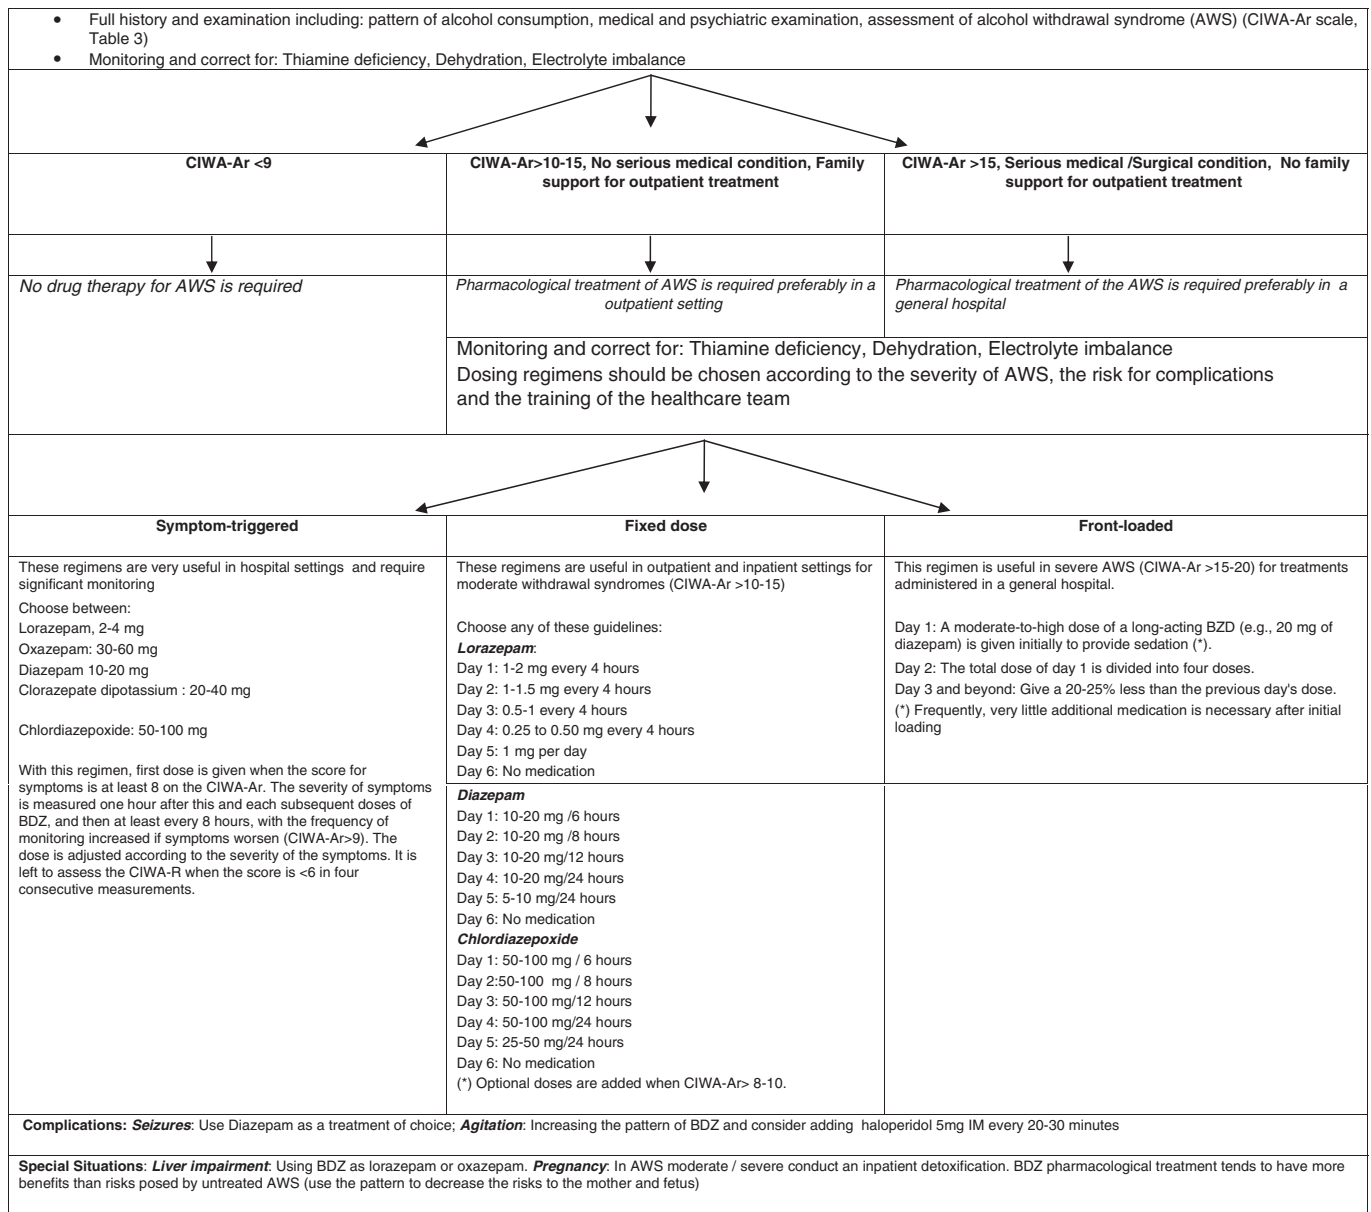

FIGURE 37.1 Algorithm for management of uncomplicated alcohol withdrawal syndrome.

then reduced over the next 5–7 days. Most include an “as required” option to treat breakthrough symptoms. In the majority of studies examining the effectiveness of various medications for withdrawal, the medications were given in *fixed amounts* and were effective in controlling most of the alcohol withdrawal manifestations.

SYMPTOM-TRIGGERED

This type of regimen tailors treatment to the person’s requirements as determined by the severity of their withdrawal signs and symptoms. Patients are regularly assessed and monitored, either using clinical experience, and questioning alone, or with the help of a designated questionnaire such as the CIWA-Ar. Pharmacotherapy is

provided only when symptoms cross a threshold of severity. Well-designed studies have demonstrated that this approach is as effective as fixed-dose therapy but leads to the administration of significant less medication and a significantly shorter duration of treatment. Symptom-triggered therapy also facilitates the delivery of large amounts of medication quickly to patients who evidence rapidly escalating withdrawal and thus reduces the risk of undertreatment that may arise with the use of fixed doses. For programs specializing in the management of addiction, use of a symptom-triggered approach with the utilization of a severity scale offers significant advantages. However, there may be situations in which the provision of fixed doses remains

appropriate. For example, with patients admitted to general medical or surgical wards, the nursing staff may not have the training or experience to implement the regular use of scales to monitor patients. In certain patients, such as those with severe coronary artery disease, the clinician may wish to prevent the development of even minor symptoms of withdrawal.

FRONT-LOADED

The loading dose regimen provides a large dose of long-acting pharmacotherapy at the start of the treatment regimen and then provides it on an “as required” basis after this. The scheme aims to induce a state of mild sedation in the patient to avoid complications such as withdrawal seizures and prevent progression to DTs. When front-loading and fixed-dosing regimes were compared, subjects treated with loading-dose schedules required lower amounts of medication.

Route of Administration

In all cases, medications should be administered by a route that has been shown to have reliable absorption. Therefore, the benzodiazepines should be administered orally or, when necessary, intravenously. An exception is lorazepam, which has good intramuscular and sublingual absorption. In the past, intramuscular administration was commonly used. However, for most agents intramuscular absorption is extremely variable, leading to problems when rapid control of symptoms is necessary and also with delayed appearance of over sedation when large amounts are administered. The use of intravenous benzodiazepines with rapid onset, such as diazepam, has been shown to provide more rapid control of the patient's symptoms. Treatment should allow for a degree of individualization so that patients can receive large amounts of medication rapidly if needed.

Anticonvulsants

Carbamazepine has been widely used in Europe for alcohol withdrawal and has been shown to be equal in efficacy to benzodiazepines for patients with mild to moderate withdrawal. Fixed, tapering doses of carbamazepine are without significant toxicity when used in 5- to 7-day protocols for alcohol withdrawal and are associated with less psychiatric distress, a faster return to work, less rebound symptoms, and reduced posttreatment drinking. When compared with placebo, there is significantly less use of benzodiazepines for breakthrough symptoms. Carbamazepine does not potentiate the central nervous system and respiratory depression caused by alcohol and has no abuse potential. Although the clinical evidence is smaller, tapering doses

of *sodium valproate* could be used in similar fashion. Both of these medications may also be used as adjuncts to benzodiazepine-based regimens in patients who have a history of recurrent withdrawal seizures, with prominent mood lability during withdrawal or with concurrent benzodiazepine withdrawal. However, studies of adequate size to assess the efficacy of these agents in preventing withdrawal seizures or delirium are not yet available. They are available only in oral form, making it difficult to titrate doses rapidly for the more symptomatic or rapidly worsening patient. For these reasons, patients treated with carbamazepine or sodium valproate should be monitored using withdrawal scales and receive benzodiazepines should more severe withdrawal symptoms emerge. Both these agents have interactions with other drugs and have hepatic and hematologic toxicities, and thus must be used carefully, if at all, in patients with certain comorbid medical and psychiatric disorders.

The routine use of *phenytoin* has been advocated as a method to prevent the occurrence of withdrawal seizures, and there is some evidence from early trials that it may be effective for this purpose. However, more recent, methodologically sound trials have failed to show evidence that phenytoin is effective in preventing recurrent withdrawal seizures. Moreover, studies have shown that appropriately used benzodiazepines are extremely effective in preventing withdrawal seizures and that the addition of phenytoin does not lead to improved outcomes, so its use has been largely abandoned. Anticonvulsants such as *gabapentin* and *vigabatrin*, *topiramate*, *oxcarbazepine*, and *zonisamide* have been used for the treatment of AWS because they have fewer side effects and a better safety profile than carbamazepine and sodium valproate.

Other Agents

Beta-adrenergic blocking agents, such as atenolol and propranolol, as well as centrally acting alpha-adrenergic agonists, such as clonidine, are also effective in ameliorating symptoms in patients with mild to moderate withdrawal, primarily by reducing the autonomic nervous system manifestations of withdrawal. However, these agents do not have known anticonvulsant activity, and the studies to date have not been large enough to determine their effectiveness in reducing seizures or delirium. Beta blockers pose a particular problem in this regard because delirium is a known, albeit rare, side effect of these drugs. In addition, there is concern that selective reduction in certain manifestations of withdrawal may mask the development of other significant withdrawal symptoms and makes it difficult to utilize withdrawal scales to guide therapy.

Neuroleptic agents (haloperidol, tiapride, amisulpride) have shown some effectiveness in reducing the signs and symptoms of withdrawal and for a time were used

extensively for that purpose. However, these agents are less effective than benzodiazepines in preventing delirium and actually lead to an increase in the rate of seizures. Neuroleptic agents are widely used to calm agitated patients and are useful for this purpose in the setting of alcohol withdrawal as well. They should not be used alone, but always in conjunction with a benzodiazepine; moreover, neuroleptic agents with less effect on the seizure threshold, such as haloperidol, should be selected. *Tiapride*, a benzamide with D2 and D3 antagonist activity, reduces hyperhidrosis, agitation, and tremor during alcohol withdrawal and may be a useful adjunct to other agents used in the treatment of AWS.

There is currently limited evidence to support the use of baclofen, amisulpride, and gamma-hydroxybutyric acid in the management of AWS.

It has long been recognized that magnesium levels often are low during alcohol withdrawal, but routine administration of magnesium, either oral or intramuscular, for withdrawal is no longer recommended.

Despite the relative lack of evidence of oral and intravenous alcohol for the management of alcohol withdrawal, several hospitals continue to use intravenous or oral alcohol in the management of alcohol withdrawal. Intravenous alcohol infusions require close monitoring because of the potential toxicity of alcohol. As a pharmacologic agent, ethyl alcohol has numerous adverse effects, including its well-known hepatic, gastrointestinal, and neurologic toxicities as well as its effects on mental status and judgment. Given the proven efficacy and safety of other agents, the use of oral or intravenous alcohol for alcohol detoxification is generally discouraged.

COMPLICATIONS OF AWS

Alcohol Withdrawal Seizures

Patients with alcohol withdrawal seizures raise a number of management issues. It is important to recognize that not all seizures in alcohol-dependent patients are the result of withdrawal. In epidemiologic studies, the rate of epilepsy and seizures rises in parallel with the amount of an individual's alcohol intake. Alcohol-dependent patients are at higher risk for seizures unrelated to withdrawal. A careful history of the temporal relationship of alcohol intake to the seizure should be obtained, and the diagnosis of withdrawal seizure should be made only if there is a clear history of a marked decrease or cessation of drinking in the 24–48 h preceding the seizure. All patients who present with their first seizure warrant a thorough neurologic examination and brain imaging, with lumbar puncture and EEG being appropriate in many cases. Patients who are known to have a history of withdrawal seizures and who present with a seizure that can be attributed

clearly to withdrawal may not require a full repeat evaluation. If the seizure was generalized and without focal elements, and if a careful neurologic examination reveals no evidence of focal deficits, there is no suspicion of meningitis and there is no history of recent major head trauma, additional testing has an extremely low yield and may be safely omitted. There is a 6- to 12-h period during which there is increased risk of seizures. Withdrawal seizures often are multiple, with a second seizure occurring in one case out of four. For the patient who presents with a withdrawal seizure, rapid treatment is indicated to prevent further episodes. The parenteral administration of a rapid-acting benzodiazepine such as diazepam or lorazepam is effective. Several studies have shown that phenytoin is no more effective than placebo in preventing recurrent seizures. Initial treatment should be followed by oral doses of long-acting benzodiazepines over the ensuing 24–48 h. Early studies indicated that a withdrawal seizure placed the patient at increased risk for progression to DTs, so close monitoring is warranted.

Delirium Tremens

DTs is a severe disorder that should be treated in an inpatient setting. Older studies showed a mortality rate of up to 30% in DTs but, with modern care, mortality has been reduced to 1%. The principles of successful treatment involve adequate sedation and meticulous supportive medical care. Such patients require close nursing observation and supportive care, which frequently necessitates admission to an intensive care unit. Careful management of fluids and electrolytes is important, given the patient's inability to manage his or her own intake and the presence of marked autonomic hyperactivity. Delirium often is encountered in patients admitted for acute medical problems whose alcohol dependence was not recognized and whose withdrawal was not adequately treated. A high index of suspicion for the development of infection – whose presenting signs may be masked by fever, tachycardia, and confusion of the underlying delirium – is essential, as is careful management of coexisting medical conditions. The use of cross-tolerant sedative-hypnotics has been shown to reduce mortality in DTs and is recommended. However, such medications have not been shown to reverse the delirium or reduce its duration.

The goal is to sedate the patient to a point of light sleep. This will control the patient's agitation, preventing behavior posing a risk to himself or herself and to staff, and allow staff to provide necessary supportive medical care. Examples of treatment regimes used for DTs patients are given in Fig. 37.2. The use of intravenous benzodiazepines with rapid onset, such as diazepam, provides more rapid control of the patient's

Monitoring of the clinical manifestations of DTs every 2 h (CIWA-Ar is usually greater than 20 at baseline)		
↓		
With impairment of liver function	Normal liver function	In case of agitation
Using IV lorazepam or midazolam	Starting with BDZ orally and in case of no response or partial response change to intravenous: <ul style="list-style-type: none"> • Diazepam IV slowly every 5 minutes until the patient is sedated. Initiating treatment with doses of 5 mg and if necessary up to 10 mg divided into two doses. The dose will be increased to achieve sedation. • Alcohol Withdrawal syndrome will be monitored every 1-2 h. • The total dose of the first day is usually required for the second and third day. Subsequently decreases to 20% of daily dose on the day prior to deletion. 	Haloperidol 2–5 mg IM alone or in combination with lorazepam 2–4 mg

FIGURE 37.2 Algorithm for management of delirium tremens (DTs).

symptoms. The main complication of therapy with diazepam is respiratory depression. Whenever this approach is used, providers should have equipment and personnel immediately available to provide respiratory support if needed. One advantage of diazepam is that its peak onset occurs within 5 min of intravenous administration. This allows the provider to deliver repeat boluses and titrate sedation quickly without a fear of a delayed appearance of over sedation. Once established, delirium can be expected to last for a number of hours, so diazepam offers another advantage in that its longer half-life helps maintain sedation with less chance of breakthrough agitation. Large doses of benzodiazepines may be needed to control the agitation of patients in DTs, with hundreds and even thousands of milligrams of diazepam or its equivalent used over the course of treatment. The practitioner should not hesitate to use whatever amounts are needed to control the agitation, while keeping in mind the possible build up of long-acting metabolites especially in patients with impaired hepatic function or the elderly.

There have been reports of the use of continuous intravenous drips of short-acting agents such as lorazepam or midazolam. Existing evidence suggests that this approach is no more effective than the use of boluses of longer-acting agents and is very expensive. In the agitated patient, benzodiazepines can be supplemented with the addition of neuroleptic agents such as haloperidol. As has been discussed, such agents should not be used alone. Also, neuroleptic agents with less effect on seizure threshold, such as haloperidol, should be used. In patients whose withdrawal is not readily controlled with oral benzodiazepines and who are beginning to demonstrate signs of agitation, intramuscular administration of a combination of lorazepam and a neuroleptic such as haloperidol often is effective in calming the

patient, thus avoiding the need to use intravenous administration.

Thiamine Deficiency and Wernicke Encephalopathy

Alcohol-dependent patients are at risk for thiamine deficiency, which may lead to Wernicke disease and the Wernicke–Korsakoff syndrome. Wernicke disease is an illness of acute onset characterized by the triad of mental disturbance, paralysis of eye movements, and ataxia. This encephalopathy is a neurologic emergency that should be treated by the immediate parenteral administration of thiamine, with a dose of 50 mg intravenously and 50 mg intramuscularly. Delay in provision of thiamine increases the risk of permanent memory damage. The provision of intravenous glucose solutions may exhaust a patient’s reserve of B vitamins, acutely precipitating Wernicke disease. Therefore, intravenous glucose should always be accompanied by the administration of thiamine in the alcohol-dependent patient.

Electrolyte Disturbance and Dehydration

Hyponatraemia is frequently seen in chronic alcoholics, particularly beer drinkers, due to intake of a large volume of fluid. In most cases, this is chronic and is best treated with restoring normal hydration and resumption of a normal diet while abstaining from alcohol. Attempts to correct the electrolyte disturbance with saline (particularly hypertonic saline, 3% sodium chloride) may result in central pontine myelinolysis (CPM), which is thought to be triggered by rapid osmotic shifts in the brain causing

complement-mediated oligodendrocyte toxicity. The clinical features of this are irreversible and severe, so prevention is critical. There is some evidence to suggest that slow correction of chronic hyponatremia minimizes the risk of CPM. Most reported cases of osmotic demyelination occurred after rates of correction exceeding 12 mmol/24 h, although cases have also been reported after corrections of 9–10 mmol/day. General recommendations include slow correction, no more than 8–10 mmol/l of correction in any 24-h period, and if severe symptomatic hyponatremia occurs, to obtain specialist advice prior to more rapid correction or use of hypertonic saline. Deficiencies in serum potassium, magnesium, and phosphate are often seen in this setting due to poor nutrition and secondary to vomiting and should be carefully corrected along with dehydration.

Disulfiram in Alcohol Use Disorders	369		

INTRODUCTION

Disulfiram, also known as tetraethylthiuram disulfide, is a thiuram derivative which has been used since the 1800s as an accelerator in rubber manufacturing. Its potential effect on alcohol consumption was noted by an American physician, E.E. Williams, in his 1937 letter to the editor of the *Journal of the American Medical Association* (JAMA). As a Connecticut chemical plant physician, he became aware that workers grinding tetramethylthiuram disulfide were no longer able to tolerate alcohol. These men experienced flushing, rapid pulse, palpitations, and “a terrible fullness in the face, eyes, and head” on ingestion of any type of alcohol and subsequently became “involuntary total abstainers.” Williams postulated that if it was not harmful to humans, disulfiram might lead to “the cure for alcoholism,” but no further developments came of his observations.

Several years later, Danish researchers Jens Hald and Erik Jacobsen were conducting research on disulfiram for the treatment of parasitic infections. By chance, they independently discovered the effect of combining alcohol with disulfiram when they ingested alcohol

during their investigations into the human tolerance of disulfiram. Together with psychiatrist Oluf Martensen-Larsen, they went on to conduct much of the initial clinical research investigating disulfiram for the treatment of alcoholism. For several subsequent decades, the large majority of clinical research and use of disulfiram was focused on the treatment of alcohol dependence. More recently, disulfiram’s potential utility in other populations, including the dually diagnosed (patients with both a primary psychiatric disorder and a substance use disorder) and those with cocaine use disorders, has received increasing attention.

EFFECTS OF DISULFIRAM

Pharmacology

Disulfiram is almost completely absorbed from the gastrointestinal tract after oral ingestion. It is metabolized by the liver and excreted renally, though up to 20% can pass unchanged in the feces. It is lipid soluble and has an estimated half-life of 60–120 h. Because of

the long half-life of disulfiram and its metabolites, it may take 7–14 days before disulfiram is totally eliminated from the body, after the last dose is taken.

Alcohol is metabolized in the human liver by a multi-step process (see Fig. 38.1). Alcohol is first converted to acetaldehyde by the enzyme alcohol dehydrogenase (ADH). Acetaldehyde is then metabolized to acetate by a second enzyme, aldehyde dehydrogenase (ALDH). Acetaldehyde causes unpleasant symptoms such as flushing, elevated heart rate, nausea, headache, and visual disturbance, among others, and is likely one of the main causes of the cluster of symptoms commonly referred to as the “hangover.” Disulfiram inhibits aldehyde dehydrogenase and in doing so causes an accumulation of acetaldehyde, which has the aforementioned toxic effect in the body.

In addition to its inhibition of ALDH in the liver, disulfiram is known to have other pharmacological effects in humans. Disulfiram inhibits dopamine beta-hydroxylase in the central nervous system. Dopamine beta-hydroxylase is an enzyme that normally converts dopamine to norepinephrine. Thus, disulfiram can increase dopamine levels in the brain, accompanied by relative decreases in norepinephrine. When exposed to thiol groups following absorption, disulfiram is reduced in the blood to diethyldithiocarbamate (DDC). This metabolite of disulfiram, DDC, is a potent copper chelator and can impact the activity of enzymes such as monooxygenases, amine oxidase, cytochrome oxidase, microsomal carboxylesterase, and plasma cholinesterase, which are copper dependent.

Combination with Ethanol

The result of combining alcohol with disulfiram is often referred to as the disulfiram–ethanol reaction. Accumulation of acetaldehyde by disulfiram produces a variety of unpleasant symptoms that become magnified in intensity and consequence with increasing concentrations. Mild disulfiram–ethanol reactions commonly consist of flushing, diaphoresis, and headache. Moderate reactions are characterized by nausea,

vomiting, increases in heart rate, palpitations, difficulty breathing, and decreased blood pressure. The most severe reactions can result in respiratory depression, cardiac arrhythmias, congestive heart failure, myocardial infarction, cardiovascular collapse, loss of consciousness, seizures, and death.

The patient should generally wait at least 12–24 h after consumption of alcohol (depending on blood alcohol concentration) before starting disulfiram. Besides refraining from drinking while taking disulfiram, one should also avoid any products containing alcohol. This includes many cold syrups, tonics, and mouthwashes. It is also advised that patients not use topical preparations which contain alcohol, such as perfume and after-shave lotion (Table 38.1).

Side Effects

In the absence of alcohol, disulfiram at clinically appropriate doses (125–500 mg daily) is generally fairly well tolerated. Common side effects are relatively minor and include headache, drowsiness, dermatitis, and a metallic aftertaste. Electrocardiogram changes can be seen, in addition to hyper- or hypotension. Disulfiram has also been associated with peripheral neuropathy, confusion, and optic neuritis. Effects on the liver include elevations in liver enzymes and, in rare cases, potentially fatal hepatotoxicity. Fortunately, disulfiram-induced hepatotoxicity is usually reversible if the medication is stopped early in the course of illness. Most cases of disulfiram-induced hepatitis occur within 4–6 weeks after starting the medication and resolve gradually over several weeks. Monitoring of liver function is recommended in all patients receiving disulfiram. In general, disulfiram is not recommended for use in patients with cardiovascular or cerebrovascular disease, significantly abnormal liver functioning, or in pregnant/nursing women. It is also not recommended for use in patients with impaired cognitive status, who would be unable to understand the disulfiram–ethanol reaction.

Over the years, there have been several reports of disulfiram causing psychiatric symptoms, including delirium, depression, anxiety, mania, and psychosis. At least some of these symptoms have been attributed to the relative increase in dopamine and decrease in norepinephrine produced by disulfiram’s inhibition of dopamine beta-hydroxylase. However, it should be noted that the reports of such symptoms were primarily made several decades ago, when clinical dosing of disulfiram was much higher (1–3 g) and the definitions of the psychiatric symptoms were not standardized. For example, the term “psychosis” was applied not only to hallucinations and delusions, but also to anxiety and depression. Current clinical dosing (125–500 mg daily)

FIGURE 38.1 Inhibition of alcohol metabolism by disulfiram.

TABLE 38.1 General Clinical Guidelines for the Use of Disulfiram

Wait at least 12–24 h after drinking before starting disulfiram.

Never take disulfiram while intoxicated.

Wait at least 7–14 days after taking disulfiram before consuming alcohol.

Alcohol should be avoided in all forms, including alcoholic beverages, vinegars, sauces, after-shave lotions and colognes, perfume, mouthwash, and alcohol-containing medications, such as some cough syrups.

Disulfiram may cause drowsiness. Caution should be used with respect to driving and performance of tasks which require alertness.

Carry identification which documents current use of disulfiram.

If signs of serious liver disease develop (loss of appetite, yellowing of the eyes/skin, dark-colored urine, light-colored stools, nausea, lethargy), seek medical attention immediately.

Disulfiram should not be used when pregnant or intending to become pregnant.

Store disulfiram in a safe location, out of reach of children.

is not thought to confer significant risk for major psychiatric symptoms.

Interactions with Other Medications

Disulfiram is known to interact with certain medications, particularly those metabolized by the cytochrome P450 system. Co-administration of disulfiram with amitriptyline has been associated with confusion and psychosis. Disulfiram decreases the body's clearance of such medications as desipramine, diazepam, chlordiazepoxide, phenytoin, caffeine, and cocaine. In combination with warfarin, disulfiram can potentiate warfarin's anticoagulant effect. Disulfiram inhibits the metabolism of theophylline. Concurrent use of disulfiram and monoamine oxidase (MAO) inhibitors is not recommended.

Other

Interestingly, disulfiram-induced inhibition of aldehyde dehydrogenase is mirrored in nature. Among humans, there is known to be genetically determined variability in aldehyde dehydrogenase. Alcohol sensitivity experienced by some Asians (e.g. flushing, tachycardia, nausea following the consumption of alcohol) is thought to be highly influenced by functional polymorphisms in the genes for alcohol dehydrogenase (ADH1B on chromosome 4) and aldehyde dehydrogenase (ALDH2 on chromosome 12). The ALDH2*2 allele is

prevalent in Asian populations but is otherwise extremely rare. Heterozygotes have a significantly lower rate of alcohol dependence in comparison to those without the allele, and alcohol use disorders are close to absent in individuals who are homozygous for ALDH2*2.

DISULFIRAM IN ALCOHOL USE DISORDERS

Disulfiram (Antabuse) was approved by the US Food and Drug Administration (FDA) for the treatment of alcohol dependence in 1951 and was the first medication to be given this indication. It remained the only FDA-approved medication for the treatment of alcohol dependence for several decades, until the approval of oral naltrexone in 1994. Disulfiram's utility in the treatment of alcohol use disorders primarily relies on "psychological deterrence," with patients ceasing consumption of alcohol in order to avoid the unpleasant disulfiram-ethanol reaction. Disulfiram is considered an "antidipsotropic" agent (one that prevents drinking) and is still referred to as an "aversive" agent. Though no longer done in current clinical practice, patients receiving disulfiram many years ago were initially administered both disulfiram and alcohol, creating an in vivo experience of aversive conditioning with the intent to eliminate drinking. This was not particularly successful, so more recently disulfiram is prescribed to help individuals avoid consuming alcohol. While taking disulfiram, its potential to foster complete abstinence from alcohol is unique among agents used to treat alcoholism and confers both great strength and weakness to the medication.

Numerous studies examining the clinical use of disulfiram have been published over a span of several decades. Early studies largely reported quite positive results. Unfortunately, many suffered from significant limitations, including lack of blinding, no monitoring of treatment adherence, inadequate follow-up periods, lack of comprehensive treatment plans, and nonrandomization. The majority of studies did not include control groups, and only very limited conclusions could be drawn from the first decades of study.

Taken as a whole, the accumulation of published literature has been equivocal in its support for disulfiram as an effective treatment for alcohol dependence. The largest and most frequently cited trial was a multi-site, Veterans Affairs (VA) cooperative study which included 605 veterans. Participants were randomly assigned to receive (1) 250 mg of disulfiram with 50 mg of riboflavin, (2) blinded 1 mg of disulfiram with 50 mg of riboflavin, or (3) no disulfiram with 50 mg of riboflavin. The inclusion of riboflavin was utilized to measure medication

adherence. The second group, who received only 1 mg of disulfiram in a blinded fashion, was included in order to confer the psychological threat of a disulfiram–ethanol reaction, without occurrence of the actual experience. All subjects in the study were given counseling.

Disappointingly, all three groups in the study showed similar outcomes, including total abstinence and time to first drink. Among those who drank and had a complete set of assessment interviews, those in the 250-mg disulfiram group, reported significantly fewer drinking days than either of the other two groups, which led to the suggestion that disulfiram may help reduce drinking frequency after relapse. Compliance with the drug regimen (in all three groups) was the best predictor of positive outcome (abstinence). However, only 20% of patients who completed the study were medication compliant. Though impressive in its scope, this study was limited by its lack of any systematic procedures known to enhance medication compliance, such as supervised use, administration by a significant other, or behavioral contracting.

Data from several smaller trials utilizing supervised disulfiram administration have produced some positive results. In a randomized, placebo (vitamin C)-controlled trial involving 126 alcohol-dependent patients, the disulfiram-treated group had a significantly higher number of abstinent days, decreased mean weekly alcohol intake, and lower total alcohol consumption over a 6-month period compared to the vitamin C group. Two-thirds of the disulfiram group requested to continue the treatment at the end of the study. Other studies have found increased rates of abstinence and “significant periods of sobriety” in the context of supervised disulfiram use.

It has been repeatedly shown that techniques known to improve medication compliance, such as incentive-driven interventions and supervised disulfiram treatment, are associated with improved outcomes, including decreased alcohol consumption and achievement of abstinence. Based on these findings, it is strongly recommended that disulfiram use should be supervised and prescribed within a comprehensive treatment program. A small body of literature suggests that court mandates may also improve adherence with disulfiram therapy.

In attempting to address issues with compliance, investigations have been conducted on the use of disulfiram implants. The technique of subcutaneous disulfiram implantation was first introduced in the 1960s. Implants were intended to release disulfiram at a consistent rate and sufficient dose to invoke the disulfiram–ethanol reaction if the patient consumed alcohol. However, the effectiveness of disulfiram implants remains in doubt. Many studies utilizing disulfiram implants have suffered from methodological flaws.

Furthermore, significant concerns regarding the implants themselves have arisen, including insignificant absorption and/or inadequate release of drug, infections, and other adverse physiological consequences. Disulfiram implants are not currently licensed for use in the United States.

The relationship between medication compliance and the effectiveness of disulfiram treatment is admittedly complex. It has been suggested that patients who are able to maintain compliance with disulfiram likely represent a more motivated, treatment-adherent subset of individuals whose success in achieving abstinence may not be attributable to the drug itself. These patients are hypothesized to be more likely to achieve positive outcomes, regardless of the treatment prescribed. Furthermore, a patient’s willingness to take a medication, such as disulfiram, which confers the risk of a significantly unpleasant bodily experience, is likely indicative of a heightened level of determination.

It is possible that disulfiram may be more useful in patients with certain characteristics. Though the literature on this topic has been unable to draw definite conclusions, patients who are older (over 40), socially stable, highly motivated, and able to tolerate treatment relationships have been shown to be more likely to benefit from disulfiram treatment. Additional predictors of positive response include longer drinking histories and Alcoholics Anonymous (AA) involvement.

Disulfiram may be particularly useful in the abstinence initiation phase of treatment, given its likelihood of eliminating impulsive drinking. However, it is not useful in preventing alcohol consumption planned in advance (allowing for premeditated nonadherence with the medication). The total prohibition of drinking fostered by disulfiram may also reduce preoccupation with alcohol, as craving has been shown to be related to perceived availability of substances.

In summary, the use of disulfiram in the treatment of alcohol dependence has garnered mixed results to date. However, there is evidence that disulfiram can be useful in reducing alcohol consumption and increasing rates of abstinence, particularly in the context of supervised use and among motivated individuals. Despite its potential utility, however, disulfiram is infrequently prescribed and, even then, often used for brief periods of time only. The exact reasons for this are unclear, though likely multifactorial. Patient acceptance can be hampered by fear of side effects or the disulfiram–ethanol reaction itself. Many patients are ambivalent about taking medication which dictates abstinence rather than allowing for occasional consumption. Physicians may be uncomfortable prescribing disulfiram due to lack of knowledge and experience with the medication, and many lack sufficient time/resources to comprehensively manage these patients. Additional factors include doubts about

pharmacotherapeutic effectiveness, concern that medication might reduce motivation for psychosocial treatment and mutual-help group attendance, and cost. In spite of the high prevalence of alcohol dependence and its consequences, disulfiram remains underutilized.

COMPARISONS AND COMBINATIONS WITH OTHER AGENTS

In addition to disulfiram, three other medications have received FDA approval for the treatment of alcohol dependence: oral naltrexone, acamprosate and, most recently, an extended-release injectable form of naltrexone (Vivitrol). Naltrexone, an opioid antagonist, gained FDA approval for the treatment of alcohol dependence in 1994. In clinical studies, naltrexone has been shown to reduce both alcohol use and “craving.” In decreasing the positive reinforcement associated with alcohol consumption, naltrexone has been associated with significant decreases in heavy drinking. Acamprosate (calcium acetylhomotaurinate) was approved for use in the United States in 2004. Though its exact mechanism of action is unclear, studies suggest that acamprosate may alter neuronal excitability at the *N*-methyl-*D*-aspartate glutamate receptors and/or facilitate the function of gamma-aminobutyric acid-A receptors. In doing so, acamprosate is thought to reduce protracted withdrawal symptoms which contribute to relapse.

There are few published studies directly comparing disulfiram with these agents. In a pilot study which looked at patients with both alcohol and cocaine dependence, disulfiram (250 mg per day) was found to be superior to naltrexone (50 mg per day) in reducing the frequency and quantity of alcohol consumption, in addition to lowering cocaine use. In a later study, 254 dually diagnosed patients (with an Axis I psychiatric disorder and comorbid alcohol dependence) were randomly assigned to one of four groups: (1) 50 mg of naltrexone, (2) placebo alone, (3) 250 mg of (open-label) disulfiram and (blinded) naltrexone, or (4) (open-label) disulfiram and (blinded) placebo. Individuals treated with an active medication sustained significantly more consecutive weeks of abstinence and reported less craving than those treated with placebo, but neither disulfiram nor naltrexone was more effective than the other. There was no advantage found in the combination of the two medications. A more recent double-blind placebo-controlled trial ($N = 208$) found that patients with co-occurring cocaine and alcohol dependence who received disulfiram (alone or in combination with naltrexone) were most likely to achieve combined abstinence from cocaine and alcohol. In contrast to the previous study, combination treatment with disulfiram and naltrexone

resulted in the highest achievement of three consecutive weeks of abstinence from both substances.

In a Swiss study investigating acamprosate (assigned randomly versus placebo) and disulfiram (as an “optional” medication chosen by patients) for the treatment of chronic or episodic alcohol dependence, similar outcomes were seen with each medication. Patients who received concomitant administration of the two medications showed the highest cumulative abstinence duration. However, potentially confounding factors included both the optional nature of receiving disulfiram and increased contact with treatment providers among disulfiram patients, due to the practice of daily handout of disulfiram in Switzerland.

In addition to contrasting medications, these studies also highlight the recent interest in combining medications for the treatment of alcohol dependence. Given their different mechanisms of action, it has been hypothesized that each medication may make a unique contribution within treatment, thus enhancing overall outcomes if administered in combination. For example, prescribing a medication that decreases craving for alcohol may enhance a patient’s ability to maintain adherence with disulfiram and benefit from its administration.

Once again, investigations utilizing combination treatment have been small in number and have produced mixed results. Other than those studies already described, an additional trial looking at the combination of disulfiram and naltrexone suggested possible support for combination treatment. Patients were randomly assigned to receive (1) naltrexone (25 mg) and disulfiram for 6 months, followed by 6 months of disulfiram or (2) disulfiram for 1 year. At the end of 1 year, 73% of the combination treatment group was abstinent from alcohol compared to 34% of the disulfiram-only group. At 2 years, 40% of the combination group remained abstinent, in comparison to no patients in the disulfiram-only group. Unfortunately, a naltrexone-only group was not included in the study, making it difficult to assess the actual benefit of combination therapy.

To date, the combination of disulfiram with either naltrexone or acamprosate has not resulted in additional patient safety concerns, including the occurrence of adverse hepatic effects. However, data remain sparse. Pharmacotherapeutic combination treatment for alcohol dependence remains an area in need of future study.

DISULFIRAM IN COCAINE USE DISORDERS

It has been observed that there is a unique association between alcohol and cocaine dependence. Data from the

Epidemiological Catchment Area study indicated that 85% of subjects who met criteria for cocaine dependence also met criteria for alcohol abuse or dependence. Co-occurrence of alcohol and cocaine dependence has been associated with increased severity of dependence, decreased treatment retention, and poorer outcomes when compared to either disorder on its own.

The association between alcohol and cocaine dependence is likely caused by multiple factors. Alcohol may be used to attenuate negative effects of acute cocaine use or withdrawal. Alcohol consumption may lead to initial or increased cocaine use, through disinhibition and impairment of judgment. When repeatedly used together, co-administration may become conditioned. There is also evidence that alcohol inhibits cocaine metabolism. Furthermore, co-ingestion of the two drugs results in the formation of cocaethylene (CE), a centrally active metabolite. The pharmacological effects of CE are similar to those of cocaine itself, but CE causes less elevation in heart rate and has a longer half-life than cocaine. In animal studies, CE has been shown to be more reinforcing and less anxiogenic than cocaine. This may help to explain why the combination of cocaine and alcohol has been reported to prolong cocaine-induced "highs," reduce paranoia and anxiety, lessen hyperactivity, and attenuate sleep disturbance.

In the early 1990s, two groups reported a positive impact of disulfiram in decreasing both alcohol and cocaine use among patients with co-occurring alcohol and cocaine use disorders. Subsequently, a larger study was conducted investigating disulfiram and three forms of manual-guided psychotherapy in the treatment of cocaine dependence and concurrent alcohol abuse or dependence. Administration of disulfiram was associated with better treatment retention and longer duration of abstinence from both alcohol and cocaine. In a 1-year follow-up study, the initial benefits of disulfiram on both cocaine and alcohol use were sustained. Furthermore, study participants continued to reduce their cocaine (but not alcohol) use after treatment ended.

Two papers published in 2000 examined the impact of disulfiram on cocaine use in patients addicted to both cocaine and opioids. One study recruited individuals maintained on methadone, while in the other, participants were maintained on buprenorphine. In these studies, disulfiram was associated with decreased cocaine use and increased cocaine abstinence. Alcohol consumption was minimal for all subjects across studies. Both sets of authors concluded by supporting the potential efficacy of disulfiram in treating cocaine dependence among methadone/buprenorphine-maintained opioid addicts.

Most recently, a randomized, placebo-controlled, double-blinded trial with 121 participants examined disulfiram, cognitive behavior therapy, and

interpersonal psychotherapy in the treatment of patients with cocaine dependence, with or without alcohol dependence. Those who received disulfiram reduced their cocaine use significantly more than those who received placebo. Positive effects of disulfiram were most pronounced in patients who did not have alcohol dependence at baseline or who completely abstained from alcohol consumption during the study. These results provided support for the concept that disulfiram has an impact on cocaine use that is independent of its effect on reducing alcohol intake.

The manner in which disulfiram may exert a direct effect on cocaine use is somewhat unclear. Given disulfiram's role in the central inhibition of dopamine beta-hydroxylase, the medication is known to increase dopamine concentrations. The use of cocaine in the presence of disulfiram then leads to further increases in dopamine. This may induce or exacerbate psychosis in certain individuals. Furthermore, disulfiram impedes the metabolism of cocaine through inhibition of plasma and microsomal carboxylesterases and plasma cholinesterase. It has been suggested that the combination of disulfiram and cocaine may result in an unpleasant "high." In altering the pleasurable effects of cocaine, leading to aversive and less reinforcing effects, cocaine use may be decreased.

Given the high rates of comorbidity with alcohol use disorders, investigation of disulfiram for the treatment of cocaine dependence needs to be approached with appropriate caution and patient education. Patients should be made aware of the potential consequences associated with alcohol consumption while taking disulfiram. Furthermore, the possibility of cocaine toxicity in the setting of disulfiram treatment has been raised. To date, however, disulfiram has been used safely in the investigational treatment of cocaine-dependent populations, with only mild adverse effects reported. At present, there are no FDA-approved medications for the treatment of cocaine dependence.

DISULFIRAM IN THE DUALY DIAGNOSED

There are currently no FDA-approved medications for the specific treatment of dually diagnosed individuals (patients with both a primary psychiatric disorder and a substance use disorder). Early reports suggested that disulfiram may precipitate or worsen psychosis, in addition to causing delirium, depression, anxiety, and mania. However, in the context of lowered disulfiram dosing and more standardized definitions of psychiatric symptoms, a growing number of recent studies have suggested that disulfiram can be used safely in patients with comorbid psychiatric disorders.

One recent large-scale placebo-controlled study compared disulfiram and naltrexone, alone and in combination, for the treatment of alcohol dependence in a veteran population with a heterogeneous set of comorbid mental disorders. The majority of participants were taking psychotropic medications at the time of study entry, and many were on more than one. There were no significant differences in serious adverse effects between groups and the study suggested that monitored use of disulfiram could be conducted safely in dually diagnosed individuals, even within the setting of concurrent use of psychotropic medications. In further analyses looking specifically at alcohol-dependent patients with comorbid posttraumatic stress disorder (PTSD), psychotic spectrum disorders, or depression, there were no significant increases in adverse effects associated with the use of disulfiram.

Notably, individuals with PTSD who were treated with disulfiram showed significantly more improvement in several symptoms of PTSD and it was suggested that such patients may respond particularly well to disulfiram. It has been hypothesized that the noradrenergic system may mediate both symptoms of hyperarousal in PTSD and the increased risk for substance abuse seen in these patients. Therefore, medications which dampen this response may be particularly effective in treating patients with comorbid PTSD and alcohol dependence. Disulfiram's central inhibition of dopamine beta-hydroxylase, resulting in increased levels of dopamine and decreased synthesis of norepinephrine, may alleviate symptoms of PTSD and decrease alcohol consumption by attenuating the vulnerability to stress-induced relapse.

Among patients with a psychotic spectrum disorder, there was no evidence that disulfiram at a dose of 250 mg daily caused a worsening of psychotic symptoms. Furthermore, patients with psychotic spectrum disorders were medication compliant and no more likely than nonpsychotic patients to consume alcohol with disulfiram. Of note, these study patients were thought to be highly motivated, clinically stable, adequately treated with psychotropic medication, and had only mild psychotic symptoms. Thus, these results may not be generalizable to the larger dual diagnosis population, particularly those who are less motivated, more unstable, and severely ill.

Effective medication treatment of alcohol dependence in patients with psychotic spectrum disorders may be particularly beneficial for several reasons. Alcohol-dependent patients with psychotic disorders may have greater reluctance to participate in self-help groups, such as AA, in which most members do not have comorbid psychiatric disorders. Furthermore, negative symptoms in psychotic disorders may undermine patients' motivation. In contrast, the use of pharmacotherapy is

usually familiar to dually diagnosed patients and generally requires less new learning than psychosocial treatments. Dose scheduling can often be readily integrated into existing treatment. Based on the small body of literature currently available, monitored use of disulfiram is thought to be safe and appropriate in dually diagnosed individuals.

CONCLUSIONS

Over several decades of research and clinical experience, disulfiram has remained an important, yet underutilized, treatment option within the addictions field. Despite some equivocal findings in the treatment of alcohol dependence, disulfiram's efficacy in the setting of supervised use has repeatedly received support. For many years, disulfiram represented the only medication approved by the FDA for the treatment of alcohol dependence. In spite of the recent addition of such medications as naltrexone and acamprosate, disulfiram continues to make a unique contribution, given its mechanism of action, reliance on "psychological deterrence," and ability to foster complete abstinence. The possibility that it may be particularly useful in patients with certain characteristics and in specific stages of treatment suggests that sophisticated prescribing may enhance disulfiram's benefit. Its combination with other agents and treatment modalities, either in parallel or in succession, may represent another avenue to maximize positive outcomes.

Though the majority of disulfiram research and utilization has taken place in the treatment of alcohol dependence, a growing body of literature has recently emerged supporting its use in the treatment of cocaine dependence and dually diagnosed individuals. The possibility of its use in additional patients, such as those with pathological gambling, has also been raised. It is hoped that additional study will help to maximize the benefit to be derived from this unique medication.

INTRODUCTION

It has been increasingly recognized by many in the treatment community that alcohol dependence is a medical illness. Surprisingly, few clinicians have utilized medications as a frontline treatment or even as an adjunct to treatment for alcohol dependence. For instance, a 2007 study from the US Veterans Health Administration reported that only 3% of veterans with an alcohol use disorder received a medication approved by the Food and Drug Administration (FDA) for alcohol

dependence. In this same study, of those who had a co-occurring psychiatric disorder, 52.6% received an antidepressant, most commonly a selective serotonin reuptake inhibitor (SSRI), while only 4.3% received a medication for their alcohol use disorder. Furthermore, alcohol-dependent individuals with no co-occurring psychiatric disorder were six times more likely to receive an SSRI than any of the FDA-approved medications for alcohol dependence.

In the United States, there are four medications approved by the FDA for the treatment of alcohol

dependence. Two of the naltrexone medications are different formulations – daily oral naltrexone tablets (ReVia®, Depade®), and a long-acting monthly injection (Vivitrol®). These medications are believed to reduce alcohol craving and blunt the rewarding properties of alcohol by blocking the opioid receptors in the brain. The other two medications are acamprosate and disulfiram. Acamprosate is thought to modulate the glutamate system and promote abstinence by alleviating aversive symptoms related to protracted alcohol withdrawal. Disulfiram interferes with the metabolism of alcohol creating an intense aversive state including flushing, nausea, and headache when the person drinks alcohol. This chapter, however, primarily focuses on the use of naltrexone and other opioid antagonists for the treatment of alcohol dependence.

DEFINITION OF THE PROBLEM

Alcohol use disorders comprise the disorders of alcohol dependence and alcohol abuse. Alcohol dependence is a chronic, relapsing disorder characterized by diminished control over the consumption of alcohol resulting in significant personal, social, and occupational consequences. The *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association defines alcohol dependence as a cluster of three to seven specific symptoms occurring in the same 12-month period that cause significant distress or impairment for the individual. The symptoms can include the physiological manifestations of tolerance and withdrawal, as well as more behavioral signs including the persistent desire to stop or cut down alcohol consumption, drinking more or longer than intended, drinking despite knowledge that alcohol is causing physical or psychological problems, spending too much time consuming alcohol or recovering from drinking, or impairment to important social, occupational, or recreational activities. Alcohol abuse is characterized by at least one of four symptoms that include failure to fulfill major role obligations, physically hazardous use, recurrent legal problems, and recurrent social or interpersonal problems. In 2000, the cost of alcohol dependence and alcohol abuse to the US economy was approximately \$185 billion per year. However, only 26% of those diagnosed with lifetime alcohol dependence based upon a national epidemiological survey ever received treatment either from professionals or from self-help groups (e.g. Alcoholics Anonymous). Furthermore, while it has been increasingly recognized by many in the treatment community that alcohol dependence is a medical illness, the majority of medical clinicians have failed to respond to the compelling evidence from controlled studies of efficacy derived with opioid antagonists in treating alcohol dependence. The need for improving education and

patient access to pharmacological treatment options while discovering new treatments is an undeniable problem.

EPIDEMIOLOGY

Alcohol use disorders affect a large segment of the population in the United States. The results of the recent National Epidemiologic Survey on Alcohol and Related Conditions reveal that lifetime prevalence of any alcohol use disorder is 30.3%. For men, 42.0% will meet criteria for alcohol abuse or dependence at some time in their lives. In keeping with the focus of this chapter, the remaining prevalence statistics will be reported for alcohol dependence only.

The lifetime prevalence of alcohol dependence in adults in Western countries ranges from 7 to 12.5%. In the United States, the 12-month prevalence (the percentage of adults with alcohol dependence in a 12-month period) is 3.8%. Men have a higher rate of alcohol dependence than women, with a lifetime rate of 17.4% versus 8.0% and a 12-month prevalence of 5.4% versus 2.3%. Within the United States, the race/ethnicity prevalence varies considerably, with Native Americans having the highest lifetime rate (20.1%), followed by Caucasians (13.8%), Hispanics (9.5%), African Americans (8.4%), and Asians (6.0%). Lifetime prevalence decreases by age cohort with 18–29 year olds reporting a 17.3% prevalence, 30–44 year olds reporting a 15.4% prevalence, 45–64 year olds reporting a 11.0% prevalence, and those 65 and older reporting a 3.4% prevalence. There are also differences based upon region of the country with those in the West and Midwest reporting higher lifetime rates (15.1 and 15.0%, respectively) than those in the Northeast and the South (10.6 and 10.3%, respectively).

In the United Kingdom, according to a 2000 national survey of those 16–74 years old (total sample size $n = 8580$), 7% of the total sample were assessed as being dependent on alcohol (ICD-10 criteria). Men had a higher rate of alcohol dependence than women, with a 12-month prevalence of 7.5% versus 2.1%. In Spain, estimates of “problematic drinking” have ranged from 3.4 to 7.2%. In other countries reporting ICD-10 or DSM-IV criteria, the lifetime prevalence rates for men and women (respectively) were Germany: 10.5 and 3.7%; Finland: 6.5 and 1.5%; Slovakia: 9.4 and 1.1%. In China, the rate of past year alcohol dependence was 5.2% (total), 9.2% (males), and 0.6% (females).

MEDICAL APPROACHES TO TREATMENT

More than a decade ago, McLellan and colleagues proposed a paradigm shift for the conceptualization and treatment of alcohol and other drug dependencies.

The prevailing view among policy makers and many in the treatment community had been that alcohol and other drug dependencies were primarily social and moral problems rather than medical illnesses. Treatments focused on acute cures or were relegated to forensic interventions. The authors demonstrated the similarities of these disorders to other chronic medical illnesses (such as type 2 diabetes and hypertension) in terms of diagnosis, genetic heritability, role of personal responsibility, pathophysiology, and response to treatment. By understanding alcohol dependence as a chronic medical illness, treatment in the primary care arena could become normative, with more difficult cases being referred to specialty care, as is typical of other chronic diseases. Frontline treatments would entail screening, diagnosis, brief interventions, medication management, and referral to specialty addiction counseling when indicated. Within this perspective, health care coverage for alcohol dependence would embrace a chronic disease model, supporting continuing care and achieving parity with other medical illnesses. In the past decade, considerable advances using this model have been made. Two new medications were approved by the FDA, and medical management protocols for treating alcohol dependence have been developed and tested. The Mental Health Parity and Addiction Equity Act of 2008, which went into effect in 2010, requires group health plans that cover 50 or more employees and offer both medical and mental health benefits to ensure that the mental health and substance abuse benefits are no more restrictive than the medical and surgical benefits. In addition, the Patient Protection and Affordable Care Act, was signed into law on March 23, 2010. Under this law, mental health coverage is considered an essential health benefit. As such, insurance companies are required to provide coverage that is equal to that provided for any other medical condition. Thus, with supportive legislation and a modern conceptualization, the field may be more open to accepting alcohol dependence as a medical illness.

NEUROBIOLOGY OF ALCOHOL DEPENDENCE AND THE ROLE OF THE ENDOGENOUS OPIOID SYSTEM

Alcohol affects all of the major neurotransmitter systems of the brain through complex, direct, or indirect processes. For example, it is hypothesized that lower doses of alcohol stimulate dopamine release via the glutamate system, and higher doses facilitate the gamma-aminobutyric acid (GABA) system and inhibit glutamate, consequently, suppressing dopamine release. This process contributes in part to the biphasic response to alcohol of early arousal followed by later sedation.

Our understanding of these mechanisms is incomplete but comes from animal models, human laboratory studies, human imaging studies, and human clinical trials. Acute exposure to alcohol facilitates GABA transmission and noradrenergic, serotonergic, dopaminergic, opioidergic, and endocannabinoid signaling while it inhibits glutamergic functioning. Chronic exposure to alcohol results in neuroadaptational changes that apparently underlie compulsive use of alcohol and the loss of consumptive control seen in alcohol dependence.

It is well established that all substances of abuse (including alcohol) facilitate dopamine release in the reward regions of the brain. The reward center includes the mesolimbic dopamine pathway with dopaminergic neurons projecting from the midbrain ventral tegmental area to the amygdala, hippocampus, nucleus accumbens, and prefrontal cortex. Alcohol is believed to have a direct impact on dopamine release in the nucleus accumbens but also impacts the dopamine system through the opioid system. Alcohol consumption increases the release of endogenous opioid peptides. The effects of opioids on reward are due in part to their ability to regulate dopamine release in the terminal regions of the reward pathway. Opioid peptides and other agonists at mu and delta opioid receptors increase extracellular dopamine levels in the nucleus accumbens. In addition, there is evidence that opioid reward also involves dopamine-independent mechanisms. Opioids can activate opioid receptors located postsynaptically to dopamine terminals in the nucleus accumbens. Given these actions, it is logical to consider medications with opioid-antagonist properties for the treatment of alcohol dependence.

OPIOID ANTAGONISTS FOR THE TREATMENT OF ALCOHOL DEPENDENCE

Oral Naltrexone

Naltrexone is an antagonist at the mu, delta, and kappa opioid receptors and was initially investigated for the treatment of opiate dependence. Oral naltrexone received FDA approval for opiate-dependence treatment in 1984 and injectable, long-acting naltrexone received FDA approval in October 2010. Early preclinical studies also demonstrated the potentiality of naltrexone for treating alcohol dependence. Based upon these findings, Dr Charles O'Brien initiated open label studies of naltrexone at the Philadelphia Veterans Affairs Medical Center in 1983. Subsequently, he and Volpicelli conducted a placebo-controlled clinical trial in chronic alcohol-dependent patients. Naltrexone significantly reduced rates of relapse to heavy drinking,

compared with placebo, with minimal side effects. These results were replicated by O'Malley and colleagues at Yale University in an independent study. These two important studies provided the basis for the FDA approval of oral naltrexone in 1994 for the treatment of alcohol dependence in the United States. Naltrexone has been approved for treatment of alcohol dependence in Canada, Australia, and a number of other countries in Europe and Asia.

Pharmacology and Mechanism of Action

Taken orally, naltrexone is quickly absorbed and undergoes first-pass metabolism in the cytosol system in the liver. Naltrexone is then converted to several metabolites. The major metabolite of naltrexone is 6- β -naltrexol, which is also an opioid antagonist and independently reduces alcohol drinking in a rat model. The mean serum elimination half-life after chronic administration of a 50 mg daily dose is 9.7 h for naltrexone and is 11.4 h for 6- β -naltrexol. PET studies show significant blocking of brain mu receptors for more than 72 h after a single 50 mg dose. By blocking the opioid receptors, naltrexone is believed to reduce the reinforcing effects of alcohol. Animal studies and human laboratory studies have shown that naltrexone reduces the reinforcing properties of alcohol. Human laboratory studies and clinical trials have shown that naltrexone reduces alcohol craving. In one human laboratory study, nontreatment-seeking alcohol-dependent subjects were randomly assigned to pretreatment with naltrexone or placebo. Subsequently, subjects were given a priming drink of alcohol and then were given a choice to consume more alcohol or earn money. The naltrexone-treated subjects reported less craving for alcohol at baseline, no change in craving score after the priming dose, drank less alcohol, and reported less alcohol craving overall during the experiment. In contrast, the placebo-treated subjects reported more alcohol craving at baseline, their craving significantly increased after the priming drink, they drank more alcohol, and reported more craving for alcohol during the experiment. Alcohol-dependent participants in human clinical trials randomly assigned to receive naltrexone have also reported less craving for alcohol than those receiving placebo.

Safety Profile

The safety profile of naltrexone provides a significant advantage for treatment of alcohol dependence. Traditionally, chronic drinkers were denied medications (except for detoxification) due to safety concerns over the potential interaction of most medications with alcohol. Naltrexone neither potentiates alcohol effects on motor skills or cognition nor does it reduce seizure threshold. Furthermore, naltrexone overdose has not resulted in any fatalities and it has no known abuse potential.

Fewer than 15% of patients report side effects with naltrexone. Nausea and vomiting are more commonly reported, while headache, low energy, anxiety, depression, rashes, and decreased alertness are less common. These side effects typically resolve spontaneously after a few doses, or with reduction of the daily dosage. Dysphoria has been reported by a few patients with opiate addiction and by a few normal volunteers who were given naltrexone. It is hypothesized that these reports may be indicative of a mild opiate "withdrawal-like" reaction in some patients that occurs when naltrexone abruptly blocks opioid receptors that are in an activated condition, possibly due to stress or substance intake. However, most studies have not found evidence of dysphoria or other mood changes with the recommended dose of naltrexone when treating alcohol-dependent patients.

There is a "black-box" in naltrexone's package insert warning of possible hepatocellular injury when taken in approximately seven times the recommended daily dose. It also warns against prescribing naltrexone in cases of acute hepatitis or liver failure. The warnings of hepatotoxic effects were derived from early studies, which prescribed dosages of up to 350 mg day⁻¹ for obesity and dementia. There are no reports of hepatotoxicity at the recommended daily dosage of 50 mg. Indeed, liver enzyme levels in alcohol-dependent patients typically are lowered with naltrexone treatment (relative to placebo), presumably due to reduced alcohol intake while in treatment. There appears to be a much greater risk of hepatotoxicity from chronic excessive alcohol drinking than from treatment with naltrexone at the recommended dosage.

The original manufacturer of naltrexone (DuPont Pharma) conducted a large safety study (~570 alcohol-dependent patients) and concluded that the medication was safe under a variety of circumstances. Naltrexone has also been studied for use in several other medical disorders, including obesity, bulimia, dementia, autism, self-injurious behavior seen in autism, and mental retardation.

Summary

Over 50 randomized, controlled trials with nearly 7000 alcohol-dependent patients have been published examining the efficacy of opioid antagonists for alcohol dependence. While not all studies have demonstrated an advantage over placebo, the results of several reviews (including two meta-analyses) clearly indicate the superiority of naltrexone over placebo in reducing relapse rates to heavy drinking, as well as in other drinking indices. The next section highlights the Combined Pharmacotherapies and Behavioral Interventions (COMBINE) study as the best example of this research, which, to date, is the largest pharmacological study of alcohol dependence.

The COMBINE Study

The COMBINE study was conducted from 2001 to 2004 at 11 academic research sites across the United States. This study enrolled 1383 patients with alcohol dependence who were randomized into 9 groups. Eight groups of patients received a new type of Medical Management (MM) intervention given with 16 weeks of naltrexone (100 mg day⁻¹ and placebo), or acamprosate (3 g day⁻¹ and placebo), or both naltrexone (100 mg day⁻¹) and acamprosate (3 g day⁻¹), or two placebos, with or without weekly sessions of a combined behavioral intervention (CBI) provided by behavioral health specialists. Medical professionals provided MM, which primarily focused on enhancing medication adherence and alcohol abstinence. A ninth group received CBI only (no MM, medications or placebo pills). After completing the 16 weeks of treatment, patients were evaluated after 1 year, and all patient groups showed substantial reduction in drinking. The baseline rate of percent days abstinent of 25.2% improved to 73.1% by the end of treatment. Percent days abstinent was significantly higher for those patients taking naltrexone with CBI (77.1%) or without CBI (80.6%), compared to those with placebo and no CBI (75.1%). One year after completing treatment, these between-group effects were similar but no longer significant. For the percentage of patients who relapsed to heavy drinking, those taking naltrexone had a better outcome than those taking placebo (68.2% versus 71.2%). This advantage for naltrexone persisted at the 1-year follow-up evaluation. The investigators also calculated the percentage of patients who achieved a good clinical outcome during the last 8 weeks of the trial. Those patients taking naltrexone with CBI or without CBI fared better than those with placebo and no CBI (74%, 74%, and 58%, respectively). One year after treatment, these between-group effects were similar but no longer significant. Interestingly, there was no advantage in taking acamprosate alone or in combination with naltrexone compared to placebo at any time during or after treatment.

Issues of Medication Adherence

In the COMBINE study, the mean medication adherence rate was excellent (86%), likely due in part to the MM intervention, which focuses a patient on treatment adherence. There were similar adherence rates for individual medication groups and for those with and without CBI. However, not all naltrexone studies have demonstrated good adherence rates and those with low rates typically were associated with reduced efficacy. One of the earliest naltrexone trials found an effect only when considering the patients that were 90% adherent.

Medication nonadherence is problematic for all chronic medical illnesses. Nearly 50% of adults evidence some problems with medication adherence. Nonadherence may be unintentional (forgetfulness or misunderstanding the medication regimen) or intentional (related to side effects, cost, or symptom improvement). Medication nonadherence rates may be higher in alcohol-dependent patients than in other patient populations for a variety of reasons. In the alcohol-treatment community, there has been a bias against medication interventions that may influence patient adherence. Furthermore, by blocking the euphoric effects of alcohol, some patients may terminate medication usage because they want to re-experience the reinforcing effects of alcohol. In addition, since the opioid antagonists selectively impact the reward centers, they neither relieve other distressing psychiatric symptoms nor provide a sense of well-being or relief. Thus, it is widely accepted that nonadherence is a major barrier to successful treatment outcome, particularly when treating alcohol dependence. Some major naltrexone trials have been published that have demonstrated that the benefits of naltrexone are evident only in patients who are reliable in taking their study medication every day. Although there may be no demonstrable advantage for naltrexone in the study sample as a whole, a clear advantage for naltrexone emerges when outcome data are based only on patients who received an adequate exposure to the medication.

Injectable Naltrexone

Injectable naltrexone formulations were designed to improve medication adherence, minimize fluctuations in plasma levels, increase bioavailability, and minimize side effects. Long-acting formulations of naltrexone were developed by encapsulating naltrexone into injectable, biodegradable polymer microspheres. Naltrexone is released continuously, achieving a stable therapeutic level that is low enough to reduce side effects. Furthermore, an intramuscular injection avoids the first-pass metabolism of the oral version, increasing bioavailability.

While at least three injectable formulations have been tested, only one is FDA-approved for the treatment of alcohol dependence (Vivitrol®, Alkermes, Inc., Cambridge, Massachusetts, USA). This formulation is given as a monthly injection. The safety and efficacy of long-acting naltrexone has been demonstrated in four randomized clinical trials. The largest trial on injectable naltrexone (Vivitrol®) is a 6-month multicenter trial (24 sites) with 624 patients randomized to monthly injections of 190 mg or 380 mg or a matched volume injectable placebo. Compared to placebo, there was a dose-response reduction in heavy drinking, but the

differential treatment response from placebo reached statistical significance only in the higher dose group (380 mg). The primary outcome variable was the event rate of heavy drinking, which proved to be 25% lower among patients who received 380 mg extended-release naltrexone compared to patients who received placebo ($p = 0.03$). Significant treatment interactions were shown for gender and pretreatment status of abstinence. Extended-release naltrexone was most effective in men and in patients who entered the study with at least 14 days of abstinence. Pettinati and colleagues also demonstrated that extended-release naltrexone was associated with improvements in quality of life, specifically in the domains of mental health, social functioning, general health, and physical functioning.

Other Opioid Antagonists

Nalmefene is the only other opioid antagonist that has been extensively studied for treating alcohol dependence. It is licensed for the treatment of alcohol dependence in various countries but not in the United States and there are several ongoing Phase III trials in Europe. While nalmefene has a similar chemical structure to naltrexone, it is purported to have improved opioid receptor binding, improved bioavailability, and less of a risk for liver toxicity than naltrexone. While these purported benefits have not been independently verified, human laboratory studies demonstrated that it was comparable to naltrexone in reducing alcohol craving and reward stimulation in nontreatment-seeking alcohol-dependent patients. Some randomized trials have supported the efficacy of nalmefene. For instance, a multicentered, placebo-controlled 28-week trial conducted in Finland randomized 403 treatment-seeking heavy drinkers to 20 mg of nalmefene per day or to placebo in a 3:2 ratio. Patients were instructed to take the medication 1–2 h before drinking when drinking seemed imminent. After 2 weeks the dose could be adjusted upward to 40 mg day⁻¹ or downward to 10 mg day⁻¹, based upon treatment response and tolerability. Patients received a brief medical intervention that focused on medication adherence. Patients receiving nalmefene demonstrated reductions in heavy drinking and improvements in liver function tests compared to those receiving placebo. Despite support from this trial, another multicenter trial conducted in the United States did not support the efficacy of nalmefene. Eleven sites participated in this trial, randomizing 270 alcohol-dependent patients to 5, 20, or 40 mg of nalmefene in a double-blind comparison to placebo. As is typically found, patients demonstrated reduced drinking, craving, and improvement on liver function tests during the course of the trial, but there were no significant differences between the active

medication and placebo groups. Thus, despite the promise of nalmefene, currently there is insufficient clinical evidence to support its use in the United States for treating alcohol dependence.

FUTURE DIRECTIONS

Subtypes of Alcohol Dependence: The Impact of Individual Characteristics on Treatment Response

The population of alcohol-dependent patients represents considerable diversity in etiology, manifestation of the illness, and response to treatment. There is a rich tradition of attempts to identify more homogeneous subgroups of alcohol dependence and match treatments to patient characteristics. This same tradition has influenced the use of naltrexone for alcohol dependence treatment. While the efficacy of naltrexone has been repeatedly demonstrated in groups of patients, individual patients vary widely in their response to opioid antagonists. Not all clinical trial studies have reported an advantage of naltrexone over placebo for alcohol treatment, including a large, multi-site Veterans Affairs study. Interestingly, a reanalysis of these data identified three subgroups based upon the drinking trajectories during the trials with different outcomes. Compared to patients randomized to be treated with placebo, naltrexone patients were more likely to be “abstainers” and less likely to be “consistent drinkers.” However, the likelihood of being classified as a “sporadic drinker” was not influenced by naltrexone. This study represents the advantage of considering more homogeneous subgroups of alcohol-dependent patients when predicting treatment response to specific pharmacotherapies.

Another promising line of research has focused on genetic factors that may impact naltrexone treatment response. A number of functional polymorphisms have been studied in the gene encoding for the mu opioid receptor, OPRM1. Particular interest has been focused on Asn40Asp polymorphism, such that individuals with one or two copies of the Asp40 allele report greater subjective feelings of intoxication, stimulation, sedation, and euphoria, compared to those homozygous with the Asn40 allele. Furthermore, in a retrospective analysis combining three clinical trials, patients with the Asp40 allele who took naltrexone demonstrated a 3.5 times better response, preventing relapse to heavy drinking. The COMBINE study replicated these findings, showing an advantage in the percent days abstinent, percent days of heavy drinking, and the percentage of patients with a good clinical outcome for the subset of patients receiving only naltrexone and

MM. However, a third clinical trial did not find an association of improved drinking outcomes with naltrexone in those with the Asp40 allele.

Another typology has been proposed by Babor and colleagues who defined Type A and Type B alcohol-dependent patients. Type A alcohol dependence is characterized by late-onset problem drinking, few childhood risk factors, lower severity of alcohol dependence, little drug use, few alcohol-related problems, little concomitant psychopathology, and a relatively promising prognosis with traditional alcohol-dependence treatment. Type B alcohol dependence, by comparison, is characterized by an early age of onset of alcohol problems, more childhood risk factors, higher severity of dependence, more evidence of polydrug use, a higher degree of concomitant psychopathology, and a poorer prognosis after treatment. This typology has been particularly promising in distinguishing response to specific SSRI treatment for alcohol dependence. For individuals with Type A alcohol dependence, SSRI treatment may be beneficial, whereas for Type B patients SSRIs may be contraindicated. One study has looked at response to naltrexone treatment using the Babor typology. In a secondary analysis of the COMBINE study data, Type A patients receiving naltrexone and MM (but not CBI) showed improved drinking outcome versus those taking placebo. Interestingly, no benefit over placebo was seen in the Type B patients, although this had been initially hypothesized, given the relationship between Type B characteristics and serotonin depletion.

Other promising typologies have been proposed by investigators such as Cloninger, Lesch, and Mann. Of particular interest, the ongoing German project "PREDICT" seeks to categorize patients according to different types of alcohol craving and evaluate the effectiveness of naltrexone and acamprosate. According to the specific mechanism of action of both substances, patients with high "reward" craving are assumed to benefit more from naltrexone, whereas patients with "relief" craving should benefit more if treated with acamprosate. The study shares several components with the COMBINE study (e.g. the same medications, inclusion and exclusion criteria, use of MM and CBI) that facilitates a direct comparison between the German and US studies. In the original design, 430 patients were to be randomized to naltrexone, or acamprosate, or placebo in a 2:2:1 ratio. Patients received medication for 12 weeks in conjunction with MM, which is extended to 6 months. Patients who relapsed were re-randomized to either MM or CBI while remaining on the same medication. The trial is in the data analysis phase. To date, there are insufficient data to support that any of these different typologies provide a reliable, replicable classification for predicting treatment outcomes with specific

pharmacotherapies. However, research efforts are ongoing.

Some investigators have proposed that naltrexone may not be efficacious for all populations. For instance, a secondary analysis of the COMBINE study data suggested that naltrexone may be most efficacious for individuals of European descent who inherited a particular polymorphism. Other investigations have questioned the efficacy of naltrexone for the treatment of women, although almost always these studies are underpowered for testing medication effects in women. A full exploration of these issues is beyond the scope of this chapter but there is general consensus in the field that naltrexone is efficacious for many African Americans and many women. Discrepancies in the findings of some studies may be a function of samples size, or too few studies that *a priori* planned to test these subgroups. Furthermore, the FDA has not restricted the use of naltrexone for these populations. Nonetheless, future research is needed on the study of such subgroups and their response to opioid antagonists, such as naltrexone.

Combining Naltrexone with Other Pharmacotherapies to Improve Treatment Response

Naltrexone and Acamprosate for the Treatment of Alcohol Dependence

Given the variability in etiology and progression of alcohol dependence and limited response to treatment for any of the available medications, it is reasonable to try combining medications if they have different but complementary mechanisms of action. Acamprosate, approved by the FDA in 2006, is thought to decrease relapse rates by its action on the glutamate system, whereas naltrexone targets the opioid system. Two randomized, placebo-controlled trials have compared the results of oral naltrexone, acamprosate, both naltrexone and acamprosate to a double placebo. In a single-site trial, 160 patients received medication and weekly psychosocial treatment for 12 weeks. All three treatment groups demonstrated better relapse rates than the placebo groups. The patients receiving the combination of naltrexone and acamprosate fared significantly better than patients who received acamprosate alone but not better than those who received naltrexone alone (time to the first drink and time to first heavy drink). In the multi-site COMBINE study described earlier, naltrexone, but not acamprosate, showed an advantage in longer times to first heavy-drinking day and higher rates of percent days abstinent. Acamprosate was not shown to be effective, either alone or in combination with naltrexone. Thus, although safe and well tolerated, there is insufficient evidence to date to

recommend adding acamprosate to naltrexone for the treatment of alcohol dependence.

High-Dose Naltrexone with and without Disulfiram for the Treatment of Alcohol Dependence and Co-Occurring Cocaine Dependence

High rates of comorbidity exist among alcohol and cocaine populations. Up to 60% of patients seeking treatment for cocaine dependence are also dependent on alcohol. Alcohol+cocaine-dependent patients suffer more addiction-related consequences, greater psychosocial problems, and higher rates of recidivism than patients addicted to alcohol or cocaine alone. Furthermore, these patients are particularly difficult to treat. Commonly, the use of one substance leads to the use of the other. In addition, concurrent use of cocaine and alcohol notably yields cocaethylene, an active metabolite associated with more lethality and toxicity than cocaine alone. From a neurobiological perspective, addiction to both alcohol and cocaine is further complicated because these agents have different and additive effects on reward-related glutamate and GABA neurons. Thus, this treatment-refractory population may require a pharmacological approach, to supplement traditional counseling, which effectively targets the potentially different neurobiology of the combination of cocaine and alcohol dependencies. It is reasonable to explore the efficacy of naltrexone for treating alcohol- and cocaine-dependent patients, because drinking alcohol can trigger cocaine use. In addition, there is some evidence that naltrexone may have a direct effect on reducing the compulsive use of cocaine, without respect to alcohol.

While two double-blind, placebo-controlled studies of 50 mg day⁻¹ of naltrexone did not reduce alcohol nor cocaine use in co-occurring cocaine+alcohol-dependent outpatients, an open-labeled trial of 150 mg day⁻¹ showed promise. Pettinati and colleagues conducted a series of naltrexone studies using higher daily doses to treat this population. In a 12-week clinical trial, 164 patients (stratified by gender) were randomized to 150 mg of naltrexone or placebo and to either cognitive behavioral therapy or a type of medical management. The higher than typical daily dose of naltrexone (i.e. 150 mg day⁻¹) was associated with gender differences in response to treatment. For men, there was a reduction in the amount of use and severity in treatment on both cocaine and alcohol. However, women dependent on both cocaine and alcohol did not appear to benefit from the daily dose. In another trial, disulfiram (250 mg day⁻¹) was added to a treatment regimen of 100 mg day⁻¹ of naltrexone. Two hundred and eight patients were randomized to receive disulfiram, naltrexone, the combination, or placebo for 11 weeks while participating in twice-weekly individual cognitive behavioral therapy (CBT). While the primary analyses

demonstrated no differences among groups in abstinence from cocaine or alcohol, secondary analyses revealed that patients taking the disulfiram–naltrexone combination were most likely to achieve three consecutive weeks of abstinence from cocaine and alcohol than were the placebo-treated groups. These studies suggest that higher doses of naltrexone may show some promise with this treatment-resistant population.

Naltrexone and Sertraline for the Treatment of Alcohol Dependence and Co-Occurring Depression

The co-occurrence of alcohol dependence and depression is highly prevalent and difficult to treat. High severity in one disorder is associated with high severity in the other, and each disorder carries a significant risk for the development of the other. The persistence of depression during abstinence from alcohol is a risk factor for relapse to heavy drinking, and alcohol dependence prolongs the course of depression. Two independent reviews of controlled trials concluded that antidepressants alleviated depression but had little effect on reducing drinking. Because antidepressants alone do not typically appear to affect drinking in depressed alcohol-dependent patients, a medication such as naltrexone that directly affects drinking may be a necessary adjunct to antidepressant therapy for successful treatment. Pettinati and colleagues randomly assigned 170 depressed alcohol-dependent patients to sertraline (200 mg day⁻¹), naltrexone (100 mg day⁻¹), the combination of sertraline plus naltrexone, or double placebo while receiving weekly CBT during a 14-week clinical trial. In this study, more depressed alcohol-dependent patients treated with the combination of sertraline plus naltrexone significantly delayed relapse to heavy drinking than patients taking single-medication treatments or placebo. Furthermore, the sertraline plus naltrexone combination produced a higher alcohol abstinence rate than the other groups. Secondary drinking analyses supported these findings and there were fewer serious adverse event reports in the medication combination group than the other groups. While all treatment groups showed a clinical reduction in depressive symptoms, those receiving the medication combination (sertraline plus naltrexone) tended not to be depressed in the last 3 weeks of treatment than those in one of the other three treatment groups. The findings from this study suggest that patients with both alcohol dependence and depression would benefit from the combination of an antidepressant and a medication for alcohol dependence.

Other Promising Medications for the Treatment of Alcohol Dependence

While the focus of this chapter has been on the use of opioid antagonists, it is important to mention other

promising medications for the treatment of alcohol dependence that are currently under investigation but are not FDA-approved for alcohol dependence. Indeed, some of these medications may complement the pharmacological effects of naltrexone and may be targets for combination therapies.

Topiramate is an anticonvulsant that has been used to treat alcohol withdrawal. It facilitates the GABA system at the GABA_A receptors and has demonstrated efficacy for the treatment of alcohol dependence in at least three double-blind, placebo-controlled clinical trials. Its use may be hampered by the side-effect profile which includes fatigue, paresthesia, weight loss, headache, taste perversion, nausea, and dizziness. However, a slow titration schedule can minimize the occurrence of adverse events and drop out from adverse events.

Baclofen is a muscle relaxer and antispastic agent used in the treatment of multiple sclerosis. As a selective GABA_B receptor agonist, it directly and indirectly inhibits dopaminergic neurons by which baclofen is believed to suppress alcohol reinforcement. Baclofen appears to be well tolerated and safe for patients with compromised liver function. Preclinical data, open-label studies, and two randomized placebo-controlled trials in Europe support its use for alcohol-dependence treatment. However, at least one well-controlled trial in the United States did not demonstrate efficacy.

Quetiapine is an atypical antipsychotic with both dopaminergic and serotonergic activity. In a recent 12-week double-blind, placebo-controlled trial of quetiapine, alcohol-dependent patients taking quetiapine were more likely to remain completely abstinent compared to placebo-treated patients. Interestingly, reduction in drinking and in craving for alcohol was seen in the Babor Type B patients but not in the Babor Type A patients. Currently, a single-site and multi-site trials are underway to further explore the potential of quetiapine for the treatment of alcohol dependence.

Ondansetron is a serotonin-3 (5-HT₃) receptor antagonist with support from preclinical and human laboratory studies for the treatment of alcohol dependence. Three double-blind, placebo-controlled trials demonstrated improvements in drinking outcomes, particularly for those with Babor Type B alcohol dependence.

SUMMARY

Charles O'Brien has described naltrexone as an optimal medication for the treatment of alcohol dependence because it has been shown to be efficacious, highly specific to opiate receptors, with no abuse potential, and a tolerable side-effect profile. This chapter reviews the latest literature on the use of opiate antagonists for the treatment of alcohol dependence, focusing

primarily on naltrexone. Alcohol-use disorders cause substantial morbidity and mortality. Alcohol is the third leading cause of preventable death in the United States according to the Centers for Disease Control and Prevention. Lifetime prevalence of alcohol dependence is higher in men (17.4%) than women (8.0%); however, only 26% of those diagnosed with lifetime alcohol dependence have received some type of treatment (professional or self-help groups).

One goal of the authors of this chapter was to promote an understanding of alcohol dependence as a chronic medical illness amenable to frontline treatment by primary care and specialty clinicians. Surprisingly, few clinicians have utilized medications to treat alcohol dependence, despite the fact that there are four medications approved by the FDA. Oral naltrexone (50 mg daily) was approved in 1994 and a long-acting, injectable formulation (380 mg monthly) was approved in 2006. Injectable naltrexone was designed to improve medication adherence, minimize fluctuations in plasma levels, increase bioavailability, and minimize side effects. The two other FDA-approved medications are disulfiram and acamprosate, both of which are oral formulations requiring daily pill taking.

Alcohol affects all of the major neurotransmitter systems of the brain through complex, direct, or indirect processes. Alcohol and other drugs of abuse facilitate dopamine release in the reward regions of the brain. Alcohol impacts the dopamine system through the opioid system. Given this, it was logical to want to test medications with opioid-antagonist properties as treatments of alcohol dependence. Naltrexone is an antagonist at the mu, delta, and kappa opioid receptors and was initially investigated for the treatment of opiate dependence.

Another opioid antagonist, nalmefene, has been studied extensively. Despite its use in other countries, there is currently insufficient clinical evidence to support its use in the United States. Overall, 50 randomized, controlled trials with nearly 7000 alcohol-dependent patients have been published examining the efficacy of opioid antagonists for treating alcohol dependence. While not all studies have demonstrated an advantage of these medications compared with placebo, the results of several reviews (including two recently published meta-analyses) clearly indicate the superiority of naltrexone over placebo in reducing relapse rates to heavy drinking and other drinking indices.

The population of alcohol-dependent patients represents considerable diversity in etiology, presentation of the illness, and response to treatment. There is a rich tradition of attempts to identify more homogeneous subgroups of alcohol dependence and match treatments to patient characteristics. A promising line of research has focused on genetic factors that may

impact naltrexone-treatment response. Individuals with one or two copies of the Asp40 allele who took naltrexone demonstrated a 3.5 times better response in relapse to heavy drinking than those homozygous to the Asn40 allele. Other promising typologies have been proposed by Babor, Cloninger, Lesch, and Mann among others.

To address the limited response to any treatment by many alcohol-dependent patients and to address co-occurring illnesses, numerous studies have combined naltrexone with other medications. Acamprosate has been added to naltrexone in two clinical trials – a single-site trial and the multi-site COMBINE study. Although safe and well tolerated, there is insufficient evidence to date to recommend adding acamprosate to naltrexone for the treatment of alcohol dependence. Higher doses of naltrexone with and without disulfiram have shown some promise for the treatment of alcohol dependence and co-occurring cocaine dependence. Combining sertraline with naltrexone was efficacious for the treatment of alcohol dependence and co-occurring depression in one clinical trial. Finally, topiramate, baclofen, quetiapine, and ondansetron are under investigation for the treatment of alcohol dependence and may be targets for combination therapies with naltrexone.

ALCOHOL DEPENDENCE

Alcohol-use disorders, which include both alcohol abuse and dependence, make up one of the most prevalent categories of substance-use disorders affecting more than two billion people worldwide. *The Diagnostic and Statistical Manual of Mental Disorders – Fourth Edition (DSM-IV)* characterizes alcohol dependence as a maladaptive pattern of drinking leading to clinically significant impairment, as manifested by a compulsion to drink, a lack of control over the amount of alcohol consumed, and continued drinking despite a realization of the problems associated with it. Alcohol dependence is a chronic relapsing disorder that has several stages that contribute to excessive drinking and dependence. Chronic heavy alcohol use can drive the neuroadaptive changes in stress and reward pathways associated with dependence and the resulting negative affective states and alcohol craving when alcohol use is discontinued. These latter symptoms comprise a syndrome referred to as protracted abstinence.

Protracted abstinence is a state that involves symptoms of anxiety, irritability, hostility, dysphoria, insomnia, fatigue, and craving and is hypothesized to be driven by dysregulation in stress and reward systems in the central nervous system (CNS) that persist long past acute withdrawal from alcohol. Clinical literature has indicated that protracted abstinence symptoms of craving, negative affect, and sleep disturbances are strongly correlated with relapse to compulsive drinking. For example, one study found that 94% of alcohol-dependent subjects experienced anxiety following cessation of drinking, and 82% of these patients reported an alleviation of this symptom after alcohol use. Relapse, or the return to alcohol abuse following periods of abstinence, is one of the principle characteristics of dependence on alcohol. Given that one of the most challenging aspects of recovering from alcohol dependence is to not relapse to heavy drinking after acute withdrawal, a recent Betty Ford consensus panel identified complete abstinence, as opposed to “controlled drinking,” as the

most reliable way for dependent individuals to avoid relapse and its associated problems.

NEUROBIOLOGY OF ALCOHOL DEPENDENCE AND PROTRACTED ABSTINENCE

Neurobiological approaches to alcohol dependence have suggested that it develops in a process of homeostatic adaptation to chronic high doses of alcohol that increases the set point for reward. The process is thought to include several neurotransmitter systems including gamma-aminobutyric acid (GABA) which is involved primarily with protective inhibitory effects and glutamate which is involved primarily with endogenous excitability. These neurotransmitter systems modulate internal states associated with positive and negative affect, states which are implicated in clinical vulnerability to relapse and protracted abstinence. The neural substrates and neuropharmacological mechanisms for the negative motivational effects of withdrawal from alcohol may involve not only disruption of the same neural systems implicated in the positive reinforcing effects of alcohol, but also recruitment of brain stress systems. During the withdrawal/negative affect stage, negative reinforcement mechanisms are in effect rather than positive reinforcement mechanisms. As such, individuals will often take the addictive substance to relieve protracted withdrawal states such as anxiety, irritability, or dysphoria, or to self-medicate the negative affect or general malaise. Acute withdrawal from alcohol dependence includes decreased dopaminergic activity, activated glutamatergic systems, an activated pituitary adrenal stress response, and activated amygdala corticotrophin-releasing factor (CRF). However, repeated cycles of relapse and withdrawal lead to a blunted pituitary adrenal response and a sensitized extrahypothalamic CRF stress system response in the amygdala. One goal of medications development for alcohol dependence is to reverse or compensate for such pathological effects.

A critical issue in the development of treatments for alcohol dependence is that relevant targets be based on an empirical understanding of the neurobiology of dependence. There is a substantial need for discovering innovative ways to provide more information on the neurobiology of alcohol dependence as well as to discover more effective pharmacotherapies for alcohol dependence.

MEDICATIONS TO TREAT ALCOHOL DEPENDENCE

Three medications are currently approved for the treatment of alcohol dependence – disulfiram,

naltrexone, and acamprosate. The first two medications, disulfiram and naltrexone, attempt to reduce pathological alcohol use by reducing the rewarding value of alcohol. Both drugs, however, have been characterized by problems with high rates of noncompliance and a return to pathological drinking when the drug is discontinued. Current research indicates that acamprosate has a unique mechanism of action, which may have implications for its therapeutic use. In contrast to disulfiram, which causes aversive behavior through negative physical effects, or naltrexone, which tempers the pleasurable effects of alcohol, acamprosate acts to normalize dysregulated brain systems caused by chronic alcohol use and withdrawal thereby decreasing an alcoholic's "need" to drink.

OVERVIEW OF ACAMPROSATE

Acamprosate is a safe and well-tolerated pharmacotherapy for alcohol dependence that has been studied in numerous clinical trials worldwide. Its safety and efficacy have been evaluated in more than 6500 outpatients participating in 23 double-blind, placebo-controlled clinical trials conducted in 15 countries. It has been used to treat alcohol dependence in over 1.5 million patients since its introduction in Europe in 1989 and is currently available in most European and North American countries, Australia, and parts of South America, Asia, and Africa. A recent survey of pharmacies found that acamprosate is now the most widely prescribed therapeutic agent for the treatment of alcoholism in the United States. It is available as a 333 mg tablet, and the recommended dosage regimen is two 333 mg tablets taken three times a day which may be prescribed in a blistercard. Clinical trials have typically shown that acamprosate is effective in maintaining abstinence in recently detoxified patients, especially when patients are motivated to be abstinent. Overall, acamprosate has been consistently associated with greater beneficial effects on measures of alcohol abstinence compared with placebo. Specifically, patients treated with acamprosate achieve greater rates of complete abstinence, longer times to first drink and/or increased duration of cumulative abstinence when compared with placebo.

Acamprosate is a synthetic taurine analog that acts centrally to restore the normal activity of glutamatergic neurotransmission altered by chronic alcohol exposure. Its mechanism of action involves normalizing the dysregulation of brain *N*-methyl-D-aspartic acid (NMDA)-mediated glutamatergic neurotransmission that occurs in alcohol dependence, thus attenuating one of the physiological mechanisms that may prompt drinking relapse.

MECHANISM OF ACTION OF ACAMPROSATE

Acamprosate is an analog of amino acid neurotransmitters such as taurine and homocysteic acid which have modulatory effects on brain NMDA receptors. Recent evidence has demonstrated that acamprosate binds to a specific spermidine-sensitive site that modulates the NMDA receptor in a complex way acting as a “partial co-agonist” at the NMDA receptor, such that low concentrations enhance activation when receptor activity is low, and high concentrations inhibit activation when receptor activity is high. In other words, at low levels of endogenous activity, the drug works as an agonist, whereas at high levels of endogenous activity, the drug works like an antagonist because it “competes” with the endogenous ligand. Thus, partial agonists serve a more modulatory role than a pure agonist or antagonist would. This may be particularly relevant to the success of acamprosate as a pharmacotherapy given that chronic exposure to ethanol results in an upregulation of NMDA receptors and an upregulation in the density of voltage-dependent calcium channels such that abstinence from alcohol induces a surge of excitatory neurotransmitters such as glutamate, which in turn activates the NMDA receptors. These alcohol-related changes in NMDA receptors are posited to contribute to the symptoms associated with protracted abstinence, such as craving and disturbances in sleep and mood. Conversely, acamprosate promotes the release of taurine in the brain. Taurine is a major inhibitory neuromodulator/neurotransmitter and an increase in taurine availability contributes to a decrease in the earlier-described hyperexcitability. Therefore, it has been hypothesized that acamprosate may promote abstinence by minimizing or negating some of the physiological changes produced by chronic heavy ethanol exposure and withdrawal that may underlie symptoms associated with relapse, such as craving, anxiety, and insomnia. Further support for this hypothesis is provided by polysomnography studies that found acamprosate reversed alcohol-related changes in sleep architecture in humans.

CLINICAL EFFICACY OF ACAMPROSATE

The safety and clinical efficacy of acamprosate have been studied in more than 6500 alcohol-dependent outpatients in 23 randomized, placebo-controlled trials conducted in Europe, Asia, North and South America, and Australia. Efficacy measures for the majority of the studies were the rate of complete abstinence (defined as zero drinks during the entire study) and the

percentage of abstinent days over the study duration. An increase in abstinence rates with acamprosate was confirmed in the majority of studies (18 of the 23 trials reported positive outcomes for acamprosate relative to placebo) as well as in meta-analyses of acamprosate clinical trials. All five meta-analyses concluded that abstinence rates were significantly higher in acamprosate-treated patients than in those treated with placebo with small to moderate, but significant effects in maintaining abstinence in alcohol-dependent patients. A recent meta-analysis found a relative benefit of acamprosate for abstinence rates to be 1.33 at 3 months, 1.50 at 6 months, and 1.95 at 12 months. Compliance rates tend to average around 85% across studies with a meta-analysis reporting a significant effect of acamprosate on compliance rates relative to placebo. Treatment durations of randomized trials ranged from 2 months to 1 year with 13 of 23 trials being greater than or equal to 6 months in duration. Patients typically underwent inpatient detoxification prior to randomization. However, the two US studies reported that only 2.3 and 7.7% of patients received inpatient detoxification prior to randomization. Most studies required abstinence at baseline for approximately 5 days (range of 3–32 days), with the exception of three studies, conducted in the United Kingdom, the United States, and Korea, that did not have an abstinence requirement at initiation of study medication. Based on the post-detoxification “normalizing” mechanism of action described earlier, it is not surprising that the three studies without an abstinent requirement at baseline did not show an effect of acamprosate on abstinence in the Intention-To-Treat (ITT) populations. Acamprosate is not indicated for the induction of abstinence but rather for the maintenance of abstinence in alcohol-dependent patients who have been withdrawn from alcohol. In addition, post hoc analyses of the US study data that controlled for baseline differences in outcome-related variables, including goal of total abstinence and stage of readiness to change, showed a significantly higher percentage of abstinent days with acamprosate versus placebo in the ITT population (58.2%, 2 g day acamprosate; 62.7%, 3 g day acamprosate; 52.3%, placebo). Furthermore, even greater treatment effects were observed in the subgroup of 241 patients having a baseline goal of abstinence (70.0%, 2 g day acamprosate; 72.5%, 3 g day acamprosate; 58.1%, placebo), suggesting that motivation to be abstinent may be an important determinant of treatment success with acamprosate.

Two randomized, controlled trials initiated double-blind treatment simultaneously with the start of detoxification to determine if, relative to placebo, acamprosate would provide an advantage in reducing withdrawal symptoms or the dose of anxiolytic required to manage withdrawal symptoms. No effect of acamprosate on

parameters relevant to acute withdrawal was found. However, the safety of the combination was supported, with the advantage that patients had achieved a steady-state dose of acamprosate at the conclusion of inpatient detoxification.

In addition to the maintenance of abstinence, clinical evidence suggests that acamprosate may help patients regain abstinence after a relapse. Pooled data from three European trials evaluated 587 patients who relapsed to drinking; 13% of relapsed patients treated with acamprosate were able to regain and maintain abstinence through study end compared to 5% with placebo. A post hoc analysis of 15 acamprosate trials showed that compared to placebo, continued acamprosate treatment during relapse episodes significantly decreased the quantity and frequency of alcohol consumption. Therefore, continued acamprosate treatment during periods of relapse may reduce the severity and duration of relapse.

A number of posttreatment follow-up studies have shown the effects of acamprosate to be sustained for periods of up to 1 year after the last dose. At the end of the 48-week posttreatment follow-up period to a 48-week trial conducted in Germany, 39.9% of the remaining patients who had been treated with acamprosate remained abstinent, compared to 17.3% of the placebo-treated patients. Similarly, a significant difference in complete abstinence at the end of a 52-week posttreatment follow-up period was also reported following a 52-week randomized, controlled trial in Austria. It is possible that the 1-year length of treatment in these trials may have had some bearing on the robustness of posttreatment effects.

Clinical histories of alcohol-dependent adults typically show age of onset of alcohol abuse to occur in the teenage years, underscoring the importance of early intervention for alcoholic adolescents. A prospective, 3-month randomized, controlled trial was conducted in 26 adolescents with alcohol dependence. Acamprosate (1332 mg/day) significantly increased the percentage of abstinent days on study relative to placebo and was well tolerated in this cohort of alcohol-dependent adolescents.

ACAMPROSATE EFFECTS ON SLEEP

Sleep disturbances are another challenge often faced by recently detoxified patients and have been shown to persist for up through 4 years of complete abstinence. These alcohol-related alterations in sleep architecture have been shown to be a strong predictor of relapse, since recovering individuals often self-medicate with alcohol to improve sleep. The sleep disturbances associated with alcohol dependence include prolonged sleep

onset latency, decreased sleep efficiency, shorter sleep duration, and reduced amounts of slow wave sleep when compared to healthy controls. Several recent studies suggest that acamprosate may normalize the underlying neurobiological mechanisms of sleep that are disrupted by alcohol. For example, compared to placebo, acamprosate demonstrated clinically significant improvements in polysomnographic parameters of sleep in alcohol-dependent individuals during the 2 weeks following alcohol withdrawal. There are no prospective assessments of sleep in the clinical trials reported to date. However, adverse events assessments from these studies show that acamprosate does not disrupt sleep.

SAFETY AND TOLERABILITY OF ACAMPROSATE

The safety profile of acamprosate appears quite favorable. The adverse event most commonly reported more frequently in acamprosate-treated patients with respect to placebo-treated patients is diarrhea (16 versus 10%). It is typically depicted as transient and of mild or moderate severity. Patients taking concomitant medications had similar adverse events in acamprosate and placebo groups, as did acamprosate-treated patients with versus without liver disease. Notably, concomitant use of alcohol has no effect on the pharmacokinetics of acamprosate, suggesting patients can safely continue acamprosate through a period of relapse. Acamprosate has not been found to affect vital signs or clinical laboratory values. No differences are found between acamprosate and placebo groups in the rate of discontinuations due to adverse events (8% of acamprosate versus 6% of placebo patients discontinued from trials of 6-month duration; 7% of patients in both groups discontinued from trials of duration greater than 6 months).

Since its approval in Europe in 1989, there have been no identified health risks of acamprosate use in more than 1.5 million patients. Additionally, the only adverse symptom reported following acute overdose of acamprosate was diarrhea, with no reports of hypercalcemia. A risk of hypercalcemia should be considered in chronic overdose only. Acamprosate is assigned a Category C labeling in pregnancy. The animal reproduction studies demonstrated some teratogenic effects in rat fetuses at doses comparable to the human dose and in rabbit fetuses at doses approximately three times the human dose. In the rat, these malformations included hydronephrosis, malformed iris, retinal dysplasia, and retroesophageal subclavian artery; hydronephrosis was also observed in the rabbit. To date, there are no adequate well-controlled studies of acamprosate use in pregnant women; therefore, acamprosate should only be used

during pregnancy if the potential benefit justifies the potential risk to the fetus.

DRUG–DRUG INTERACTIONS

Acamprosate is not metabolized by the liver and is not likely to cause clinically significant pharmacokinetic drug–drug interactions through inhibition of the cytochrome P450 enzyme system. When combined with diazepam, disulfiram or alcohol, the pharmacokinetic profile of acamprosate was not modified. This lack of interaction is important due to the potential concomitant use of these drugs in patients with alcohol dependence. In addition, acamprosate does not influence the kinetics of imipramine or its metabolite desipramine. Results of pharmacokinetic studies in humans reported that co-administration of naltrexone increased the rate and extent of acamprosate absorption. However, a complete absence of negative interactions on measures of safety and cognitive function suggests that no adjustment in acamprosate dosage is required when co-administered with naltrexone. To date, no pharmacokinetic studies of acamprosate have been conducted in patients who are receiving renally excreted medications, such as lithium, or drugs that bind to the NMDA receptors; thus, a potential for drug–drug interactions of such combinations remains unknown.

CONCLUDING REMARKS

The major therapeutic challenge to successful management of alcohol dependence is the maintenance of abstinence and prevention of drinking relapse. Prevention of relapse has the potential to reduce hospitalization and rehabilitation costs, as well as alcohol-related loss of productivity in the workplace. Over the past two decades, numerous well-controlled clinical trials have found that acamprosate, in combination with psychosocial support, is a safe and well-accepted therapy. Acamprosate has been demonstrated to increase abstinence rates and reduce the risk of return to drinking in alcohol-dependent patients significantly more than placebo across 18 of 23 randomized, placebo-controlled trials. Given its excellent safety record and the positive results of a majority of clinical trials, it is not surprising that it is now the most widely prescribed drug therapy in the treatment of alcoholism. Pharmacoeconomic studies both in Europe and in the United States have demonstrated the potential cost-saving benefits of prescribing acamprosate as an adjunct to psychosocial support compared with nonpharmacological techniques alone. Based on these findings, it

appears that acamprosate is an important advancement in the treatment of alcohol dependence.

Acamprosate can be viewed as a prototype of a neuromodulatory approach in the treatment of alcohol dependence. More specifically, earlier drugs used a punishment model (as in the case of disulfiram) or an antagonist approach to decrease the reinforcing value of alcohol (as in the case of naltrexone). Rather, acamprosate appears to work by ameliorating some key underlying changes in neurochemistry caused by chronic heavy alcohol intake and withdrawal, thus restoring homeostasis to those systems. Importantly, acamprosate's neuromodulatory (indirect) approach is associated with less serious side effects and superior compliance rates among patients relative to disulfiram and naltrexone. It is our opinion that the neuromodulatory approach exemplified by acamprosate will provide a heuristic framework for developing more efficient and effective pharmacotherapies for alcohol dependence.

INTRODUCTION

Considerable progress has been made in the understanding of the specific neurotransmitter systems and brain pathways involved in alcohol drinking. An important pathway that provides extensive neuromodulation to the reward pathway (the cortico-mesolimbic dopamine (CMDA)) is the excitatory glutaminergic system, which is correspondingly modulated by inhibitory inputs from gamma-aminobutyric acid (GABA) neurons. Chronic alcohol ingestion results in an increased sensitization of glutamate receptors and enhanced activity at voltage-sensitive calcium channels as well as reduced GABA-A (GABA_A) function. This has led to an increased scientific interest in the development of pharmacotherapy targeting these particular systems to avoid the direct postsynaptic blockage that is likely to lead to neuroadaptation. Repeated alcohol ingestion also leads to a process of neuronal "sensitization" which causes increased neurophysiological response with future use also known as kindling. This phenomenon resets a lower "trigger" for continued alcohol use. A pharmacological agent that would block

this kindling phenomenon and prevent the summative effects of each drinking episode may interrupt this process of sensitization. Medications with anti-glutamnergic and/or GABAergic function may have therapeutic potential for the treatment of alcohol dependence.

Anticonvulsant drugs by virtue of their sedative-like activity and nonaddictive property are ideal agents to consider for the treatment of acute alcohol withdrawal symptoms while transitioning care into an outpatient setting. In fact, anticonvulsants such as carbamazepine, gabapentin, and topiramate have been safely used in the treatment and prevention of alcohol withdrawal. Sleep disturbances are among the most common complaints of alcoholics during the protracted withdrawal phase. Other withdrawal symptoms include anxiety, dysphoria, and irritability. These symptoms may last for weeks to months after the cessation of drinking and increase the risk for alcohol relapse. It is possible that the continuation of agents that were effective in the treatment of acute withdrawal into this protracted withdrawal period could alleviate some of these symptoms and lead to lower relapse rates. Given

the cross tolerance that alcoholics often have to sedative/hypnotic GABAergic drugs, the use of anticonvulsant medication offers the advantages of safety, mood stabilization, and lack of addictive properties that make them a significant tool to use in the treatment for alcohol dependence.

In this review, we focus on the anticonvulsant agents that have been evaluated for the treatment of alcohol dependence with an overview of their mechanism of actions.

PHARMACOLOGICAL TREATMENTS FOR ALCOHOL DEPENDENCE

Carbamazepine

Among anticonvulsant agents evaluated for efficacy in alcohol dependence, some studies have found that carbamazepine treatment might reduce drinks per drinking day and time to first drink after withdrawal. The mechanism of action of carbamazepine remains unknown, although data from rats and mice suggest that it is chemically related to the tricyclic antidepressants and it appears to exert its anticonvulsant properties by reducing the polysynaptic response and blocking post-tetanic potentiation. The rationale for carbamazepine use in treating alcohol dependence is based on its potential to suppress withdrawal-induced kindling in limbic structures and to affect improvement in symptoms such as sleep disturbances, anxiety, and mood instability, which are common in the protracted withdrawal syndrome. However, the exact mechanism by which carbamazepine might reduce alcohol consumption remains unknown.

A study by Kranzler and colleagues in 1995 evaluated the efficacy of carbamazepine in a 12-week, placebo-controlled trial of relapse prevention in 40 cocaine-dependent male subjects. Assessments of alcohol use and alcohol history were conducted at study entry, at the end of the 12-week treatment period, and at 3 months posttreatment. Assessment tools included the addiction severity index and the Timeline Followback assessment method. The results of the study showed that carbamazepine did not affect cocaine use but the number of days of alcohol use declined in both the carbamazepine- and placebo-treated groups. There were no between-group differences in either measure during the active treatment period. At 3 months posttreatment, the placebo-treated group resumed their pretreatment severity of drinking while the carbamazepine-treated subjects maintained a lower drinking frequency. The addiction severity index alcohol score increased slightly for placebo-treated subjects during follow-up and was consistent with the finding that placebo-treated subjects

drank on significantly more days during the posttreatment period than did the carbamazepine-treated subjects. It is important to note that the participants were not alcohol-dependent subjects and, therefore, the effect occurred in the context of mild to moderate alcohol drinking and the reduction in drinking days among carbamazepine-treated subjects occurred only during the posttreatment so the clinical significance of these results is unclear.

In another study conducted by Mueller and colleagues in 1997, 29 subjects were enrolled in a 12-month double-blind placebo-controlled pilot study evaluating the efficacy of carbamazepine for the treatment of alcohol dependence in recently detoxified alcoholics. Assessments were conducted at baseline and bimonthly for a 12-month follow-up period. Subjects were contacted monthly by phone and twice a month in person for 12 months after discharge. Due to the large drop out rate (46% of the treatment group) after the first 120 days, outcome measures were evaluated at 120 days, the time point at which at least 50% of subjects reported taking the medication. Despite the small sample size at 120 days, survival analysis revealed that during the first few months, carbamazepine showed a nonsignificant trend toward increasing mean time to first drink ($P = 0.23$) and a significant reduction in time to return to heavy drinking (>5 drinks day⁻¹ for men and >4 drinks day⁻¹ for women) compared with placebo ($P = 0.04$). Mueller and colleagues proposed that their findings were consistent with the kindling model of alcoholism. The kindling model suggests that the repeated withdrawal episodes occurring in alcohol dependence result in long-lasting neuronal and neurochemical changes in the brain that ultimately alter the response to ethanol, so that successive withdrawal episodes are increasingly severe and, therefore, rendering any attempt to quit drinking even more difficult. Agents such as carbamazepine, which might interrupt the kindling process, would prevent the summative effects of each drinking episode, so its chronic administration would reduce more extensive or uncontrolled heavy use once drinking had occurred, as was demonstrated in this study.

Adverse effects of carbamazepine, particularly in the initial stages of therapy, include dizziness, drowsiness, ataxia, and gastrointestinal disturbances, such as nausea and vomiting. Carbamazepine should be dispensed with caution to patients with a history of blood disorders or with cardiac, hepatic, or renal disease. Photosensitivity reactions have been reported and transient leucopenia is common and usually resolves with continued therapy. However, in rare cases, blood disorders including agranulocytosis, aplastic anemia, thrombocytopenia, and purpura have been reported. Carbamazepine is metabolized by CYP3A4, therefore interactions with other drugs that induce, inhibit, or

compete for CYP3A4 are relatively common, which may limit its use.

Valproate

Valproate sodium is an antiepileptic agent with unknown therapeutic mechanism of action, although it is believed to exert its effect by increasing the concentrations of GABA in the brain.

In a small ($N = 16$) pilot study conducted by Longo and colleagues in 2002 comparing the safety and efficacy of the anticonvulsant agent valproate (divalproex sodium) with standard benzodiazepine detoxification for alcohol withdrawal and relapse prevention, 16 alcohol-dependent patients were randomized to either standard benzodiazepine detoxification, valproate detoxification, or valproate detoxification plus 6-week maintenance. The results showed that at the 6-week follow-up, 4 out of 5 patients (80%) in the valproate maintenance group were completely abstinent compared with the detoxification-alone group (4 out of 11 patients, or 45%), and none relapsed to daily or heavy drinking. Despite the small sample size, this study indicated that valproate might have utility as a post-detoxification relapse-prevention agent.

Another study by Brady and colleagues in 2002 provided additional support for the use of valproate as an agent for alcohol-relapse prevention. This was a 12-week, double-blind, placebo-controlled trial of divalproex in 31 alcohol-dependent subjects. The study was based on the idea that the continued use of an agent, such as divalproex, which is effective in alcohol withdrawal, might be effective in treating protracted-abstinence syndrome. Drinking decreased significantly in both the placebo and the active medication groups. However, in the divalproex group a significantly smaller percentage of individuals relapsed to heavy drinking, but there were no significant differences in other alcohol-related outcomes. There was a significantly greater reduction in the irritability scale of the anger, irritability, and aggression questionnaire and a trend toward greater reduction in indirect hostility subscales of the Buss-Durkee hostility index in the active medication group compared with placebo ($P = 0.009$).

More recently, Salloum and colleagues studied in 2005 the efficacy of valproate in the treatment of bipolar alcohol-dependent patients in a 24-week, double-blind, placebo-controlled, randomized parallel-group trial. Fifty-nine participants who were alcohol dependent, actively drinking in the past month and had a concurrent acute episode of bipolar 1 disorder (manic, mixed, or depressed) were enrolled in the study. All participants received their usual treatment, including lithium carbonate and were randomized to receive valproate or placebo as adjunctive therapy. The valproate group

had a significantly lower proportion of heavy drinking days (HDDs; $P = 0.02$) and a trend toward fewer drinks per HDD ($P = 0.055$) than the placebo group. Furthermore, higher valproate serum concentration significantly correlated with improved alcohol use outcomes. In summary, valproate might be a promising medication for treating alcohol-dependent patients with comorbid bipolar disorder.

Valproate is usually well tolerated with most common adverse events including somnolence, headache, nausea vomiting, hair loss, rash, and thrombocytopenia: there is an FDA black box warning for hepatotoxicity, teratogenicity, and pancreatitis linked to the use of valproate. Hyperammonemia has been reported in association with valproate therapy and may be present despite normal liver function tests. Most adverse events are dose related and require close monitoring.

Topiramate

Topiramate exerts its anticonvulsant effects through blockade of voltage-dependent Na^+ and L-type high voltage-gated Ca^{++} channels and facilitation of GABAergic neurotransmission via GABA_A ; additionally, it inhibits the activity of the α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) and kainate subtypes of glutamate receptors as well as carbonic anhydrase (CA)-II and CA-IV, and enhances K^+ conductance.

The rationale for topiramate as treatment for alcohol dependence is based on its neurochemical activity. Topiramate might antagonize alcohol's reinforcing effects by suppressing the dopamine release in the midbrain ventral tegmental area (VTA) via facilitation of GABA activity and inhibition of glutamate function. The midbrain VTA dopamine pathways that project to the nucleus accumbens are believed to mediate the craving and rewarding effects associated with alcohol use. In chronic alcoholics who have increased hippocampal and cortical glutamate binding sites, dopaminergic neurotransmission might be facilitated and brain reward enhanced. Thus, the rationale for topiramate as treatment for alcohol dependence might stem from an ability to increase GABAergic activity and suppress CMDA activity after alcohol intake.

Johnson and colleagues tested this hypothesis in 2003 in a randomized, double-blind, 12-week controlled proof-of-concept study. One hundred and fifty alcohol-dependent men and women were enrolled in this study. Topiramate and placebo were both administered on an escalating schedule beginning at 25 mg day^{-1} at week 1 and increased by 50 mg day^{-1} each week until a dose of 300 mg day^{-1} was reached at week 8. The 300 mg day^{-1} dose was then maintained from week 8 to 12. Participants

were encouraged to attempt drinking cessation but were not required to be abstinent in order to participate. All participants received weekly, standardized, brief behavioral medication compliance enhancement treatment focusing on medication and visit compliance only. At the end of the 12-week course of treatment, both the topiramate and placebo groups showed lower self-reported and objective drinking measures than at baseline. Over the 12-week treatment period, topiramate treatment was significantly more effective than placebo in improving self-reported drinking outcomes, including drinks per day ($P = 0.000$ 6), drinks per drinking day ($P = 0.000$ 9), percentage of HDDs ($P = 0.000$ 3), and percentage of days abstinent ($P = 0.000$ 3). Additionally, topiramate treatment resulted in a greater reduction in log plasma gamma-glutamyl transferase ratio, an objective measure of drinking ($P = 0.004$ 6). The significant differences between topiramate and placebo on self-reported drinking measures were apparent at week 6 while the dose was about 200 mg, while differences in objective measures were observed at week 8. The probability of non-abstinence decreased over time in the topiramate-treated group and was significantly lower than in the placebo group ($P = 0.003$). Topiramate treatment also produced a significantly greater reduction in subscale scores in the Obsessive Compulsive Drinking Scale (OCDS) craving factors, including drinking obsessions ($P = 0.003$ 1), automaticity of drinking ($P = 0.001$ 0), and interference due to drinking ($P = 0.000$ 3), compared with placebo. The alcohol consumption subscale was not included in the analysis due to its colinearity with the other self-reported drinking measure, the Timeline Followback. There was no evidence for a differential response between early-onset and late-onset alcoholics on any of the six primary outcome measures.

The topiramate-treated group reported more frequent adverse events, including dizziness (topiramate versus placebo, 28.0% versus 10.7%, $P = 0.007$), paresthesia (topiramate versus placebo, 57.3% versus 18.7%, $P < 0.001$), psychomotor slowing (topiramate versus placebo, 26.7% versus 12.0%, $P = 0.023$), memory impairment (topiramate versus placebo, 18.7% versus 5.3%, $P = 0.012$), and weight loss (topiramate versus placebo, 54.7% versus 26.7%, $P = 0.001$). Approximately 4% of topiramate-treated subjects and 7% of those in the placebo group discontinued their participation in the study due to adverse events. This study suggests a possible role of topiramate in reducing drinking and promoting abstinence in alcohol-dependent adults. Topiramate treatment had robust effects on self-reported drinking outcomes that were supported by decreases in an objective measure of drinking. Additionally, topiramate treatment significantly reduced craving as measured by the drinking obsessions, automaticity of drinking, and interference due to drinking subscales of

the OCDS. Due to the fact that the craving and drinking reductions occurred contemporaneously, it is tempting to speculate that an important mechanism of action for topiramate is as an anti-craving medication. Nevertheless, it cannot be discounted that it was simply the marked reduction in drinking that occasioned the decrease in craving.

The pharmacokinetic profile of topiramate offers advantages over traditional anticonvulsants such as carbamazepine. Absorption of orally administered topiramate tablets is rapid and nearly complete, with peak plasma levels reached within 2 h of dosing following a 400-mg oral dose. Its pharmacokinetic profile is linear across the range of therapeutic doses. Since the extent to which topiramate is absorbed is not affected by its administration with food, it can be taken either as tablets or as sprinkled granules with meals without affecting plasma levels.

Due to its poor binding to plasma proteins (9–17%), topiramate is unlikely to be displaced by highly protein-bound drugs, thus limiting the likelihood for its interaction with other drugs. Furthermore, because topiramate is eliminated predominantly in the urine, with an elimination half-life of approximately 21 h, and is not metabolized extensively in humans (~20%), topiramate will not exacerbate the hepatic-enzyme-inducing properties of alcohol.

In a 14-week, double-blind, randomized, placebo-controlled multisite trial, 378 alcohol-dependent men and women aged 18–65 years were enrolled. Participants were seen weekly for 14 weeks and received weekly compliance enhancement intervention. Effects of topiramate up to 300 mg per day versus placebo were evaluated on drinking outcomes. Treating all dropouts as relapse to baseline, topiramate was superior to placebo at reducing percent HDDs from baseline to week 14 – mean difference of 8.44, 95% confidence interval 3.07–13.80 ($P = 0.002$). Prespecified mixed model analysis also showed that topiramate compared with placebo decreased percent HDDs – mean difference = 16.19, 95% confidence interval 10.79–21.60 ($P < 0.000$ 1) – and all other drinking outcomes ($P < 0.000$ 1 for all comparisons). Adverse events more common with topiramate versus placebo included: paresthesia – 50.8% versus 10.6%; taste perversion – 23.0% versus 4.8%; anorexia – 19.7% versus 6.9%; and difficulty with concentration – 14.8% versus 3.2%.

Another study has shown that topiramate may be more effective than oral naltrexone for treatment of alcohol dependence. A 6-month naturalistic, randomized, open-label, trial of topiramate 200 mg versus naltrexone 50 mg, with assessments at enrollment and after 3 and 6 months of treatment was conducted by Flores and colleagues in 2008. One hundred and two alcohol-dependent patients were enrolled in the study.

Both topiramate and naltrexone groups received psychological relapse prevention therapy. At the end of the trial both groups showed substantial reduction in their drinking. Topiramate was better at reducing alcohol-related cravings throughout the study and at the 6-month evaluation, patients taking topiramate had significantly lower scores on the OCDS (all subscales) and Europe Addiction Severity Index (EuropASI) for medical, alcohol, family, social, and psychiatric subscales. More patients taking topiramate remained in the abstinence and the moderate drinking groups.

These results provide strong evidence that topiramate is efficacious for the treatment of alcohol dependence even when compared with an FDA approved drug. Cognitive side effects represent the biggest barrier to its widespread use. Most adverse events could be minimized using a slow titration. The importance of slow titration of topiramate is demonstrated by the small clinical trial by Alapati in 1999. This study reviewed the side-effect profile of topiramate at two starting doses as adjunctive therapy for partial seizures in 84 adult patients. Forty-two patients were started on a 25-mg dose of topiramate with a dose escalation of 25 mg week⁻¹, and 42 patients received an initial dose of 50 mg with a dose escalation of 50 mg week⁻¹. The observed adverse events included neurocognitive effects, such as psychomotor slowing, word-finding difficulty, and speech or language difficulties, and psychiatric side effects, such as psychosis or altered perception, depression, agitation, and altered behavior. The incidence of these side effects, as well as the rate of discontinuation, was lower in the group who were started on the 25-mg dose and titrated slowly than in those who initially received 50 mg day⁻¹.

Levetiracetam

Levetiracetam is an anticonvulsant that binds to a synaptic vesicle protein, SV2A, which is believed to impede nerve conduction across synapses. It therefore inhibits burst firing without affecting normal neuronal excitability, which suggests that it may selectively prevent hypersynchronization of epileptiform burst firing and propagation of seizure activity. On a biochemical level, levetiracetam could block ethanol-seeking behavior by inhibiting α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, and reduce excitability associated with alcohol withdrawal by attenuating the negative allosteric effects of zinc and β -carboline on brain GABA and glycine receptors.

Evidence supporting the clinical efficacy of levetiracetam for alcohol dependence has been suggested in three small, open-label preliminary studies. In a study reported by Mariani and Levin in 2008, three patients with alcohol dependence and anxiety disorders were

treated with levetiracetam IR: 1000–1500 mg twice daily. The percentage of HDDs and anxiety scores decreased by at least 50% for each of the three patients over the 6–8 weeks of the trial. In another study conducted by Krebs and colleagues in 2006, 15 patients seeking treatment for alcohol detoxification received 2000 mg of levetiracetam IR per day. Levetiracetam was found safe and efficacious in the treatment of alcohol withdrawal. In a more recent open-label pilot study by Sarid-Degal and colleagues in 2008 with the aim to assess the efficacy and safety of levetiracetam for the treatment of alcohol dependence, a maximal dose of 2000 mg was administered daily for 10 weeks to 20 alcohol-dependent subjects. Patients were titrated up to 1000 mg twice daily over a period of 3 weeks, and then maintained on a dose of 2000 mg daily for 7 weeks further. Of the 20 patients enrolled in the study 13 (65%) completed the full maintenance dose phase of the study. The number of standard drinks per day consumed by the 16 evaluable subjects decreased from approximately 5.3 at baseline, to approximately 3.0 at 2 weeks, to approximately 2.0 at the end of the 10-week treatment period. Alcohol craving (OCDS scores) declined significantly from baseline. There were no significant changes in any measures of sleep quality (Medical Outcomes Sleep Scale). Two subjects reported irritability and one subject reported sedation.

Double-blind randomized studies are needed to better assess the efficacy of levetiracetam for the treatment of alcohol dependence. The metabolism of levetiracetam is less complicated than older antiseizure medications, which makes it easier to use and better tolerated, and it is not likely to interact with other medicines. Levetiracetam has also been shown to cause less cognitive function impairment than topiramate which could make it a more acceptable drug amongst patients.

Zonisamide

Zonisamide is a sulfonamide anticonvulsant. Its exact mechanism of action is not known but it is believed that while zonisamide may be a carbonic anhydrase inhibitor like acetazolamide, its primary mechanisms of action might be blocking repetitive firing of sodium ion channels and reduction of T-type calcium channel currents. Another theory is that zonisamide binds allosterically to GABA receptors like benzodiazepines or may be inhibiting the uptake of the inhibitory neurotransmitter GABA while enhancing the uptake of the excitatory neurotransmitter glutamate. Zonisamide may have an effect similar to that of topiramate and, therefore, has been tested for similar indications including the treatment of alcohol dependence.

In an open-label trial, the efficacy of zonisamide was examined in 22 outpatients with a diagnosis of alcohol

dependence. Zonisamide was started at a dose of 50 mg day⁻¹ and was titrated to a maximum dose of 300 mg day⁻¹. Alcohol craving and alcohol consumption were assessed at weeks 2, 4, 6, 8, 10, and 12. The concentration of gamma-glutamyl transferase was used as an indirect measure of alcohol consumption. Significant improvement was observed in the visual analog scale for craving severity scores, weekly drink consumption, and gamma-glutamyl transferase. Zonisamide was well tolerated, with only a dropout due to adverse events. In a 12-week, double-blind, placebo-controlled, pilot trial conducted by Arias and colleagues in 2010, 40 alcohol-dependent subjects were randomly assigned to receive either placebo or zonisamide. Zonisamide was initiated at a dosage of 100 mg day⁻¹, which was increased by 100 mg day⁻¹ every 2 weeks for 8 weeks to a maximum dosage of 500 mg day⁻¹. The medication was continued for 4 weeks at the target dosage and then tapered and discontinued. The primary outcomes were drinks per week, HDDs per week, and abstinent days per week, which were measured using the Timeline FollowBack method. There was a significant medication by treatment week interaction effect favoring the zonisamide group for HDDs ($P = 0.012$), drinks per week ($P = 0.004$), and alcohol urge scores ($P = 0.006$). There was not a significant effect on the number or rate of increase in abstinent days. There were no serious adverse events reported and zonisamide treatment was well tolerated.

These findings provide preliminary support for the use of zonisamide to treat alcohol dependence. It appears to be safe and well tolerated in this sample and associated with improvement in both alcohol craving and alcohol consumption. Efforts to replicate and extend these findings are needed with bigger sampler sizes. It will be of interest to study whether zonisamide is associated with improvement in withdrawal symptoms, sleep, and dysphoria that alcoholics often report when they attempt to stop or reduce their drinking. The most common side effects commonly seen in patients taking zonisamide include drowsiness, loss of appetite, dizziness, headache, nausea, and agitation/irritability.

SUMMARY AND CONCLUSIONS

Anticonvulsant medications are a new vista in medications-development efforts, not only for treating

alcohol dependence but also for alleviating alcohol withdrawal symptoms. Indeed, anticonvulsants appear useful both for treating the acute withdrawal symptoms and, once abstinence has been achieved, for preventing relapse by modulating post-cessation craving and affective disturbance. Obviously, this is an attractive pharmacological prospect as the use of a single medication that is efficacious at the various stages of treatment reduces the need for polypharmacy, facilitates the buildup of dosing levels early in treatment, and minimizes the potential for unexpected adverse events. Research specifically designed to determine the utility and feasibility of such an approach is needed. Furthermore, because of the potential utility of certain anticonvulsants (e.g. valproate) in treating other psychiatric disorders such as bipolar disorder, it is possible that their utility might also be extended to treating comorbid psychiatric disorders.

Acknowledgments

The author thanks the National Institute on Alcohol Abuse and Alcoholism for their support through grants 1 R01 AA019720-01, and for the National Institute of Drug Abuse for their support through 5R01DA021776-02. We also thank the staff at the University of Virginia Center for Addiction Research and Education (CARE), as well as Ann Richards, for her assistance with this chapter preparation.

List of Abbreviations

CMDA	cortico-mesolimbic dopamine
GABA	gamma-aminobutyric acid
HDD	heavy drinking day
OCDS	Obsessive Compulsive Drinking Scale
VTA	ventral tegmental area

Marijuana Withdrawal	398	Blunting the Positive or the Reinforcing Effects of Marijuana in the Laboratory	402
Marijuana Dependence and Demand for Treatment	399	What Works in the Clinic?	403
Pharmacotherapy: Approaches for Substance Dependence	399	Directions for the Future	405

Public awareness of the difficulties experienced by some heavy marijuana users has increased in recent years, as has scientific and clinical interest in marijuana-related problems. Despite the growth of research in this field, development of evidence-based treatments for marijuana dependence lags substantially behind research investigating treatments for dependence on other drugs. In this chapter, we focus on the status of evidence regarding pharmacological treatment for marijuana dependence. Although animal studies clearly provide important directions, we focus on providing a comprehensive overview of existing evidence about pharmacotherapy for marijuana dependence in humans. We begin with a short introduction to the use and neurobiological effects of marijuana, as well as a discussion of evidence demonstrating marijuana withdrawal and dependence and demand for treatment. After briefly considering different approaches to medication development for drug dependence in general, we provide an overview of research coming from the human

laboratory about possible medications for marijuana dependence. The small body of clinical research addressing pharmacotherapy for marijuana dependence is then presented, followed by an overview of likely future directions. Although there are currently no approved pharmacotherapies for marijuana dependence, we identify promising directions that will, we hope, yield efficacious treatment approaches in coming years.

MARIJUANA USE AND NEUROBIOLOGY: A BRIEF OVERVIEW

Marijuana, the dried flowering tops, buds, leaves, and stems of the hemp plant *Cannabis sativa*, is the most commonly used illegal drug worldwide. Recent estimates indicate that between 130 and 190 million people across the globe used marijuana at least once during 2008, representing 2.9–4.3% of the world population

from 15 to 64 years old. In the United States, 6.6% of people of 12 years old and over are estimated to have used marijuana at least monthly in 2009. This is an increase from the past 7 years, when estimates remained stable at around 6% of the adolescent and adult population. Rates of use are predictably higher in some segments of the population; for instance, just under 50% of 18-year olds in the United States report using marijuana at least once. Of people who ever try marijuana, a subset goes on to use daily, with progression to daily use thought to occur in 10–20% of those ever trying the drug. This rate of progression from initiation to daily marijuana use is lower than that for some other drugs, such as heroin. However, the large number of people who experiment with marijuana ensure that regular marijuana users constitute a larger group than regular users of any other illegal drug.

Marijuana contains at least 60 different cannabinoids; the effects and psychoactive characteristics of many remain poorly understood. However, the feeling of being “high” and other behavioral effects experienced after marijuana have been found to be primarily related to the actions of Δ^9 -tetrahydrocannabinol (THC), a cannabinoid that easily crosses the blood–brain barrier to enter the brain. The effects of THC appear to be mediated primarily by its action at cannabinoid receptors type 1 (CB1). CB1 receptors are found throughout the body, but occur at high densities in brain areas involved in bodily coordination, attention, memory and higher cognitive processes, sensory and time perception, and reinforcement of behavior by drugs as well as natural rewards such as sex. This pattern of brain CB1 receptor expression is consistent with the behavioral effects of marijuana, which in addition to feelings of relaxation, positive mood, and being “high”, may include alterations to normal thought processes, reduced physical coordination, and changes to time perception.

MARIJUANA WITHDRAWAL

As noted, a substantial minority of people who try marijuana go on to use daily, a usage pattern conferring increased risk of marijuana-related problems. One problem experienced by heavy, regular marijuana users is withdrawal. The existence of a clinically significant withdrawal syndrome in regular marijuana users has long been a subject of debate. Indeed, the *Diagnostic and Statistical Manual of Mental Disorders – Fourth edition (DSM-IV)*, the most commonly used psychiatric diagnostic system in the United States, does not recognize cannabis withdrawal. This situation, however, is likely to change in the next DSM edition, in recognition of substantial evidence that heavy marijuana use may result in significant negative symptoms on abstinence.

The first reports detailing symptoms of marijuana withdrawal were published over 30 years ago. Today, evidence of a marijuana withdrawal syndrome comes from a range of sources including animal studies, case reports, controlled laboratory studies of marijuana administration to humans, clinical studies in treatment-seeking marijuana users, and epidemiological investigations. Across studies, marijuana withdrawal comprises a relatively predictable, time-limited pattern of prominent negative affect, including irritability, anxiety and depressed mood, coupled with craving for marijuana, appetite loss, and insomnia. Increased aggression has also been reported. Symptoms of withdrawal commonly appear after around 24-h abstinence, reach their peak from 2 to 6 days, and largely abate within 2 weeks.

Although it has been debated whether such symptoms represent a ‘true’ withdrawal rather than an unmasking of previously existing psychiatric problems, there is now substantial evidence in favor of the former interpretation. In animals trained to self-administer THC, administration of a THC antagonist precipitates behavioral alterations indicative of withdrawal. In humans, marijuana withdrawal symptoms are reversed by double-blind administration of marijuana, but not by placebo marijuana. Double-blind administration of low-dose oral THC (dronabinol) improves withdrawal symptoms without detectable psychoactive effects. This pharmacological specificity of marijuana withdrawal is inconsistent with unmasking of pre-existing psychological distress. Remission of withdrawal symptoms, which commonly occurs within 2 weeks of ceasing use, also supports the existence of “true” marijuana withdrawal.

Thus, marijuana withdrawal appears due primarily to marijuana abstinence rather than unmasking of underlying psychopathology. A second question is the clinical significance of these symptoms in terms of both distress experienced and their role in precipitating relapse. Clearly, marijuana withdrawal is not medically dangerous, as can be withdrawal from alcohol or benzodiazepines. It is not as physically severe as withdrawal from some other drugs, such as opiates. Moreover, despite evidence that most daily marijuana smokers experience withdrawal symptoms, some do not. Thus, withdrawal from some other drugs produces symptoms of greater magnitude and severity than those experienced by heavy marijuana smokers. However, this does not indicate that marijuana withdrawal symptoms are not clinically significant; marijuana withdrawal appears similar in magnitude and severity to nicotine withdrawal, which is known to produce clinically significant distress and disrupt normal functioning. Moreover, the extent of nicotine withdrawal predicts relapse to cigarette smoking. Consistent with this evidence in cigarette

smokers, many marijuana smokers in treatment report that withdrawal symptoms contribute to relapse. Thus, evidence suggests that marijuana abstinence produces withdrawal symptoms of clinically relevant severity, and that these symptoms likely contribute to relapse and ongoing use of marijuana in heavy marijuana users.

MARIJUANA DEPENDENCE AND DEMAND FOR TREATMENT

Relative to other abused drugs, marijuana has not typically been regarded as a drug of dependence. Moreover, targeted treatment for marijuana dependence has often been thought unnecessary. However, recent years have seen accumulating evidence that a percentage of regular marijuana users endorse criteria for dependence, most commonly uncontrolled use, unsuccessful efforts to stop or reduce use, and withdrawal symptoms. Of 18-year olds surveyed in the United States reporting use of marijuana, 16% met DSM-IV criteria for cannabis dependence. In Australia, one study found that 7% of young adults (of average age of 21) met cannabis dependence criteria. At a population level, 1.5% of Australians over 18 have been estimated to meet criteria for current cannabis dependence, endorsing on average four dependence symptoms. In the United States, lifetime cannabis dependence prevalence is estimated at around 4%. Thus, a subset of regular marijuana users endorse criteria indicative of problematic use and dependence on the drug.

Consistent with marijuana dependence, neurobiological and behavioral pharmacology data indicate that cannabinoids such as THC share mechanisms and characteristics with other drugs that produce dependence. In animals, THC induces dopamine release in the mesocorticolimbic circuitry, which is hypothesized to underpin reinforcement by drugs and other types of rewards. Consistent with this, rodents acquire self-administration of cannabinoids in a dose-dependent fashion. Moreover, in rodents, low doses of THC produce conditioned place preference, a behavioral measure used to test the conditioned positive effects of drugs.

Also consistent with evidence of dependence are data showing that a subset of marijuana smokers voluntarily present for treatment when such treatment is available. One study employed newspaper advertisements to recruit individuals seeking treatment for marijuana use, and reported that approximately 350 people presented over 3 months. In Western countries, treatment admissions for marijuana have increased in the past decade, with presentations doubling in the United States and tripling in Europe and Australia. Psychotherapeutic approaches including cognitive-behavioral therapy, motivational interviewing, and contingency management improve

outcomes for people with marijuana dependence, but rates of relapse are high at around 70%, consistent with relapse rates for other drugs. Thus, there is a clear rationale to develop treatments to improve the efficacy of currently available psychological interventions. Combination treatment with psychotherapy and pharmacotherapy provides the best outcome in other psychiatric disorders such as depression. Therefore, development of efficacious medications for marijuana dependence will likely complement existing options and improve treatment outcomes for this group.

PHARMACOTHERAPY: APPROACHES FOR SUBSTANCE DEPENDENCE

Recovery from substance dependence is best conceptualized as a dynamic process, with diverse pressures acting for abstinence and relapse at different stages. For instance, in the early days of abstinence, withdrawal symptoms are most prominent. Such symptoms may be strong motivators for relapse, and are known to predict relapse to a range of drugs. After withdrawal symptoms abate, however, other factors such as desire for the positive effects of the drug may be more relevant to the likelihood of relapse. In addition to these changing pressures over time, individuals vary in their experiences of withdrawal symptoms and cravings. Thus, there is a need for a range of medication approaches to assist different people, at different stages, to maintain abstinence.

Consistent with this need, there are a variety of approaches to pharmacotherapy for drug dependence. One approach is to use medications to alleviate the negative symptoms of withdrawal from the substance. Two kinds of medications can alleviate withdrawal. The first is substitute, or agonist, medications. These medications act in similar ways to the drug of dependence, but typically have slower onset and longer-lasting actions than the drug they replace, producing a less intense positive mood experience and having a lower liability to be abused. Examples of substitute medications include methadone for opiate addiction and nicotine patches for cigarette smokers. Substitute medications have the advantage of at least partially alleviating the range of withdrawal symptoms associated with the drug, because they work on the same neurobiological systems. However, although they have lower abuse liability than the drug they replace, agonist medications may be abused under certain circumstances (e.g. when the primary drug is not available).

A second approach is to employ medications to treat specific symptoms of withdrawal associated with the drug. For example, benzodiazepines are used to treat some symptoms of alcohol withdrawal, including anxiety and agitation, insomnia, and seizures. Cigarette

smokers may be prescribed bupropion to treat anxiety, irritability, and cravings occurring during nicotine withdrawal. Advantages of this approach include the fact that the medications are less frequently liable to be abused (although benzodiazepines have a recognized abuse liability). Conversely, this treatment strategy only addresses specific withdrawal symptoms compared to substitute medications, which address a broader symptom range.

An alternative to treating withdrawal symptoms is to focus on blocking the positive subjective effects of a drug, or reducing the extent to which the drug is reinforcing. Medications falling into this category promote abstinence because the drug is no longer enjoyed or experienced as reinforcing. This approach commonly involves administration of an antagonist to block the receptors on which the drug exerts its influence. For example, naltrexone substantively attenuates the effects of opiates. Alternatively, a partial agonist can also block some of the positive subjective or reinforcing effects of the drug; for instance, buprenorphine is a partial opiate agonist used to treat opiate dependence.

There are also alternative approaches to medications for drug dependence, such as medications that, when combined with the drug of dependence, produce aversive effects, thus limiting use. Recent evidence also indicates that vaccines, which bind to the drug in plasma and prevent it from crossing the blood–brain barrier, may prove an effective addition to nicotine and cocaine treatment. However, these approaches have not been employed for the treatment of marijuana dependence, and so will not be discussed further here.

REDUCING MARIJUANA WITHDRAWAL SYMPTOMS IN THE LABORATORY

Most existing evidence about medications for marijuana dependence in humans comes from laboratory studies, which model the circumstances involved in drug use, withdrawal, and relapse in a controlled environment. Laboratory studies allow detailed, objective investigation of effects of medications on different aspects of drug-using behavior. For instance, whereas outpatient clinical trials measure treatment effects on drug use with urine screens and self-report, laboratory studies can monitor actual drug use as it happens. Laboratory testing also offers a small-scale, cost-effective way to assess likely medication benefits before starting more expensive randomized controlled clinical trials. In addition, initial laboratory studies can investigate potentially dangerous interactions between medications and the drug of abuse in a medically supervised environment. This is an important issue given that many drug users

will, at least at some point, use their drug of choice while also taking the treatment medication.

One challenge of this type of research is that it involves controlled administration or self-administration of the drug of dependence, procedures requiring careful management of ethical issues. An important ethical constraint is that treatment-seeking drug users are not recruited. Instead, regular drug users who do not wish to stop drug use, and who use more drug than is offered in the laboratory, are enrolled. The methods of laboratory studies, then, endeavor to recreate (or “model”) the pressures experienced by abstaining drug users.

A variety of potential treatment medications have been evaluated in laboratory research about marijuana withdrawal. Most promising to date are the results of studies incorporating an agonist approach, assessing effects of treatment with dronabinol on withdrawal in heavy marijuana smokers. In the first study using dronabinol, 10-mg capsules were administered five times daily while participants underwent monitored withdrawal. Dronabinol reduced negative feelings like anxiety and depression, as well as reports of sleeping difficulties, chills, and craving, without producing intoxication. Dronabinol also reversed the appetite loss common to marijuana withdrawal. Consistent with this laboratory investigation, an outpatient controlled study in non-treatment seekers also reported that dronabinol (30 mg and 90 mg daily) attenuated marijuana withdrawal in a dose-dependent way.

This initial evidence, then, suggested that an agonist approach could prove effective for marijuana withdrawal. However, although 50-mg daily dronabinol reduced a range of withdrawal symptoms in the laboratory, it did nothing to improve other symptoms, such as irritability. Moreover, in the initial laboratory study, participants took five capsules daily, a very difficult pattern to maintain in outpatients. To address these issues, a second laboratory study, assessing the effects of 20-mg dronabinol three times daily, followed. This follow-up study also built on the first by aiming to model not just withdrawal, but also relapse. Modeling relapse in a study of this kind is difficult, because participants are not treatment-seeking and so have no reason not to “relapse” (i.e. use the drug as soon as it becomes available). This is particularly the case if they have just experienced withdrawal. To model relapse, this second study therefore required participants to purchase marijuana using study earnings. After 3 days of withdrawal, subjects were offered active marijuana, but had to buy it by the puff. The first puff of the day was expensive (\$10), whereas after that, the price dropped. This approach aimed to mimic the pressures of “real world” relapse, where the first drug use is the most costly, representing a failed quit attempt. In contrast to the first study using the lower, more frequent dose of dronabinol, 20-mg

dronabinol three times daily produced some intoxication. As in the initial study, dronabinol reversed the appetite loss associated with withdrawal and decreasing reports of having chills and feeling restless. Disappointingly, dronabinol did not decrease rates at which participants relapsed to marijuana use in the laboratory.

However, this study also assessed another medication, lofexidine, an anti-hypertensive now more commonly used to reduce opiate withdrawal symptoms. Lofexidine, which reduces noradrenaline neurotransmission, was investigated for marijuana withdrawal because animal studies have shown that noradrenergic signaling increases during cannabinoid withdrawal. It was reasoned that lofexidine might reverse this noradrenergic hyperactivity. Results of the study suggested that this reasoning was sound; lofexidine (2.4 mg day^{-1}) reduced symptoms such as chills, gastrointestinal complaints, and restlessness, while increasing sleep. Importantly, it also reduced relapse. However, lofexidine also decreased food intake and produced feelings of sedation.

Both dronabinol and lofexidine, then, showed some potential as medications for marijuana withdrawal, with some limitations. Importantly, however, the study included a combination condition, and the combination of dronabinol and lofexidine was the most effective approach to reduce both marijuana withdrawal symptoms and relapse. When treated with both medications, participants had better sleep and reported less restlessness and marijuana craving, as well as fewer gastrointestinal complaints and less chills. They also smoked less marijuana during the relapse phase. Thus, a combination medication approach employing both an agonist and another medication targeted to specific effects of withdrawal produced a reduction in a broad range of symptoms, as well as reducing relapse to marijuana use. These findings are the most promising laboratory evidence to date, showing medication effects on both marijuana withdrawal and relapse.

A range of other medications has also been studied for specific symptom alleviation in marijuana withdrawal, with varying degrees of success. Bupropion, an antidepressant acting on the noradrenaline and dopamine systems, is effective in reducing nicotine withdrawal symptoms. This medication was tested in marijuana smokers because some mood symptoms of nicotine withdrawal overlap with those of marijuana withdrawal. However, maintenance on bupropion (300 mg day^{-1}) actually increased negative mood (irritability, depression, and restlessness) and reports of sleeping difficulties in marijuana smokers in withdrawal in the laboratory. Thus, bupropion is unlikely to be effective for marijuana dependence.

One possible reason for these results is that bupropion produces mild stimulant effects, which may have exacerbated the agitation and insomnia many marijuana smokers experience during abstinence. To address this possibility, a subsequent laboratory study assessed the effects of nefazodone (450 mg day^{-1}), an antidepressant with a more sedating profile, on withdrawal symptoms in regular marijuana smokers. Nefazodone, which acts primarily through serotonergic and noradrenergic mechanisms, reduced anxiety and muscle pain during withdrawal. However, nefazodone did not reverse other negative mood symptoms or the decreased food intake associated with withdrawal. Thus, this study did not provide support for broad benefits of nefazodone in marijuana withdrawal.

Following a similar rationale, a recent study assessed effects of mirtazapine, also an antidepressant with sedative properties that acts on the noradrenaline and serotonin systems, on marijuana withdrawal and relapse in the laboratory. Despite reversing sleep disruptions and appetite loss, mirtazapine (30 mg day^{-1}) did not improve participants' mood during withdrawal, and did not decrease relapse. Overall, therefore, laboratory studies on antidepressants in marijuana withdrawal have yet to provide compelling evidence for their utility.

Another medication trialed in the laboratory is divalproex, a mood stabilizer that controls irritability, anger, and mood swings in bipolar disorder. Divalproex is also used to treat anxiety, irritability, and insomnia in alcohol withdrawal, suggesting that it might be useful in marijuana withdrawal. A laboratory study using divalproex, however, failed to support this, with divalproex (1500 mg day^{-1}) increasing reports of anxiety, irritability, and sleepiness during withdrawal. More broadly, divalproex also impaired cognitive performance and increased food intake regardless of whether marijuana was smoked or not, suggesting that this medication is unlikely to be well tolerated clinically.

Similarly, a recent laboratory study assessing the effects of baclofen, an antispasmodic agent that increases inhibitory gamma-aminobutyric acid signaling, failed to suggest likely clinical benefits for marijuana withdrawal. Baclofen ($60, 90 \text{ mg day}^{-1}$) had few positive effects on mood or behavior during withdrawal, and did not reduce relapse. Moreover, baclofen also reduced cognitive performance across conditions.

In sum, a variety of different medications have been tested in the laboratory for their potential to alleviate withdrawal and relapse occurring during withdrawal. Most of these medications did not substantially reduce the broad range of marijuana withdrawal symptoms, and some actually made them worse. A combination of dronabinol and lofexidine, however, was the exception; this combination improved sleep and cognition, reduced craving and restlessness, and importantly,

reduced relapse. This combination approach, therefore, is a promising candidate for future testing in the clinic.

BLUNTING THE POSITIVE OR THE REINFORCING EFFECTS OF MARIJUANA IN THE LABORATORY

An alternative to medications for withdrawal is to develop medications that reduce the positive subjective effects of marijuana, or the capacity of marijuana to reinforce behavior. This approach, for example, has been used for treatment of opiate dependence. The CB1 receptor antagonist, rimonabant, used to treat obesity, was found to block many behavioral effects of cannabinoids in animals. In humans, an initial laboratory study found that acute doses of rimonabant blocked the effects of smoked marijuana in a dose-dependent way. Compared to placebo, the highest rimonabant dose tested (90 mg) reduced reports of feeling “high” and “stoned” after a marijuana cigarette by around 40%, while also reducing heart rate by about 60%. A follow-up study assessed the effects of 8 and 15 days of daily rimonabant (40 mg) on responses to marijuana. Compared to placebo, this dose significantly reduced heart rate effects of smoked marijuana on both days 8 and 15; it also reduced self-reported positive marijuana effects on day 8 but not 15. A single dose of 90-mg rimonabant was also tested in this study and reduced heart rate reactivity to marijuana, replicating findings of the earlier study. However, the blunting of positive subjective marijuana effects after single doses of 90-mg rimonabant in the first study was not replicated. Thus, these trials provided some evidence that rimonabant might be useful in partially blocking the positive effects of marijuana. However, clinical use of rimonabant for obesity in Europe demonstrated high rates of adverse psychiatric reactions, including severe depression and suicidality. Rimonabant was therefore not approved in the United States, and cannot be further investigated for marijuana dependence at this time.

Agonist treatments can also blunt the positive effects of drugs and their reinforcing potential, and there is some evidence that dronabinol may reduce the positive subjective effects of marijuana. The only laboratory study to have investigated this question to date used two doses of dronabinol (40 and 80 mg daily) with participants receiving each dose for 3 days. On each day, participants smoked a single marijuana cigarette, followed by four opportunities to choose between smoking a marijuana cigarette or collecting a \$2 voucher to be redeemed for cash at study completion. Both dronabinol doses reduced ratings of feeling high and experiencing positive effects from the morning marijuana

cigarette by day 3 of dronabinol dosing, and this effect persisted until day 4 even though no dronabinol was administered that day. Despite these changes to the effects of marijuana, however, dronabinol did not change the amount of marijuana participants chose to self-administer. Thus, while there is evidence that dronabinol reduces the positive effects of marijuana, this study did not indicate that it also blocks the reinforcing effects of the drug. It is possible, however, that the money offered as an alternative to marijuana (\$2) was not enough, and that dronabinol might reduce marijuana smoking under different circumstances.

An alternative approach to medications directly blocking the cannabinoid receptor is to target associated neurotransmitter systems that have been implicated in the effects of marijuana. The endogenous opiate system is one such system, with animal evidence indicating that opiate antagonists attenuate some behavioral effects of THC. Based on this evidence, a number of laboratory studies have assessed the effects of acute doses of naltrexone, an opiate antagonist used to treat alcohol and opiate dependence, on responses to dronabinol and marijuana in humans. Evidence is mixed. Early laboratory studies found that single naltrexone doses (50 or 200 mg) did not alter the effects of either dronabinol (either 7.5 or 15 mg) or marijuana in regular marijuana smokers, although naltrexone increased the positive subjective effects of higher doses of dronabinol (30 mg). Naltrexone also marginally increased the extent to which marijuana smokers chose to self-administer dronabinol (30 mg). Thus, this early evidence indicated a difference between the acute effects of opiate antagonists on cannabinoid responses in animals, where blunting of behavioral effects was observed, and in humans, where naltrexone appears to have no effect at lower THC doses and to produce an enhancement of both positive THC effects and cannabinoid reinforcement at higher THC doses. Although a lower, more opioid-selective dose of naltrexone (12 mg) has been shown to blunt the positive effects of 20 mg (but not 40 mg) of dronabinol in regular marijuana smokers, a laboratory study designed to test the effects of a range of single naltrexone doses (from 12 to 100 mg) on responses to marijuana cigarettes in marijuana smokers found that all naltrexone doses increased marijuana’s positive subjective and cardiovascular effects. Thus, despite evidence in animals and one study in humans showing a blunting of cannabinoid effects after opiate antagonists, the balance of evidence in humans suggests that acute naltrexone doses actually enhance the positive effects of marijuana in regular marijuana smokers, indicating that naltrexone administration is unlikely to be effective in the treatment of marijuana dependence.

Other individual laboratory studies have assessed the effects of various medications on responses to

marijuana. Clonidine, an anti-hypertensive that decreases noradrenergic release, is used to treat opiate, alcohol, and nicotine withdrawal. A laboratory study testing three regular marijuana smokers found that acute clonidine (0.1–0.4 mg) did not affect subjective responses to marijuana, but did blunt the cardiovascular increases after marijuana. Given the absence of any change in the mood effects of marijuana, the authors of this small study concluded that clonidine did not appear likely to be useful for marijuana dependence; no further research was undertaken.

The study testing effects of bupropion on marijuana withdrawal described above also assessed the effects of bupropion maintenance (300 mg day⁻¹) on response to smoked marijuana. Bupropion reduced some subjective effects of marijuana including feelings of sociability and feeling “high”; it also decreased social behavior after marijuana smoking. However, there were few other effects of bupropion on marijuana response. Similarly, maintenance on nefazodone (450 mg day⁻¹) and mirtazapine (30 mg day⁻¹) did little to alter the direct effects of marijuana. Existing data, therefore, do not support the likely utility of the antidepressants tested in terms of reducing the positive subjective effects of marijuana.

Individual studies, described above, have also assessed the effects of divalproex and baclofen on response to smoked marijuana. Divalproex (1500 mg) produced small but significant increases in ratings of feeling high after marijuana, with few other effects. Baclofen (60 mg) reduced feelings of being high after marijuana while the higher dose (90 mg) decreased ratings of both marijuana and cigarette craving during repeated marijuana administration. Again, there were few other effects of baclofen on response to smoked marijuana.

Thus, of medications assessed for their potential to blunt the positive effects of marijuana or its reinforcing capacity, the antagonist rimonabant and agonist treatment with dronabinol appear the most promising. However, rimonabant produces unacceptably high risks of adverse psychiatric reaction and is not available for clinical or research use in the United States or Europe. Whereas dronabinol appears to reduce the positive subjective effects of smoked marijuana, it did not reduce the reinforcing effects of the drug, as indicated by choice to self-administer marijuana. However, there are few studies addressing this possibility, and further research is required.

WHAT WORKS IN THE CLINIC?

Although laboratory studies provide important information and are cost and time effective, the utility of a medication ultimately depends on outcomes in clinical

settings. To date, there are only three published reports of randomized controlled trials (RCTs) assessing the effects of medications for marijuana dependence. The first report was a double-blind, placebo controlled pilot study of divalproex (250–2000 mg daily; adjusted to individual response) in combination with cognitive-behavioral relapse prevention therapy for adults with marijuana dependence. Twenty-five patients were randomized to either divalproex or placebo for an initial 6-week period after 2 weeks of placebo lead-in (a period in which participants receive placebo, used to stabilize baseline measurements, etc.). There was also a 6-week crossover phase; however, due to low retention during the final weeks of the study, data from the crossover were not analyzed. In the 19 patients who completed at least the initial 8 weeks (2-week placebo lead-in plus the initial 6-week double-blind period), self-reported irritability, marijuana craving, and marijuana use decreased over time. However, there was no difference between groups, indicating that divalproex did not offer any improvement over placebo. Similarly, divalproex did not affect rates of negative urine screens. Moreover, despite modest decreases in THC positive urine samples during treatment in the sample overall, few patients attained sustained abstinence. There was some evidence of poor medications compliance, possibly influencing results. Although the preliminary nature of this study prevents firm conclusions, these negative results are consistent with the laboratory study described above, which did not support the likely utility of divalproex.

A more recent, larger clinical trial assessed effects of the antidepressants bupropion (300 mg daily) and nefazodone (600 mg daily) versus placebo in participants with marijuana dependence seeking treatment for marijuana use. The trial lasted 13 weeks, with 1 week of placebo lead-in, 10 weeks of study medication, and 2 weeks of lead-out. All patients completed weekly sessions of a coping skills psychosocial intervention. One hundred and six participants were randomized to one of the study medications or placebo, and around half completed the 10-week medication phase. The findings of this trial, similar to those of the divalproex trial, were that marijuana use decreased with time, but was not affected by either bupropion or nefazodone. Moreover, these results were not altered after accounting for medication adherence. Similarly, although marijuana dependence and withdrawal symptoms decreased in the sample with time, there was no effect of bupropion or nefazodone. Results of this clinical trial are, therefore, consistent with the conclusions of earlier laboratory studies, suggesting that despite the rationale for investigating these medications, neither bupropion nor nefazodone are likely to be a useful adjunct to psychotherapy for marijuana dependence.

A final published randomized, controlled clinical trial was based on documented high levels of anxiety in chronic marijuana users, and the anxiety that marijuana smokers report during withdrawal. The authors reasoned that given that marijuana users report that marijuana reduces negative emotions like anxiety, reducing these emotions by use of the non-benzodiazepine anti-anxiety medication buspirone might assist marijuana smokers to maintain abstinence. This 12-week trial recruited marijuana-dependent participants seeking treatment, and used buspirone in conjunction with a psychological intervention (two or three sessions of Motivational Interviewing during the first 4 weeks). Of 50 participants who were randomized, received the study medication, and provided at least one urine drug screen, 48% completed the trial. The buspirone condition had a target dose of 60 mg day⁻¹, depending on individual response. Although there was no significant effect of buspirone on marijuana abstinence as indicated by negative urine drug screens, there were trends toward patients in the buspirone condition having more frequent negative results, and providing a negative screen sooner after trial initiation. There was no direct effect of medication on self-reported anxiety, withdrawal symptoms, or craving. However, exploratory analyses indicated that decreased anxiety over the study predicted marijuana abstinence, suggesting that anxiety symptoms may prove a useful treatment target. Further research with buspirone or other anxiolytics therefore appears warranted.

In addition to these RCTs, a number of small open-label trials and case studies have used a range of medications for marijuana dependence. There are two case reports of treatment of chronic, long-term marijuana smokers with dronabinol and other medications as necessary. In one case, the patient was medicated with dronabinol (40 mg daily) for 6 months and divalproex (250 mg) for irritability. In the second, the patient was maintained on dronabinol (10–15 mg daily) and also received modafinil (100 mg) to counter the energy decreases he experienced after dronabinol. In both cases, patients achieved and maintained abstinence, consistent with evidence from controlled studies suggesting that dronabinol may be an effective addition to marijuana dependence treatment.

Following a preclinical study showing that lithium carbonate inhibited the development of cannabinoid withdrawal in rodents, two open-label pilot studies investigated marijuana withdrawal after treatment with lithium. The first assessed withdrawal symptoms in treatment-seeking marijuana users on lithium (600–900 mg daily) for 6 days as outpatients. Of the nine patients enrolled, four reported that lithium improved withdrawal symptoms whereas five did not. However, patients were maintained in an uncontrolled environment without the

capacity to prevent continued marijuana use, a substantial limitation. A second open-label trial of lithium addressed this limitation by maintaining marijuana-dependent patients in an inpatient setting for 7 days while they were treated with lithium (1000 mg daily). Lithium was generally well tolerated in this short-term, inpatient protocol, supporting the safety of using lithium in this population. Although rates of reported withdrawal symptoms were lower and follow-up reports of abstinence higher than in some previous studies, whether this was an effect of lithium cannot be determined.

A case series assessed the effects of baclofen in six patients with both marijuana and nicotine dependence. Common side effects were sedation and lethargy, consistent with the cognitive impairment demonstrated in the earlier laboratory trial. The authors report that these effects were well tolerated, and that withdrawal symptoms decreased in patients, who maintained abstinence for between 1 and 13 months. However, the negative results of the earlier laboratory study of baclofen suggest that these case studies be interpreted cautiously.

The non-stimulant attention deficit hyperactivity disorder treatment atomoxetine, which acts on the noradrenergic system, has also been assessed in an 11-week open-label trial for treatment-seeking marijuana-dependent patients. The rationale for this trial was that cognitive enhancing effects of atomoxetine might be useful for marijuana smokers, given that some studies have identified lowered cognitive function in heavy marijuana users. Fourteen patients received atomoxetine (25–80 mg daily), with a 2-week titration period to the maximum tolerated dose followed by 7 weeks of treatment and a 2-week taper off the medication. Patients did not substantively reduce marijuana use; moreover they had high rates of negative gastrointestinal effects and other side effects such as anxiety. Further investigation of this medication for marijuana dependence does not appear warranted.

A recent open-label study in adolescents employed a novel approach to pharmacotherapy for marijuana dependence. This study employed the anti-oxidant *N*-acetylcysteine (NAC), a medication shown in animal studies to reverse alterations to the glutamate system associated with repeated self-administration of a range of addictive drugs. Thus, NAC is thought to normalize addiction-related neuropharmacological changes in the brain more generally, rather than targeting mechanisms associated specifically with marijuana dependence. Twenty-four participants took part in this study, in which they received NAC daily (2400 mg daily) over a 4-week period with no other intervention. The medication produced some mild to moderate side effects but was generally well tolerated. Self-reported, but not urine toxicology based, marijuana use decreased during treatment with NAC. Marijuana

cravings also decreased. Thus, this medication may be a candidate for further, more controlled, investigation.

DIRECTIONS FOR THE FUTURE

Over the past decade, there has been a significant increase in laboratory-based and clinical research focusing on medications for marijuana dependence. A range of different treatments has been trialed, many with disappointing outcomes. However, there are some promising directions. Most promising to date is the combination of dronabinol and lofexidine, which was shown in a human laboratory study to reduce a broad range of withdrawal symptoms associated with marijuana abstinence in daily users. Importantly, this combination also reduced the amount of marijuana smoked during the 'relapse' phase of the study. A separate laboratory study also found that dronabinol reduced the positive subjective effects of smoked marijuana, however it did not affect the amount of marijuana participants self-administered. A recently completed clinical trial assessed the effect of dronabinol in treatment of marijuana dependence; the results of this trial are not yet available. Overall, existing evidence indicates that dronabinol in combination with lofexidine may be a useful approach to be tested in clinical settings. We are aware of an ongoing clinical study investigating this combination.

In addition to this combination, there are a number of possible directions that may yield effective treatments for marijuana dependence in the future. Despite overall disappointing results in clinical trials conducted to date, one trial found that improvement in anxiety symptoms over treatment predicted marijuana abstinence, suggesting that anxiety symptoms may prove a useful target. Thus, investigation of anxiety medications without abuse liability may present treatment opportunities. Two open-label studies have suggested that lithium is tolerated and may improve withdrawal symptoms, however, a study in animals showed that this effect of lithium was blocked by an antagonist of the neuropeptide oxytocin, suggesting that oxytocin release may mediate the effects of lithium on marijuana withdrawal. Thus, an intriguing possibility is whether administration of oxytocin would also attenuate withdrawal. An advantage of oxytocin over many other medications is that it does not appear to have effects such as sedation. A clinical study investigating the effect of intranasal oxytocin on marijuana withdrawal and dependence is currently in progress. Other possible directions for the future include new CB1 antagonists currently in development. In addition, fatty acid amide hydrolase inhibitors may have similar effects to agonists such as

dronabinol by reducing the extent to which endogenous cannabinoids are metabolized.

Thus, a range of compounds may, in the future, yield treatments to improve outcomes for marijuana dependence. One other potential factor that may affect the outcomes of clinical trials is the extent to which individual participants, although recruited into abstinence-based programs, have abstinence versus moderation as their treatment goals. Taking these differences into account could contribute to a better understanding of the ways in which pharmacotherapy can assist those with marijuana dependence to achieve their goals with regard to marijuana use.

In summary, research into marijuana withdrawal, dependence, and treatment has expanded rapidly in the last decade. There remains much to understand about risk factors leading to chronic heavy marijuana use, and ways to assist users in treatment. However, existing evidence suggests that, in common with other drugs of dependence, combination treatment including an agonist component is likely to reduce aversive withdrawal symptoms, thus leading to better treatment outcomes for marijuana dependence.

Opioid addiction is a chronic disease characterized by frequent relapses. Methadone maintenance has been an effective model for treatment of this chronic disease since the 1960s. Extensive research confirmed the safety and efficacy of this model for treatment of opioid dependence. Modern technology like brain imaging has been used recently to provide more information about methadone maintenance for treatment of opioid dependence. In this chapter, the reader will be updated about the basic and most recent information available about this model for treatment of opioid addiction.

MECHANISM OF ACTION OF OPIOIDS

Opioid drugs act by binding to certain receptors in the brain, which lead to specific actions based on the type of the receptor involved. There are four types of opioid receptors including mu, kappa, delta, and

orphanin FQ nociceptin. The opioid receptors are also the binding sites for endogenous peptides (e.g. endorphins and enkephalins) which play an important role for modulating the response to pain, regulation of body temperature, respiration, endocrine and gastrointestinal activity, mood, motivation, and other functions. Exogenous opioids may act as agonists, partial agonists, or antagonists to these receptors. Most of the opioids with addictive potential are agonist at the mu receptor. These drugs activate the mesocorticolimbic dopaminergic system through their mu agonist property leading to euphoria, positive reinforcement, and drug-seeking behavior. When opioid receptors are activated by an agonist (endogenous or exogenous), a chain of intracellular changes, involving second and third messenger systems, is usually activated. These changes not only produce immediate changes in the responsiveness of the opioid receptor-bearing neurons, but also lead to adaptive changes in other neuronal

systems that interact with them. Tolerance (decreased responsiveness to the same concentration of the opioid at the receptor) usually occurs on continued activation of the receptor and altered excitability (withdrawal) develops, when the agonist is removed after a period of receptor occupancy.

PHARMACOLOGIC PROFILE OF OPIOIDS

Opioids are classified into natural and synthetic subclasses. Morphine is a natural opioid and can be detected in urine by immunoassay screening tests. Heroin (diacetylmorphine) is a synthetic opioid and is considered to be an illicit drug in many countries. It is rapidly hydrolyzed to 6-monoacetylmorphine (half-life 3–6 min) as a result of spontaneous hydrolysis and hydrolysis by cholinesterase, which in turn is hydrolyzed to inactive morphine-3-glucuronide and the active morphine-6-glucuronide following intravenous (IV) administration in humans. Duration of action of heroin is usually short, but elimination of its metabolite (morphine) depends on route of administration, drug dose, body weight, time elapsed since the last dose, and inter-individual pharmacokinetics. Heroin is mainly excreted in the urine as free and conjugated morphine.

Methadone is a long-acting synthetic opioid. It is a mu and delta receptor agonist, and *N*-methyl-*D*-aspartate antagonist. Methadone was originally developed by a German scientist in the late 1930s for treatment of pain. Methadone is a lipid-soluble medication. It can be detected in the blood within 15–45 min after oral administration. The peak plasma concentration occurs at 2.5–4 h after dosing with some dose-independent differences among patients (range 1–5 h). A second plasma peak may be detected probably due to enterohepatic recirculation. The oral bioavailability of methadone was found to be around 70–80% for doses between 10 and 60 mg with marked inter-subject variation (range 36–100%). The hepatic enzyme cytochrome P 450 (CYP) 3A4 plays a major role in the metabolism of methadone, with a predicted first-pass metabolism around 20%. CYP 2C19, CYP 2C9, and CYP2D6 are involved in the metabolism of methadone to a lesser extent. Methadone is highly bound to plasma protein including albumin, lipoprotein, and alpha-1 acid glycoprotein. Methadone has a low hepatic extraction and changes in the binding of methadone to plasma proteins can alter its total hepatic clearance but the free methadone concentration is expected to remain unchanged. Elimination of methadone is mediated by transformation, followed by renal and fecal excretion. Methadone is extensively metabolized in the body mainly in the liver but also by intestinal CYP 3A4. The main metabolite of methadone (2-ethylidene-1,5-dimethyl

1,3-diphenylpyrrolidine; EDDP) is inactive. In addition to methadone nine metabolites, including EDDP, have been identified in urine and three in feces.

OPIOID INTOXICATION AND OVERDOSE

Opioid intoxication and overdose may constitute a medical emergency. It usually happens in the context of illicit opioid use to achieve euphoria especially with IV heroin use. Prescribed opioid overdose has also been reported and the prevalence of mortality related to prescription opioid overdose increased drastically in the United States between 1999 and 2006. The number of emergency department visits related to nonmedical use of prescribed opioid significantly increased (111%) between 2004 and 2008. The highest numbers of visits were recorded for oxycodone, hydrocodone, and methadone. Cardinal signs of opioid intoxication and overdose include a reduced level of consciousness, which may range from drowsiness to a stuporous state to a coma. Other cardinal signs include pinpoint pupils and a depressed respiratory rate. Cyanosis, hypotension, bradycardia, and hypothermia may also be present. Death is usually from respiratory depression. Some case reports described nonfatal heroin overdose that was associated with significant morbidity. The most commonly reported signs and symptoms of overdose morbidity are pulmonary conditions such as edema and pneumonia and muscular complications such as rhabdomyolysis from prolonged pressure on muscles during coma and renal failure from lysis of muscle tissue. Cardiovascular and cognitive impairment have been reported. Warner Smith et al. also reported overdose-related morbidity including peripheral neuropathy, vomiting, temporal paralysis of limbs, chest infection, and seizures.

OPIOID WITHDRAWAL

Opioid withdrawal is a syndrome related to sudden discontinuation of opioids after prolonged period of use. Short-acting opioids such as heroin usually exhibit signs and symptoms of withdrawal within 8–12 h after the last dose. If untreated, it reaches a peak within 36–72 h and usually subsides substantially within 5 days. For long-acting opioids like methadone, withdrawal may reach a peak between 5 and 6 days, and the syndrome will not usually subside for 14–21 days. The signs and symptoms of opioid withdrawal may be classified as objective and subjective. Objective signs include vomiting, lacrimation, rhinorrhea, pupillary dilatation, piloerection, sweating, diarrhea, yawning, fever, and elevated pulse and blood pressure. Subjective symptoms may include dysphoric mood, insomnia, muscle aches and

cramps, abdominal pain, and colic. The clinical opiate withdrawal scale is usually used to classify the severity of opioid withdrawal based on the generated score.

OPIOID ABUSE AND DEPENDENCE

Opioids abuse and dependence reflect the behavior manifestations for the loss of control over opioid use. Abuse may reflect a milder degree of the deviated behavior associated with opioid use. The American Psychiatric Association, Diagnostic and Statistical Manual of Mental Disorders fourth edition text revision (DSM-IV-TR), defines opioid abuse as a maladaptive pattern of opioid use leading to clinically significant impairment or distress as manifested by one or more of the following occurring within a 12-month period: recurrent opioid use resulting in a failure to fulfill major role obligations at work, school, or home; recurrent opioid use in situations in which it is physically hazardous; recurrent opioid-related legal problems; and continued opioid use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of opioids. It is important to note that opioid abuse does not include a pattern of use that could lead to physical impairment, that is, tolerance and withdrawal. Therefore, this pattern of the opioid use is mostly associated with loss of control, which may impair important areas of behavioral functioning. On the other hand, opioid dependence reflects severe forms of loss of control that could affect behavioral and physical functioning as well. DSM-IV-TR defines opioid dependence as a maladaptive pattern of opioid use leading to clinically significant impairment or distress as manifested by three or more of the following occurring at any time in the 12-month period: tolerance, as defined by a need for markedly increased amounts of opioids to achieve intoxication or desired effect, or markedly diminished effect with continued use of the same amount of opioids, opioid withdrawal signs and symptoms on discontinuation of opioid use, the opioid is often taken in larger amounts or over a longer period than was intended, there is a persistent desire or unsuccessful efforts to cut down or control use, a great deal of time is spent in activities necessary to obtain the opioid, use of opioid or recover from its effects, important social, occupational, or recreational activities are given up or reduced because of opioid use, opioid use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by opioid. It is also important to note that the signs and symptoms of physical dependence, that is, tolerance and withdrawal without other behavioral manifestations of the loss of control overuse would not be considered problematic use.

UTILIZATION OF METHADONE FOR TREATMENT OF OPIOID DEPENDENCE

Illicit opioid use produces euphoric effect which is usually the incentive for the drug-seeking behavior and addiction. Heroin has been the main source for illicitly used opioids for decades. Sniffing, smoking, and IV administration have been the most common routes for illicit heroin use. Recently, a new epidemic of nonmedical use of prescribed opioids emerged in the United States. New routes of administration of prescribed opioids have been reported in order to achieve euphoria by illicit users. These routes include chewing, crushing, and IV use of controlled release oxycodone (oxycontin), and licking of fentanyl patches. Inhalation of crushed opioids and oral ingestion of prescribed opioids for nonmedical use have also been reported. Over time the pattern of opioids' use by illicit users progresses from occasional to frequent or daily use due to the development of tolerance to its euphoric effect. These individuals may experience acute withdrawal syndrome on cutting down or discontinuation of the illicit opioid. Methadone has cross tolerance with other opioids and its long duration of action would make it an appropriate agent for treatment of opioid withdrawal syndrome and detoxification. Methadone 20–40 mg is usually sufficient to block the opioid withdrawal syndrome. Gradual taper of methadone by 5–10 mg every few days reduces the withdrawal syndrome and minimizes the patient's suffering. Opioid dependence is a chronic disease and frequent relapses have been reported following ambulatory or inpatient detoxification for that matter. Opioid craving is usually the trigger for relapse even after long periods of abstinence. Patients who fail abstinence-based models of treatment would be good candidates for methadone maintenance treatment (MMT).

METHADONE MAINTENANCE FOR MANAGEMENT OF OPIOID CRAVING

Craving is a subjective phenomenon that may be defined as an increased desire to use drugs or alcohol while being drug abstinent. It is associated with the use of substances that have reward reinforcing (euphoric) properties like alcohol, cocaine, and heroin. While craving is a subjective phenomenon, it can be triggered by environmental factors such as being exposed to drug-related cues. In the case of opioids, craving may occur due to the need to alleviate withdrawal symptoms (negative craving) or an increased desire to use opioids due to their euphoric effect (positive craving). A number of imaging studies have examined the neurobiologic correlates of heroin craving. Zijlstra et al. reported in their imaging study using single photon emission computed

tomography that opioid-dependent subjects had lower baseline dopamine type 2 receptors (D2Rs) in the left caudate nucleus compared to normal subjects. They also found that opioid-dependent subjects demonstrated higher dopamine (DA) release after cue exposure in the right putamen than that of controls. They added that chronic craving and anhedonia were positively correlated with DA release. They suggested that treatment strategies that increase D2Rs may, therefore, be an interesting approach to prevent relapse in opiate addiction. Sell et al. used positron emission tomography (PET) to study brain activity in opioid addicts being exposed to heroin related and neutral cues. They found that the self-reports of "urge to use" correlated strongly with increased regional blood flow in the inferior frontal and orbitofrontal cortex target regions of the mesolimbic dopaminergic system implicated in conditioning and reward. Xiao et al. studied brain activity in a group of thirsty heroin addicts being exposed to water and drug-related cues using functional magnetic resonance imaging (fMRI). They found that drug-related cues activated bilateral inferior frontal cortex confirming the critical role of prefrontal cortex in opioid craving. Their results suggest that heroin craving may involve different neural circuits other than the desire from basic physiological derives, such as thirst. Shi et al. reported in two studies that MMT reduces cue-induced heroin craving. They assessed craving by a 10-point visual analog scale where participants were asked "How much do you feel the urge to use heroin?" In their most recent study, brain imaging PET was used to study the integrity of the striatum DA neurons in patients receiving MMT and patients with prolonged abstinence compared to non-opioid-dependent individuals. They found that there is a long-lasting impairment in the striatal DA neurons (DA transporter uptake in bilateral putamen but not in bilateral caudate), which is more prominent in methadone-maintained patients compared to patients with prolonged abstinence. However, heroin craving was significantly less in patients receiving MMT. So, in spite of the efficacy of MMT in reducing subjective heroin craving, it may prolong the recovery process of the striatum DA neurons in the brain of recovering addicts. Langleben et al. also studied heroin craving using fMRI in methadone-maintained patients. They postulated that the medial prefrontal cortex and the extended limbic system in methadone-maintained patients with a history of heroin dependence remain responsive to salient drug cues, which suggest a continued vulnerability to heroin craving and relapse (Fig. 43.1).

One may understand from these studies that heroin-dependent patients may have structural and functional brain abnormalities, which could increase their risk for heroin craving and relapse. This may also be the case for patients receiving MMT. Fareed et al. reported in

a recent review study that methadone may help with heroin craving but patients in MMT may still be at risk of cue-induced heroin craving and relapse. Methadone has been the standard treatment of heroin dependence since 1960s. Despite the effectiveness of methadone in reducing heroin use, there have been reports about patients using heroin while receiving MMT. Opioid craving may play a factor for the continued use of heroin despite receiving MMT. There is evidence that methadone reduces heroin craving. Several studies supported that notion. Most of these studies reported an essential role for the methadone dose on heroin craving. They reported that being on higher doses of methadone may protect against craving in patients receiving MMT while being on lower doses or undergoing detoxification may increase the risk of craving. Therefore, it may be important to address heroin craving and risk of relapse for patients who are requesting detoxification. Also these data may provide a guideline for effective methadone dosing and prevention of relapse especially for patients who continue to experience heroin craving while being on lower doses of methadone. Methadone dose seems to be an important factor for blocking the euphoric effect and reduction of heroin craving for patients receiving MMT.

There is also evidence that patients in MMT are not immune from experiencing opioid craving. Some studies reported that patients in MMT may experience subjective craving for heroin while being on methadone. Childress et al. studied the risk of craving while being in MMT by examining the effect of the environment on the experience of craving. They found that a sizable proportion of the study Patients experienced subjective craving, subjective withdrawal, and withdrawal like physiological changes in response to drug-related stimuli, even in the artificial environment of a lab and despite maintenance on methadone. They also found that these patients are at more risk when they are in their home environment. Walter et al. demonstrated that methadone-maintained patients may be highly susceptible to drug cues even during time periods when peak methadone levels are expected. In their study, they reported discrepancy between saliva cortisol level as an objective measure of craving and self-reported heroin craving. As expected, they found a decrease in cortisol level after daily methadone dosing but unexpectedly, a greater increase in craving and negative affectivity after drug cues were detected post-methadone as compared to pre-methadone intake. Other studies reported a pattern of vulnerability to craving in response to being exposed to heroin cues or high level of stress. This pattern was significantly higher before methadone dose than after methadone dose (Fig. 43.1). The pharmacodynamic properties of methadone may play an important factor for this pattern of vulnerability to heroin craving before methadone dosing compared to after dosing.

FIGURE 43.1 Activation maps of brain fMRI response to heroin-related stimuli in methadone maintenance patients before and after daily methadone dose. Top row: Heightened response to heroin-related stimuli compared with neutral stimuli, before the daily methadone dose, in the left and right orbitofrontal cortex, ventral anterior cingulate cortex, and hippocampal complex, the left insula, and the right amygdala. Middle row: After the daily methadone dose, heightened response to heroin-related stimuli in the left and right orbitofrontal cortex and hippocampal complex and the left insula. Bottom row: Significant differences between the response to heroin-related stimuli before the methadone dose compared with after the methadone dose, in the left amygdala, the left and right hippocampal complex, and the left insula. Images are displayed over a Talairach-normalized template in radiological convention (left hemisphere to the viewer's right) and thresholded at $z > 1.64$, with spatial extent threshold of > 20 voxels, uncorrected for multiple comparisons. Reprinted with permission from Langleben et al., Mar 2008. *Acute effect of methadone maintenance dose on brain fMRI response to heroin-related cues. American Journal of Psychiatry* 165, 390–394, (Copyright © 2008). American Psychiatric Association.

Methadone has a large inter-individual variability in response and some patients might be rapid metabolizers of methadone while others might be slow metabolizers. Genetic polymorphisms in genes coding for methadone-metabolizing enzymes, transporter proteins (p-glycoprotein; p-gp), and mu-opioid receptors may explain part of the observed inter-individual variation in the pharmacokinetics and pharmacodynamics of methadone. Genetic polymorphism could be the cause of high inter-individual variability of methadone blood concentration for a given dose. Therefore, the practice of obtaining methadone trough and peak levels for patients expressing craving while being on high dose is recommended. This practice may provide more objective data about the casual relationship between the methadone dose and opioid craving. Split dosing may also be recommended for patients with substantial difference between the trough and peak levels who may express craving at the end of the day.

DOSING GUIDELINES FOR MMT

Despite the common agreement that methadone is an effective treatment for opioid dependence, there has

been a wide variation for dosing among clinicians. Some clinicians have been conservative and leaning toward the low dose regimen. This practice may have a better safety profile for methadone side effects and overdose. However, patients who are treated with the lower dose range tend to do worse regarding illicit opioid use and retention in treatment. Several studies reported that methadone dose in the range of 60–100 mg daily is safe and effective for MMT compared to lower dosages. Based on these reports, the National Institute of Health (NIH) made a consensus to help clinicians with proper methadone dosing. They recommended a guideline for the proper methadone dose to be at least 60 mg daily. Despite the NIH consensus, many methadone programs are still using doses below the recommended guidelines. A survey was done to examine the extent to which US methadone clinics meet established standards for minimum dosage between 1988 and 2005. It was found that 40% of patients receive doses of at least 80 mg daily the threshold identified as recommended practice in recent work, 34% receive doses below 60 mg daily, and 17% receive doses below 40 mg daily. Some recent studies explored the efficacy and safety of methadone doses above 100 mg daily. Two

naturalistic studies with a large number of patients reported that doses above 100 mg daily are safe and effective in long-term maintenance treatment. They indicated that response to MMT can be optimized when doses are individually titrated against signs and symptoms just like any chronic medical disease. Two recent clinical trials with a small number of patients reported that doses in the range of 120–150 mg daily are more effective in reducing heroin self-administration and suggest that the mechanism of this increased efficacy is by reduction of the positively reinforcing (euphoric) effect of heroin and not by reduction in opioid withdrawal discomfort.

It is noteworthy that the historic interest in methadone dosages. Most of the studies that were done in the 1980s and early 1990s used low doses below 60 mg daily. Then, this trend changed in the mid- and late 1990s where most of the studies looked at doses in the range of 60–100 mg daily. Since the early 2000s, a new interest in studying doses above 100 mg daily emerged. It seems that this historic interest in studying higher doses for MMT stems from the desire to reduce the illicit opioid use without jeopardizing safety. Methadone itself could impose some risk factors like cardiotoxicity and prolongation of QT interval (QT) on the electrocardiogram (EKG). This cardiotoxic side effect led the Food and Drug Administration (FDA) to mandate a black box label to be added to the methadone brochure by the manufacturers. QT prolongation and Torsade de Pointes (TdP) have been reported in patients treated with methadone for opioid dependence or pain management. A dose-dependent effect on QT prolongation has been shown in some studies. Overall, prolonged QT or TdP has been observed at a wide range of methadone dose from 10 to 1200 mg daily.

The NIH did not yet provide recommendations for EKG screening for patients who are in MMT. However, an expert panel for EKG screening and monitoring for patients in methadone treatment recommended obtaining a pretreatment EKG for all patients to measure the QT interval and a follow-up EKG within 30 days and annually. Additional EKG is recommended if the methadone dosage exceeds 100 mg/day or if patients have unexplained syncope or seizures. If the QT interval is greater than 450 ms but less than 500 ms, the clinician needs to discuss the potential risks and benefits with patients and monitor them more frequently. If the QT interval exceeds 500 ms, the clinician needs to consider discontinuing or reducing the methadone dose; eliminating contributing factors, such as drugs that promote hypokalemia; or using an alternative therapy. Clinicians should be aware of interactions between methadone and other drugs that possess QT interval-prolonging properties or that slow the elimination of methadone.

At the present time, we have data to support the fact that the dose range of 60–100 mg daily is safe and effective for reducing illicit opioid use. However, this recommendation may change as there are some promising data about the safety and better efficacy of doses above 100 mg daily.

DRUG TO DRUG INTERACTION WITH METHADONE

Methadone is metabolized mainly through the hepatic CYP enzymes. Medications that induce the CYP 3A4 enzyme may increase the elimination of methadone and decrease its blood level. This effect may increase the possibility of opioid withdrawal. On the other hand, CYP 3A4 inhibitors may slow the metabolism of methadone and increase its blood concentration. The high blood concentration of methadone may increase the risk for side effects, for example, sedation and drowsiness.

Several medications such as rifampicin, phenobarbital, phenytoin, and carbamazepine increase methadone metabolism and the risk for opioid withdrawal. Other medications, for example, fluconazole, voriconazole, ciprofloxacin, and clarithromycin decrease methadone metabolism and increase its plasma concentration.

Anti human immunodeficiency virus (HIV) medications, for example, darunavir, nelfinavir, nevirapine, efavirenz, and lopinavir/ritonavir, may also increase methadone metabolism and result in opioid withdrawal. Methadone may decrease the blood level of didanosine and stavudine and increase the blood level of zidovudine. Drug to drug interactions between methadone and anti-HIV medications have the most clinically significant adverse effects. HIV is a common disease for patients receiving MMT. Therefore, clinicians need to be aware of this important drug to drug interaction to consider adjusting the methadone dose as needed.

Obtaining peak and trough level for methadone may help in the detection of this possible drug to drug interaction. Methadone dose may need to be adjusted based on the peak and trough levels to reduce the risk of side effects, overdose, or opioid withdrawal. The dose of methadone needs to be reduced for patients with liver diseases like hepatitis C due to impaired hepatic function.

RETENTION IN MMT

Retention in MMT is associated with better treatment outcome and dropping out is associated with poor outcome. Maddux et al. reported that time on methadone was inversely related to positive urine drug screens for morphine. Patients maintained on

methadone for 3 years or longer showed a marked decrease in urine drug screens positive for morphine. Another study reported that retention in MMT is associated with reduced risk for overdose mortality and dropping out increases that risk. Other studies reported that retention in MMT could improve other outcomes like spread of HIV and hepatitis, criminal activities, employment, and mortality. The goal of MMT should not be time limited. Some studies reported that the methadone dose range of 60–100 mg daily is associated with significantly improved retention in opioid maintenance treatment compared to lower doses. Other studies that compared doses in the range of 60–100 mg daily to lower doses did not find any statistically significant difference for retention. Therefore, the methadone dose by itself may not play an essential role for retaining patients in treatment. One study reported that receiving take home early in treatment enhanced treatment retention. Several factors might be associated with poor retention in MMT. Comorbid cocaine, alcohol, other illicit drugs, or psychiatric disorders may be associated with poor retention if they were not addressed early in treatment. Therefore, it is important to address the cocaine and other drug comorbidities early in treatment. Offering a referral to evidence-based psychotherapeutic intervention designed for treatment of drug addiction like cognitive behavior therapy or contingency management might be appropriate for this patient population. Also a higher level of care like intensive outpatient or residential treatment may be needed for some patients with comorbid drug addiction. Psychopharmacologic intervention for comorbid psychiatric disorders is also important to be addressed as part of the treatment plan. MMT programs may vary in offering ancillary services like case management, evidence-based psychotherapy, and resources to refer patients to a higher level of care if needed. Some programs may lack human and financial resources that contribute to their inability to meet care standards. Therefore, retention in treatment may vary across MMT programs.

METHADONE MAINTENANCE FOR PREVENTION OF ILLICIT OPIOID OVERDOSE

Some studies reported that nonfatal illicit drug overdose significantly predicted subsequent nonfatal drug overdose. Therefore, prevention of future opioid overdose in high-risk patients may reduce the mortality and morbidity in this population. Several studies reported that MMT could reduce the risk of overdose and mortality in this population. Brugal et al. recently reported that the life expectancy of their cohort of heroin users in MMT increased by 21 years during the period of

the study. They reported that the increased life expectancy was not just due to the decline in death due to acquired immune deficiency syndrome but also due to reduction of death related to illicit drug overdose. Caplehorn et al. performed a meta-analysis to study the relationship between being in MMT and the risk of drug-related mortality. They found that the MMT reduced the risk of overall mortality in this population by a quarter. They reported that the MMT reduced the risk of mortality primarily due to reduction of the risk of accidental overdose. They added that MMT primarily reduced the risk of mortality in these patients due to prevention of heroin overdose in particular. While being in MMT is protective against the risk of drug overdose and mortality, dropping out of MMT increases such risk. Langendam et al. reported in their cohort of drug users that attending a harm reduction MMT is associated with reduction of overdose death, while leaving treatment is associated with increasing the risk. On the other hand, several studies reported an increased risk of fatal drug overdose during the first few weeks of initiating MMT. Therefore, the induction period for MMT may constitute high risk for drug-related overdose. Illicit use of central nervous depressants like benzodiazepines or alcohol during this period may increase the risk of overdose and mortality. Increased patient monitoring and education about this risk during the induction phase of MMT may reduce mortality and morbidity related to drug overdose. Buprenorphine maintenance treatment (BMT) might be an alternative to MMT for certain high-risk patients. Buprenorphine may have a better safety profile than methadone due to its pharmacokinetic and pharmacodynamic properties. It is a partial agonist of the mu-opioid receptor and has a ceiling effect which may reduce the risk of drug overdose. It is also safer than methadone as regards its cardiotoxic effect. Bell et al. reported that the risk of overdose death during the 9-month period of their study was significantly lower for patients receiving BMT compared to patients on MMT. In another study, Bell et al. reported that BMT was associated with less mortality during the induction phase of treatment but shorter retention in treatment compared to MMT. Overall, one may understand from these data that opioid maintenance treatment with methadone or buprenorphine may reduce the risk of illicit opioid overdose and should be considered as a preventive measure for high-risk patients.

MANAGEMENT OF CO-OCCURRING MEDICAL CONDITIONS FOR METHADONE-MAINTAINED PATIENTS

Premature death is common in heroin-addicted patients. Some studies reported that the annual death

rate in this population is about 1–3%. Symth et al. reported that heroin addicts not receiving opioid agonist treatment die at an average age of 47 years. Several factors contribute to premature death in this population, including overdose, chronic liver disease, HIV infection, and accidents. Impulsivity, personality disorders, unemployment with lack of medical insurance, legal problems, high-risk behaviors such as IV drug use, and psychiatric comorbidity may also contribute to premature death in heroin addicts. Fortunately, MMT can prolong survival in this population because of the reduction in the aforementioned risk factors. MMT protected many patients from risks associated with illicit opioid use (e.g. drug overdose, accidents, homicide, suicide), so that these patients lived longer than heroin addicts who did not enter methadone treatment. However, patients maintained in long-term methadone treatment are still likely to have a higher incidence of chronic medical conditions and unhealthy life styles that may affect their quality of life and predispose them to premature death compared with the general population. Nevertheless, although patients on methadone may be protected from risk factors associated with active IV drug use, they are not immune from other diseases that increase the risk for premature mortality, for example, chronic obstructive pulmonary disease (COPD), hypertension (HTN), diabetes mellitus (DM), HIV, and/or hepatitis C. Indeed, the prevalence of chronic health conditions has been shown to be much greater in MMT patients than community populations. Howard et al. reported that men receiving methadone were more than six times more likely to have previously diagnosed DM compared with men who were not receiving methadone. Fareed et al. reported that 28% of MMT patients in their clinic also suffer from DM, a rate much higher than that seen in the general population (6.2%). They also found that an extraordinarily high percentage (86%) of the premature deaths in their MMT clinic occurred in patients with DM. Rosen et al. found that nearly 45% of MMT patients over the age of 50 suffer from HTN. In comparison, Fareed et al. describe the prevalence of HTN to be nearly 60% in patients receiving MMT in their clinic.

Although patients with history of heroin dependence and in MMT are at increased risk for chronic medical conditions, such as hepatitis C, HIV, HTN, and DM, there are minimal federal guidelines for medical care, specifically a physical examination on admission and annual screening for some infectious diseases, for example, HIV and hepatitis C. Medical care for patients in MMT varies across programs, and most programs provide minimal onsite medical services other than urine drug screening. Patients in MMT with medical comorbidities across the United States usually have limited access to laboratory testing, EKG screening,

and proper diagnosis and management of their medical comorbidities. This is not the case for MMT programs enrolled in the Veterans Healthcare Administration (VHA) system. The VHA system is unique among MMT programs in its capacity to provide comprehensive medical services, such as laboratory testing, access to routine EKG, medications for co-occurring conditions (e.g. for hepatitis C treatment and smoking cessation), and referral to subspecialty clinics if needed (e.g. hepatology and cardiology).

MMT has been available since 1960s. Because of the effectiveness of methadone maintenance in preventing drug use and its associated mortality, some patients, have been in MMT for decades. As this population becomes older, they are experiencing the emergence of medical problems associated with unhealthy life styles (i.e. cigarette smoking, obesity, lack of exercise) and with aging. Comorbid medical conditions may increase the risk of premature death in this population. The high rates of past IV drug use and, consequently, of hepatitis C and HIV in this patient population could be a risk factor for liver cancer, other types of malignant tumors, diabetes mellitus, and other chronic medical conditions. Smoking is a risk factor for different types of malignant cancer, including colorectal and lung cancer. Smoking is also a risk factor for COPD, coronary artery disease, cerebrovascular accidents, and other chronic medical conditions. Thus, the high rates of hepatitis C, HIV, and smoking in this patient population at entrance into methadone treatment may play a significant role in the later development of chronic medical diseases and increasing the odd of premature death. Thus, identifying risk factors for chronic medical conditions and potential targets for early intervention at entrance to MMT may reduce rates of morbidity and premature mortality in patients who are receiving methadone maintenance.

MANAGEMENT OF CO-OCCURRING ACUTE PAIN FOR METHADONE- MAINTAINED PATIENTS

Patients in MMT should not be denied adequate management of their acute pain conditions, for example, pain secondary to postsurgical conditions or bone fractures. These patients usually develop tolerance to the analgesic effect of their methadone dose. Methadone is usually prescribed once daily for treatment of opioid dependence. While the daily dosing may prevent withdrawal and block opioid craving, it may not provide analgesic effects for more than 4–6 h. Methadone duration of analgesia and potency are similar to morphine. Patients receiving MMT with co-occurring acute pain may need management with short-acting full opioid receptor agonists. Some clinicians may be reluctant to

prescribe short-acting opioids for this population due to the drug-seeking behavior of these patients. Therefore, ordering short-acting full agonists three or four times per day as a standing order is preferable to as needed orders. Clinicians also need to be aware that ordering partial opioid receptor agonists like pentazocine or buprenorphine may precipitate opioid withdrawal and should be avoided for patients receiving MMT. Patients in MMT may need higher doses of the short-acting opioids than other patients due to their high tolerance. Over-sedation and respiratory rate should be monitored in these patients. The opioid dose may need to be adjusted if the patient experiences over-sedation, decreased respiratory rate, or other side effects.

METHADONE MAINTENANCE FOR TREATMENT OF OPIOID-DEPENDENT PREGNANT WOMEN

Illicit opioid use during pregnancy has been reported to be associated with adverse outcome to the mother and the fetus. Intrauterine growth retardation, premature delivery, low birth weight, small head circumference, still birth, and fetal death are common fetal complications among opioid pregnant women. Pregnant women with active illicit opioid use are at higher risk for poor nutrition, health status, and inadequate prenatal care. They usually have poor social support and may lose the custody of their infants due to their active opioid addiction. Offering treatment for opioid-dependent pregnant women may drastically improve the outcome for the mothers and their babies. MMT has been the standard treatment for opioid-dependent pregnant women. It reduces the high risk of relapse in this population which has been reported to be 41–96% after medication assisted detoxification. MMT can also reduce the adverse fetal outcome like premature delivery. Jones et al. compared the neonatal and maternal outcome for a group of opioid pregnant women receiving MMT versus another group who received methadone-assisted detoxification. They found that the group who received methadone-assisted withdrawal had a poorer maternal outcome compared to the methadone-maintained group. They concluded that MMT should be strongly considered as the primary treatment approach for opioid-dependent women. MMT has been reported to be associated with neonatal abstinence syndrome (NAS) characterized by nervous system hyperirritability and gastrointestinal, respiratory, and autonomic nervous system dysfunction. NAS may require pharmacologic treatment and prolonged hospitalization after delivery.

MMT has been recommended as the standard treatment for opioid-dependent pregnant women. This

recommendation may change due to a recently published multicenter, international, double-blind randomized clinical trial. In this study, Jones et al. compared the maternal and neonatal treatment outcome for a group of opioid-dependent pregnant women receiving MMT and another group receiving BMT. They found that the group who received BMT needed significantly less morphine for managing their NAS, had a significantly shorter hospital stay, and had a significantly shorter duration of treatment for the NAS. However, treatment was discontinued by 16 of the 89 women in the methadone group (18%) and 28 of the 86 women in the buprenorphine group (33%). Most of the women who left the buprenorphine group reported that they were not satisfied with treatment. The higher rate of satisfaction with methadone confirmed the important role it plays in treating pregnant women who are dependent on opioids. Moreover, given the partial agonistic activity of buprenorphine and its ceiling effect at maximal doses, it may not be the optimal treatment for all pregnant women with opioid dependence. They concluded that buprenorphine is an acceptable treatment for opioid dependence in pregnant women. Based on these new data, BMT might be recommended as an additional standard treatment for some opioid-dependent pregnant women.

Induction, Stabilization, Maintenance, and Discontinuation	421		

BUPRENORPHINE OPIOID AGONIST THERAPY

Opioid dependence is a chronic relapsing medical disorder afflicting millions worldwide, including as many as two million people in the United States. Untreated and ineffectively treated opioid dependence contributes to premature mortality and costly emergent use of health care and social services. A broad evidence base demonstrates the efficacy of opioid agonist therapy (e.g. methadone), and it is now considered the “gold standard” treatment for opioid dependence. In March 2005, the World Health Organization added buprenorphine as a complimentary medicine to the Model List of Essential Medicines thus encouraging access to buprenorphine treatment and legitimizing its role in opioid agonist treatment worldwide. Despite the strong evidence for the clinical effectiveness of opioid agonist therapy and the number afflicted with opioid dependence, medication-assisted recovery is offered to only

a small proportion of those diagnosed. Lack of or suboptimum treatment contributes to incidence of other diseases, such as human immunodeficiency virus (HIV), viral hepatitis including hepatitis C, and a multitude of other mental and physical health disorders. People with opioid dependence also are disproportionately afflicted with social and environmental morbidities; illicit opioid use contributes to unemployment, homelessness, legal problems, and marital and family instability.

Opioid agonist therapy using buprenorphine or buprenorphine/naloxone (hereafter collectively termed “buprenorphine”) is safe, effective, and cost-efficient treatment for opioid dependence. Since its introduction, buprenorphine has been an effective adjunct to other treatment. Buprenorphine opioid agonist therapy has the advantage of availability outside of specialized addiction treatment settings, thereby improving access to pharmacotherapy for opioid dependence. This is of particular importance

in resource-poor environments (e.g. under-developed countries, rural areas) where medication-assisted recovery may be the only option for opioid dependence treatment.

IMPROVING ACCESS TO OPIOID AGONIST THERAPY

In the 1980s, buprenorphine was first made available for prescription as an intravenous formulation for the treatment of pain. In the United States prior to October 2002, opioid agonist therapy – mainly through methadone opioid agonist treatment – was available only in licensed drug and alcohol programs. These programs continue to be regulated by state and federal entities that mandate clinical and programmatic procedures dictating whom can be admitted to the programs and how medication and non-pharmacotherapy (e.g. individual or group counseling) is provided over time. These requirements provide little flexibility in individualizing care. Meanwhile, several patient-, provider-, system-level barriers have been identified restricting quality methadone opioid agonist treatment in specialized programs. These barriers can include a finite capacity to treat patients, restrictive admission patient requirements (e.g. age, duration of physical opioid dependence), and physical distance from patients' homes. Several insurance barriers have also been identified.

Large health care systems generally provide opioid agonist treatment in formal programs, or they contract this type of care to out-of-network service providers. For instance, the Veterans Health Administration, a national health care insurance and provider network for United States military veterans, provides methadone in 42 programs and contracts out of network at an additional 10. Consequently, the treatment is effectively unavailable to patients who live prohibitively far from those facilities. Non-veteran populations in the United States are also limited in access to methadone treatment due to insurance, geographic, or ideological limitations. These barriers to methadone treatment (or any addiction treatment) may dissuade patients from entering treatment programs or providers from referring patients to this type of care.

In an effort to expand access to opioid agonist therapy beyond licensed addiction settings, the United States Congress made an amendment to the Drug Addiction Treatment Act (DATA-2000) in October 2002, allowing qualified physicians to prescribe and dispense approved medications in office-based practices for opioid dependence. In the United States, buprenorphine and buprenorphine/naloxone formulations continue to be the

only medications approved under this legislation for the treatment of opioid dependence.

In the United States, in order to begin prescribing buprenorphine in office-based practice, physicians must be appropriately qualified and have applied for a waiver from the United States Drug Enforcement Agency. Most practitioners become eligible to apply for a waiver by attending an 8 hour training through an approved training organization. Topics for these 8 hour trainings are uniform and include pharmacology of buprenorphine, guidance for its use, office policy, and common medical and psychiatric comorbidities of opioid dependence. As of 2006, over 10 000 physicians had completed the 8 hour courses, yet fewer than three-quarters actually requested and received a waiver to prescribe. Approved and waived physicians may treat up to 30 patients with buprenorphine at any one time. After 1 year of being waived, they may request an increase allowing a 100-patient census.

PHARMACOLOGY

Buprenorphine is a thebaine derivative significantly more potent than morphine. Buprenorphine has several actions physiologically. It is a mu-opioid receptor partial agonist, an epsilon-opioid receptor antagonist, a kappa-opioid receptor antagonist, and a partial-to-full agonist at the ORL1 nociceptin receptor. Once absorbed, buprenorphine is metabolized primarily by the CYP3A4 isozymes of the hepatic cytochrome P450 system into the active metabolite norbuprenorphine via *N*-dealkylation. Buprenorphine and norbuprenorphine are metabolized through glucuronidation and eliminated in the bile.

There are several formulations of buprenorphine and buprenorphine/naloxone that allow for several routes of administration. Currently, there are two sublingual formulations of buprenorphine: buprenorphine hydrochloride and a combination of buprenorphine hydrochloride and naloxone hydrochloride in a ratio of 4:1. Other formulations include a parenteral injection (buprenorphine), sublingual film (buprenorphine/naloxone), subdermal implants (buprenorphine), and transdermal patch (buprenorphine). Other formulations are also under investigation. While buprenorphine can be administered orally in an ethanolic solution, it undergoes extensive first-pass metabolism, limiting its oral bioavailability. Both the sublingual tablet and liquid formulation (used in early studies on buprenorphine) are effective when administered sublingually.

Buprenorphine has several pharmacologic properties that makes it a compelling treatment for opioid dependence. These properties include: (1) partial agonist characteristics, (2) high affinity to the opioid receptor, (3) long half-life and slow elimination, and (4) high safety

profile. These properties render buprenorphine efficacious and potentially safer in the treatment of opioid dependence as compared to other pharmacologic therapies such as methadone.

Buprenorphine is a partial opioid agonist at the mu-opioid receptor. Like full opioid agonists (e.g. morphine, heroin), it interacts with nerve cells to produce analgesia, respiratory depression, and euphoria; however, it stimulates the receptor only partially. As the dose of buprenorphine increases, a ceiling effect much lower than that of full agonists is reached. Clinically, the partial agonist properties of buprenorphine provide the patient with the same effects as full agonists, such as heroin, morphine, and methadone, but with less intensity. The medication reduces craving associated with chronic opioid use, minimizes any euphoria associated with its administration, and eliminates or greatly reduces the opioid withdrawal syndrome.

In addition to the partial agonist effect, buprenorphine has a high affinity to opioid receptors making it useful in reducing illicit use in a buprenorphine-maintained patient. If a pure opioid is taken concurrently, the patient will not experience the full effect of the pure opioid because it will be essentially blocked from the mu-opioid receptor. Likewise, if a patient under the influence of an opioid takes buprenorphine, the patient may experience precipitated opioid withdrawal syndrome as the full opioid agonist is suddenly displaced from the receptor. This necessitates monitoring and thorough patient education during the induction phase of buprenorphine treatment. Buprenorphine's long half-life – approximately 36 h – is advantageous because it allows longer dosing intervals. Some clinicians note success with dosing every other day or even three times weekly.

Research into the safety of buprenorphine has been encouraging. Buprenorphine does not appear to affect the QT interval, a problem often associated with other opioids, including methadone. Because of the partial agonist and ceiling effects of buprenorphine, the risk of overdose is reduced. However, concurrent use of alcohol and other respiratory depressants such as benzodiazepines has been implicated in some morbidity and mortality, particularly in countries where high doses of benzodiazepines and buprenorphine (though not buprenorphine/naloxone injection) are more common. As with other opioid medications, buprenorphine can cause such findings as miosis (constricted pupils), somnolence/drowsiness, and generalized pruritus (itchy skin), but since buprenorphine is a partial agonist, patients experience these side effects to a lesser extent than with full agonists.

Diversion is the act of using a medication inappropriately or distributing it to others. Several pharmacologic and formulation characteristics discourage patients from diverting buprenorphine. As discussed above,

buprenorphine is a partial agonist. As such, its effects are less intense (e.g. less euphoria) than those of full agonists; therefore, patients who abuse illicit opioids may not seek buprenorphine to “get high.” Rather, if supplies of illicit pure opioids (e.g. heroin, prescription opioid medications) are unavailable, buprenorphine may be used as a form of self-medication to simply stave off withdrawal until a pure opioid is available. Second, because buprenorphine has a long half-life and slowly dissociates from the opioid receptor, one who uses it illicitly will be under its effects for some time, thereby reducing the effect of pure agonists (e.g. heroin). In sum, buprenorphine's ceiling effect and long half-life may deter opioid misusers from abusing buprenorphine.

The third property of buprenorphine that discourages diversion is present only in the combination formulations of tabs and films, which contain both buprenorphine and naloxone; the latter is an opioid antagonist, and its presence reduces the attractiveness of injecting the medication. While buprenorphine is absorbed sublingually (55% bioavailability), sublingual bioavailability of naloxone is negligible. Both have 100% intravenous bioavailability. If a patient takes buprenorphine/naloxone appropriately (i.e. sublingually), the buprenorphine is absorbed while the naloxone is not, and the patient will experience a buprenorphine effect. If a patient takes buprenorphine/naloxone intravenously after mechanical or chemical reconstitution, naloxone inhibits buprenorphine; in the opioid dependent, the withdrawal syndrome will be acutely precipitated. The naloxone in the combination tablet serves to temper desire to inject the medication. This reduces diversion and indirectly reduces spread of communicable comorbid conditions associated with opioid dependence (e.g. HIV, hepatitis).

The general consensus is that the only patients who should receive the buprenorphine mono-product are pregnant women. As of this writing, at least two pharmaceutical companies are making generic buprenorphine mono-product tablets that are cheaper than the yet still trade-only buprenorphine/naloxone tablet and films, raising fears that when physicians opt to prescribe the less expensive formulation, risks associated with diversion will increase.

Of the formulations, only the sublingual tablets and films are approved for use in the treatment of opioid dependence. Other formulations have been increasingly examined for the treatment of pain, particularly perioperative pain (primarily through the parental formulation), articular/spinal analgesia, chronic pain (primarily transdermal formulations), and noncancer pain. These other formulations may eventually be approved and used for the treatment of opioid dependence. There is some interest in buprenorphine being used for

hyperalgesic syndromes; however, there is no methodologically rigorous literature to support the use of sublingual buprenorphine in treating pain. Nonetheless, a growing number of clinicians are using buprenorphine for pain and pain syndromes. Some practitioners believe that the strong safety profile of buprenorphine may make the medication a preferred agent for pain. Additionally, some believe that buprenorphine may reduce the incidence of opioid addiction in the pain patient. Further studies of buprenorphine for pain are certainly called for.

CLINICAL CONSIDERATIONS

Several clinical guidelines, protocols, and other guidance have been published and disseminated by various organizations, governmental agencies, and expert panels to assist practitioners in buprenorphine care for the treatment of opioid dependence. Currently, there are but a handful of studies that suggest buprenorphine therapy over other evidence-based treatments, including methadone opioid agonist therapy. Furthermore, there is little evidence available to guide clinicians about which patient characteristics or environments may predict a better response with buprenorphine opioid agonist therapy over other treatments. There appear to be some patient and provider selection biases regarding entry into buprenorphine care. In some samples of patients, younger patients and patients with fewer medical and mental health disorders may preferentially seek buprenorphine over other agonist treatments. The ability to consolidate regular medical care with treatment of opioid dependence may be attractive to patients. Patients may preferentially choose not to go to licensed specialty addiction treatment programs to avoid requirements in treatment and for fear of the stigma associated with such programs.

Several patient and environmental factors should be assessed in any patient seeking office-based treatment using buprenorphine. At a minimum, patients should be or have been diagnosed with opioid dependence. Clinicians should assess and document history of and current opioid use, other substance use, and comorbid medical and psychiatric conditions. Attention should be paid to communicable diseases associated with illicit opioid use, such as HIV and viral hepatitis. Prior to initiating any opioid agonist therapy, the clinician should assess for the presence of social supports, family, friends, employment, housing, finances, legal problems, and patients' readiness to participate in treatment. Essentially, a comprehensive history and physical exam is necessary for any patient who is being

considered for opioid agonist treatment, including buprenorphine treatment.

TREATING OPIOID WITHDRAWAL SYNDROME

Buprenorphine can be used to treat acute opioid withdrawal syndrome or provide maintenance therapy over weeks, months, and years. Opioid withdrawal syndrome – also called opioid abstinence syndrome – can be thought of as a two-phase process: an acute initial phase where patients experience physical and psychological consequences of reduction or elimination of opioids, and a longer phase – the protracted abstinence syndrome – which is predominately a long-term urge to use opioids. Physical symptoms of opioid withdrawal syndrome can last as long as 6 months, and psychological aspects of withdrawal can last much longer. There may be some advantage in using buprenorphine to manage opioid withdrawal. Buprenorphine's slow dissociation from the opioid receptors imparts a long duration of action and less severe withdrawal symptoms compared to other pure opioid agonists that are often used to "detoxify" patients using medically assisted withdrawal protocols.

In several research studies, buprenorphine has been shown to be an effective agent in pharmacological tapered management to reduce acute opioid withdrawal severity, morbidity, and frequency of opioid withdrawal symptoms. In a large study of heroin-dependent patients in a primary care setting, buprenorphine was superior to clonidine and combined clonidine and naltrexone in reducing opioid withdrawal symptoms. Furthermore, patients were more likely to more deeply engage in treatment of their opioid dependence when treated with buprenorphine. In a large study in clinical practices in the National Institute of Drug Abuse's Clinical Trial Network, buprenorphine was found to be superior to clonidine in 13-day medically supervised withdrawal. In several large reviews of the literature, good summative evidence exists that medically supervised withdrawal using buprenorphine is superior to other medications, including methadone and other opioids.

The goal of any medically supervised withdrawal using pharmaceutical agents is continued engagement in treatment of opioid dependence and potentially further opioid agonist maintenance therapy. While buprenorphine is effective for the treatment of opioid withdrawal and opioid withdrawal syndrome, the benefits of maintenance therapy with buprenorphine are superior to those of medically supervised treatment of withdrawal. In one study, investigators compared subjects who were maintained on buprenorphine over a year versus those who were "detoxified" in

standardized treatment of opioid withdrawal syndrome over a few weeks. Intense, comprehensive psychosocial treatments were available to each subject, and subjects were encouraged to continue the addiction treatments. All of the subjects who were detoxified were lost to follow-up and accrued a 20% mortality rate; there was no mortality in the buprenorphine-maintained subjects. This study was the first to conclude that opioid agonist maintenance therapy using buprenorphine achieves better patient outcomes than detoxification using buprenorphine.

INDUCTION, STABILIZATION, MAINTENANCE, AND DISCONTINUATION

Long-term treatment with buprenorphine occurs through a series of phases known as (1) induction, (2) stabilization, (3) maintenance, and (4) discontinuation. The length and intensity of these phases are often patient-specific, but some general consensus practices have been described.

Induction is the phase in which the clinician guides the patient in transitioning from pure opioids to buprenorphine, both physiologically and psychologically. As discussed above, buprenorphine may cause acute withdrawal if taken concurrently with pure opioids; the first dose of buprenorphine must be timed correctly to avoid this. When the induction appointment is scheduled, the clinician advises the patient to end opioid use at a certain time based on the length of action of the patient's drug of choice. The importance of establishing rapport and garnering the trust of the patient cannot be overstated because the patient needs to present to the induction visit in mild-to-moderate withdrawal. An objective measure of opioid withdrawal should be used, such as the clinical opiate withdrawal scale (COWS), to assist clinicians in accurately assessing the severity of opioid withdrawal. Once in moderate withdrawal (e.g. a score of 13 on the COWS), the first dose of buprenorphine – usually between 2 and 16 mg – is administered, and the patient is monitored. Earlier guidelines recommended that the buprenorphine mono-product be used for induction, but clinical experience has proven that the buprenorphine/naloxone combination formulation is just as efficacious and discourages surreptitious diversion. The majority of clinicians induct patients as described above in an office environment. It should be noted, however, that several investigators have found some patients to be candidates for induction in nonoffice settings, including home-induction, and this strategy appears to be more cost-effective.

Stabilization is the phase in which the clinician seeks to find the optimal dose of buprenorphine for each

patient; that is, the dose that eliminates withdrawal symptoms and cravings for illicit opioids. While this varies by country, region, and population treated, patients are generally stable on 8–24 mg of buprenorphine daily. Dosing adjustments may be necessary due to disease processes, relapse, drug cravings, liver disease, medications that interact with the cytochrome P450 system, and other factors. However, an adequate dose is essential. In a study of patients taking up to 16 mg of buprenorphine, increasing doses of buprenorphine incurred an improved outcome – opioid-free urine drug screens – but a dose response effect did not occur for the clinical outcome of opioid craving. A recent consensus panel indicated that many patients do not require doses above 16 mg and that maintenance doses above this level may encourage buprenorphine diversion.

Maintenance is considered a period when patients' other medical and psychosocial needs can be addressed. Patients often work on vocational, family, and housing stability. During this phase, patients are encouraged to engage in other treatment modalities, such as formal individual or group counseling, self-help programs or groups, and provider-initiated therapy such as motivational interviewing, contingency management, or cognitive behavioral therapy. The role of non-pharmacologic treatment is important and should be considered essential for all patients treated with buprenorphine for opioid dependence. Current regulations in the United States are such that access to additional, specialty addiction treatment is required prior to initiating buprenorphine office-based care, and emerging evidence suggests that patients do better on buprenorphine when non-pharmacologic treatment is part of their treatment.

There is a paucity of evidence to guide clinicians regarding the length of buprenorphine maintenance for the best outcomes; patients have been maintained on opioid agonist therapy (i.e. methadone) for a lifetime. In addition, because of the short history of buprenorphine care for the treatment of opioid dependence, little clinical or anecdotal evidence exists. Several studies suggest that longer buprenorphine agonist therapy is better than shorter duration of care, that premature discontinuation is associated with worse outcomes, and that a flexible medically supervised taper of buprenorphine should occur when the goal is discontinuation of the medicine. In a review of more than 30 methadone discharge studies, investigators found that most patients who left methadone treatment were not assessed by their clinicians as being ready for discharge; among patients who began a therapeutic methadone discharge, most did not complete the detoxification; and among patients who completed a planned methadone discharge, most relapsed to heroin use. Thus far, there

is little reason to expect a different outcome when discontinuing buprenorphine treatment.

CLINICAL OUTCOMES

Buprenorphine has been shown to be safe and effective in the treatment of opioid dependence both in clinical trials and in real-world practice. Physicians who have been prescribing buprenorphine in office-based settings have found that the medication is effective and results in high levels of overall patient and provider satisfaction. There has been extensive research on the use of buprenorphine in reducing the use of illicit opioids and the harm associated with opioid dependence, and office-based care with buprenorphine improves behavior- and disease-specific metrics associated with illicit opioid use, best exemplified by reduction in HIV risk behaviors and improvement of HIV disease indices such as viral load. Further investigations have demonstrated positive system-level outcomes, such as reduced inappropriate utilization of health services and improved cost-effectiveness compared to traditional treatments, including methadone. These findings have been replicated in large health care and health system environments. Several studies are highlighted below.

Buprenorphine opioid agonist therapy combined with non-pharmacologic addiction treatment seems to be better than non-pharmacologic treatment alone. In one study, investigators examined patients in outpatient treatment settings and found that buprenorphine mono- and combination tablets were superior to placebo with the outcomes of drug-free urine samples and diminished craving for opioids. In another study, investigators assessed the rate and predictors of treatment retention for patients induced and maintained on buprenorphine in a primary care setting in a 6-month period. At 24 weeks, 59% of patients on buprenorphine opioid agonist therapy remained engaged in treatment. The investigators concluded that abstinence during the first week of treatment and engagement in addiction counseling were critical for patient retention. Employment was also a predictor of retention.

Buprenorphine opioid agonist therapy seems to be equivalent to opioid agonist treatment using methadone in several controlled research studies. In a 17-week randomized study of 220 subjects, investigators compared levomethadyl acetate (LAAM, 75–115 mg (taken off the United States market in 2003 due to cardiac arrhythmias)) administered three times a week, buprenorphine (16–32 mg) administered three times a week, and high-dose (60–100 mg) and low-dose (20 mg) methadone administered daily as

treatments for opioid dependence. Clinical outcomes investigated were treatment retention, 12 or more consecutive opioid-negative urine specimens, and subject report of drug use severity. Treatment retention and subject report of severity was worst in the low-dose methadone group. The percentage of subjects with 12 or more consecutive opioid-negative urine specimens was 36% in the LAAM group, 26% in the buprenorphine group, 28% in the high-dose methadone group, and 8% in the low-dose methadone group, which was a highly significant finding. In sum, buprenorphine was found to be as efficacious as high-dose methadone in promoting drug-free urine and treatment retention. Other investigators demonstrated that in subjects provided 8 mg buprenorphine or 50 mg of methadone with flexible dosing regimens, treatment retention in both groups over 16 weeks was similar. In another study, investigators found that methadone- and buprenorphine-maintained subjects experienced similarly reduced craving and illicit opioid use; however, the buprenorphine-maintained individuals were more likely to continue abstinence from illicit opioid abstinence over time.

Emerging results indicate that buprenorphine results in lasting positive outcomes in primary care settings. In one study, investigators examined office-based outcomes of subjects with both low and high socioeconomic status on buprenorphine opioid agonist therapy. They found that 77% of patients in buprenorphine therapy remained in buprenorphine therapy for 42 months and that retention in treatment was associated with participation in a self-help group, employment, abstaining from illicit substances, and improved functional status. Interestingly, there was no difference in outcomes based on socioeconomic factors. The investigators concluded that buprenorphine office-based treatment in primary care practices was a viable option that conferred improvement in outcomes when coupled with abstinence-oriented counseling programs.

Other investigators examined long-term outcomes of primary care office-based treatment using buprenorphine. They followed 53 patients who had already been stabilized for 6 months on buprenorphine and evaluated retention, illicit drug use, dose, satisfaction, and any adverse events. Of those in care, 91% had opioid-negative urine specimens with a mean dose of buprenorphine at 17 mg. The investigators concluded that selective opioid-dependent patients exhibit moderate levels of retention in primary care office-based treatment, no adverse events were related to buprenorphine, and 40% of patients who had been stabilized on buprenorphine for 6 months maintained abstinence for an additional 2 years, which is typical of patients on methadone maintenance.

The site of care, whether within an addiction or general medical clinic, may not predict success of buprenorphine opioid agonist therapy. In one investigation, investigators compared outcomes, costs, and incremental cost-effectiveness of detoxification and subsequent maintenance therapy between a drug treatment center and six outpatient general medical practices in Australia. They found that buprenorphine care was similar in terms of efficacy and cost-effectiveness in the two different settings.

USE IN SPECIAL POPULATIONS

Studies indicate that buprenorphine treatment reduces incidence of disease associated with illicit opioid use and improves disease-specific metrics of other diseases. A preponderance of the evidence suggests that opioid agonist therapy reduces drug-related behaviors that carry a high risk of HIV transmission. For instance, in one study, investigators found that primary care-based buprenorphine treatment reduced drug-related HIV risks. Buprenorphine may be an ideal treatment for opioid dependence in HIV patients and has been successfully integrated with ongoing HIV care. While buprenorphine does appear to interact with some HIV medications, this interaction does not appear to be clinically important. Buprenorphine has been used in several countries with significant HIV populations and is specifically advocated for because of its association with reduction of risk of HIV infection. A recent study found that among eight countries – Australia, as well as select developing countries in Asia, Eastern Europe, and the Middle East – opioid agonist therapy substantially reduced in HIV-exposure risk associated with intravenous drug use.

Several investigators examining buprenorphine for subjects with HIV have found positive outcomes that are of particular clinical relevance to this population: decreased HIV RNA levels, increased CD4 counts, and improved compliance to HIV treatment. In addition, other investigators have found improvement in drug-related outcomes of integrated HIV and buprenorphine care. In a large prospective study of opioid-dependent subjects with HIV, investigators found that for a clinical outcome of any previous 30-day illicit drug use, buprenorphine was associated with a decrease in illicit use among patients; 84% at baseline reported any illicit use in the past 30 days whereas 42% of those remaining in care after 1 year reported illicit use. In addition, quality of life and quality of care indicators may be improved for HIV patients taking buprenorphine. Integrated buprenorphine and HIV care may address transmission risk behaviors – an important secondary HIV prevention strategy among adults and youth.

HIV-infected patients seem to prefer buprenorphine care over other opioid dependence treatment modalities. Despite these preferences and buprenorphine's efficacy in HIV populations, there are physician and systemic barriers to implementing office-based opioid agonist treatment. Some cite concern about lack of access to addiction experts. Financing issues, workforce and training issues, lack of experience, operational consequences of conceptual differences between HIV care and addiction treatment, and other policies are barriers to the integration of buprenorphine into HIV care as well.

Emerging evidence indicates that buprenorphine may be a useful adjunctive treatment for patients infected with hepatitis or with coinfection of hepatitis and HIV. In addition, there is some evidence of successful use of buprenorphine in prison and re-entry populations, and further emerging evidence suggests that buprenorphine may be safe and effective for adolescents and youth who use illicit opioids. In an interesting study comparing homeless and non-homeless patients in office-based buprenorphine care, investigators examined rate of treatment failure, time to treatment failure, and any illicit drug use. They found that while homeless patients had more comorbid conditions than non-homeless patients, outcomes were similar; only 21% of homeless patients and 22% of housed patients failed office-based treatment. Both housed and nonhoused samples had median retention of treatment at 9 months, only 4% of both groups who remained in care at one year had used illicit opioids, employment rates increased in both groups, and one-third of the homeless sample obtained stable housing.

Illicit opioid use among pregnant women is a growing problem, and it has deleterious consequences for mother and infant. There is burgeoning clinical and investigative evidence that buprenorphine use in pregnancy results in positive outcomes for both the mother and infant when compared to no treatment or traditional therapies such as methadone. One group recently summarized the literature regarding buprenorphine versus methadone in the treatment of pregnant opioid-dependent patients and concluded that buprenorphine is safe and effective in pregnant adults. In another recent double-blind, double dummy, flexible dosing, randomized controlled study in which buprenorphine and methadone were compared in pregnant opioid-dependent patients, investigators found that buprenorphine was an acceptable treatment for opioid dependence in pregnant women. Neonates needed less morphine for neonatal abstinence syndrome and had shorter hospital days when buprenorphine was used in pregnancy compared to methadone. Several prior studies did not find a dose relationship between buprenorphine dose and neonatal abstinence syndrome.

ACCESS AND COST-EFFECTIVENESS OF BUPRENORPHINE CARE

Access to buprenorphine care is increasing worldwide. In 2008, an estimated 16 232 physicians in the United States had been certified to prescribe buprenorphine (i.e. completed the 8-h training). Approximately 585 000 patients have been treated with buprenorphine in the United States; as many as 70% are receiving maintenance treatment, and there have been approximately 4.1 million total prescriptions written.

The adoption of office-based buprenorphine opioid agonist therapy in the United States over the last decade represents a dramatic paradigm shift regarding how patients seek and receive care, as well as how providers care for opioid-dependent individuals. The shift from specialty addiction treatment in designated, tightly regulated addiction programs to more integrated outpatient primary care, psychiatric care, addiction care, and specialty (e.g. HIV, pain clinics) environments continues to challenge health care providers. Implementing buprenorphine care within large health networks may be particularly challenging, and it tends to be slow. For example, 3 years after the introduction of buprenorphine in the United States Veteran Health Administration, only 719 Veterans had been treated with it. In addition, implementation of buprenorphine has not been uniform across the country; provider-, administrative-, and facility-factors impede buprenorphine use. These numbers are especially disappointing when contrasted with the rate of buprenorphine adoption in the United Kingdom; prescribing rapidly increased in England upon introduction in 1999 such that by the end of 2003, buprenorphine represented 23% of all opioid prescriptions.

Despite the help buprenorphine offers to patients with opioid dependence, there appears to be concern over continued access to this medication for vulnerable populations. For example, among United States Medicaid populations, investigators found that patients with heart failure, diabetes, hepatitis C, major depression, and anxiety were less likely to receive buprenorphine treatment. This may suggest variability in patient access, treatment preferences, and level of care. High co-payments for medications, even through government assistance programs such as Medicare in the United States, may limit patient access to opioid agonist therapy.

In research abroad, buprenorphine was found to be cost-efficient compared to other forms of pharmacotherapy. Several studies have demonstrated a cost equivalency and cost-benefit of using buprenorphine over other treatment modalities. The costs associated with buprenorphine use within the confines of

outpatient care are generally limited to the physician costs and the medication. In contrast, in the United States, methadone maintenance therapy incurs significant infrastructure, labor, and dispensing costs because it is dispensed in tightly regulated settings. In essence, when compared to methadone treatment, despite the higher medication cost, buprenorphine treatment in outpatient offices may be less costly. Other investigators found that buprenorphine maintenance therapy (up to 12 months) was cost-effective compared to brief buprenorphine detoxification in a clinical trial of opioid-dependent youth.

When buprenorphine was first introduced in the United States, a study found that only at a price of \$5 or less per dose would buprenorphine opioid agonist therapy be more cost-effective than methadone. The same authors later found that in the United States Veterans Health Administration, treatment with buprenorphine was no more expensive than with methadone. Another group of investigators evaluated the cost of treatment for opioid dependence; they compared methadone provided in specialty clinics, office-based methadone, and office-based buprenorphine. While clinic-based methadone was found to be least expensive, the cost of buprenorphine tablets accounted for the majority in the difference in costs; thus, depending on benefits and co-payments, office-based treatment using buprenorphine may be less expensive for patients.

Investigators recently found that flexible-dose methadone and buprenorphine maintenance opioid agonist therapy are more clinically effective and more cost-effective than no drug therapy in opioid-dependent patients. A flexible dosing strategy with methadone was found to be somewhat more effective in maintaining individuals in treatment than flexible-dose buprenorphine and was therefore associated with slightly higher health gain and lower costs. In a randomized controlled trial using flexible-dose regimens in drug treatment specialty clinics in two Australian cities, other investigators concluded that buprenorphine treatment was not as effective as methadone treatment, but neither was more cost-effective. Similarly, in a randomized, open-label, 12-month study of heroin-dependent subjects receiving individualized treatment of buprenorphine or methadone opioid agonist therapy in a community setting, investigators did not find any significant differences in costs or outcomes between either treatment.

Buprenorphine care may reduce overall costs of health care. In one study, for patients with documented use of prescription opioids prior to initiation, treatment with buprenorphine was associated with a reduction in opioid utilization and cost in the first year of follow-up.

There may be attitudinal and logistical barriers that inhibit implementation of buprenorphine therapy. Providers may perceive a lack of resources to handle

office-based opioid dependence therapy, they may believe such treatment is inappropriate outside of licensed, opioid agonist treatment programs, or they may simply choose not to treat it. Several studies have found provider reluctance in prescribing buprenorphine, but several reveal a positive attitude of physicians and pharmacists toward buprenorphine. Physician certification trainings and retraining may help. A major focus in the United States is mentoring and training physicians in appropriate care of patients with opioid dependence using office-based treatment modalities.

MISUSE AND DIVERSION

As access to buprenorphine has increased, so has concern about misuse and diversion of the medication. The addition of naloxone to buprenorphine reduces its overdose, abuse, and diversion potential. While there has been minimal diversion of buprenorphine in the United States compared to methadone and oxycodone – both widely prescribed by physicians – buprenorphine misuse does occur. Several population-based investigations in a variety of countries indicate that buprenorphine can be counted as a widely abused illicit substance. Some investigators found that over 30% of patients beginning treatment with buprenorphine in office-based practice subsequently injected it, although clinical experience in the United States indicates that it is not a typical practice. Most diversion occurs due to sublingual route. Other investigators have confirmed this; while diversion of buprenorphine is common, it is done more often to alleviate opioid withdrawal symptoms through a sublingual route and reduce use of other illicit opioids rather than to seek a high through sublingual or injection routes of administration. Major predictors of misuse included perceptions of inadequate dose and psychiatric comorbidity, including suicidality or prior suicide attempt. In Australia, investigators found that compared to methadone diversion in methadone care, buprenorphine diversion in buprenorphine care was threefold.

In general, providers are finding that while diversion of buprenorphine is occurring, the misuse tends to be limited to use in lieu of other opioids when they are not available or for self-medicating opioid withdrawal symptoms. Anecdotally, this diversion has led more patients to seek treatment for their opioid dependence. Many patients try buprenorphine illicitly, find it effective in reducing craving, and then seek out practitioners who provide the medication in office-based care. It is rare that a patient first entering treatment claims to have not heard about or tried buprenorphine.

SUMMARY

Opioid dependence is a disease that is best treated with a comprehensive treatment paradigm. Medication-assisted treatment using opioid agonist therapy has a vast evidence-based documenting reduction of illicit opioid use, improvement of comorbid conditions and functioning, and improvement of retention in a longitudinal, comprehensive treatment program. Recently, office-based treatment using the partial opioid agonist buprenorphine has improved patient access to opioid agonist treatment. In the United States, office-based buprenorphine care has provided addiction treatment outside of licensed opioid agonist treatment programs.

Buprenorphine has unique properties that make it attractive in the treatment of opioid dependence including low ceiling effect compared to full agonist opioids, high affinity for opioid receptors, and long half-life. A multitude of studies have demonstrated the efficacy, clinical effectiveness, safety, and cost-effectiveness of buprenorphine opioid agonist therapy. In certain populations, buprenorphine has been shown to be superior to other medications for treatment of opioid withdrawal syndrome and maintenance opioid agonist therapy. In concert with non-pharmacologic treatments for opioid dependence, buprenorphine therapy may be an essential adjunct treatment, especially in resource-poor locations or for patients who do not have access to other modalities of opioid dependence care.

INTRODUCTION

Unlike many therapeutic agents, naltrexone (NTX) was not discovered by chance. It was a result of the US government program to produce opiate antagonists, specifically because it was thought that they might be useful in the treatment of opiate dependence. Some early creations of this program turned out to be unsuitable because of toxic effects. Cyclazocine, for example, could produce hallucinations. On the other hand, the program also led to the development of naloxone, which has been very widely used and, like naltrexone, has very low organ toxicity. Indeed, given that product information sheets for NTX still routinely contain warnings about hepatotoxicity, it

is appropriate at this stage to note that for nearly two decades, NTX has been routinely, safely, and effectively used – often at relatively high and prolonged dosage – to treat the distressing pruritus that frequently accompanies severe jaundice caused by a variety of serious and life-threatening liver diseases (see below).

RATIONALE AND THEORETICAL BACKGROUND

The rationale for using opiate antagonists to treat opiate dependence is to some extent self-evident: a drug that effectively blocks the attractive effects of

heroin and other agonists is likely, on commonsense grounds, to reduce or abolish the intake of opiates while effective antagonist blood levels exist because using opiates would be pharmacologically pointless. On that basis, one might predict the rapid resumption of opiates when NTX use ceased, which was exactly what happened in many (but not all) earlier studies of oral NTX. However, Wickler theorized two decades before NTX was synthesized that an effective antagonist might help to achieve a more lasting abstinence from opiates by the cognitive-behavioral processes of extinction and negative reinforcement. To this end, some heroin addicts were encouraged to inject or smoke heroin while their opiate receptors were blocked with NTX, albeit for rather short periods. Unfortunately, no significant lasting reduction in craving was observed. While there is now good evidence from randomized controlled trials (RCTs) for the effectiveness of NTX in treating opiate dependence, it may be that the use of NTX in the real world of opiate dependence as opposed to the clinical or animal laboratory setting needs alternative or additional theoretical arguments. We address this issue later in the chapter.

CLINICAL BACKGROUND AND THE COMPLIANCE PROBLEM

When NTX became available for clinical use in the early 1970s, it soon became apparent that although it effectively blocked opiate agonist effects in humans as it had done in laboratory animals, humans had an annoying (if unsurprising) tendency to discontinue NTX if they were simply given a supply and advised to take it daily to protect themselves against temptation. Within a couple of years of its first clinical use, the need for a long-acting preparation was becoming apparent and the first studies of potential matrices and vehicles for such preparations appeared. As was said in the context of disulfiram (DSF) – another addiction treatment medication that has important conceptual similarities with NTX, which we will discuss later – “For any drug which has to be taken daily on a chronic basis and for which compliance is a problem, administration in depot form as an implant is an obvious solution.” Here, we merely note that ambivalence about taking medication – “poor compliance” or, in the current politically correct locution, “poor adherence” – is a common problem with most treatments, especially when treatment must be prolonged. However, it is important to note that in some oral NTX studies, compliance was considerably improved by therapeutic contracts that involved third parties (ranging from family members and colleagues to probation officers) in supervising

oral consumption. Not surprisingly, outcomes also improved.

It might seem obvious that compliance with a particular treatment is crucial to the outcome of that treatment but that is too simplistic in approach. It is now clear from several studies that patients who comply with treatment not only have better outcomes but also differ in several other important respects from patients who do not comply. Compliance, in essence, means following medical instructions. People who do not follow medical instructions may have several reasons for their lack of cooperation, ranging from failure or inability to understand the instructions, to various beliefs and attitudes that make them actively hostile to the proffered advice. They may also be generally inefficient and disorganized in their lives, or affected by short-term stress or distress that distracts them from their usual efficiency. People who comply are thus more likely to have social and personality characteristics, which lead to more favorable outcomes (compared with noncompliers) regardless of the treatment.

However, at a strictly therapeutic level, compliance with a particular pharmacological or psychological treatment only matters if the treatment in question actually has specific positive effects over and above any placebo or nonspecific effects that it may have. To comply perfectly with an objectively ineffective treatment confers, by definition, no benefit over equally perfect compliance with an appropriate and equivalent placebo treatment. For example, RCTs of DSF implants often show quite impressive levels of abstinence but no difference between active and placebo implants, because no commercially available DSF implant has provided effective or even measurable blood levels of DSF or its active metabolites; or any response to unanticipated alcohol challenges given intravenously. Conversely, even partial compliance with a significantly effective treatment may give better outcomes than good compliance with an ineffective one. Since NTX blocks opiates very effectively, it follows that maximizing compliance is more than usually important, and the most recent systematic review confirms that without supervised administration, the effectiveness of oral NTX in opiate abuse is modest at best.

The compliance problem is surely even greater in patients who request treatment for addictions because such patients are, we suggest, usually ambivalent by definition about having treatment. If they were consistently 100% in favor of discontinuing their addiction, they would hardly need treatment, except perhaps for transient help in managing unpleasant physical withdrawal symptoms. Conversely, if they were consistently 100% opposed to discontinuing their addiction, they would not be willingly present for the treatment in the first place. Thus, the large majority of patients seeking

or accepting treatment can be assumed to have mixed feelings about taking medication designed to discourage them from doing what a part of them very much wants to carry on doing. This is not likely to be a prominent factor in poor compliance with antihypertensive or antidiabetic medication, since few, if any, patients want to be hypertensive or suffer from poorly controlled diabetes. Poor compliance with this sort of medication probably stems more from forgetfulness, ordinary (as opposed to pathological) human failings, confusion (especially with multiple medications), inadequacies in the doctor-patient relationship, and side effects rather than from any fundamental ambivalence about treatment.

Indeed, the more effective the anti-addiction medication, the greater the ambivalence, for there is less potential for conflict about complying with a medication (or with a nonpharmacological treatment) that actually has little or no specific effect on consumption of the target drug of abuse. It is not difficult (to put it mildly) for patients to relapse while consistently taking NTX or acamprosate for alcohol abuse, or while regularly attending Alcoholics Anonymous meetings. In contrast, it really is impossible to relapse to true opiate dependence while maintaining adequate NTX blood levels, though this statement needs a few qualifications, as we discuss later.

THE DEVELOPMENT OF NALTREXONE IMPLANTS (NTXI) AND DEPOT INJECTIONS OF NALTREXONE (DINTX)

The first animal studies of possible depot preparations appeared in the mid-1970s. Human studies, under the aegis of NIDA, with a range of implant formulations, such as esterification and NTX microspheres covered with biodegradable plastics, were published in the 1980s. The implants were small enough to be inserted subcutaneously with a trocar and cannula and gave NTX levels lasting up to several weeks. Attempts to make a commercially viable depot preparation began in the early 1990s but despite the obvious and pressing need, nothing was clinically available by the mid-1990s even for "named patient" use.

In 1996, George Malmberg of Wedgwood Pharmacy, Sewell, NJ, produced some experimental implants based on standard implant technology as applied to a number of other drugs, using NTX powder compacted with a small amount of magnesium stearate. The first developed implants contained only 100 mg of NTX and were inserted subcutaneously with a trocar and cannula. Early studies with volunteers, including a physician, indicated that tissue tolerance was acceptable and that clinically effective blood levels were reached, as judged

by the ability of the implants to block challenge doses of opiates. To increase the duration of action, larger implants containing 1 g of NTX were manufactured. They were cylindrical in shape but at approximately 9 mm diameter (and about 20 mm long) needed to be inserted through a c.1 cm incision under local analgesia. They appeared to provide blockade for 5-7 weeks on average and completely prevented relapse during the first four weeks after detoxification in a consecutive series of the first 54 patients treated in Britain. All patients were made aware that these implants had not passed through any of the usual testing and licensing procedures (or indeed, any animal studies) but both patients and physicians could be reassured by previous NTX implant studies and by the very low organ toxicity of NTX (see below) as demonstrated in over a decade of oral use.

In Germany in the late 1990s, Partecke and her hospital pharmacist produced implants made of compressed pure NTX base, rather than the hydrochloride salt of NTX used in previous implants and without any stearate component. They contained 800 mg of NTX. Clinical studies indicated the expected improvement in outcomes compared with oral NTX and pharmacokinetic studies confirmed that effective blood NTX levels were maintained for several weeks.

Despite their immediately obvious value in preventing early relapse, it was also soon apparent, as with oral NTX, that most patients needed the protection of NTX for much longer than the 6-8 weeks, which was the typical maximum duration of these "first-generation" implants. If patients did not have further implants early in treatment, relapse quite often (but by no means always) tended to follow, sometimes quite soon after the blockade had worn off. This problem would also have occurred with the injectable, microsphere depot preparations that were being developed, had they been available for treating opiate abusers, since they only provided adequate blockade for 4-5 weeks. It is true that clinicians using these preparations had more time before opiate antagonism disappeared to persuade reluctant patients of the need for a further NTX treatment than is the case with oral NTX. However, given the typical ambivalence about treatment discussed above, it was to be expected that the uptake of repeated implants would decline over time, unless treatments were tied to, for example, a probation order, as discussed above.

Accordingly, alternative implant technologies were exploited to extend the duration of blockade not just by a few weeks but also by several months. By 2001, unlicensed but pharmacologically active "second generation" NTX implants became available, produced by Dr George O'Neil of Go Medical in Australia, referred to henceforth as the Go Medical Implant (GMI). They used some of the technology studied in the early 1980s

in that the NTX was contained in biodegradable (polylactate or poly-glycolate) plastic-covered microspheres. However, instead of being suspended in an inert liquid vehicle, as with depot injections, the microspheres were compressed with additional biodegradable plastic into pellets about 8 mm in diameter for subcutaneous insertion through a small incision, so that diffusion – and hence duration of action – could be prolonged almost at will, depending on microsphere size, rate of biodegradation, the proportion of NTX to matrix, and the number of pellets that were inserted. From the earliest publications, it appeared that this implant could maintain effective blockade for as much as six months in some cases.

In 2007, Vivitrol, became the first of several depot injections of NTX under development to receive a license, initially for alcohol abuse treatment only. It is still (at the time of writing) the only licensed injection but in 2010 its license was extended to include opiate-abuse treatment, though it had already been used “off label” for this purpose.

PHARMACOKINETICS OF NTXI AND DINTX

Hulse et al. (2004) compared blood NTX and 6-βnal-trexol (6BNTX) with single ($n = 10$) or double ($n = 24$) GMIs in patients having treatment for heroin abuse. In most patients, free NTX levels remained above 2 ng ml^{-1} and 1 ng ml^{-1} for approximately 90 and 136 days, respectively, with the single GMI containing 1.1 g of NTX. For the double implant, the figures were 188 and 293 days. In a later study by Ngo et al. (2008), the additive effect of a triple implant was compared with the data already obtained by Hulse et al. (2004). As expected, the triple implant maintained levels above 2 ng ml^{-1} (standardized for a 70 kg body weight) for longer periods (145 days versus 136 days for the double and 95 days for the single implant). However, the difference was not statistically significant. In a study by Kunoe et al. (2009) described in more detail below, blood samples were taken from 14 of the 26 patients with the GMI. NTX levels remained above 1 ng ml^{-1} throughout the 6 months of the study and above 2 ng ml^{-1} for about 5 months.

In several implant studies (and as is true of many other drugs) NTX levels showed marked variation between subjects. Since this has also been observed during constant dosing with oral NTX, it is unlikely to be due entirely, or even largely, to the release characteristics of the implant. However, some variation in release rates seems to bound arise from variations in such local and general factors as vascularity, age, sex, and liver function. There were also 16 cases in which, rather than showing a steady fall, a later blood sample gave a higher level than the previous one. This, too, probably

reflects variation in the rate at which local tissue fluids reach and penetrate the implant matrix.

Comer et al. (2002) studied NTX blood levels and the response to various test doses of diamorphine (up to 25 mg) in 12 heroin-dependent patients. Half of them received a low dose (194 mg NTX base) and the other half received a higher (double) dose of 384 mg of a DINTX under development. Plasma NTX levels remained above 1 ng ml^{-1} for 3 and 4 weeks after the lower and higher doses, respectively. Subjective effects of heroin were antagonized for 3 and 5 weeks respectively.

Using first generation Wedgewood implants, Waal et al. (2002) showed that blood NTX at or above the widely accepted minimum effective level of $1\text{--}2 \text{ ng ml}^{-1}$ were maintained for periods ranging from 5 to 10 weeks. However, in both the first-generation implants and DINTX preparations and unlike GMIs, once NTX blood levels decline to this minimum figure, NTX usually disappears entirely from the blood within a week or two. This means that – as with any conventional medication-free abstinence-based treatment program – patients who use heroin, especially by injection, are at risk of potentially lethal opiate overdose (OOD). In contrast, the long pharmacological “tail” of the GMI means that even when NTX blood levels drop below the conventional minimum at around 6 months, they may still prevent lethal respiratory depression for a further 3–6 months.

OPIOID OVERDOSE PREVENTION

During the period when an implant provides serum NTX levels at or above the conventional minimal effective range of $1\text{--}2 \text{ ng ml}^{-1}$, it will generally block all agonist effects of even large doses of heroin and most other opiates including both the desired euphoriant effects and the dangerous (and usually undesired) respiratory depressant effects. The highest reported medically observed challenge dose, described in more detail below, involved the administration of 500 mg of pure diamorphine intranasally with no sign of any agonist effects. This is much more than the diamorphine contained in typical individual doses of street heroin used by all but the most severe and well-supplied addicts. As NTX levels fall, heroin users may eventually obtain a euphoriant effect, but it seems that the level needs to fall further still before respiratory depressant effects are seen. This is a very fortunate feature of NTX pharmacology because patients whose opiate receptors have been blocked (or who have simply abstained without NTX) for several months lose their tolerance and risk death or anoxic/apneic brain damage if they abuse opiates again. In one case, an implanted patient,

abstinent for several months, was employed as a heroin courier in Russia precisely because he was assumed to be immune to temptation. However, he injected an unknown but evidently enormous amount of the heroin he was supposed to be selling. He experienced brief unconsciousness and apnea but recovered spontaneously and completely in a minute or two. Clearly, the NTX blocked all but the transient highest peak of the agonist effects. Without NTX, he would almost certainly have died.

It was thus reassuring but unsurprising when two GMI studies found large reductions in the expected incidence of OOD for as much as a year after implantation. This was true both for a group of adolescents at high risk for OOD and for implanted patients in general. Interestingly, in the latter study, there was an increase in nonopioid sedative overdoses from eight cases of preimplantation to 16 afterward. However, 9 of the 16 occurred in the first week or two after implantation and were probably caused by attempts to deal with the unpleasant withdrawal symptoms (including intractable insomnia) that normally make the period immediately following detoxification (by any method) such a difficult and relapse-prone stage in treatment.

EFFECTIVENESS STUDIES OF NTXI AND DINTX

Having described the theoretical and historical background and pharmacokinetics of depot and implanted NTX and the marked OOD-preventing qualities of longer-acting implants, we now summarize the RCTs that have been published in the last few years. They have largely confirmed the positive results that were consistently reported in earlier uncontrolled studies. The first three studies below used the GMI.

Hulse et al. randomized 70 patients to active GMI (2.3 g of NTX) and placebo NTX capsules, or to placebo implant and oral NTX 50 mg day⁻¹. In both the cases, family members were encouraged to supervise consumption of oral medication. At 6-months follow-up, more implant than oral patients had NTX levels above 2 ng ml⁻¹ ($p < 0.001$); 17 versus 62% of patients reported regular heroin use; 63 versus 26% reported being abstinent ($p < 0.003$), 49 and 21% respectively being confirmed by urinalysis. Patients on oral NTX started using heroin at an earlier stage (median (SE) 115 (12) versus 158 (9.4) days); NTX levels in implant patients were above 1 and 2 ng ml⁻¹ for 101 (95% CI 83–119) and 56 (39–73) days respectively for men and 124 (88–175) and 43 (16–79) days for women.

It is important to note that all patients who presented for withdrawal and NTX induction were successfully started on oral or implanted NTX with no dropouts,

using an outpatient procedure lasting only a few hours. The study, therefore, did not exclude those heroin addicts with unusually severe withdrawal symptoms (or ambivalence) who often discharge themselves prematurely from conventional inpatient or, even more often, outpatient withdrawal programs. The typical true completion rate even in many “centers of excellence” is less than 30%. In contrast, on an “intention-to-treat” (ITT) basis, 100% of the patients in this study reached this vital stage of treatment.

Kunoe et al. conducted a multicenter, open-label study of 56 patients (approximately 85% heroin injectors) aged ≥ 18 years from various inpatient detoxification programs in SE Norway and willing to be randomized. If detoxification was completed, they received either normal post-detox care (control) or normal care plus a GMI. Participants were fairly typical of the total population of the 15 clinics. ITT analysis showed significantly less opioid use than controls on all opioid use measures. For example, implant patients used heroin for a mean of 17.9 days (versus 63.6 days for controls) in the 180-day follow-up. Differences were even more significant in the 49 patients who completed treatment. A follow-up study found that 51% requested and received a second implant.

Lobmaier et al. studied imprisoned heroin-related offenders, who are at especially high risk of relapse (and fatal overdose) after release. They compared the effects of GMI or methadone maintenance treatment (MMT) on the use of heroin (and other illicit drugs) and criminality among heroin-dependent inmates after they left prison. Forty-six volunteers were randomly allocated to GMI or MMT before release, though they found it unexpectedly difficult to recruit the planned number of inmates willing to be randomized. However, ITT analyses showed reductions in both groups in the use of heroin and benzodiazepines, as well as criminality, 6 months after prison release. They concluded that NTX implants “may be a valuable treatment option in prison settings.”

In Russia, RCTs have recently been completed and published involving both Prodetoxon, a “first generation” type of implant, and Vivitrol. The first long-acting, sustained-release NTX formulation available in Russia was an implant (Prodetoxon; Fidelity Capital, Moscow, Russia). It contains 1000 mg of NTX that is slowly released after being inserted subcutaneously in the abdominal wall via a small incision. It was registered in Russia in 2005 and shown to block opioids for 2 months, but this time frame was extended to 3 months during the past year, based on clinical experience. As of this writing, it is the only officially registered NTX implant in the world. In this large scale double-blind, double dummy placebo-controlled RCT comparing NTX implant to both oral NTX and placebo implant, 306 recently detoxified opioid addicts were randomized

to a 6-month course of biweekly drug counseling and one of three medication groups, each having 102 patients: NTX implant (1000 mg, 3 times – every other month) + Oral placebo daily (NI + OP), Placebo implant + Oral NTX (PI + ON) (50 mg day⁻¹), and double placebo (implant and oral) (PI + OP). Medications were administered under double-dummy/double-blind conditions. Urine drug testing and brief psychiatric evaluations were done at each biweekly visit. Oral medication compliance was evaluated using a urine riboflavin marker. According to the study results, the number of heroin negative urines revealed a clear advantage of the NTX implant group over the two others: The cumulative proportion of heroin negative urines in NI + OP group was 63.6% compared to 42.7% in PI + ON group and 34.1% in PI + OP group ($p < 0.0001$, Fisher Exact test). Survival analysis also revealed a significantly greater retention in NI + OP group compared to two other groups: 53% of the patients in NI + OP group completed treatment compared to 16% in PI + ON and 11% in PI + OP groups ($p < 0.001$). The number of nonsurgical adverse events was limited with no difference between groups. However, surgical adverse events (wound infections, local site reactions) were higher in the NI + OP group (5% of all implantations) compared to the two other groups (1%). Thus, this long-acting NTX implant was generally well-tolerated and more effective than oral NTX and placebo for preventing relapse to opioid dependence. No significant differences were detected between groups in physical and social anhedonia, thus implying that the long-acting NTX did not interfere with normal pleasurable stimuli. As with our previous studies oral NTX, psychiatric symptoms (anxiety, depression, opioid craving) were markedly reduced in patients who remained in treatment and did not relapse, and no differences were noted between groups for those who remained in treatment and did not relapse.

Implantable NTX formulations have several limitations. First, they require a minor surgical procedure that carries with it the risk of wound infections and cosmetic defects. Second, it is possible for the patient to remove the implant within the first few weeks, as Prodetoxon slowly dissolves and can be removed reasonably intact in that period. Third, in some patients (<10%), the implant appeared to block opioids for less than 2 months. Therefore, a long-acting, slow-release formulation that is injectable and simple to use and does not require surgery might have some advantages over an implant formulation.

Three sustained-release, DINTX formulations have been developed in the past 10–15 years: Vivitrol (Alkermes, Waltham, MA), Depotrex (Biotech, Bethesda, MD), and Naltrel (DrugAbuse Sciences, Hayward, CA). Only Vivitrol has US Food and Drug Administration

approval. It is administered via a monthly intramuscular injection and approved for prevention of relapse to alcohol dependence. It is available in the United States, Europe, and Russia, and recent studies have found that a monthly intramuscular injection also blocks the subjective effects of opioids. A multicenter study of Vivitrol has recently been completed in Russia and led to FDA approval of Vivitrol for opiate dependence. A double-blind, placebo-controlled, randomized 24-week trial recruited adults with opioid dependence disorder, ≤ 30 days of inpatient detoxification and ≥ 7 days off all opioids. Participants received monthly intramuscular Vivitrol 380 mg ($n = 126$) or an identical looking placebo ($n = 124$) with 12 biweekly counseling sessions. The primary outcome was confirmed abstinence, based on opioid-negative urine drug tests as well as self-report of nonuse during weeks 5–24.

Group differences on the primary outcome of confirmed abstinence were significant ($p = 0.0002$) with Vivitrol yielding a median of 90% confirmed abstinent weeks versus 35% for placebo. Vivitrol-treated patients self-reported a median of 99.2% opioid-free days versus 60.4% for placebo ($p = 0.0004$). An anti-craving effect was observed, with an average reduction of -10.1 for Vivitrol versus $+0.7$ for placebo ($p < 0.0001$). Median retention was >168 days with Vivitrol versus 96 days with placebo ($p = 0.0042$). Naloxone challenge confirmed relapse to physiological opioid dependence in 17 placebo patients versus one Vivitrol patient, a 94% difference ($p < 0.0001$). Reduced HIV risk behavior, improved mental health function, and higher global clinical index ratings were observed with Vivitrol versus placebo. Vivitrol was well-tolerated and no Vivitrol-treated patients died, overdosed, or discontinued due to severe adverse events. Vivitrol, in conjunction with psychosocial treatment, demonstrated efficacy versus placebo across multiple recovery goals, including prevention of relapse, in patients with a history of opioid dependence. Thus, Vivitrol represents a new medical approach, quite distinct from opioid maintenance treatment, through once-monthly, injectable, opioid blockade.

LOCAL SIDE EFFECTS

Histological changes in tissues adjacent to GMIs have been studied at 1–38 months post-insertion. Initial and expected inflammatory and foreign body reactions steadily reduced until they disappeared by the end of the period. In a later GMI study, ultrasound was used to monitor the in vivo changes at 139 implant sites in 71 subjects at periods ranging from 2 to 1808 days after implantation. Patients were recruited by being approached, in sequential order, within four time blocks

postimplant (1–142 days, 216–399 days, 439–756 days and 896+ days). The ultrasound appearance of the separate tablets of the implant changed from being well-demarcated to less demarcation, followed by gradual coalescence into a single mass. A second radiologist, together with the first, independently assessed the amount of the remaining implant material. This had completely disappeared by an average of 1201 days postimplant. The radiologist who assessed the appearances was blind to the length of time since implantation. Additional assessment was provided by a nurse (also blinded to the time period) who examined the implant area visually and by palpation and also by patient self-reports. Both studies showed that in general, the implants were well-tolerated. As the authors note, the polymer used in the implants has been safely used for many years, not only in the comparatively small volumes required for absorbable sutures but also, since at least the mid-1980s, for the much larger volumes needed, for example, in absorbable screws for the fixation of bone fractures.

With first-generation implants containing magnesium stearate, both giant cells and stearate crystals may be seen. Some formulations incorporate a slow-release corticosteroid trying to reduce tissue reactions.

SYSTEMIC SIDE EFFECTS

Liver

One potential disadvantage of any implanted drug is that if significant side effects of the active constituent occur, the implant may have to be removed. This is of particular concern where DINTX is concerned, since it is almost impossible to remove the intramuscular drug deposit but it is also an important consideration for any still-unlicensed preparation. Fortunately, in some 40 years of clinical use, NTX has not been associated with any serious organ toxicity that might limit its prescription. The only one regularly mentioned as important is hepatotoxicity, and a special warning about it still appears in the prescribing literature of most countries where NTX is marketed. These warnings are misleading but the reason for their existence (and persistence) is little known. H. Kleber was involved in some early 1970s clinical studies and reports (personal communication) that there was pressure to change NTX's status from "experimental" to a drug that could be used without too much bureaucratic obstruction in clinical trials. The pressure originated in many US servicemen who started abusing heroin in Vietnam in that period and were expected to need treatment when they returned home. Full toxicity trials had not been concluded but the evidence

was reassuring. The authorities agreed in 1972 to ease restrictions on its use, provided that "black box" warnings about possible hepatotoxicity were displayed, since some studies had raised concerns. Having entered the official literature, the warning has remained there, though its justification is now very questionable.

As noted by and Brewer and Wong, the best evidence for this statement is not the numerous toxicity studies published since 1972 but the fact that for nearly two decades, oral NTX has been safely used, often for many months and at high daily doses, to relieve the intense pruritus of severe jaundice. The high bilirubin levels are usually due to serious liver disease, sometimes life-threatening. Even if jaundice is secondary to obstruction, severe biliary stasis itself often causes significant disturbance of liver function tests (LFTs). While NTX use may occasionally be associated with moderately abnormal LFTs, they did not cause any obvious abnormal deterioration in health or lead to any clinical alarm in any of the reported cases. All abnormalities disappeared rapidly when NTX was discontinued and sometimes even when it was not. Consequently, where strong indications exist for NTX treatment in either opiate or alcohol abuse, even serious liver disease should not be an automatic contraindication, and the appearance of LFT abnormalities after starting NTX treatment should lead to observation and frequent review rather than to instant termination of treatment. Brewer and Wong described a patient who became jaundiced from Hepatitis B 1 week after NTX implantation, having apparently become infected some 6 weeks earlier. The implant was not removed but the acute illness followed its normal course and the jaundice resolved in the normal way without specific treatment. In real clinical life, NTX appears to have no significant hepatotoxicity. Rashes due to specific hypersensitivity to NTX have been reported but are very rare.

NTX in Pregnancy

O'Neil, Pereira, and Brewer described their experiences of treating 25 pregnant heroin addicts with oral NTX in three different countries (Australia, Portugal, and Britain, respectively). Interestingly, all the women were started on NTX – mostly in the second or third trimester – using relatively rapid NTX induction under oral or intravenous sedation. In four cases contributed by O'Neil (who is an obstetrician and gynecologist as well as an addiction physician) NTX induction was done with ultrasound fetal monitoring. In none of the 25 cases was any fetal distress observed during NTX induction and precipitated withdrawal. Obstetric

outcomes were “reasonably unremarkable.” All had good APGAR scores and all, except two with marginally low birthweights, had normal head circumference. Delivery was vaginal and spontaneous in all except two cases. In the single case among this group contributed by Brewer and treated in the late 1980s, it proved possible to follow-up the child involved at the age of 10. Her milestones and development were normal and she was making satisfactory progress at an ordinary school. After starting NTX, only 3 of the 25 women resumed heroin use before delivery and two of those requested and received further treatment with NTX before giving birth.

Hulse and O’Neil reported a series of eight pregnancies involving women with long histories of refractory heroin abuse. Six of them became pregnant not long after NTX implantation, underlining the rapidity with which normal fertility and menstruation may return when heroin abuse ceases. All eight were free of opiate dependence throughout pregnancy, following implantation, and delivered infants who showed no withdrawal symptoms and had high APGAR scores. Four had normal, full-term deliveries, one was induced, and three had elective Caesarians.

In a nonrandomized study, pregnancy outcomes in a group of 17 women treated with GMIs (16 of whom conceived after implantation) were compared with a group of 90 pregnant women treated with MMT. The results were also compared with national Australian averages. There were significantly more low-birthweight infants in the MMT group (24 versus 5.6% national average and 5.9% in the NTX group); significantly more deliveries ≤ 37 weeks in MMT group (23 versus 4.6% national average and 11.7% in the NTX group); and significantly higher APGAR scores in the NTX versus the MMT group. Again, all infants in the NTX group were free of opiate withdrawal symptoms on delivery. Even without confirmation from randomized studies, these findings may already have important implications for the choice of management offered to opioid-dependent women who are either pregnant or have a high likelihood of childbearing in the short-term. The advantages of avoiding the problems of neonatal withdrawal, distress to mother, baby, and nursing staff alike and often involving prolonged and costly intensive care, hardly need to be pointed out. These reports suggest that for pregnant opiate addicts (a group of women who typically have less than ideal obstetric and fetal outcomes), treatment with NTX merits urgent studies comparing it with MMT – the current gold standard. Furthermore, it is a common experience that at least for the duration of the pregnancy, pregnant women are much more highly motivated than the average heroin addict to give up drugs of dependence, not excluding tobacco.

MENTAL HEALTH AFTER IMPLANTATION

Lowered mood and energy levels are common in the weeks and months following opiate withdrawal. The theory that at least some heroin addicts use opiates to self-medicate for underlying mood disorders created understandable concern that prolonged and inescapable blockade of opiate receptors might lead to an increase in depression and/or other psychiatric conditions. Fortunately, a study by Ngo et al found that in 359 patients followed for an average of 1.78 years postimplantation, hospital admission rates for all psychiatric diagnoses declined significantly, except for mood disorders (predominantly depressive rather than manic) which, however, did not show any increase.

NEW TREATMENTS, NEW PROBLEMS: SOME NOVEL PHENOMENA OCCASIONALLY APPEARING DURING NTXI AND DINTX TREATMENT

Can the Antagonist Effects of NTX Implants Be Overridden?

As early as 1998, it was reported that a “first-generation” implant produced blood levels 2 weeks after insertion that were clearly sufficient to block the effects of 1000 μg of fentanyl administered in 50 μg doses intravenously every minute over the course of 20 min. This total dose is equivalent to about 1000 mg of pethidine (ten times the usual maximum analgesic dose in opiate-naïve patients) or between 0.3 and 0.5 g of British street heroin. However, the NTX blood level at the time of challenge could not be measured. In 2002, Brewer described two patients who received relatively large doses of pure diamorphine to test the blocking power of implanted NTX. (It should be mentioned that in Britain, diamorphine may be – and quite commonly is – prescribed for analgesia by any physician, though to prescribe it for the treatment of heroin addiction itself, a special license is required. Since NTX-implanted patients are, almost by definition, not addicted to heroin, this means that diamorphine, like any other opiate or opioid, can be legitimately prescribed for diagnostic purposes in such patients.)

In one case, the patient claimed a heroin-sniffing habit of up to 10 g day⁻¹. Following a supervised test dose that confirmed his very high tolerance, he was maintained for a week on 200 mg of oral morphine four times daily until, during rapid antagonist induction (RAI) under general anesthesia, a GMI containing 2.2 g NTX was inserted subcutaneously. Six days later, blood was taken for NTX levels. The next day, he sniffed 500 mg

of pharmaceutical diamorphine under medical supervision over a period of 40 min. No changes in pupil size or respiratory rate were seen during this period or subsequently. Serum NTX was 2.8 ng ml^{-1} (i.e. not much higher than the usual minimum effective range) and $6\text{-}\beta\text{NTX}$ was 9.0 ng ml^{-1} . Serum levels of morphine and $6\text{-monoacetyl morphine}$ were 525 ng ml^{-1} and 164 ng ml^{-1} respectively (These opiate levels were so high that the laboratory asked whether the sample was taken for postmortem).

In the same paper, Brewer described another patient who normally smoked 1 g day^{-1} of heroin and had a 24-h RAI under oral sedation in hospital, during which a "first generation" 1 g NTXI was inserted. When he tried using heroin again out of curiosity about 3 weeks later, he claimed that he could feel typical effects and he used several times subsequently. It seemed important to discover whether or not this was a true opiate effect. Blood was taken and immediately afterward 100 mg of diamorphine was injected intravenously over 3 min ($\approx 250 \text{ mg}$ of typical British street heroin). No objective opiate effects were observed but he reported feeling "slightly relaxed" after 70 mg of dosage. A challenge with intravenous infusion of $800 \mu\text{g}$ of naloxone produced no reaction. Had he been experiencing true agonist effects, this relatively large dose of antagonist would surely have produced significant withdrawal symptoms. After these opiate and antagonist challenges, he swallowed 50 mg of NTX. Another blood sample was taken 4 h later, and the challenge repeated with 100 mg of intravenous infusion of diamorphine. There were similar mild subjective sensations but again, no objective changes occurred. It is unlikely that he experienced partial breakthrough of the blockade since the sensations were similar even when antagonist levels were considerably increased after oral NTX. Serum NTX levels before and 4 h after oral NTX were 5 and 15 ng ml^{-1} , respectively. $6\text{-}\beta\text{NTX}$ levels were 12 and 56 ng ml^{-1} , respectively. This is an example of "pseudo-breakthrough" (see below).

NTX is a competitive antagonist and can therefore, in principle, be overridden by sufficiently high serum levels of agonists. Buprenorphine, with its high receptor-affinity, is the opioid most capable of overriding the blockade but its intrinsic antagonist effects mean that overriding carries little risk of respiratory arrest. Clearly, even modest NTX levels can block very large amounts of heroin but as with all drugs, some patients will need higher (or lower) doses than usual to achieve the desired effects. Brewer and Streel reported a case in which an NTX level of only 1.5 ng ml^{-1} blocked a test dose of $500 \mu\text{g}$ of intravenously infused fentanyl but also another patient who showed euphoria and sedation (but no respiratory depression) after smoking only about 100 mg of pure diamorphine equivalent

despite a blood NTX level above 4 ng ml^{-1} . However, they stressed that such cases of overriding are rare. As with all drugs, if the effect is inadequate, increasing the NTX dose and blood level is an obvious therapeutic response.

As was described by Krupitsky et al., the blockade provided by prodetoxon is very difficult to override. However, it is possible to accomplish it with a very high dose of heroin (~ 10 -fold compared with the usual daily dose). Attempts to overcome the naltrexone implant blockade are not common and are usually unsuccessful because naltrexone has high affinity for the μ -opioid receptor. If a patient can obtain a large dose of heroin or other opiate, he or she may be able to feel the opioid effects, but they are usually attenuated. Patients on naltrexone have survived even a very high dose of heroin. Of course, a patient who stops naltrexone and then returns to his or her pre-NTX dose of heroin will have diminished tolerance and could suffer a serious or fatal overdose.

Breakthrough and Pseudo-Breakthrough

Overriding NTXs opiate blockade is clearly possible if blood NTX levels are below the conventional minimum and sometimes even if they are not. Overriding is also possible if agonist levels are high enough, though the dose may need to be extremely high. However, the matter is more complex than it appears, because not everything that sounds like breakthrough, from the patient's description, represents true breakthrough, for there is much more to opiate dependence than the pharmacological effects of the drug in question. There are large psychosocial components of most forms of drug dependence and some addictions – e.g. to food or sex – involve no external pharmacology at all. The ritual of drug-taking can be even more important than the pharmacology as is shown by case reports of addiction to placebos including an apparent withdrawal syndrome. This is especially the case when heroin is injected, partly because a separate "needle addiction" has been convincingly documented and partly because the "rush" or "pharmacological orgasm" that follows intravenous injection is probably more rapid and more intense than is obtainable by slower means of putting relatively large doses of intoxicants into the cerebral blood supply.

Another factor may be that when heroin is injected intravenously, it causes – like other opiates to a greater or lesser extent – histamine release. This presumably accounts for the local or generalized flushing that is often seen after intravenous heroin or morphine infusion and since histamine release is not mediated through opiate receptors, it is not blocked by opiate antagonists. We speculate that it may contribute to the problem

posed by a small but particularly interesting group of patients who continue to inject heroin despite experiencing no true opiate effects following appropriate test doses of morphine or diamorphine.

Brewer and Streef's chapter also describes a young woman with a history of anxiety preceding intravenous heroin abuse and of much failed treatment, who received a first-generation Malmberg implant. She injected heroin occasionally during the first month after implantation but following a third consecutive implant, started to inject almost daily. Though she insisted that she was getting typical heroin effects, there was no objective opiate response to appropriate test doses of intravenous diamorphine. There was no reaction to high doses of intravenous naloxone either. On two occasions, serum NTX and 6- β NTX were well above conventional minimally effective antagonist levels. Fortunately, with appropriate counseling and support, she was able to abandon this behavior. Eight years later (at the time of writing) she remains opiate-free and leads a full and fairly conventional life.

COGNITIVE-BEHAVIORAL ASPECTS OF DEPOT AND IMPLANTED NTX TREATMENT

The rationale of depot injections or implants of NTX is that once the patient's ambivalence about starting treatment has been overcome at least for long enough to accept the first implant or injection, that ambivalence cannot easily (or at all, in the case of depot injections) lead to withdrawal from antagonist treatment within a few days or even hours. This may be more important in treating opiate dependence than the use of depot NTX in alcohol abuse (which we mention only in passing) because while alcohol withdrawal symptoms are relatively short-lived and often mild or absent even in daily drinkers, some purely physiological opiate withdrawal symptoms typically persist for weeks or months and may, for an unfortunate minority, be both persistent and seriously distressing. Addicts know from experience that these symptoms can be instantly relieved by taking opiates and this knowledge is a factor in the typically high rates of relapse in the first month or two after withdrawal, even in programs that report "unusually high rates of abstinence." As well as exposure to opiate- and addiction-related cues, which we will discuss shortly, patients commonly cite poor sleep as a reason for early relapse. Post-withdrawal insomnia is often persistent.

The earliest studies of the first, unlicensed and relatively short-acting NTX implants that became available in the mid-1990s showed that, as theoretically predicted, they could virtually abolish relapse to dependent use

during the crucial first month. As mentioned above, those "first generation" implants typically gave adequate NTX blood levels (i.e. $\geq 1-2$ ng ml⁻¹) for at least 6-7 weeks. This meant that whether or not patients consistently wanted to remain physiologically opiate-free throughout that period, they had little alternative in practice. Not surprisingly, when NTX levels eventually fell below blocking levels, some patients returned to regular opiate use, either because they succumbed to the temptations to resume their old habits or because they were so distressed by persistent withdrawal symptoms that they chose, often with regret, to start or resume agonist maintenance. As we have noted, helping patients to resist temptation, of various kinds, is a central goal of all addiction treatment. It seemed likely that for a useful proportion of patients who might otherwise have had an early relapse, this implant-mediated 1-2 months abstinence helped them to get through the worst of withdrawal and get used to opiate-free habits of thought and behavior for long enough to have a better chance of persisting in those habits during the next few months. However, the optimal duration of treatment with depot or implanted NTX is a crucially important issue. So is the duration (and relative importance) of the psychosocial interventions that are usually advised in addition to NTX treatment.

HOW LONG SHOULD NTX DEPOT/ IMPLANT TREATMENT LAST?

In their 2003 paper, Brewer and Streef suggested a controlled trial of single short-acting versus single long-acting implant (i.e. 1-2 months versus 5-6 months). They predicted that, other things being equal – including access to psychosocial interventions – the long-acting implant would prove more effective at 12 months, because recovery from opiate dependence requires not only the acquisition of new, more adaptive habits but also the abandonment or weakening of old, maladaptive ones. This is an educational process and in all such processes, outcome is proportional to the length of exposure to the learning intervention. As yet, no such trial has been carried out. Their testable hypothesis was that patients who had their opiate receptors consistently blocked for longer rather than shorter periods would have a correspondingly higher chance of both learning and consolidating these vital new cognitive-behavioral responses and of extinguishing the old, undesired ones, with fewer possibilities of interrupting the educational process by even brief relapses. In that respect, Wickler's original theory may still have some validity. But whereas he seemed to be expecting the behavioral process to be a relatively rapid one involving simple Pavlovian extinction, we suggest that the main psychological process that

reinforces the pharmacological effects of NTX is *exposure and response-prevention* (ERP), the standard, evidence-based cognitive-behavioral treatment for compulsive behavior. For while attempts to equate addictions with obsessive-compulsive disorder have not proved very persuasive, there is clearly an element of compulsivity about addictive behaviors and they are also clearly cue-related, even at a fundamental neurophysiological level, as shown by several fMRI studies involving exposure to appropriate cues.

That ERP in addiction usually needs to last not just for a few weeks or months but for more than a year emerges from a study which found that alcoholics usually needed to abstain for 18 months before they had made and consolidated “a pronounced (cognitive) shift from ‘deprived users’ to ‘determined abstainers’.” They were “able to say, ‘well, that’s how I used to handle these problems, but no longer’.” Similarly, in a 7-year follow-up of alcoholic patients treated with supervised DSF and regular psychosocial input, it was found that relapse was less likely if DSF was taken for more than 20 months.

A 2.5-year follow-up study found that: “Achieving abstinence from illicit opioids was associated with concurrent improvement in other aspects of functioning including reduction of criminal activity, improved medical status, improved social functioning, and reduced abuse of other psychoactive substances. However, many of these improvements were reversed immediately if relapse to opioid use occurred.” During this time, it hardly needs to be said, attention may be needed to aspects of the patient’s life other than the temptation to relapse to opiate use. Alcohol abuse quite often accompanies opiate dependence and may become more prominent after opiate withdrawal. In this context it is significant that even good compliance with oral NTX at this stage does not prevent the emergence or recurrence of alcohol abuse and supervised DSF may be indicated. If the patient was a poly-drug abuser, NTX should not be expected to prevent the continuing abuse of nonopiate drugs. However, if opiate abuse was the major problem, then removing opiates from the patient’s drug menu and assistance with social integration may lead to reductions in the use of other drugs. One must also distinguish between the short-lived increase in nonopiate drug use – especially sedatives – that often seems to represent the self-medication of opiate withdrawal symptoms, and more persistent patterns of abuse, which may obviously be more therapeutically challenging.

All this is entirely consistent with the theory and practice of relapse-prevention, which emphasizes relearning, self-efficacy, self-control and an altered self-image and sees alcoholism (and in principle, the abuse of other substances) as inappropriate, learned behavior in general and as inappropriate coping behavior in

particular. Control is regained by successfully and repeatedly confronting, without alcohol, the situations and attitudes, which formerly resulted in excessive drinking. Other studies stress the importance of substance-related cues in relapse and note that patients rated them as the most important precipitant. Negative emotional states and social pressure are also important factors. Another Wicklerian relapse-prevention paper argues that: “To obtain maximum protection against relapse, extinction should ‘recreate’ all the original learning contexts (i.e. all possible drug cues).” Brewer and Strel’s paper makes an analogy between ERP for addictions and “immersion” methods of teaching foreign languages. One language-teaching authority states that the most effective and efficient methods of foreign language learning involve intensive exposure to the new language and pressure to use it, even imperfectly, combined with not allowing the student to use his or her habitual language. An even more intensive learning technique is “submersion,” in which during the hours outside school, students are urged to avoid speaking their first language and to live and associate only with people who speak the new language. “The real language laboratory” according to this authority, “is the foreign country....One obvious explanation for failure to achieve fluency ... is lack of exposure....Progress can only be achieved through extending the length of contact time between learner and language.”

“In short” Brewer and Strel stated, “our hypothesis is that abstinence becomes easier with practice; that the longer and more uninterrupted the practice, the better; and that [NTX implants] can facilitate this process. The idea is not a new one. As Hamlet says to Gertrude, (Act 3, Sc. 4.): ‘Refrain tonight, and that shall lend a kind of easiness to the next abstinence; the next more easy. For use almost can change the stamp of nature, and either curb the devil, or throw him out, with wondrous potency.’ Or as Aristotle (in his *Nicomachean Ethics*) put it even earlier: ‘We become temperate by abstaining from indulgence and we are the better able to abstain from indulgence after we have become temperate.’”

CONCLUSION

Treatment with depot-injections and implants of NTX has the ability to transform the management of opiate/opioid dependence or abuse by making relapse to opiates difficult or impossible provided the patient attends as planned for treatment. This is not the case with any other intervention in this field. Long-acting implants also increase the chance that patients will avoid dying from accidental or intentional OOD in the difficult first few months after withdrawal, before new

opiate-free cognitive-behavioral habits have become ingrained. NTX preparations of this kind are emphatically not a substitute for the therapeutic relationship and psychosocial interventions but they can greatly reinforce these important components of treatment. Even in countries or organizations where depot or implanted preparations are not available, much can be done – especially with parole- or probation-linkage but also by using Community Reinforcement and Network techniques – to improve compliance with oral NTX and thus improve outcomes.

INTRODUCTION

The United Nations Office on Drugs and Crime reported that in the past decade encouraging trends in cocaine use have emerged in the United States. Annual prevalence among adults is estimated at 2.6%, and 4% among high school seniors – striking declines from the late 1980s when rates exceeded 10%. Positive tests for cocaine in the US workforce have declined substantially and the size of the cocaine market has stabilized. Nevertheless, cocaine abuse and dependence continues to represent a formidable worldwide public health burden. Escalating patterns of use have been observed in other parts of the world, notably, Europe, and the United States remains the largest single consumer of the drug. Each year, 15.9 million people use cocaine worldwide and it is estimated that 18% are cocaine dependent – a dependence ratio higher than any drug other than heroin. The drug causes tens of thousands of deaths annually and accounts for a significant proportion of emergency room visits.

Psychosocial interventions such as contingency management and cognitive behavioral therapy reduce cocaine use. Indeed, one meta-analysis published in 2008 reported an effect size of $d = 0.62$ for psychosocial

treatments for cocaine dependence, which is in the moderate-to-large range. However, treatment response is highly variable and almost 70% of participants in clinical trials, where treatment quality is likely to be high, fail to achieve abstinence. This highlights the urgent need for efficacious treatment strategies, notably, pharmacotherapy. This chapter describes the rationale and targets for cocaine pharmacotherapies, reviews the evidence for select agents, discusses emerging pharmacogenetic data, and proposes directions for future work.

RATIONALE OF MEDICATION TARGETS FOR COCAINE PHARMACOTHERAPY

Addiction is a complex disorder with multiple biological systems that interact to produce symptoms of uncontrolled drug-seeking behavior. Pharmacotherapies target different mechanisms of addiction, including the positive reinforcement of the intoxicating effects, the negative reinforcing effects of withdrawal and craving, and the pathologic neuroadaptations within related neurotransmitter systems. Cocaine is a psychostimulant but its neurobiological effects differ

from other stimulants, such as methamphetamine. While methamphetamine increases extracellular levels of monoamines, in part, through the disruption of vesicular storage, cocaine acts primarily to inhibit dopamine reuptake through blocking the dopamine transporter system. This action of cocaine quickly and dramatically increases the amount of dopamine in the synapse, which corresponds with the rewarding effects experienced acutely with use.

The positive intoxicating effects of cocaine are mediated by neurotransmitter systems including dopamine and norepinephrine, although dopaminergic effects appear primary in the acute euphoric effects making this a clear target for pharmacotherapy. Using preclinical models, Koob's work has shown that after repeated administration, a series of neuroadaptations occur, which described as an opponent process model whereby within-system and between-system neuroadaptations occur as a response to the acute reinforcing effects of repeated drug administration. This process is characterized by the increasing recruitment of anti-reward processes, including hypoactivity in the dopaminergic system and alterations in hypothalamic–pituitary–adrenal (HPA) axis functioning. It is during this period of neuroadaptation that motivation to obtain nondrug rewards is attenuated and behavioral symptoms of abuse and dependence are observed as correlates. Changes in these circuits are also associated with chronic irritability and dysphoria that are commonly experienced during early periods of abstinence from cocaine, lending more support for identifying these mechanisms as potential targets to develop pharmacotherapies.

The vast majority of clinical trials of cocaine pharmacotherapies have evaluated medications that target one or more of these neurobiological systems that support cocaine dependence and have mechanisms of action that can be broadly classified as either agonists or antagonists. Antagonist approaches are medications that bind to receptors and block activity of the cell, altering neurotransmission and attenuating or eliminating reinforcing effects of acute cocaine administration. Antagonists compete with agonists but have minimal or no intrinsic activity at the receptor site. Notable examples of antagonist approaches in addiction medicine include the opioid antagonist naltrexone for opioid dependence – a well-studied compound also showing efficacy for alcohol and perhaps amphetamine dependence. In contrast, agonist therapies seek to promote cocaine abstinence by reducing withdrawal symptoms and negative affective consequences in the early abstinence. Agonists act pharmacologically similar to the targeted drug and typically feature high receptor affinity but lower intrinsic activity, thereby mitigating withdrawal. Agonist therapies are preferred treatments for opioid dependence (e.g. methadone,

buprenorphine) and for nicotine dependence (nicotine replacement therapies).

Meta-analyses on cocaine pharmacotherapy have been conducted for agonist strategies, antipsychotics, anticonvulsants, disulfiram, and for different classes of medications including antidepressants. The next section summarizes those findings and focuses on subsequent pharmacotherapy developments.

CLINICAL STUDIES OF PHARMACOTHERAPIES FOR COCAINE DEPENDENCE

GABAergic Therapies

In response to emerging clinical and preclinical data, the gamma aminobutyric acid (GABA) system has gained increasing attention as a pharmacotherapy target for cocaine dependence. GABA is the major inhibitory neurotransmitter system and modulation of GABA has indirect effects on dopaminergic neurotransmission. GABA neurons participate actively in the mesolimbic dopamine system – the neurological system that mediates the reinforcing effects of cocaine. Medication approaches that potentiate GABA-mediated inhibitory neurotransmission may work to block reinforcing effects of elevated drug-induced extracellular dopamine concentrations following cocaine use, ultimately leading to reduction or elimination of drug use. GABAergic medications that have been evaluated include marketed drugs with anticonvulsant and antispastic indications. These medications act on the GABA system through a range of pharmacologic mechanisms, including functioning as agonists, inhibiting reuptake of GABA by disrupting GABA transporters, or inhibiting the enzymatic degradation of extracellular GABA.

Two recent meta-analyses examined the efficacy of anticonvulsants for cocaine dependence. Minozzi and colleagues reviewed 15 randomized controlled trials of medications including carbamazepine, tiagabine, gabapentin, phenytoin, lamotrigine, and topiramate. The methodological rigor of the studies was good, although sample sizes were generally small. Overall, 1066 cocaine-dependent participants were randomized to this set of studies. Meta-analytic findings showed no evidence of efficacy for these medications in terms of the two primary outcomes: use of cocaine (assessed via self-report or urinalysis) or study retention. Similarly, secondary outcome measures including craving, dependence severity, depression, and anxiety all evidenced equivalence between active and placebo conditions. In head-to-head comparisons between specific medications and placebo, no additional evidence for efficacy emerged. While no effects were observed, one

notable pilot trial from Kampman's group showed statistically significant reductions in cocaine use during the last 4 weeks of a 13-week trial for 20 cocaine-dependent subjects assigned to 200 mg day⁻¹ topiramate compared to 20 subjects assigned to placebo. There is continued interest in evaluating topiramate as a potential mono- or combination pharmacotherapy for cocaine dependence. A more recent meta-analysis by Alvarez and colleagues largely confirmed an overall lack of efficacy for cocaine pharmacotherapies with some kind of GABAergic activity. Using a slightly different pool of studies, one report of carbamazepine showed weak evidence over placebo for increased retention among cocaine-dependent users with comorbid affective disorders, though no differences were observed for cocaine use.

Subsequent to the publication of these two meta-analyses, a great deal of excitement was generated by a randomized placebo-controlled, double-blind trial of γ -vinyl- γ -aminobutyric acid (vigabatrin), which inhibits the catabolism of synaptic GABA, thereby elevating GABA concentrations. One hundred and three cocaine-dependent, treatment-seeking parolees, not mandated by the judicial system to seek treatment, participated in 9 weeks of active treatment and 4 weeks of follow-up. Subjects in the treatment group (28%) featured significantly greater end-of-trial abstinence as compared with the placebo group (8%). This finding is especially important as the US Food and Drug Administration requires that an experimental medication must significantly improve abstinence rates during the last weeks of a trial over placebo as a condition for approval for marketing as a cocaine pharmacotherapy. More recent evidence has dampened enthusiasm for studying vigabatrin with stimulant abusers, including concerns regarding visual field defects. Some data show vigabatrin raises blood pressure and heart rate in the presence of relevant doses of methamphetamine and one episode of medication-induced hypertension was noted in the cocaine trial, although symptoms resolved and did not require additional treatment. While results of a replication study have not been published, concerns regarding side effects of vigabatrin dampen enthusiasm for the compound. The potential risk-to-benefit ratio for vigabatrin in the absence of clear efficacy may slow its future development. The pharmaceutical company that developed vigabatrin has manufactured a similar and new compound that has shown promise as a cocaine pharmacotherapy in preclinical studies.

A great deal of energy has been expended evaluating the antispastic medication, baclofen, a GABA-B agonist as a cocaine pharmacotherapy. In Shoptaw's initial clinical trial, no main effect of baclofen over placebo was observed in reducing cocaine use or in increasing retention in a 16-week double-blind, randomized trial.

Secondary analyses, however, showed that baclofen appeared to have differential efficacy for subjects with more severe levels of cocaine dependence at baseline. Additional evidence for baclofen includes reliable effects observed in reducing cocaine self-administration in primates and in human laboratory settings. Self-administration of stimulants in experimental settings with laboratory animals and humans is thought to provide the best evidence that a medication will show efficacy as a treatment in outpatient settings. Yet, in an adequately powered ($n = 160$), multisite, randomized, placebo-controlled replication trial, baclofen produced no significant effect over placebo along cocaine use – retention or subjective effect measures. The only rational conclusion regarding the clinical utility of baclofen at this point is that while it is possible that the medication has effects on reducing cocaine use in some subgroups, such effects are not observed in general samples of cocaine-dependent individuals.

As a class of medications, the preponderance of the evidence provides little support for anticonvulsants as treatment for cocaine dependence. Some relatively small effects were observed for topiramate and vigabatrin over placebo, although confirmatory evidence has been elusive. The failure to find an effect in clinical trials is frustrating, given some of the strong preclinical findings, but the negative findings in clinical trials highlight the complexity of identifying an effective cocaine pharmacotherapy.

Dopamine Antagonists and Partial Agonists

Due to the prominent role of dopamine in the acute rewarding effects of cocaine use and abuse, the rationale for evaluating medications that dampen or block dopamine transmission (i.e. antipsychotics) has strong theoretical attraction. In addition, the availability of atypical antipsychotics, with their reduced likelihood of extrapyramidal side effects, made this class of medications attractive candidates as cocaine pharmacotherapies. However, antagonist medications consistently fail as a cocaine pharmacotherapy. In a large, early trial of the D₂/5-HT₂ antagonist risperidone, cocaine-dependent individuals were randomized to placebo – 2 mg, 4 mg, or 8 mg of active medication. Findings showed no statistically significant effects of risperidone at any dosage over placebo along retention or proportion of benzoylecgonine-positive urine screens (benzoylecgonine is the primary metabolite of cocaine in urine), leading to the conclusion that dopamine antagonists, as a class, likely would not have a place in treatment of nonpsychotic cocaine-dependent individuals.

Several trials of antipsychotics for cocaine dependence, mostly at low to moderate doses, were

summarized in a Cochrane meta-analysis that reviewed outcomes for three risperidone studies, three olanzapine studies, and two trials with haloperidol. The manner in which cocaine use outcomes were reported precluded easy summarization, but the preponderance of evidence suggested no benefits to treatment using these antipsychotics as measured by benzoylecgonine in urine, treatment retention, levels of craving, or psychiatric symptoms. A few reports not included in the Cochrane review showed similarly disappointing outcomes. A subsequent trial of olanzapine found no effect on any outcome measure. Long-acting injectable risperidone was assessed in a small randomized placebo-controlled trial with cocaine-dependent men. Although underpowered to detect treatment differences, no advantage for active medication over placebo was observed. Among cocaine-dependent individuals with schizophrenia, haloperidol decreased cocaine craving but increased cocaine use compared to placebo.

Although antipsychotics with purely antagonist properties have effectively been ruled out as a medication for cocaine dependence, there has been intensive interest in considering partial dopamine agonists as a strategy for treating stimulant dependence, likely due to the wildly successful use of the partial agonist medication buprenorphine in treating opioid dependence. Aripiprazole is a new generation antipsychotic medication that features partial dopamine agonist properties at D₂ which may reflect functional selectivity and has diverse effects at both serotonin and other dopamine receptors. Outside one open label trial of aripiprazole with 10 cocaine-dependent men with comorbid schizophrenia, we are aware of only one trial with a targeted enrollment of 275 subjects that is presently being conducted as part of the National Institute on Drug Abuse's (NIDA) Intramural Research Program. In amphetamine-dependent individuals, aripiprazole had an iatrogenic effect on drug use in one trial, leading many trialists to have skepticism for the treatment of stimulant dependence using this approach. More, aripiprazole caused a dose-dependent enhancement of the reinforcing effects of cocaine in one human laboratory study. So while some antipsychotics have shown some promise for other addictive disorders (a recent review highlighted some efficacy for clozapine in the treatment of alcoholism and cannabis dependence), the available evidence does not support further evaluation of dopamine antagonists or partial agonists as cocaine pharmacotherapy.

Dopaminergic Neurotransmission Enhancing Therapies

Research evaluating medications that enhance dopamine transmission shows some elements of efficacy.

One early review of nonpsychostimulant dopaminergic agonists (i.e. direct agonists) that included amantadine, bromocriptine, and pergolide reported that although there were glimmers of medication effects in some of the findings, the preponderance of the evidence showed no robust efficacy as measured by benzoylecgonine-negative urine screens or by treatment retention. One small, early screening trial of the long-acting dopamine agonist cabergoline suggested the medication produced significantly more benzoylecgonine-negative urine screens than placebo. In a secondary analysis of all dopamine agonists in the NIDA-sponsored effort to identify candidate medications, the cocaine rapid evaluation screening trial (which included the cabergoline trial), no significant effect was observed as a class along any main outcome measure.

Mixed evidence of efficacy is observed for the dopamine precursor, levodopa. In two randomized trials, using two doses of levodopa, no evidence for efficacy was seen for benzoylecgonine-free urine screens, retention, craving, or mood. In a third trial of levodopa that incorporated behavioral treatments of clinical management, cognitive behavioral therapy or cognitive behavioral therapy, and voucher-based incentives for cocaine urine screens, however, a main effect was found for medication – 62% benzoylecgonine-positive screens for the active conditions and 79% for placebo. Specific behavioral intervention by medication effects was observed to suggest that levodopa enhanced the reinforcing salience of contingencies in behavioral therapy. This finding illustrates the complex interplay between medications and behavioral treatments, but also provides an indication that agonist strategies may help subgroups of individuals access behavioral treatments to reduce their cocaine use.

Agonist medications with similar pharmacological profiles to stimulants but with low abuse liability have been proposed as replacement therapies for cocaine dependence. There is a strong conceptual argument for “indirect” agonist replacement treatment for stimulant dependence, particularly dexamphetamine, methylphenidate, modafinil, and bupropion as treatment candidates. While substantial preclinical and human laboratory evidence suggests that efficacy should be strong with these medications, the review of clinical trials provides more tentative evidence. In a meta-analysis of trials of dexamphetamine, methylphenidate, modafinil, bupropion, selegiline, and mazindol for cocaine dependence, no effects of these medications on cocaine use were observed as measured by urine screen or self-report nor were there medication effects on treatment retention. There was, however, a statistical trend favoring medication for sustained abstinence. Subgroups of cocaine-dependent individuals who have comorbid opioid dependence benefitted substantially

from dexamphetamine and bupropion in terms of heroin use and as a rule appeared to benefit more from psychostimulants in terms of cocaine abuse than did cocaine-dependent individuals who were not opioid dependent.

Indeed, findings for primary cocaine-dependent versus cocaine-dependent individuals with other comorbidities, including opioid dependence, can be divergent. In a randomized controlled trial with cocaine-dependent adults comorbid for attention deficit hyperactivity disorder (ADHD), methylphenidate did not improve ADHD symptoms, yet did show a significant and independent effect on reducing the probability of a benzoylecgonine-positive urine sample. These trials and their meta-analysis are consistent in articulating that agonist medications have a significant and consistent effect on at least some aspects of cocaine use when evaluated in randomized controlled trials.

Subsequently, two high-quality randomized trials were conducted with oral methamphetamine and modafinil as therapies. In one, cocaine-dependent individuals were randomized to immediate release methamphetamine (30 mg day⁻¹), sustained release methamphetamine (30 mg day⁻¹), or placebo. The 30 participants in the sustained release arm exhibited lower rates of benzoylecgonine-positive urine samples (29%), compared with the two other arms, which were not distinguished from each other. Medication adherence was good as several measures were taken in order to minimize the threat of misuse or diversion.

Dackis' original positive finding of modafinil over placebo for reducing cocaine use injected a great deal of enthusiasm to the field and to the approach of agonist treatment for cocaine dependence. Yet in the context of the meta-analytic methods, weaker medication effects of the medication were noted. Specifically, when outcomes from the original trial were examined in the meta-analysis, the proportion of benzoylecgonine-free urine screens was not different for medication and placebo groups, though there was an interaction between medication by time favoring modafinil. In a replication trial, the protocol was extended to 12 weeks of treatment and 4 weeks of follow-up visits, with two doses of modafinil: placebo, 200 mg day⁻¹, or 400 mg day⁻¹. Results showed no differences in the proportion of cocaine nonuse days and treatment retention between any active and placebo conditions. In *post hoc* analysis, however, participants without current or past alcohol dependence showed significant effects of modafinil over placebo – those with the comorbid dependence did not. There are other factors that can diminish enthusiasm for the utility of modafinil as a treatment agent, including a lack of preclinical and human laboratory support. Still, two recent reviews highlighted promise for modafinil as an abstinence initiation medication and an anti-relapse agent and it is possible

that effects may be observed for the medication to have significant effects in specific subgroups.

Antidepressant and Serotonergic Therapies

During the 1990s, the tricyclic antidepressant, desipramine, was extensively examined as was fluoxetine as cocaine pharmacotherapy. An early meta-analysis reviewed outcomes of 18 studies of antidepressants for cocaine dependence, with the majority of studies included evaluating desipramine or fluoxetine. Only three studies showed a medication effect on reduction of cocaine use; the remaining 15 were null. No medication effects were observed for retention. In cocaine-dependent patients with comorbid depression, participants assigned to a desipramine condition showed antidepressant effects of the medication and showed improved mood that correlated negatively with cocaine use. Yet there was no evidence of a direct medication effect on cocaine use. Consistent with levodopa, contingency management seemed to boost desipramine efficacy in buprenorphine-maintained individuals with comorbid cocaine dependence. As with other putative cocaine pharmacotherapies, desipramine produces an interesting pattern of outcomes, although no consistent effects in the broad population of cocaine-dependent individuals are observed for the medication.

No consistent effects are observed for the broad category of serotonergic medications. In a placebo-controlled trial of fluoxetine in the presence or absence of contingent vouchers for sustained abstinence with methadone-maintained comorbid cocaine-dependent individuals, no medication effects were observed. The group receiving placebo and the vouchers, however, evidenced the lowest probability of cocaine usage and the highest retention in treatment. In a similar placebo-controlled randomized trial of the serotonin precursor tryptophan, participants completed a 5-day residential stabilization period, which insured initial cocaine abstinence, and were randomized to a 2 (tryptophan, placebo) by 2 (attendance-based contingency, cocaine abstinence contingency) design. While no significant medication effect was observed along any marker of drug use or retention, there was an effect for the vouchers, with abstinence-based vouchers outperforming attendance-based vouchers in producing superior outcomes in cocaine abstinence. Nefazodone, a weak serotonin–norepinephrine–dopamine reuptake inhibitor, similarly showed no effects on cocaine use or retention in a large sample ($n = 210$) of cocaine-dependent adults, though attrition was high in both conditions (79% total) complicating conclusions on efficacy. Interestingly, Moeller's group studied the selective serotonin reuptake inhibitor citalopram and reported initial efficacy of citalopram over placebo in reducing cocaine-positive urine samples in a randomized trial of 67 participants. All subjects received contingency

management and cognitive behavioral therapy. In light of the persistently negative findings with selective serotonin reuptake inhibitors, the authors theorize the observed citalopram effect could be due to the selectivity of the medication – particularly its low affinity for 5-HT_{2C} receptors.

Three doses of the anti-emetic 5-HT₃ receptor antagonist ondansetron (0.5, 2, and 8 mg day⁻¹) were compared to placebo for 8 weeks in the context of weekly cognitive behavioral therapy. Cocaine-dependent participants randomized to the 2 mg condition performed worse in terms of percentage of weekly mean nonuse days compared to placebo. In contrast, the 8 mg group outperformed all others in terms of reductions in cocaine use and increases in retention. Explanations for results using ondansetron as a cocaine pharmacotherapy become more difficult to explain in the context of the same group's observation of a pharmacogenetic effect in a similarly designed trial of ondansetron for alcohol dependence. In this trial, alcohol-dependent participants who had homozygous long form (LL) of the 5'-regulatory region of the 5-HT transporter (5-HTTLPR) showed significant reductions in drinking days and drinks per drinking day compared to participants with other variants (heterozygous long short (LS) or homozygous short (SS)). Importantly, this genetic analysis was prospectively planned and genotype was used as a factor in the randomization. Analyses of the full sample without genotype data showed no effects of ondansetron on drinking outcomes. Together, these findings imply that the negative trial of ondansetron for cocaine may have been due to unmeasured variation related to genotypes. A well-sized, randomized, placebo-controlled trial of ondansetron for methamphetamine dependence at the three active doses that also failed to include a prospective genotype hypothesis showed no differences between conditions. As with other medication strategies as cocaine pharmacotherapy, subgroups may exist for which serotonergic medications improve treatment outcome. On balance, however, there is little compelling support for further evaluation of serotonergic medications.

Disulfiram

Disulfiram has been utilized as a treatment for alcoholism for over 60 years. It functions as an aldehyde dehydrogenase inhibitor. The impaired metabolism of alcohol and increased concentration of acetaldehyde creates unpleasant subjective effects that deter alcohol consumption. As cocaine and alcohol are co-abused, one plausible mechanism by which disulfiram might exert effects is through a reduction of alcohol and its cueing effect for cocaine usage. Yet a more likely mechanism to explain disulfiram efficacy in cocaine-dependent populations involves inhibition of dopamine beta-hydroxylase. Recent work that disentangled

disulfiram effects on cocaine abstinence initiation from its ability to support relapse prevention has demonstrated that disulfiram blocks cocaine-induced reinstatement in laboratory animals through disruption of the conversion of dopamine and the resultant altered ratio of dopamine to norepinephrine. This strong evidence points to inhibition of the enzyme dopamine beta-hydroxylase as the mechanism of action for disulfiram action in reducing cocaine use.

Several randomized, placebo-controlled trials support disulfiram as a cocaine pharmacotherapy. The interpretation of data on the clinical utility of disulfiram for cocaine dependence, however, is complicated by much of the human work being completed using subjects who are comorbid opioid dependent or comorbid alcohol dependent in the clinical trials. No major clinical trial of disulfiram has been conducted for patients with primary cocaine dependence as their sole diagnosis. The presence of a second chemical dependency may index a higher level addictive process and thus complicates interpretation of these data.

In a recent Cochrane review, seven trials of disulfiram that involved 492 subjects each included individuals with two substance dependencies – five included patients with cocaine dependence and alcohol abuse or dependence; two enrolled individuals with cocaine dependence with concurrent opioid dependence who were maintained on methadone or buprenorphine. Four direct comparisons between disulfiram and placebo were made, while other arms tested disulfiram against naltrexone or a nonpharmacologic treatment. In the comparisons with placebo, there was no significant effect of the medication on treatment retention. Though variability across the studies in the measurement of cocaine use precluded meta-analytic comparisons, the available evidence failed to identify a strong general effect of disulfiram over placebo. Disulfiram, however, demonstrated superior effects over naltrexone.

Subgroup analyses of disulfiram effects in the review showed interesting findings. In two randomized clinical trials, secondary analyses showed gender to moderate treatment responsiveness, whereby men benefitted from disulfiram and women did not. In one trial, the benefits of disulfiram accrued only to those who were abstinent from alcohol during the course of the treatment. Specifically, for those who abstained, disulfiram, cognitive behavioral therapy, and their combination were effective in reducing cocaine use and these outcomes improved over the course of the 12-week treatment period. In contrast, for those reporting a single drink or more during treatment, medication or therapy showed no benefits in terms of cocaine usage. This finding suggests two conclusions: insofar as disulfiram positively affects cocaine usage, this effect is not fully mediated by a reduction in alcohol consumption; second,

it is possible that individuals with comorbid alcohol abuse may be medication nonadherent or that comorbid alcoholism dampens the therapeutic utility of the medication (as observed in the large modafinil trial).

A recent report by Oliveto's group found a nonlinear dose-response relationship for disulfiram as a cocaine treatment. After a period of stabilization on methadone, cocaine and opioid-dependent participants were randomized to placebo or 62.5 mg, 125 mg, or 250 mg of disulfiram for 12 weeks. Participants were included in the analyses only if they completed the first 2 weeks of treatment. Over the full course of treatment, disulfiram did not impact opioid use, compliance with methadone treatment, nor did it exert an effect on drinking, although this may have been due to a very low level of drinking in the sample. In terms of the percentage of urine samples negative for benzoylecgonine, generalized linear mixed effects models showed that both the 250 mg and the placebo condition significantly reduced cocaine use. By contrast, the midrange dosage conditions for disulfiram increased cocaine consumption. The "inverted U" effects on cocaine use observed in this trial are difficult to explain and may be best understood as a function of the complex pharmacology and behavioral effects of disulfiram. The authors conclude that disulfiram in doses lower than 250 mg may be contraindicated for cocaine and opioid-dependent individuals. The viability of 250 mg compared to a higher dose (e.g. 500 mg) remains unclear.

New Directions

The variable and overall weak effects of medications evaluated for cocaine dependence contribute to an intense interest in identifying novel compounds that may help patients reach their cocaine use goals. The cannabinoid system is of relevance in addiction based, in part, on its selective increase of dopaminergic transmission in the nucleus accumbens – a brain region critically involved in addictive disease. CB₁ receptor modulation inhibits glutamate release broadly across the striatum and its inhibition has been shown to attenuate cocaine prime-induced reinstatement in a rodent model. There is substantial preclinical evidence for the utility of CB₁ receptor antagonists, highlighting the potential of this mechanism as a cocaine pharmacotherapy. One such agent, rimonabant, was being evaluated as an anti-obesity treatment and as a candidate for treating nicotine, cannabis, and alcohol dependence. Emerging concerns, however, over suicidal behaviors led to the termination of numerous clinical trials. Still, the evidence for medications that modulate the cannabinoid system is strong and other CB₁ receptor modulators are under development.

Koob's model highlights the importance of the stress systems in perpetuating addictive processes. According

to his model, three stages are distinguished within the addictive cycle that starts with drug preoccupation, proceeds to drug intoxication, and follows with withdrawal and prominent negative affect. Several neuropharmacological mechanisms are involved in this cycle, including norepinephrine, orexin, vasopressin, dynorphin, and corticotrophin-releasing factor. Dysregulation of biological stress response systems are implicated in a range of physical and psychological disorders with the HPA axis receiving considerable attention as the biological intermediary linking stress and disease. When appropriately regulated, the HPA axis describes an integrated system linking brain structures and a cascade of hormonal effects that provides an adaptive basis for responding to threats to homeostasis. In response to acute stress, corticotropin-releasing hormone (CRH) is released, which in turn activates the synthesis of adrenocorticotrophic hormone (ACTH). ACTH enters general circulation and triggers the release of adrenal cortical glucocorticoids.

Koob's group provided initial preclinical evidence supporting his model showing alterations of CRH functioning partially mediated increases in drug taking, in anxiety-like symptoms of withdrawal, and in stress-induced reinstatement. Additional support for the model is found in humans. Among cocaine-dependent adults who completed a social stress test, attenuated ACTH and cortisol responses associated with shorter latency to first cocaine use and with cocaine use in the 30 days after discharge from inpatient detoxification. More, CRH administered ($1 \mu\text{g kg}^{-1}$) intravenously to cocaine-dependent men and women produced a craving response and caused a stress response that was higher than that observed in control participants. Together, these findings highlight potential pharmacologic approaches modulating HPA function as cocaine pharmacotherapy. The approach is also being evaluated in alcohol dependence. An investigative selective CRH antagonist is currently being evaluated by researchers within the National Institute on Alcohol Abuse and Alcoholism for its ability to reduce alcohol craving in detoxified alcohol-dependent women.

A different and very innovative approach to cocaine pharmacotherapy involves immunotherapy and has been dubbed the "cocaine vaccine," though its mechanism is different from vaccines for infectious diseases. The cocaine vaccine is theorized to minimize the amount of cocaine that acts on the central nervous system using antibodies. This mechanism of the vaccine couples a cocaine derivative with a carrier protein, which elicits an immune response, that is, production of cocaine antibodies. Once antibodies are developed, future administrations of cocaine are bound to the antibodies, thereby preventing uptake of cocaine across the blood-brain barrier. This effect also reduces or eliminates the
