Attentive effects include engagement, or covert shifts of visual attention toward the salient cue location before the probe appears, as well as overt shifts in gaze direction, and can be found with brief supraliminal cues, typically presented for 50–500 ms. These effects seem to occur for a wide range of cues, including food-related

words and pictures for people deprived of food, body shape, and weight cues for people with eating disorders, and substances related cues for users of those substances.

Post-attentional effects, found in studies with longer cue durations, counteract initial shifts of attention toward a stimulus that people are trying to avoid, or disengagement. An increase in disengagement leads to a bias away from the salient stimulus location, which coupled with subsequent inhibition of return effects, leads to a slowing in detection of a collocated probe (inhibition of return is an attentional effect that makes it hard to attend to a stimulus or location that one has already engaged with and disengaged from). Strictly speaking, disengagement refers to the attentional effects rather than gaze, and may be followed by a shift in covert attention to another location, where it may be engaged on another stimulus.

The relative contribution of these phases of attention to attentional biases was summarized by Weierich, Treat, & Hollingworth as two hypotheses: Vigilance-Avoidance and Attentional Maintenance. Vigilance-Avoidance argues that biases are due to enhanced engagement with a stimulus (vigilance) coupled with delayed avoidance: so substance-dependent or craving individuals would be quicker at allocating their attention toward substance-related cues, and then less able to disengage from them. Attentional Maintenance argues that once salient stimuli have gained attention, they hold it, making it difficult for substance-dependent people to disengage from them. The two ideas are not incompatible, and make similar claims for differences in the pattern of attentional allocation, but deal with different timescales: the overt avoidance of the vigilance-avoidance hypothesis occurs later than the covert disengagement of the attentional maintenance hypothesis. Both hypotheses indicate that people who are actively trying not to attend toward substance-related stimuli, or to look away if they find themselves attending to them, will have relative difficulty employing such a strategy.

Another distinction that can be made takes into account the relative salience of the stimuli. While most anxiety studies have used stimuli that either are threatening, or are not threatening, Wilson and MacLeod used faces varying through five levels from very low to very high threat. When these faces were paired with a neutral face in a visual probe task, they found that while all participants showed attentional bias away from the low threat and toward the very high threat, anxious participants attended to the moderate threat faces, while normal participants avoided them. This, they concluded, supported models in which attentional bias occurs after the salience of the stimulus is assessed, and affects the degree of engagement appropriate to the stimulus. For anxious people, low threats can be avoided but moderate threats become worthy of attention, whereas for normal people, only high threats need to be attended to. To date, varying the salience level of substance-related cues in this way has not been attempted, but it would be a useful way of testing incentive sensitization theory, since this would predict that as individuals become more dependent, the salience of all substance-related cues would change, rather than just the degree of response to cues of intermediate salience.

In their review, Weierich, Treat, and Hollingworth point out that because studies tend to use one (or at most two) cue durations they do not allow any interpretation of the time course of attentional allocation, and so make it difficult to contrast alternative hypotheses about engagement and disengagement, and the role of covert shifts in attention as opposed to overt changes in gaze direction. One obvious way of differentiating between overt changes in gaze location and covert changes in attentional engagement and disengagement would be to use eye-tracking techniques. Mogg, Bradley, Field, and De Houwer, for example, measured gaze location during a visual probe task in which smokers were presented with smoking and neutral pictures as cues for 2000 ms, in a task where they were not instructed to maintain gaze upon the central fixation cross. They found that smokers made their initial shift of gaze away from the fixation cross more often (54% of the time) toward the smoking-related picture, and then looked at the smoking-related pictures for longer, while non-smokers made initial shifts equally to smoking and neutral pictures, and looked at both for the same length of time. Unsurprisingly, the smokers in this study also responded faster to probes replacing the smoking pictures than the neutral pictures, whereas the non-smokers did not. The attentional bias measure in this study might simply reflect the fact that participants who are looking at a picture that is then replaced by a dot probe find it easier to detect and respond to that probe. An alternative approach would be to exclude trials on which participants made eye movements, and to see if there is still a location effect. If a difference can still be found, this would mean that overt attentional shifts are not necessary to facilitate probe detection, and that covert attentional biases are responsible.

Attentional Retraining

In an attempt to resolve the controversy about the causal role that attentional biases play in anxiety, MacLeod and colleagues used a visual probe task to induce an attentional bias toward threat cues. Half of their participants completed 576 trials of a normal

visual probe task, in which the dot that they had to detect followed threat cues and neutral cues with equal probability. The other half of the students completed 576 attentional retraining trials in which the dot probe always followed a threat word. This manipulation successfully trained the experimental participants to allocate attention toward the threat cue: it created an attentional bias toward threat. The manipulation did not affect participants' mood, but when they were then subjected to a mildly stressful task, the experimental group responded with higher levels of anxiety.

In a subsequent study, the contingencies during the attentional retraining trials were reversed to induce an attentional bias away from the threat cues, with correspondingly opposite results: participants now showed a less anxious response to a stressful event. To show the potential therapeutic role that such manipulations might have, this study was carried out using a real world stressor: the participants were emigrating from Singapore to Australia to enroll at University, and they completed the training online in their own homes once a day for 15 days prior to leaving (*see* Technology-Delivered Treatments for Substance Use Disorders: Current Status and Future Directions by Bickel for accounts of computer-based therapies).

Other researchers have used the attentional retraining techniques to modify social anxiety and general anxiety. Along with techniques that address biases in memory encoding, retrieval, and inference, attentional retraining is grouped under the general term Cognitive Bias Modification and now forms a component of cognitive behavioral therapies (CBT; *see* Cognitive Behavioral Therapies by Carroll). Attempts to apply the procedure to retrain attentional biases in substance abusers have reported limited success, however. Field and Eastwood successfully induced attentional biases toward and away from alcohol related cues, and the attentional bias group reported a greater urge to drink and also consumed more in a post-induction test. However, the avoid group did not show a reduction in urge to drink, and neither group showed changes in a general craving measure. Other studies confirmed the power of the visual probe task to induce an attentional bias toward or away from substance-related stimuli, but limited or weak generalization of the bias to stimuli other than those used in the training set, and no generalization to other tasks.

Subsequent studies have increased the number of stimuli, have used repeated training sessions, have been coupled with motivational enhancement, and have had more success. However, there is some doubt about the role that attentional biases alone are playing in the modification of craving and behavior, since the increased intensity of the retraining is very apparent to participants, and induces a great deal of additional processing and awareness. Indeed, emphasis has now moved on to other cognitive biases, in the form of Approach-Avoidance tasks, in which participants have to make overt physical movements toward or away from stimuli (this work is described in Implicit and Associative Processes in Addiction by Wiers & Stacy). While these tasks share some conceptual similarity with attentional bias tasks, they are clearly different and involve many other aspects of cognition, including conscious strategies for controlling and overriding automatic behavior.

Overall, the evidence to date gives attentional biases a real but limited role in addiction. Craving, and hence motivated substance use, can be brought about by an increased sensitivity to substance-related cues, but involves more explicit controlled processes that may themselves affect responses on the tasks conventionally used to measure attentional bias. Whereas attentional retraining tasks do have an effect upon craving and substance use, they may work more through their effect upon later strategic responses to attended cues than upon early and automatic attentional biases.

Glossary

Addiction in this chapter, addiction is generally given a wider definition than the clinical diagnoses of Substance Abuse, Dependence, or Harmful Use. For the purposes of experimental cognitive research, 'addicted' individuals may only show some features such as mild tolerance or withdrawal, or may self-identify as addicted or problematic users.

Addiction Stroop a measure of attentional bias in which participants name the color in which substance-related and neutral words are printed, with slower color naming indicating a difficulty in ignoring the meaning of the words (see Fig. 45.1).

Attentional retraining modification of attentional biases through repeated sessions of tasks that require substance users to ignore substance-related cues.

Elaboration a cognitive response to intrusive substance-related thoughts that involves controlled access to memory resources and the creation of sensory mental imagery of substance acquisition and use.

Subliminal and supraliminal a stimulus in the environment or a cognitive experiment is defined as supraliminal if its content can be reported (i.e. it is above a subjective threshold). Subliminal stimuli, in contrast, may be too briefly or faintly presented to be reportable (they are below the subjective threshold), but might still lead to detectable behavioral differences (i.e. they can be above the objective threshold).

Visual probe task a measure of attentional bias in which responses to probes are faster if they are presented in the same spatial location as previous salient cues rather than a simultaneous neutral cue (see Fig. 45.2).

Sensory Imagery in Craving

Jackie Andrade

University of Plymouth, Drake Circus, Plymouth, UK

OUTLINE

WHAT IS SENSORY IMAGERY?

Advertisers have long known the power of mental imagery in creating and sustaining desires. Phrases such as "sun-kissed beaches" and "turquoise waters" help us to conjure up an image of an island paradise and stimulate our desire for a relaxing holiday. We mentally enjoy the beautiful view, feel the warm sand between our toes, and hear the gentle splash of waves on the shore. "Sensory imagery" refers to this ability to mentally simulate the sight, sound, smell, taste, and feel of an experience.

Sensory imagery is used in clinical settings and in laboratory research to stimulate or exacerbate craving for drugs. For example, smokers crave cigarettes more after being asked to imagine relaxing with friends who are lighting up and to imagine the taste and effects of smoking, than after imagining a neutral scenario unrelated to smoking. More vivid imagery of the smoking scenarios is associated with stronger urges to smoke. Likewise, alcohol craving can be induced by asking clients to imagine entering their favorite bar, ordering, holding and tasting a cold, refreshing glass of their favorite beer.

Sensory imagery is a powerful tool for inducing craving because it taps into the cognitive system that underpins human motivation and supports complex behaviors. Imagery plays an important role in motivation because it conveys the emotional qualities of the desired event, mimicking anticipated pleasure or relief.

THE ROLE OF SENSORY IMAGERY IN MOTIVATION

Imagery and Emotion

Sensory images are emotive; imagining a happy event makes us feel happier, and imagining a stressful event makes us anxious. Imagining events has greater effects on emotion than merely thinking about them. Vivid, intrusive imagery is a symptom in a wide range of psychological disorders, from posttraumatic stress disorder to depression and bipolar disorder, obsessive-compulsive disorder, and a variety of anxiety disorders, and is thought to contribute to the maintenance of those disorders. A new line of research and therapy in clinical psychology is showing how psychological disorders can be remedied by "imagery rescripting," encouraging clients to modify their images of experienced traumatic events or feared future events. Laboratory evidence, discussed below, suggests that sensory imagery is also a useful target for tackling craving in addiction, though to date the focus has been on preventing or disrupting imagery.

Elaborated Intrusion Theory

The role of imagery in motivation is explained by elaborated intrusion theory (Fig. 46.1). According to this theory, desires can be triggered by a wide range of stimuli, which includes physiological cues (salivation, stomach rumbles), negative mood, environmental cues, and related thoughts. These triggering stimuli increase the likelihood that we will experience a conscious thought about the target of desire. The thought is intrusive in the sense that it interrupts one's train of thought, but in many cases it may be fleeting, for example, when a momentary thought about lunch interrupts an interesting conversation. Intrusive thoughts become desires when they are elaborated, as might happen when the thought about lunch interrupts one's attention to a dull lecture. Elaboration includes planning ways of achieving the desire ("I could buy a sandwich"), generating expectancies about satisfying the desire ("I'd be able to concentrate better once I've had something to eat"), and thinking about one's self-efficacy or ability to obtain the desired object or activity ("I'm sure I could find a shop that's still open."). Importantly, though, elaboration involves sensory imagery. We imagine engaging in the desired activity and the image conveys some of the pleasure or relief of the real thing. We imagine the sort of food we will buy, the smell and taste of it, and the satisfaction of relieving our hunger. More vivid and realistic images convey greater pleasure but they also make us more acutely aware of the separation between our current state and desired state. Thus desire imagery is briefly pleasurable but ultimately aversive. It is the negative emotion it causes that spurs us to action to achieve our desire and change our current situation.

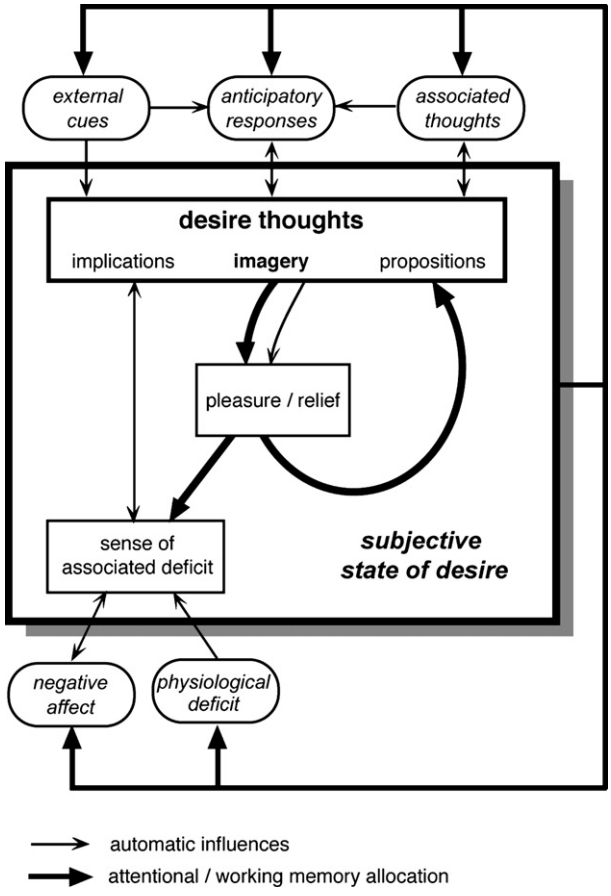

FIGURE 46.1 The elaborated intrusion theory of motivation, showing the contribution of triggers (rounded external boxes), intrusive thoughts ("desire thoughts"), and sensory imagery to craving (central square box). Thick arrows show the controlled processing cycle of conscious imagery and associated affect; thin arrows represent automatic influences on desire. *Adapted from Kavanagh, D. J., Andrade, J. & May, J. (2005). Imaginary relish and exquisite torture: The Elaborated Intrusion theory of desire, Psychological Review, 112(2), 446–467*

SENSORY IMAGERY AND CRAVING

Automatic and Controlled Cognitive Processes in Addiction

Addiction to substances develops through sensitization of the brain's reward system to drug-related stimuli (see Chapter 39 by Robinson, Berridge, & Robinson), and development of highly conditioned responses. Sometimes, exposure to conditioned stimuli is sufficient to trigger drug use with minimal conscious oversight and little or no craving, as when a smoker absent-mindedly lights another cigarette before finishing the current

one. In this situation substance use is automated, with behavior driven by automatically activated action schemas without intervention from top–down control processes.

Such situations are rare, because substance use usually requires more complex sequences of behaviors over extended time periods. Conscious mediation is needed to orchestrate these sequences of behavior and to carry them out in the face of competing goals. So, a typical instance of substance use might involve planning (a telephone call to a drug dealer, a trip to a bar or shop, a break from work), assessing self-efficacy ("could I resist temptation?"), generating expectancies ("a drink would feel great now"), and inhibition of competing goals (to be healthier, to save money, to finish a piece of work). Sensory images are the medium by which we keep in mind the goal of obtaining a drug during this extended sequence of thoughts and actions, and the medium by which we compare competing goals.

Elaborated Intrusion Theory Applied to Addiction

Elaborated intrusion theory views sensory imagery as a key component of consciously mediated substance use behaviors. As with other desires, sensory imagery serves as a mental bridge between our initial thoughts about drug use and actual consumption, and allows us to mentally compare conflicting goals. Craving is the cognitive-emotional state that pertains when sensory imagery of drug consumption is accompanied by felt relief or pleasure and also aggravated feelings of deficit. We shall consider three phases in craving:

Triggers

Craving for drugs can be triggered by drug-related stimuli in the environment (e.g. drug paraphernalia), related thoughts (e.g. thinking about a friend with whom one uses drugs), physiological withdrawal symptoms, anticipatory responses such as salivation, and negative mood. Negative mood is strongly associated with craving and may become increasingly important as addiction develops and negative mood is increasingly attributed to lack of the drug. Development of attentional biases in addiction increases the likelihood that drug-related stimuli will trigger the intrusive thoughts that lead to substance craving (see Chapter 45 by May).

Intrusive Thoughts

Craving triggers do not generally lead directly to consumption but instead increase activation of drug-related information in memory, which in turn increases the likelihood of experiencing a thought about drug use. These intrusive thoughts may be verbal thoughts or image fragments, and may be fleeting. In a study of clients beginning clinical treatment for alcohol dependence, we found that the majority of the sample occasionally experienced thoughts about drinking that popped into mind and then vanished spontaneously. Trying to suppress intrusive thoughts about substance use tends to exacerbate rather than reduce their occurrence.

Elaboration

Thoughts about drug use trigger craving when they are elaborated. In this sense, intrusive thoughts are the gateway to craving. As described above, elaboration includes planning acquisition of the drug, evaluating self-efficacy in resisting craving, comparing conflicting goals, and generating expectancies of the effects of consumption. The key component though, and the one that gives elaboration of its emotional bite, is sensory imagery.

Imagining the sight, smell, taste, and bodily effects of consuming the drug mimics the experience of actually consuming it. This imagery supports the other aspects of elaboration and provides a mental bridge between the trigger and eventual behavior. Imagery sustains motivation in this way because it is emotionally charged. When a smoker imagines smoking a cigarette, they are not merely imagining what the cigarette would look like and taste like, they are also imagining how pleasurable the taste and effects of inhalation would be. An alcoholic anticipating the first drink of the day not only visualizes the drink but, by doing so, also experiences the same pleasure or relief expected from actually drinking it. The pleasure or relief felt when imagining substance use may be weaker than the real thing – a mere simulacrum – but at times it may be even stronger because imagery allows us to mentally conjure up our ideal experience, where substance use is perfectly rewarding and lacks the inconveniences of everyday life, such as having to stand outside in the rain to smoke a cigarette.

The pleasure or relief embodied by the initial image encourages further imagery, but imagery also has aversive effects. Imagery enhances awareness of deficit, as when a smoker imagines the satisfaction of taking a drag on a cigarette and, by comparison of their imagined and actual state, feels more keenly their current discomfort and lack of satisfaction. The ensuing worsening of mood stimulates further, increasingly vivid and realistic imagery in a downward spiral of briefly pleasurable imagery leading to enhanced awareness of deficit and worsening mood.

Competing Goals

Substance use often persists in the face of good intentions to quit. The central role of sensory imagery in craving and substance use helps to explain the relative

weakness of our good intentions. Goals to change our lives, for instance to become healthier, can usually be imagined less vividly than can habitual behaviors, because we have less information in memory to draw on, and in particular little sensory information on which to base an image of an ideal future self that we have never before experienced. This lack of sensory information means that goals to cope with withdrawal symptoms, to resist temptation, or generally to become healthier are difficult to imagine vividly. Images of habitual substance use are more vivid and therefore feel more salient or urgent when weighing up whether to give into an intrusive thought about substance use or to resist temptation for better future health.

Experiences of Sensory Imagery and Craving

Sensory imagery is a consistent feature of people's reports of their craving experiences. Imagery (of sights, tastes, smells, physical sensations, and sometimes sounds) is reported as a feature of craving for a range of addictive substances including alcohol and nicotine, and nonaddictive substances and activities such as snacks and sport. Elaborating sensory imagery not only extends episodes of craving, it makes the craving more intense as the images become more articulated and vivid. Particularly in the case of visual imagery, the strength or vividness of imagery, and the frequency of imagery, correlates with craving strength. For example, most people in our clinical sample with alcohol dependence problems had sensory imagery during their strongest craving episodes when they were trying to control their alcohol use, with their imagery combining more than two senses on average. The most common elements of alcohol imagery were imagining tasting a drink, picturing the drink, and imagining swallowing alcohol. As predicted by elaborated intrusion theory, frequent sensory imagery was associated with stronger and longer-lasting episodes of craving for alcohol.

The cognitive psychology of mental imagery explains how imagery can be prevented or weakened, while research into craving shows how preventing or weakening mental imagery can lead to reductions in craving.

COGNITIVE PSYCHOLOGY OF IMAGERY – CLUES TO TACKLING CRAVING IMAGERY

Mental imagery involves activation of the same brain regions that are activated by actual perception, thus neuroimaging studies show increased activity in visual areas of the brain when participants are seeing an object and when they are picturing an object. This mental "seeing" also requires retrieval of information from long-term memory (generic knowledge of an object's shape and color, for instance, and specific memories of having seen such objects before), generation of an image from the information thus retrieved, and maintenance of that image in consciousness. Retrieval, image generation, and maintenance are carried out by a set of cognitive processes that are collectively known as "working memory." Neuroimaging studies show increased activation in brain regions that support working memory during substance craving (see Chapter 47 by Paulus). To date though, brain imaging has not been used specifically to test the prediction that sensory areas underpinning imagery are activated during craving.

Working Memory

Working memory is the means by which we are able to keep information consciously in mind while transforming it or using it to achieve some goal. For example, when mentally adding up a shopping bill we use working memory to hold or "carry" subcomponents of the sum; when planning a route, we use working memory to visualize landmarks and links between them. In craving, working memory is involved when we recollect where we put our cigarettes, work out if we have time to stop and smoke one, and visualize taking a cigarette out of its packet and lighting it.

Subsystems of working memory are specialized for processing auditory or visuospatial information. Imagining the appearance of a bartender pouring a drink uses visuospatial working memory while imagining the clatter of coins as you win the slot machine jackpot uses auditory working memory. There is a limit to how hard these working memory systems can work. Using visual working memory to remember and tap a pattern on a keyboard, for example, makes it harder to imagine a visual scene such as a busy train station or a rose garden, and such images are rated as less vivid than when participants are doing an auditory task that does not impinge on the visual working memory processes needed for visual imagery. This limited capacity is seen across a range of imagery tasks, from imagining verbally cued neutral scenes as in this example, to keeping recently perceived stimuli vividly in mind, to recollecting personal experiences. Even highly emotive autobiographical memories feel less vivid and less distressing (or less pleasurable) if they are recalled while performing a task that loads working memory.

Working Memory and Craving

Working memory is involved in all aspects of craving, from the elaboration of plans to acquire a drug to trying

to focus on competing goals and inhibit thoughts about drug use. Not surprisingly, people perform less well on a range of working memory tasks when they are craving than when they are satiated. There is a two-way relationship, thus people crave food and drugs less strongly when they carry out tasks that require working memory than when they have nothing else to do.

For clinical purposes, maintaining a perpetual, general working memory load sufficient to block craving is impractical, because it would block most normal cognitive activity as well as craving. Instead, this area of craving research has focused on simpler tasks that selectively compete with aspects of working memory needed for craving imagery. The aim is to blunt the craving or provide a brief respite rather than eliminate it altogether.

INTERFERING WITH CRAVING

The limited capacity of working memory is the clue to reducing craving by reducing craving imagery. As the visuospatial and verbal subsystems of working memory can only hold and process a certain amount of information at a time, occupying them with a simple visual or verbal task is sufficient to inhibit visual or auditory imagery (imagery of sounds). In most substance use, auditory imagery is less likely than visual, gustatory, or olfactory imagery, unless sounds are highly associated with the person's preferred substance (e.g. the sound of popping champagne). Experimental studies have often therefore compared the effects on craving of performing visual working memory tasks versus auditory or verbal tasks that control for generic working memory factors and allow us to test the specific effects of blocking visual imagery. Tasks that involve manipulating, remembering, or imagining visual information make it difficult to visualize drug use simultaneously, and have been shown to lead to lower craving than verbal tasks that permit concurrent sensory imagery.

Cigarette Craving

Imagining neutral scenes (e.g. a rose garden) as opposed to neutral sounds (e.g. a telephone ringing) reduces cigarette craving in abstinent smokers to the levels reported by smokers who are allowed to smoke ad lib before the experiment. Imagining neutral odors is also effective. Blockade of craving imagery need not be achieved through competing imagery; it can also be achieved with tasks that require the same visuospatial working memory processes that are needed for imagery. For example, the development of cigarette craving is inhibited by asking smokers to create specific forms out of modeling clay or plasticine, for example, spheres, cubes, or animal shapes. This clay modeling task is assumed to involve maintenance of a visual representation of the intended shape in working memory plus spatiomotor control processes that are also involved in rehearsal, or "replaying," of visuospatial information in working memory.

Food Craving

Effects of selective cognitive blockade on craving have also been tested in relation to craving for food, either with hungry participants craving food in general or with participants craving chocolate, which is associated with rather specific cravings that cannot be satisfied by nutritionally similar foods. This research has shown that craving can be reduced by imagining neutral scenes, by watching a rapidly changing visual display, and by performing tasks that require spatiomotor control as well as visual working memory processes, for example, making side-to-side eye movements or tapping a pattern on a keyboard. The similarity in effects on food craving and cigarette craving supports the argument that substance craving in general can be reduced by selectively blocking visuospatial working memory.

DIRECTIONS FOR TREATING ADDICTION BY TACKLING CRAVING

Craving is an important target for addiction treatments because it helps to sustain addictive behaviors (more cigarettes are smoked "to relieve craving" than for any other reason) and makes quitting difficult. Intense craving can occur long after physiological withdrawal symptoms have faded (e.g. because of exposure to previously conditioned cues), inducing discomfort and distress and increasing the likelihood of relapse. Psychological treatments are effective generally in addiction, both on their own and combined with pharmacological treatments, but there is much room for improvements in treating craving during the quit attempt and providing better tools to help clients cope with recurrences of craving after quitting.

Imagery Interventions

Because craving, as opposed to addiction, is essentially a conscious, cognitive phenomenon, it is susceptible to interference from ongoing cognitive activities. The laboratory studies discussed above suggest a range of simple tasks that might be useful for controlling craving, tasks that selectively engage processes of visuospatial working memory. Extrapolating to everyday life,

craving should be reduced by spending a few minutes vividly recollecting a happy memory or scene, playing a computer game such as Tetris™ or Puzzle Express™ that requires mental manipulation of visual stimuli, making models from a piece of plasticine, or even watching a screensaver with high contrast, continually changing visual properties.

However, strategies that only target craving imagery may be less than optimally effective because they require a choice to be made, on experiencing an intrusive thought about drug use, about whether to take the drug or try to alleviate craving by performing the imagery-blocking task. People may choose to take the drug because the initial thought is particularly appealing or intrusive, or because they do not want to be distracted from the task in hand – stopping work for a cigarette may seem less distracting than stopping to carry out the intervention or trying to continue working in the face of frequent intrusive thoughts about smoking.

More effective strategies are likely to be those that combine imagery blockade with techniques that interrupt the pathway from initial craving trigger to intrusive thought to elaboration. Simply telling oneself not to think about drug use is counterproductive, as monitoring one's success at not thinking actually triggers thoughts about drug use ("Have I thought about smoking recently? Oops, now I have"). Research with nonclinical samples has shown that telling oneself to ignore, rather than suppress, intrusive thoughts is more effective. Clinical approaches that encourage people to ignore or accept intrusive thoughts are effective across a wide range of disorders where intrusive thoughts are problematic and hold promise for treating addiction and craving.

Thought Acceptance and Mindfulness

Acceptance therapies encourage individuals to view thoughts as transient events and to accept that unwanted thoughts will sometimes pop into mind. Accepting that thoughts come and go again unbidden breaks the cycle of attempted thought suppression, increased thoughts, feelings of failure or rumination on the thoughts, followed by renewed but counterproductive efforts at suppression. In terms of addiction, the aim is to instill an acceptance of the fact that there is no need to elaborate a thought about substance use, or to act on it, because it will go again of its own accord.

Mindfulness-based therapies extend this acceptance approach by teaching individuals to become aware of their whole, changing, sensory experience. Training in mindfulness aims to increase awareness of all thoughts and sensations, and by doing so to decrease the salience of, and elaboration of, unwanted thoughts. Mindfulness-based interventions also reduce distress about the craving, by helping the person observe their thoughts without engaging with them or being concerned about what they may mean.

Implementation Intentions

A simple but effective way of increasing the likelihood that someone sticks to their good intentions and resists temptations, is to ask them to make an "if…then" plan or implementation intention that specifies when, where, and how they will achieve their goal. For example, someone trying to quit smoking might make the plan that "if my friends start lighting up at tomorrow's party, then I shall chew a piece of chewing gum instead." Specifying how one will achieve a goal in this detailed, concrete fashion has several beneficial effects:

- it increases the salience and memorability of the important cues ("my friends lighting up") and intended behaviors (chewing gum rather than smoking a cigarette)
- it strengthens the link between the cues and the intended behavior, so that seeing someone else smoking automatically cues thoughts about chewing gum
- it may also encourage sensory imagery of the desired outcome, so that the abstaining smoker has a ready-made image of themselves in a specific situation taking out a piece of gum and chewing it, reducing the likelihood that they start imagining themselves smoking a cigarette instead.

Implementation intentions may thus bypass elaboration of thoughts about drug use, or at least strengthen the vividness of imagery of the intended rather than habitual outcome. Although this aspect of implementation intentions has received little research attention, there is recent evidence that explicitly encouraging participants to imagine carrying out their "if…then" plan enhances the efficacy of implementation intentions.

FUTURE DIRECTIONS FOR CRAVING INTERVENTIONS

Mindfulness training includes strategies such as body scanning that help increase awareness of experiences and thoughts other than the unwanted ones. Body scanning involves shifting attention from one part of one's body to another, a process that is likely to involve visual imagery of the attended parts of the body. Recent studies with nonclinical populations have shown that body

scanning reduces intrusive thoughts about food as effectively as a distraction technique involving guided sensory imagery of a woodland walk and that it reduces smokers' desire to smoke compared with listening to a natural history tape.

Interventions like body scanning that combine positive or neutral sensory imagery, or blockade of visuospatial working memory, with acceptance of intrusive thoughts should be particularly effective at reducing drug craving because they should reduce the likelihood of intrusions being elaborated while simultaneously reducing the vividness of any sensory drug imagery that does occur, breaking the vicious circle whereby intrusive thoughts trigger sensory imagery which in turn triggers further thoughts. Helping clients to create positive images of abstinence behaviors should also be effective in helping to bypass the process whereby initial thoughts about substances lead to sensory imagery of substance use. Future research might trial combinations of thought acceptance and visuospatial working memory tasks, or test the effect of including a vivid, pleasant image in an implementation intention plan.

Reduced sensory imagery of substance use may be playing a role in another intervention that is currently attracting research attention. Brief periods of moderate physical exercise have been shown to be effective at reducing desire to smoke. The mechanisms are not well understood and may include effects on mood and confidence as well as attention to the benefits of health and the debilitating effect of smoking on lung function. General distraction is not the mechanism, but competing visual distraction or visual imagery may be contributing to the effects, particularly in the case of exercise in natural settings rather than the gym.

CONCLUSIONS

Sensory imagery is central to craving, giving craving its emotional bite and prolonging episodes of craving in the face of competing desires to abstain. Stronger, more vivid imagery predicts stronger craving in clinical and nonclinical samples, while blocking imagery with simple working memory tasks has been shown to reduce craving. Studies of food craving and of smokers' craving for cigarettes suggest that techniques combining thought acceptance and competing sensory imagery will be effective for reducing the frequency and strength of episodes of craving. Self-report data show similar craving phenomenology across addicted and nonclinical samples; therefore, we predict similar effects of these techniques in clinical populations. Effective interventions for substance craving in addiction are likely to be those that combine strategies for disrupting the elaboration of intrusive thoughts about substance use with strategies for blocking any ensuing sensory imagery.

Glossary

Desire a state in which thoughts and images about a target behavior carry emotional weight, both pleasure or relief associated with achieving the target and negative affect from awareness that it has not yet been achieved. Cravings are desires to consume substances.

Elaborated intrusion theory a theory of human motivation in which desires are sustained by emotionally charged sensory imagery

Elaboration mentally embellishing an initial thought or stimulus, for instance a thought about alcohol might be elaborated by retrieving memories of yesterday's drinking session, imagining the taste of beer, or planning a visit to a bar.

Implementation intention a plan stating how, where, and when one will perform a desired behavior

Intrusive thought a seemingly spontaneous thought that interrupts our stream of consciousness

Sensory image a mental representation or simulation containing information about appearance, sound, smell, taste, or physical sensations

Vividness the extent to which sensory imagery mimics actual experience

Working memory the mental processes by which we temporarily store and manipulate information to perform tasks such as mentally planning a route, taking part in a conversation, or imagining smoking a cigarette

Neural Correlates of Craving for Psychoactive Drugs

Jennifer L. Stewart, Martin P. Paulus

University of California, San Diego, CA, USA

OUTLINE

INTRODUCTION

Craving consists of two fundamental processes and can be defined as: (a) a conscious, intense emotional feeling that is associated with (b) a strong urge to act to obtain and use drugs. More specifically, over time a stimulus associated with prior drug use triggers brain mechanisms associated with a physical need, or urge, to respond to the stimulus in drug-addicted individuals. This bodily urge is then translated into a targeted goal to obtain and use the drug. Actions are deployed to fulfill the urge and evidence is collected and evaluated

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00047-4

by neural systems to determine the relative outcome (success or failure) of the urge-related action. Finally, the sensory system determines whether the urge was satisfied.

Craving and urges depend upon the current body state of the individual; for example, the strong urge to eat occurs more frequently in a hungry individual or the need to seek shelter from the cold is particularly strong in a person experiencing hypothermia. Thus, craving can be considered a part of a homeostatic regulatory process. Cravings and urges can arise from the positively reinforcing properties of drugs, wherein the individual experiences cravings to feel better, but they can also emerge due to the negatively reinforcing aspects of the lack of the drug, in instances which the individual experiences cravings to avoid feeling bad. In addition, stress and negative affect may result in homeostatic imbalances that can intensify craving, disrupt decision-making processes, and reduce control over urges, thereby increasing the probability of drug use.

Craving is thought to be an important factor in the maintenance of drug addiction and the probability of relapse. However, there is no universally accepted definition of craving, and debate exists in the field regarding the optimum way to measure the craving experience. Although the focus of this debate has been on self-report indices of craving, a growing literature demonstrates that the craving experience also encompasses changes in patterns of physiology and behavior that influence the desire to use drugs. In recent years, research examining brain mechanisms involved in craving has benefited from advances in neuroimaging technology, which have fostered considerable progress in the identification of brain regions involved in drug addiction.

Neuroimaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) offer whole-brain measurements of regionally specific changes in brain activity that can be measured during the craving experience. In addition, event-related brain potentials (ERPs), indices of cortical electrical activity, have temporal resolution on the order of milliseconds and can be used alone or in conjunction with other imaging methods to better explain how craving-related processes unfold over time.

The present review of craving has two main objectives. The first objective is to examine the status of neuroimaging research on craving – what we have learned and what we have yet to learn – predominantly within the context of stimulant addiction. Our primary focus will be the study of craving in cocaine addiction, since few studies have examined the neural correlates of self-reported craving responses in methamphetamine and other stimulant drugs that have become increasingly popular, such as dextroamphetamine and methylphenidate, or in other drugs such as cannabis and heroin. However, we will also provide relevant examples, when available, from neuroimaging studies of other drugs (with an emphasis on alcohol and nicotine) in order to demonstrate similarities across substances. The second objective is to explain how the study of brain regions involved in interoception, an intrinsic but largely overlooked component of the craving experience, may contribute to knowledge regarding precipitating factors for drug dependence and relapse and improve treatment outcome for addicted individuals. Before discussing neural systems involved in the implementation of the craving response, however, we will first review paradigms utilized in the neuroimaging literature to elicit craving in drug users and the measurements of craving that are then correlated with brain activation during these paradigms.

CRAVING ELICITATION AND MEASUREMENT

In this section, we explain three paradigms used to elicit craving and provide an overview of self-report measures researchers use to determine the extent to which an individual is craving drugs as a result of these paradigms.

Cue-Reactivity Paradigms

Neuroimaging researchers have successfully elicited heightened levels of craving and urges in drug-dependent individuals using cue-reactivity paradigms, imagery scripts linked to an individual's personalized drug use experience, and drug self-administration schedules, although the latter is less frequently utilized. Cue-reactivity paradigms appear to be the most popular tasks utilized in alcohol, cocaine, and nicotine craving research, and within the context of cocaine addiction these paradigms have often involved films depicting an individual or group of users smoking or snorting cocaine. These films are then contrasted with a neutral film, such as those depicting nature scenes, and in some cases, films associated with appetitive motivation (sex, displays of happiness) or aversive motivation (displays of negative affect), in order to show that self-reported craving is higher in the cocaine film than the other films and then demonstrate that the neural mechanisms of craving are specific to cocaine and not to other types of emotional experiences. In addition to films, pictures of cocaine paraphernalia (e.g. glass pipe, mirror, razor blade, straw, and dollar bill) have been shown in conjunction with audiotapes of individuals simulating the use of cocaine or describing their experience with the drug. One study

allowed cocaine users to touch drug paraphernalia and compared brain activation and craving levels with conditions wherein cocaine pictures or audiotapes were played.

Personalized Imagery Scripts

Similar to cocaine stimuli used in cue-reactivity tasks, personalized imagery scripts used to evoke cocaine craving are compared with other personalized scripts describing neutral events or types of negative affect (anger, stressful situations) to determine specificity of brain activation linked to craving. A recent study paired personalized neutral and cocaine scripts with threat of electric shock to examine whether stress intensified brain regions involved in craving specifically during the cocaine script.

Drug Self-Administration Paradigms

Whereas cue-reactivity and imagery paradigms are common in the cocaine craving literature, few studies have examined craving as a function of drug self-administration, potentially due to the ethical limitations of such a design. Although not a study of cocaine self-administration, two additional studies have examined craving in cocaine abusers after administration of another stimulant (methylphenidate) compared to a placebo. In addition, a paradigm relevant but not identical to drug self-administration tasks has been implemented in several studies of nicotine craving, wherein individuals are tested once during drug abstinence and tested again in a satiated state in order to compare changes in craving at rest or in response to drug cues within the context of cue-reactivity paradigms. Overall, the fundamental approach to examine craving has been to change the individual's homeostatic state toward a need state that elicits feelings to approach and actions to acquire the drug of choice.

Self-Report Measures of Craving

In most imaging studies of cocaine craving, brain activation during the cocaine cue or script condition is contrasted with the remaining conditions and correlated with craving self-reports that are administered before, during, or after the imaging session. Debate exists regarding how best to measure craving, and as a result, there is no gold standard self-report index of the experiential craving response. Some researchers have advocated the collection of moment-by-moment measures of craving instead of administering trait levels of craving, since many studies indicate that craving fluctuates significantly even during a 1-day period. For example, an electronic diary study examining the frequency and duration of craving in 112 cocaine users demonstrated that during the 5 h prior to cocaine use, ratings of craving significantly increased, and in periods of verified cocaine use, craving rates increased during the day and were higher than during periods of cocaine abstinence.

Although, in rare instances, cocaine users are selected as participants on the basis of high levels of craving in the previous week, the most common indices of self-report craving in neuroimaging studies of cocaine addiction are Likert or visual analog scales administered immediately before, during, and/or immediately after exposure to cocaine and comparison cues, asking questions regarding, in the present moment, what degree and/or frequency the cues elicited a craving, urge, want, or need for cocaine; whether the participant could resist cocaine if it was offered; or how much the cues excited or energized the participant. A measure used less frequently in imaging studies is the cocaine craving questionnaire (CCQ), a 45-item scale indexing several factors of drug use, such as desire to use cocaine, intention to use cocaine, lack of control over cocaine use, anticipating positive outcomes from cocaine use, and anticipating relief from withdrawal symptoms.

A comparison of cocaine craving measures endorsed by patients in a substance treatment program for cocaine abuse and dependence determined that one-item visual analog and Likert scales are best at predicting positive urine screens and short-term cocaine use, whereas the CCQ is the best predictor of future long-term cocaine use. Since self-reported measures of craving do not always correlate highly with one another nor do they consistently predict drug use and relapse, craving studies in general have been critiqued for not recording multiple measures of the craving response, such as indices of urge-related behavior (how much the individual would be willing to pay for the desired drug) and additional physiological indices of arousal and intensity (skin conductance and heart rate) or affect (electromyographic activity, coding of facial expressions, and startle responses).

Determining the Brain Regions Linked to Indices of Craving

The fundamental goal of neuroimaging research in craving is to relate the intensity of the craving experience to the degree and timing of activation in brain regions thought to be involved in the implementation of craving within the context of addiction. Three possible avenues exist to accomplish this goal. First, verbal behavior associated with the craving experience (such as the desire to use a drug and perceived control

over drug use) can be measured with self-report rating scales. Second, behavioral consequences associated with increased craving (such as stronger motivated actions to acquire drug-related stimuli) can be assessed. Third, nonverbal hedonic changes in the individual (such as facial expression) can be indexed. It is advantageous to use multiple methods to study the neural mechanisms of craving in order to limit the influence of demand characteristics and provide convergent validity for craving as a multidimensional construct involving experiential, behavioral, and physiological changes within the individual.

SPATIAL DYNAMICS OF NEURAL SYSTEMS INVOLVED IN DRUG CRAVING

It has been argued that initial drug exposure activates the mesolimbic dopamine system in subcortical neural systems involved in reward processing, wherein ventral tegmental neurons release dopamine in their projections to the ventral striatum and amygdala. Dopamine release signals other brain regions to develop behavioral action plans in response to the drug, and as a result, learned associations are formed that reinforce the rewarding qualities of drug use. Repeated drug use renders these regions hypersensitive, increasing the drug's incentive salience, or its desirability and ability to command attention and induce appetitive motivation. Moreover, this heightened incentive salience is critical for the expression of urges and craving. Finally, the repetitive emergence of rigid behavioral patterns expressed as habitual, compulsive drug seeking is thought to be mediated by the dorsal striatum. The reinforcing properties of the drug are exaggerated relative to natural reinforcers in the environment. Whereas the influence of the subcortical reward system intensifies during drug use, the contribution of the executive function system of frontal brain regions weakens, which is important for decision making and inhibitory control by signaling future outcomes or consequences (reward or punishment) of drug use. As a result, executive control over drug seeking is diminished and areas of the prefrontal cortex become hyper-responsive to cues predicting drug availability. Figure 47.1 illustrates subcortical and cortical brain regions implicated in the drug craving experience.

Ventral Striatum, Amygdala, and Hippocampus

The ventral striatum, amygdala, and hippocampus are components of the mesolimbic dopamine pathway, which has been implicated in the rewarding effects

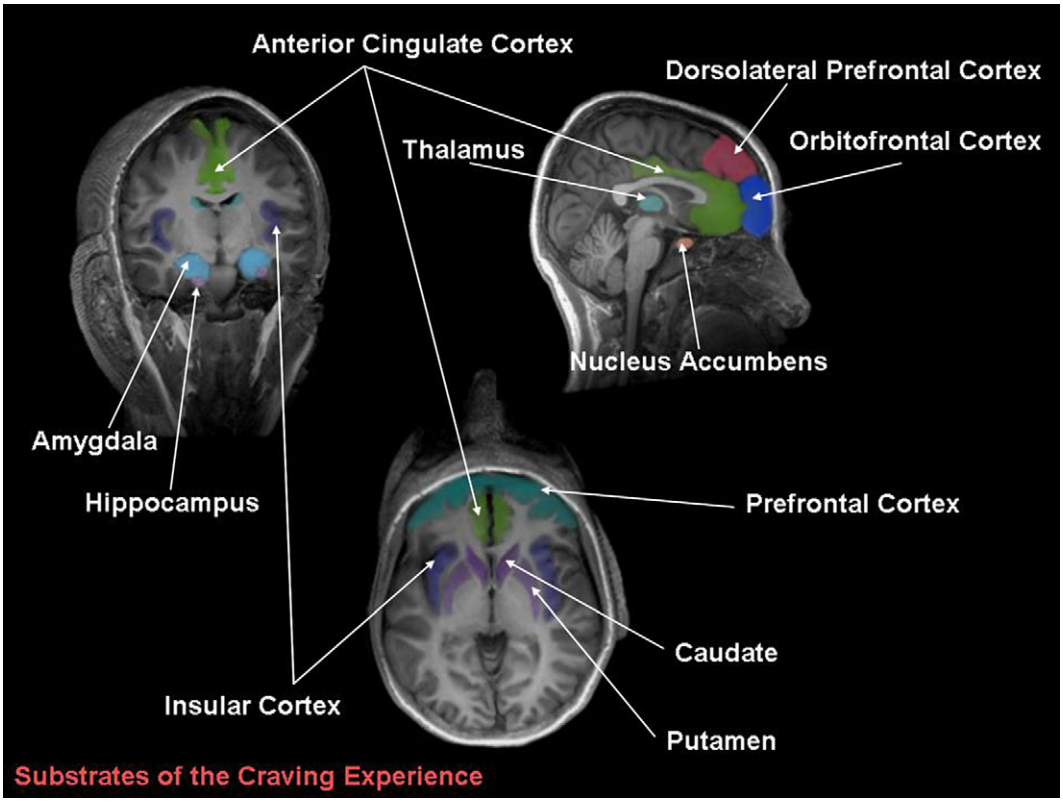

FIGURE 47.1 A primer on the subcortical and cortical substrates of the craving experience.

of drugs, drug-related memories, and conditioned responses. The ventral striatum consists of the nucleus accumbens, which receives dopamine input from the ventral tegmental area as well as input from the amygdala, hippocampus, and prefrontal cortices. Although the ventral striatum is thought to be involved in the rush or high experienced after ingesting a drug, a few studies also implicate this region in the craving process. Two studies of cocaine self-administration have demonstrated that heightened ventral striatum activation was associated with self-reported craving levels in cocaine-dependent individuals, and an additional study found that right nucleus accumbens activation was associated with higher craving ratings during script-guided imagery of acts and sensations linked to cocaine use in a small sample of cocaine-dependent men.

Furthermore, the link between craving and ventral striatum activation has been shown in the nicotine fMRI literature, wherein nicotine-abstinent female smokers exhibited greater nucleus accumbens activation in response to nicotine-related pictures that was associated with baseline pre-fMRI scan craving ratings. Similarly, a recent PET study of alcohol craving indicated that subjective craving ratings in recently detoxified alcohol-dependent men were linked to ventral striatum activation that increased in response to alcohol cues but decreased during the expectation of reward. These alcohol, cocaine, and nicotine data are in line with additional research suggesting that the ventral striatum is involved in the initial rewarding effects of a drug, and neurochemical changes in this region spread progressively to more dorsal regions of the striatum to instantiate a pattern of habitual drug-taking behavior.

In addition to the ventral striatum, the amygdala may contribute to the craving experience by establishing associations between the rewarding effects of drug intake and initially neutral predictors of impending drug administration, such as paraphernalia and individuals associated with drug use, which eventually signal the potential for reward over time. In addition to facilitating conditioned learning, the amygdala may also enhance emotional memory for episodes of and contexts involving drug use. For example, one PET study demonstrated that, compared to a neutral imagery condition, craving ratings during personalized autobiographical memories and sensations associated with cocaine use were linked to greater bilateral amygdala activation (with right amygdala activation larger than the left) in abstinent cocaine-dependent men. Moreover, two additional PET studies have shown that heightened amygdala activation was linked to higher levels of craving in response to cocaine cues (scripts, videotapes, and paraphernalia) in samples of cocaine abusers. The available literature implicates the amygdala in cue and context learning that may facilitate craving processes.

Like the amygdala, the hippocampus may be critical for the formation of associations between drug use and particular spatiotemporal events, which can subsequently serve as stimuli triggering craving. This hypothesis is consistent with alcohol, cocaine, and nicotine research on the craving experience. For instance, an fMRI study examining nonabstinent male smokers with varying levels of nicotine dependence observed a relationship between self-reported craving intensity in response to nicotine-related pictures and amygdala, hippocampus, and parahippocampal gyrus activation. In addition, a PET study indicated that recently detoxified alcohol-dependent men exhibited heightened amygdala and hippocampus activation in response to ethanol odors that correlated with higher craving scores. Although this pattern of results was seen prior to alcohol-related treatment, these correlations did not emerge posttreatment, suggesting that neural indices of craving may be able to predict future use and relapse. Furthermore, an fMRI study that measured brain activation before and after cocaine infusion revealed that higher craving levels were linked to increased bilateral parahippocampal and right hippocampal activation in a sample of cocaine-dependent individuals. In addition to being correlated with craving, right hippocampal and left parahippocampal activations were linked to self-reported "rush" after cocaine administration, suggesting that these regions are involved in the formation of new memories of declarative drug-taking experiences as well as the retrieval of these memories, which may be an important aspect of the craving process.

Dorsal Striatum

Although imaging studies of cocaine addiction implicate both the dorsal and ventral striatum in the craving process, the former has been reported more frequently, particularly within the context of heightened dopamine concentrations in this area. The dorsal striatum consists of the caudate nucleus and putamen and is thought to be involved in the implementation of automatized, or well-learned, habitual drug use urges, cravings, and actions that develop with repeated drug usage. With respect to craving processes, imaging studies involving drug administration have demonstrated a link between dorsal striatum activation and the craving experience that may be associated with habitual patterns of drug use.

For instance, PET research has demonstrated a link between right dorsal striatum activation and cocaine craving approximately 30 min following administration of another stimulant (methylphenidate) in cocaine-abusing individuals. Moreover, a follow-up PET study

demonstrated that during administration of methylphenidate to cocaine users, dopamine levels increased in the dorsal striatum. This relationship held during films depicting cocaine use but not during videos depicting nature scenes, suggesting that dopamine is rendering the dorsal striatum hypersensitive only within the context of drug-related stimuli. In addition to imaging studies of methylphenidate administration, an fMRI study of cocaine self-administration reported a correlation between putamen activation and craving in cocaine-dependent males.

Imaging studies employing drug cue stimuli have also shown that the dorsal striatum is implicated in craving processes. For example, heightened dopamine receptor occupancy in the putamen as measured by PET has been correlated with higher craving intensity during a videotape of cocaine use as well as an audiotape describing pleasurable experiences associated with cocaine use in a sample of frequent cocaine users. Similarly, in response to films depicting users smoking cocaine, cocaine-dependent individuals exhibited increased extracellular dopamine in the caudate and putamen in a recent PET study. This dopamine increase correlated with self-reported craving and was strongest in participants who reported the greatest levels of withdrawal and overall drug addiction severity, suggesting that craving processes become automatized as a function of chronic drug use.

Taken together, findings from this literature support the idea that repeated drug use is linked to dorsal striatum hyperactivity in response to cocaine cues and/or intake, thus increasing salience for the drug that is expressed as craving. However, drug cues or intake may not be required for activation of habitual responses associated with drug use such as craving. For example, an fMRI study demonstrated that right caudate activation was correlated with cocaine craving scores during stress-related imagery in recently abstinent cocaine-dependent individuals, evidence suggesting that the experience of negative affect may be sufficient (and cocaine-related stimuli are not necessary) to trigger regions involved in cocaine habit formation. Although the dorsal striatum – subjective craving link is prominent in cocaine studies, this relationship has not yet been strongly established for drugs such as cannabis, nicotine, or opiates. Additional research is needed to examine this issue.

Thalamus

The thalamus has been viewed traditionally as an important subcortical structure involved in filtering and gating sensory information processing. In the context of drug addiction, thalamic processing may be critical for the selective processing of stimuli that have become associated with drug cues. Thalamus dysfunction may contribute to the craving process by inducing an experience of sensory overload, in which the addicted individual is flooded with stimuli signaling the rewarding properties of drug use, thereby eliciting craving responses. An fMRI study examining differences in craving levels and executive functioning in two groups of cocaine-dependent participants demonstrated that an early-abstinent group (individuals who had been cocaine-abstinent for about a week) exhibited higher thalamus activation and higher craving ratings than a late-abstinent group (individuals who had been cocaine-abstinent for more than 2 weeks) in response to errors during a stop signal task, and this thalamus activation also correlated with craving ratings, suggesting that excessive thalamic responses to conditioned cues may precipitate craving. An fMRI study also showed that higher right thalamus activation was linked to self-reported levels of craving during stress-related imagery in cocaine-dependent individuals who were substance-free for at least 2 weeks. However, studies of cue-elicited cocaine craving have not described a link between thalamus activation and the craving experience, so additional research is needed to clarify the specific role of the thalamus within the context of craving responses.

Dorsolateral Prefrontal Cortex

Whereas heightened activations in subcortical regions such as the thalamus, amygdala, and striatum are implicated in conditioned reward responses that serve to perpetuate drug use, heightened activation in frontal cortical regions such as the dorsolateral prefrontal cortex (DLPFC) during craving may instead reflect a thwarting of cognitive control processes, wherein resources typically used to inhibit behavior resulting in negative consequences are instead channeled into seeking and using drugs despite these consequences.

Although numerous imaging studies of cognition and emotion have linked the DLPFC to executive functioning processes such as planning for future events and maintaining current goals in working memory, much less research exists on the role of DLPFC in the experience of cocaine craving. However, the few available studies on this topic suggest that DLPFC may be lateralized to reflect different reinforcing mechanisms underlying craving, wherein left DLPFC activation is linked with positive drug reinforcement (reflecting the rewarding, appetitive effects of cocaine) and right DLPFC activation is associated with negative drug reinforcement (reflecting avoidance of withdrawal and distress due to homeostatic imbalances and/or lack of recent drug use).

Two PET studies used identical stimuli (cocaine films, scripts, and paraphernalia compared to art-related cues) to examine craving in cocaine abusers, and one of these studies attempted to increase the likelihood of craving by pairing cocaine cue-exposure with the anticipation of drug use (the ability to use cocaine after cocaine cues were presented). Although both studies demonstrated that right DLPFC activation was linked to craving in response to cocaine cues, the study allowing cocaine self-administration showed that left DLPFC activation was also linked to craving responses, suggesting that left DLPFC is recruited to maintain goal set (using drugs) during craving experiences that are linked to an expected reward outcome (having the definitive opportunity to use drugs). Comparable results have been found in an fMRI study of smokers, wherein left DLPFC was associated with smoking image-induced craving as a function of drug use expectancy: the DLPFC activation increased with craving when subjects expected to smoke immediately after their MRI scan, whereas DLPFC activation decreased with craving when subjects knew that they had to wait 4 more hours to smoke after their MRI scan ended. A PET study of nicotine addiction also found heightened DLPFC activity in heavy smokers that linked to self-reported craving in response to handling a cigarette and watching a nicotine video. Left DLPFC activation may be associated with increased appetitive/incentive motivation to obtain drugs, since growing electroencephalography (EEG) and fMRI literatures implicate left prefrontal regions in approach motivation and behavior.

In addition to PET findings of DLPFC activation in cocaine users, one fMRI study demonstrated that right DLPFC activation was correlated with distress and cocaine craving in response to personalized stressful event scripts in recently abstinent cocaine-dependent individuals. Given that several EEG and hemodynamic imaging studies have implicated right prefrontal regions in the experience of withdrawal-related negative emotions, the neuroimaging findings presented above suggest that right DLPFC activity may be linked to a negatively valenced component of the craving process. This negative affect may not be measured by all craving questionnaires or instruments; however, since the majority of imaging studies of cocaine craving have not found a link between the experience of craving and the right prefrontal activation.

Orbitofrontal Cortex

The orbitofrontal cortex (OFC) is thought to play an important role in drug addiction due to its function in the learning of stimulus-reinforcement situations and the prediction of reward. The OFC activation in response to drug-related stimuli may signal prediction of immediate reward of drug use that likely contributes to the craving process. One PET study has indicated that left lateral OFC activation was linked to craving during presentation of cocaine scripts, films, and paraphernalia in cocaine abusers. Likewise, a study demonstrated that heavy smokers exhibited heightened bilateral OFC activity that was linked to self-reported craving in response to handling a cigarette and watching a nicotine video. However, three additional cocaine studies found that right, not left or bilateral, lateral OFC activation was correlated with craving experienced after self-administration of stimulant drugs. For example, PET studies (one with cocaine abusers, one with cocaine-dependent individuals) demonstrated a link between cocaine craving approximately 30 min following administration of another stimulant (methylphenidate). Similarly, an fMRI study also showed that right lateral OFC activation correlated with craving following self-administration of cocaine in cocaine-dependent individuals. The fact that OFC has been linked to craving ratings within the context of definitive future drug administration suggests that this brain region is likely signaling the reward value for situations in which impending drug use is certain.

ROLE OF INTEROCEPTION IN CRAVING: INSULAR CORTEX AND ANTERIOR CINGULATE CORTEX

Models of Addiction Integrating Interoception with Drug Use

Although much of the research spotlight has focused on the role of dopamine in drug addiction, in recent years models of addiction have begun to highlight the role that internal bodily sensations and feelings may play in the maintenance of compulsive drug use. For example, Bechara and colleagues have proposed a somatic marker model of addiction, wherein drug-addicted individuals make poor decisions (continue to use drugs to obtain immediate reward despite negative future consequences) as a result of dysfunctional physiological feeling states expressed in response to rewarding or punishing stimuli. In addition, Siegel developed a conditioned opponent process model, in which he posited that over the course of drug addiction, the body develops negative homeostatic processes to counteract the positive effects of the drug, wherein craving experiences become negatively valenced conditioned responses to drug-related stimuli. Furthermore, in their model of implicit and explicit drug motivational processes, Baker, Curtin, and colleagues have asserted that interoceptive bodily cues are much stronger than

exteroceptive cues in eliciting craving and triggering drug use within the context of addiction.

Interoceptive Processing and Sensations

Implicit in the craving process is the current state of the individual, which is largely a function of the interoceptive experience, the sense of the physiological condition of the entire body. Interoceptive processing involves the ongoing afferent monitoring and efferent modulatory control of inputs arising from the inside of the body. In the process of drug addiction, interoception reflects the experience of intensity or arousal associated with a homeostatic imbalance of the body, resulting in a conscious feeling of the urge to use drugs. Habitual use of a particular drug (e.g. snorting cocaine) is associated with specific interoceptive sensations that are an integral component of the conscious pleasure derived from the drug ritual itself. Research has shown that cocaine-dependent individuals report interoceptive sensations such as restlessness, butterflies in stomach, warm excitement, jitteriness, bodily tension, and rapid heartbeat in response to real-life scenarios involving drug-related cues (e.g. receiving a paycheck, encountering drug dealers or friends who use cocaine, celebrating special occasions, having a surplus of money available) that were accompanied by craving and eventually resulted in cocaine use.

Neural Network of Brain Regions Involved in Interoception

These types of experiences involving somatosensory and autonomic information are relayed from ascending brain areas such as the reticular formation and thalamus to the insular cortex, where they are synthesized and represented as self-aware feeling states. The insula then generates a body prediction error, which is a signal indexing the difference between the individual's current versus predicted bodily state. Next, the insula relays this body prediction error involving emotional feeling states and sensations to the anterior cingulate cortex (ACC). The ACC, in turn, generates an error signal between the correct (or probable) versus incorrect (or improbable) potential outcome, otherwise known as a value signal, to indicate the need to employ attentional resources to adjust a behavior or cognition and thus regain a homeostatic balance (Fig. 47.2). A strongly felt body state (represented by the insula) linked with the incentive to act (represented by the ACC) is an important characteristic of craving. Interoception and its amplification or attenuation by top-down or bottom-up modulation are important determinants of the craving experience.

The insula and ACC both provide information about an individual's interoceptive state to frontal circuitry involved in executive function (DLPFC, OFC) and subcortical circuitry involved in reward processing (striatum, amygdala). The insula possesses reciprocal connections with these regions and is thus centrally placed to receive information about appetitive and aversive salience and the relative value of the stimulus environment in order to integrate this information with the effect that these stimuli may have on the internal body state. Monitoring these bodily sensations is important for the integrity of internal body state and for connecting to systems involved in allocating attention, evaluating context, and planning actions.

Functions of the Insula and Anterior Cingulate Cortex

One function that has been proposed for the insular cortex is to monitor and predict the current versus predicted interoceptive state of the individual, and the role of the ACC is to receive this prediction and generate an "error" or "conflict" signal to initiate new motor behaviors and cognitive plans in order to correct an interoceptive imbalance. Given that the insula registers the homeostatic imbalance of the body – the violation of interoceptive expectancy – it is predicted that higher levels of craving should be associated with greater insula activation in individuals who abuse or are dependent on drugs, reflective of heightened somatic conflict linked to hyperarousal. Similarly, greater ACC activation should also be linked to higher craving in drug users, reflective of heightened attentional resources required to determine action plans in the midst of potentially conflicting alternatives.

NEUROIMAGING EVIDENCE LINKING INTEROCEPTION AND CRAVING

Cue-Reactivity Paradigms

Hemodynamic imaging studies utilizing cue-reactivity paradigms demonstrate a link between cocaine craving and brain regions implicated in interoceptive processing. For example, prior fMRI work has indicated that crack cocaine users exhibited greater left ACC and right insula activation than comparison subjects without drug use in response to a crack cocaine film compared to a nature film. In addition, ACC activation was larger for the cocaine film than a sex film in cocaine users, suggesting that ACC is a brain region specific to craving, not a region simply generalized to reward processing. Furthermore, PET research comparing cocaine cues to art cues using audio scripts, videotapes, and

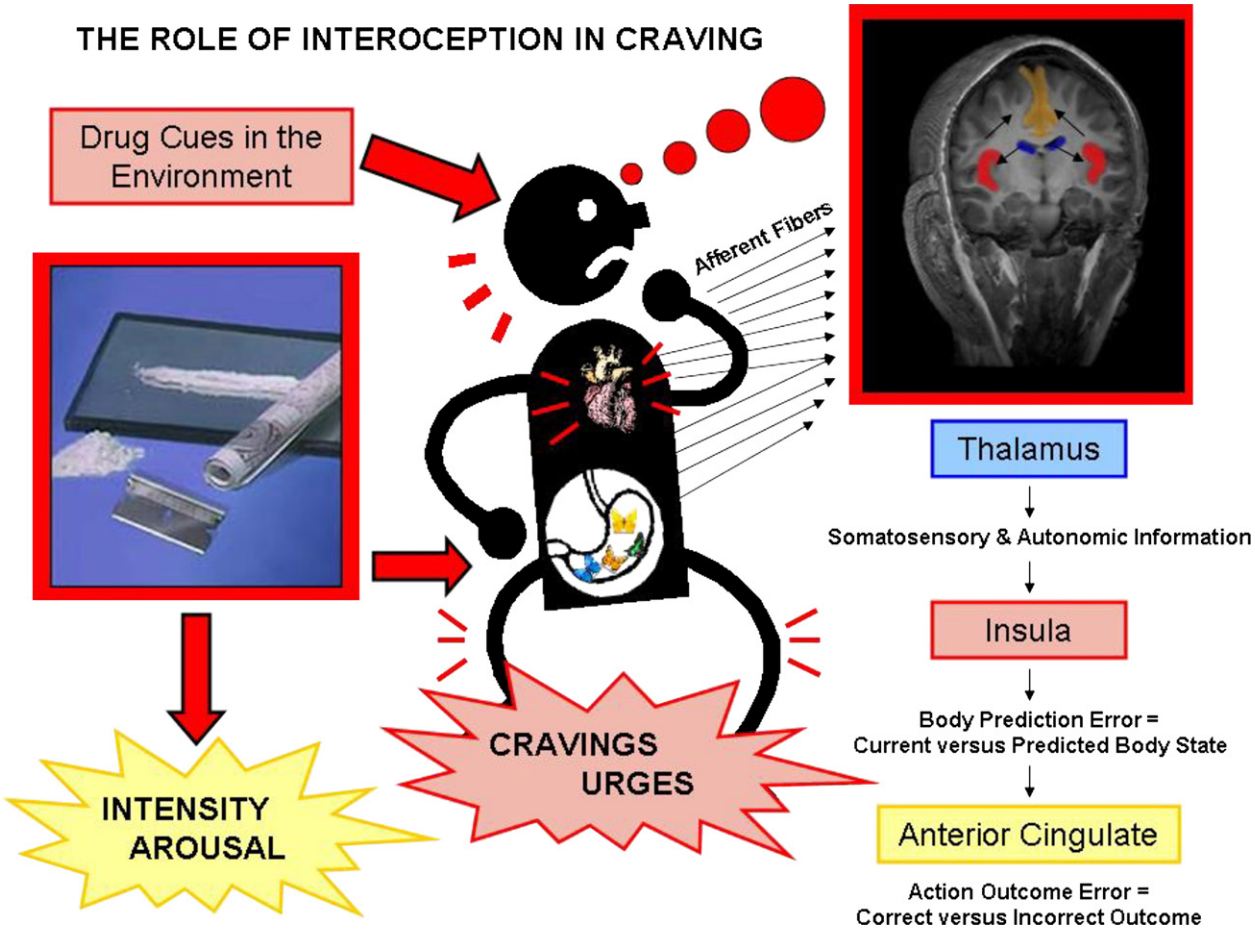

FIGURE 47.2 The role of interoception in craving: Drug cues trigger somatosensory and autonomic changes (e.g. butterflies in the stomach, racing heartbeat, sweating) indicative of heightened intensity and arousal that are relayed by afferent fibers to the thalamus (illustrated in blue) and then to the insula (shown in red), where they are synthesized and represented as self-aware feeling states associated with the craving experience. The insula generates a body prediction error that is relayed to the anterior cingulate cortex (ACC) (illustrated in yellow). The ACC then generates an error signal between the correct (or probable) versus incorrect (or improbable) potential outcome to indicate the need to regain a homeostatic balance.

paraphernalia demonstrated that left insula and the ACC correlated with cocaine craving in response to cocaine cues in cocaine abusers, the majority of whom were dependent on cocaine.

Similarly, nicotine cue-reactivity studies of craving have demonstrated results congruous with the cocaine craving literature. For instance, a PET study of nonabstinent heavy smokers and nonsmoking individuals contrasted brain activation when subjects were confronted with nicotine cues (e.g. watching a video involving a cigarette and handling a cigarette) as well as neutral stimuli (e.g. watching a nature video and handling a pencil). Changes in smokers' craving intensity from the neutral stimuli and to the nicotine cues were associated with heightened bilateral insula activation. Furthermore, an fMRI study of nicotine smokers requiring two MRI scans (one while subjects were abstinent and another when they were nicotine-satiated) showed a relationship between pre-fMRI craving for cigarettes and ACC activation during viewing of nicotine-related pictures, but only during the condition wherein smokers were required to be nicotine-abstinent for 24 h prior to their scan and were thus experiencing heightened craving during that time.

Personalized Imagery Scripts

Similarly, studies employing personalized imagery scripts of drug use also implicate insula and the ACC in craving. For example, fMRI research has shown that during guided imagery and recall of three stressful situations, left insula activation was linked to distress and cocaine craving in cocaine-dependent participants, suggesting that the insula may be linked with high negatively valenced arousal potentially exacerbated by stressful events. The interaction between craving and stress is important to examine, since stress-induced

craving states have been associated with relapse vulnerability for cocaine-dependent individuals in early recovery. Prior work in cocaine-dependent patients has demonstrated that several interoceptive sensations (racing heartbeat, bodily tension, perspiration, gastrointestinal changes, and blood flow sensations such as face flushing) were common to real-life stressful scenarios as well as situations involving explicit drug cues, and these commonalities may explain why stressful events may exacerbate the craving experience.

However, a PET study of abstinent cocaine-dependent men established that craving during cocaine scripts was correlated with left insula and the ACC compared to both neutral and anger scripts, demonstrating that activation in these regions were not due to high levels of negative affect alone. Moreover, an fMRI study examining cocaine and neutral scripts in cocaine-dependent men with and without the presence of electric shock demonstrated that higher left insula and ACC activation were present for cocaine scripts, and craving reports were the highest for the cocaine script independent of risk of electric shock, suggesting that some types of stressful situations (general threat of shock versus personalized scripts of previous stressful situations) may not activate interoceptive regions above and beyond the intensity activated by drug cues.

Drug Self-Administration Paradigms

Like cocaine cue-reactivity paradigms, a cocaine self-administration study using fMRI methodology demonstrated that ACC activation was negatively correlated with the cocaine high, but positively correlated with cocaine craving in a small sample of cocaine-dependent men. Overall, neuroimaging research of cocaine addiction provides substantial evidence that the insula (often left-lateralized) and the ACC are associated with the craving experience, presumably due to the role of the insula in predicting and monitoring an individual's current versus expected interoceptive state (e.g. detecting a homeostatic imbalance) and the role of the ACC in receiving the prediction and creating a conflict signal to initiate a change in upcoming actions and plans (e.g. obtaining and using drugs).

MODEL OF INTEROCEPTIVE DYSFUNCTION ASSOCIATED WITH CRAVING

Although the insula and ACC are crucial components of the interoceptive craving process, they function within a larger neural system to send and receive information from cortical and subcortical brain regions that serve to maintain compulsive drug use. Paulus, Tapert, and Schulteis have proposed a model of dysregulated interoception in drug addiction that explains how interoceptive processing serves to maintain drug use. When a drug-addicted individual encounters a stimulus associated with drug use, peripheral sensory receptors relay information to the thalamus regarding the location and identity of the stimulus, which is then sent to the sensory cortex and posterior insula to provide a representation of the internal body state.

In addition, centrally generated interoceptive states created from contextual memory associations are transported from the hippocampus and amygdala to the insula, which then creates an integrated current interoceptive feeling state and compares this to the predicted interoceptive state. This discrepancy is then made available to the OFC to evaluate the rewarding properties of the stimulus and the ACC to generate an error signal to initiate new motor behaviors to correct an interoceptive imbalance. Bidirectional connections between the amygdala and the striatum assist the insula in calculating this bodily prediction error and providing information on the deserved attentional salience of the stimulus. The experienced bodily state represented by the insula and the urge to act represented by the ACC are important components of the craving experience. Brain regions involved in executive control such as DLPFC then shift goal orientation in the direction of appetitive pursuit of reward propelled by craving and urges to use drugs.

SPATIOTEMPORAL DYNAMICS OF CRAVING

Comparison of Neuroimaging Techniques

Neuroimaging studies examining the spatial dynamics of craving (e.g. fMRI, PET) within the context of cocaine addiction greatly outnumber those studies using electrical measurements to determine the temporal dynamics of this phenomenon (e.g. ERPs), and it is difficult to directly compare results of hemodynamic and electrophysiological studies due to differences in spatial and temporal resolution between methods. For example, although ERP research demonstrates a link between dysfunction in lateral frontal regions and craving levels in cocaine users, due to the poor spatial resolution of EEG, it is unclear whether this dysfunction originates from the OFC, or whether it may reflect sources from the insula, the ACC, or other regions of the prefrontal cortex instead of, or in addition to the OFC unless source localization methodology is utilized in conjunction with ERP methods.

Advantages of Event-Related Potentials

ERP measures alone are helpful, however, in revealing the magnitude of attentional resources that are being recruited (reflected in ERP amplitude) and the duration that these resources are being utilized (reflected in ERP latency) to process a particular stimulus or set of stimuli. For example, two ERP studies that displayed cocaine and neutral pictures to recently abstinent cocaine-dependent individuals found that greater frontal ERP positivity was linked with cocaine craving, particularly within the context of the late positive potential (LPP), an ERP component that lasted up to 1500 ms in these studies and is thought to reflect the motivational salience of a stimulus. These findings suggest that cocaine users employ heightened attentional resources in response to cocaine stimuli for an extended duration of time, potentially due to the appetitive motivational salience that these stimuli possess, that may perpetuate the cocaine craving experience.

Although no relationship between LPP and self-report indices of craving has emerged thus far in alcohol, cannabis, or nicotine addiction research, a recent study has demonstrated this relationship within the context of opiate addiction. Within this study, abstinent heroin-dependent patients exhibited larger LPP amplitudes in central brain regions in response to heroin-related images, activation that was correlated with higher post-experiment negative reinforcement craving ratings (desired relief from negative feeling states).

Although no link between LPP and subjective craving reports has been demonstrated in alcohol or nicotine addiction, another prominent ERP component, the P300, has been related to craving in these substances. A substantial literature spanning over two decades has indicated that P300 amplitude is prominent 300–600 ms after stimulus presentation and reflects the amount of attentional resources recruited for the evaluation of stimulus significance. Thus, heightened P300 amplitude in drug users in response to drug-related stimuli may reflect heightened emotional significance and attentional bias to these stimuli. For instance, a study of abstinent current smokers, ex-smokers, and nonsmokers showed an association between heightened frontal P300 amplitude to smoking cues and ratings of the desire and intention to smoke cigarettes. Moreover, a recent study indicated that alcohol-dependent individuals exhibited higher P300 amplitude to images of alcoholic beverages than nonalcohol-dependent social drinkers, brain activation that correlated with subjective ratings of alcohol craving.

Advantages of Electroencephalography

Future research using EEG and ERP source localization methods may provide valuable information regarding the timing and sources of cortical activation associated with real-time craving processes. Source localization is a method of obtaining spatial information from EEG data wherein sources of electrical signals visible at the scalp are modeled. Although it has been assumed that the insula is activated prior to ACC during craving responses, this hypothesis has yet to be thoroughly tested, but can be evaluated using data from multielectrode EEG montages subjected to source localization. In recent years, EEG and fMRI recordings (either recorded concurrently during the same session or in separate sessions) have been used in conjunction to evaluate source and timing information, often with fMRI regions of interest utilized to determine source dipoles for initial EEG analysis.

METHODOLOGICAL ISSUES

A growing literature investigating the neural mechanisms of cocaine addiction has provided us with beneficial information regarding the brain systems involved in the craving experience. However, a few methodological issues related to self-report craving measures, sizes of samples recruited for studies, and the examination of gender differences hamper the generalizability and interpretation of these findings as a whole and can thus be improved upon.

Incorporating Self-Report Measures of Craving

It is often assumed that an experimental manipulation succeeds in inducing a craving experience without evaluating this assumption by correlating self-reported craving measures with brain activation. For example, a recent fMRI study identified tentative "craving sites" by selecting brain regions that were more active in crack cocaine users than comparison subjects during a cocaine film compared to a nature film. The researchers then examined whether any of these brain regions were more active in the users during the cocaine film compared to a sexually explicit film to rule out the possibility that the cocaine-related activations were due to general appetitive processing. Although findings demonstrated that cocaine users exhibited higher craving and greater ACC and caudate nucleus activation than during an appetitive film showing explicit sexual content, no correlations were performed between the self-reported craving index and putative "craving sites." Instead of reflecting craving processes *per se*, ACC activation in this context could instead index greater attention allocation to a conflictual, highly familiar, and emotional stimulus,

whereas dorsal striatum activation could reflect the learned experience of a cue.

Similarly, a recent fMRI study of cannabis users (most meeting criteria for cannabis dependence) asserted that marijuana cue-elicited craving was linked to greater ACC, amygdala, insula, and ventral tegmental area activation because tactile marijuana stimuli (e.g. a pipe) elicited more activation in these regions than neutral tactile stimuli (e.g. a pencil). However, no significant correlation emerged between self-reported craving ratings and these brain regions, despite the fact that a higher number of problems associated with marijuana use were linked to greater activation in brain regions implicated in reward and interoception (e.g. OFC and ACC). In studies such as this, it is crucial for researchers to link specific, reliable, and valid measurements of the craving experience (indexed by verbal reports, behavior, and/or psychophysiology) to brain activation in order to differentiate the craving experience from drug stimuli familiarity, conflict, or emotional significance that may also influence brain activation during drug-related paradigms.

Sample Size Limitations

The majority of imaging studies of cocaine craving have utilized small sample sizes (typically <20 individuals diagnosed with cocaine addiction or abuse). However, drug use disorders in general and cocaine addiction in particular is a heterogeneous disorder. Thus, different mechanisms may play a role in subgroups of cocaine-dependent individuals; for example, craving may be the result of an overwhelming ascending interoceptive afferent input, emerge from the inability to filter out drug-cue associated stimuli, or result from an inability to engage inhibitory top-down regulatory processes. Yet, small sample sizes may not allow us to detect these different mechanisms. Nevertheless, identifying the specific component processes that are dysfunctional and lead to craving could have profound clinical or treatment relevance. Small sample sizes are also common in neuroimaging studies of alcohol, cannabis, nicotine, and opiate craving, limiting generalization and power to detect significant differences as a function of the craving experience.

Examination of Gender Differences

The small sample sizes recruited for cocaine-related studies are predominately male, so it is difficult to generalize findings to women. This limitation is also true of the existing craving literatures concerning alcohol, cannabis, nicotine, and opiate addiction. The sole imaging study of gender differences in cocaine craving revealed that cocaine-dependent women exhibited greater ACC activation to cocaine scripts than neutral scripts, but cocaine-dependent men displayed greater left insula activation than women in response to cocaine scripts, suggesting that interoceptive responses to drug cues may differ in men and women, with women experiencing a more heightened error signal of homeostatic imbalance, and men experiencing more bodily intensity or arousal during interoceptive imbalance. However, in this study brain activation was not directly correlated with levels of cocaine craving, making it difficult to draw conclusions regarding gender differences in craving-related brain mechanisms.

FUTURE DIRECTIONS

Interoceptive Interventions for Drug Users

Assuming that interoceptive processing plays an integral role in the craving experience, it would be important for future investigations of drug craving to examine interventions that are targeted at processing interoceptive stimuli to alter an individual's internal state with the goal to decrease the rewarding properties of drug-related cues. For example, listening to a dripping faucet an individual experiences an increased sensitivity to exteroceptive stimuli (the auditory signal). However, one may also develop specific interventions to increase or decrease the sensitivity to interoceptive stimuli; for example, breathing, gastrointestinal, specific skin-related, or temperature stimuli, in order to decrease the urge to use related to interoceptive stimuli associated with craving.

Linking Insula Function to Positive and Negative Reinforcement

Research is also needed to examine whether intact insula and anterior cingulate function are necessary for individuals to experience conditioned positive reinforcement (approaching the rewarding aspects of the drug) or negative reinforcement (avoiding the negative consequences of drug withdrawal). Subsequent imaging studies may determine whether interoceptive craving experiences are positively or negatively valenced by requiring additional behavioral, self-report, or psychophysiological information of participants. Incorporating interoceptive processes into existing approaches to drug addiction will enhance our understanding of craving and urges within the context of drug use and relapse and point the field toward behavioral and pharmacological targets for intervention.

CONCLUSION

Neuroimaging research utilizing both hemodynamic (fMRI, PET) and electrocortical (EEG, ERP) methodologies has implicated a wide network of subcortical and cortical brain regions in the implementation of the cocaine craving experience induced by cue-reactivity, autobiographical imagery, and drug administration paradigms and measured by various self-report indices. Subcortical regions such as the amygdala, hippocampus, and striatum are implicated in conditioned reward responses that serve to perpetuate drug use, whereas frontal cortical regions that typically engage in executive control processes are instead activated by the rewarding properties of drug cues. Interoceptive sensory and autonomic information (felt as a homeostatic imbalance in response to drug cues) is relayed from the thalamus and other subcortical regions to the insula, where it is integrated into an emotional feeling state (craving) and compared to a predicted feeling state. This information is transported to the ACC, which attempts to recreate a homeostatic balance by modifying incentives to act (urges). Both the insula and ACC provide information about an individual's interoceptive state to frontal circuitry involved in executive function and subcortical circuitry involved in reward processing to maintain drug addiction. Although interoception appears to be an integral component of the craving process, additional research is warranted to determine whether interoceptive modulation in addicted individuals will result in successful new interventions.

Glossary

Amygdala a subcortical brain region located deep in the brain in close proximity to the hippocampus, which is important for processing highly salient information.

Anterior cingulate cortex (ACC) a cortical brain region that is part of the executive cognitive control system. The ACC receives interoceptive predictions from the insular cortex and generates a conflict or error signal to initiate new urges to correct an interoceptive imbalance.

Caudate nucleus a subcortical brain region, which is part of the dorsal striatum and situated near the thalamus. The caudate is important for instrumental learning and habit processing and is implicated in habitual patterns of drug urges, cravings, and use.

Cocaine a stimulant drug of abuse obtained from the leaves of the coca plant that can be orally ingested, snorted, smoked, or injected and is known to increase alertness, energy, concentration, self-esteem, euphoria, and sexuality.

Cognitive control a type of flexible information processing thought to involve the prefrontal cortex that allows behavior to change successfully as a function of current goals. Cognitive control processes include inhibition, attention allocation, and goal representation and maintenance.

Craving an emotional feeling state of strong wanting, which is accompanied by strong incentive to act, which has been implicated as an important factor in the maintenance of drug addiction and the probability of relapse.

Dextroamphetamine a stimulant drug often prescribed to treat attention deficit hyperactivity disorder that is also used recreationally as a drug of abuse. It is taken orally (in pill form) and is known for increasing and/or maintaining alertness and improving attention.

Dopamine a monoaminergic neurotransmitter associated with learning and the reward system of the brain.

Dorsal striatum a subcortical brain region comprised of the caudate nucleus and putamen.

Dorsolateral prefrontal cortex (DLPFC) a brain region situated in the prefrontal cortex thought to be involved in working memory and goal maintenance.

Drug abuse a maladaptive pattern of substance use that does not involve substance dependence but does lead to at least one symptom of clinically significant impairment or distress within a 12-month period (e.g. failure to fill major role obligations, use-related legal problems, use despite interpersonal problems, and/or use in physically hazardous situations).

Drug dependence a maladaptive pattern of substance use leading to at least three symptoms indicative of clinically significant impairment or distress within a 12-month period (e.g. tolerance, withdrawal, use in greater amounts or longer than intended, unsuccessful efforts to cut down, activities reduced due to use, significant time spent obtaining and using or recovering from use, and/or use despite exacerbation of a physical or psychological problem).

Electroencephalography (EEG) the measurement of electrical signals of the brain, usually through electrodes placed on the scalp.

Event-related potential (ERP) the average electrical signal evoked by a particular event or stimulus, such as an auditory tone or visual picture.

Exteroception the experience of intensity or arousal associated with stimuli located outside the body.

Functional magnetic resonance imaging (fMRI) a neuroimaging technique that measures the changes in blood flow and blood oxygenation associated with neural activity.

Hippocampus a subcortical brain region situated below the amygdala thought to be involved in long-term memory processing.

Homeostasis regulation of physiological processes inside the body used to maintain its internal stability and balance in response to external fluctuations.

Incentive salience the desirability of a drug that can eventually be extended to stimuli that signify or are associated with the drug (e.g. individuals associated with drug use or drug paraphernalia) that can lead to increased drug urges and cravings.

Insular cortex a cortical brain region, which is surrounded by the cortical mantle and is divided into anterior and posterior insula by the central sulcus. The insula is involved in the craving process by monitoring the current versus predicted interoceptive state of the individual and generating a signal aimed at maintaining homeostasis.

Interoception the experience of intensity or arousal associated with a homeostatic imbalance of the body, resulting in a conscious feeling of craving and the urge to use drugs.

Late positive potential (LPP) a slow-wave ERP component emerging 200 ms after presentation of a stimulus (that can last up to several seconds) thought to reflect the motivational salience of a stimulus.

Mesolimbic dopamine system a pathway carrying dopamine from the ventral tegmental area to the nucleus accumbens through the amygdala and hippocampus thought to be part of the brain's reward circuitry.

Methamphetamine a stimulant drug of abuse in the amphetamine class of drugs that can be orally ingested, snorted, smoked, or injected and is known to increase alertness, energy, concentration, self-esteem, euphoria, and sexuality.

Methylphenidate a stimulant drug primarily prescribed to treat attention deficit hyperactivity disorder that is also used recreationally as a drug of abuse. It is most commonly taken orally (in pill form) and is known for increasing and/or maintaining alertness and improving attention.

Nucleus accumbens a subcortical brain region that is part of the ventral striatum, thought to be involved in a substance rush or high as well as substance craving.

Orbitofrontal cortex (OFC) a cortical brain region located in the prefrontal cortex thought to be linked to sensitivity to reward within the context of decision making.

Parahippocampal cyrus a brain region surrounding the hippocampus thought to be involved in memory processing.

Positron emission tomography (PET) a neuroimaging technique that creates images on the basis of movement of injected radioactive material.

Prefrontal cortex the most anterior portion of the cerebral cortex that is associated with many functions including processes involved in cognitive control.

Putamen a subcortical brain region included in the dorsal striatum that is situated near the thalamus and is thought to be involved with habitual patterns of drug urges, cravings, and use.

Reticular formation a structure located in the brain stem thought to be involved in somatosensory, motor, pain, and cardiovascular modulation and control.

Source localization a computational method of determining the spatial location of electrical signals recorded at the level of the human scalp by electroencephalography.

Stimulants psychoactive drugs that result in temporary improvements of physical and/or mental function that target and stimulate the mesolimbic dopamine system. These drugs are used as prescription medications as well as drugs of abuse and dependence and include cocaine, methylphenidate, and amphetamine (and its variants such as dextroamphetamine and methamphetamine).

Thalamus a subcortical brain region located above the brain stem thought to be a gating and relay station for sensory information between subcortical and cortical areas of the brain.

Urge a strong incentive to act; for example, motivated behavior to seek, obtain, and use drugs.

Ventral striatum a subcortical brain region comprised of the nucleus accumbens.

Ventral tegmental area a subcortical brain region situated above the hippocampus that is the origin of dopaminergic neurons of the mesolimbic dopamine system.

Interference with Concurrent Tasks

Eva Kemps and Marika Tiggemann

Flinders University, Adelaide, SA, Australia

OUTLINE

OVERVIEW

Craving can be described as a motivational state that is characterized by an intense wanting or longing to seek a particular target or activity, such as a psychoactive substance. Some of the most commonly craved substances are cigarettes, alcohol, and drugs. Although we don't normally think of food as a craved substance, we can and do in fact also crave food. When people have a craving, they often experience thoughts such as "I really need a cigarette," or "I so want a pecan sundae."

The origin of cravings has been attributed to both physiological and psychological factors. The main physiological trigger is a state of deprivation, which is accompanied by symptoms such as an increased heart rate. In the food domain, hormonal changes during the menstrual cycle and pregnancy have also been associated with cravings in women. The psychological origins of cravings include both internal and external triggers. Internal triggers can involve a range of negative emotional states, such as anxiety, depression, boredom, and stress. External triggers involve any exposure to environmental cues, such as the smell of a burning cigarette or the sight of a chocolate bar.

With the exception of food cravings, which occur among a large proportion of the general population without any problem, cravings for substances such as cigarettes, alcohol, and drugs often give rise to negative consequences. In particular, such cravings can lead to (1) development and maintenance of addictive behaviors, (2) withdrawal symptoms if consumption is resisted or prevented, and (3) relapse in people who have quit substance use. Although food cravings are not necessarily pathological, these too can be maladaptive for some individuals. They too can lead to "addictive" eating patterns and withdrawal symptoms, and certainly disrupt many people's intentions to diet. In support, research shows that food cravings have been linked to early dropout from weight loss programs. They have also been identified as a precursor to binge eating, itself a risk factor for the development of obesity and eating disorders, particularly bulimia nervosa.

While these negative consequences are what people in general might expect, there is another less obvious adverse consequence that arises from cravings. This is that cravings interfere with performance on cognitive tasks, resulting in people performing less well than they otherwise would. This chapter sets out to review the literature to date on the cognitive effects of craving. First, the chapter outlines the evidence that cravings impair cognitive task performance. Second, it considers theoretical explanations for the observed cognitive

Principles of Addiction, Volume 1

interference from cravings. And finally, it discusses everyday implications of craving-induced cognitive impairments.

EVIDENCE THAT CRAVINGS INTERFERE WITH COGNITIVE PERFORMANCE

The evidence that cravings have an impact on cognition comes from two main sources: anecdotal accounts and laboratory studies.

Anecdotal evidence

Anecdotal accounts refer to what people say about themselves. These accounts consistently suggest that cravings interfere with cognitive functioning. For example, smokers have reported that their cigarette cravings interfere with their thinking. They say that when they want a cigarette badly, it takes over their thinking, and they can't concentrate. Similarly, alcoholics have complained that their cravings disrupt their daily activities by disrupting their concentration. In fact, the most consistently mentioned feature of cravings is their overwhelming nature.

Laboratory Studies

Most of the evidence that cravings impair cognition comes from laboratory studies that actually test people under controlled conditions. These studies typically induce cravings in the laboratory, and then ask people to perform standardised tests. Cravings are generally induced in research participants in one or more ways. The most common craving induction protocols involve: (1) imagery scripts, (2) substance deprivation, and (3) cue exposure.

First, imagery scripts present participants with some sort of scenario that is designed to make them crave. Participants are instructed to create an image of the described scenario. For example, cigarette smokers might be asked to imagine themselves lighting up a cigarette. A complete example of an imagery script that has been used to induce food cravings is:

> *"In a moment I am going to ask you to form an image of a scenario. It is important that you are relaxed and remain focused. Make sure you are comfortable, and clear your mind of any other thoughts. Concentrate on your breathing and try to become as relaxed as possible. There is no time limit on this exercise so take as long as you need to form a really clear and vivid image of the scenario I am about to ask you to imagine.*
>
> *Now, imagine you are eating your favorite food. Bring this experience to mind as vividly as you can, as if it were happening right now. Provide as much detail from your imagination as you possibly can to make the image as real as if you are actually eating the food. When you feel you have formed the clearest and best image of this scenario that you can, let me know."*

Second, substance deprivation involves instructing participants to abstain from the craved substance for a set period of time before the laboratory session. Usually participants are deprived for 6, 12, or 24 h. So, cigarette smokers might be asked to not smoke for 12 h. Or, people who crave chocolate might be asked not to eat it for a day.

Third, cue exposure involves exposing participants to the actual substance in the laboratory (but without allowing them to consume it). For example, in studies of alcohol craving, to induce a craving, participants might be presented with a glass containing an alcoholic beverage. Similarly, in the food domain, chocolate cravings might be induced by showing participants actual chocolate.

Following one or more of these induction procedures, participants are generally asked to report their level of craving. This is generally done by completing a rating scale that ranges from "no urge at all" to "extremely strong urge to smoke, drink, eat chocolate (as appropriate)." Each of the three urge induction protocols (imagery scripts, substance deprivation, cue exposure) has been shown to individually successfully elicit cravings in the laboratory. But the most effective methodology for eliciting cravings seems to be substance deprivation in conjunction with cue exposure. For example, smokers who abstain from smoking for 12 h and are subsequently exposed to a lit cigarette in the laboratory report stronger cigarette cravings than those who are only nicotine deprived or are only exposed to cigarettes. Additionally, cue exposure is maximally effective if the participant interacts with the craving induction stimulus in some way. For example, asking a smoker to pretend that they are smoking a lit cigarette that they are holding produces stronger cravings than asking them to hold the lit cigarette, which produces stronger cravings than asking them simply to view a lit cigarette.

Next, participants are asked to perform a cognitive task. The earliest laboratory studies have used a simple reaction time task to examine the cognitive effects of craving. In this task, participants are presented with a series of stimuli. These are presented either visually (e.g. a series of asterisks that appear on a computer screen) or orally (e.g. a series of tones). The stimuli are presented at varying and random intervals. Participants have to respond (by pressing a button) as quickly as possible whenever they see or hear the stimulus.

Using this task, a number of studies have shown that experimentally induced cigarette cravings increase reaction times in smokers. For example, in one study regular smokers created images of scenarios. Some were about smoking (e.g. smoking at a party with friends) and others were not about smoking (e.g. watching and admiring a fireworks display). The participants were asked to imagine themselves participating in these scenarios and subsequently rated their urge to smoke. They then performed a reaction time task in which they were instructed to press a button as quickly as possible whenever they heard a tone. Smokers who imagined smoking scenarios reported stronger cigarette cravings and took longer to respond to the series of tones than those who imagined nonsmoking scenarios. Similar increases in response times have also been shown in alcoholics, opiate users, and weight loss dieters following experimental induction of alcohol, drug, and food cravings, respectively.

Cognitive decrements during craving episodes are not limited to slower response times to stimuli on a simple reaction time task, but also occur on other, more complex tasks. In particular, several studies have shown that experimentally induced cigarette cravings impair language comprehension and mental arithmetic in smokers. In each study, cigarette cravings were induced via an imagery script. Half the participants were asked to form an image of a scenario about smoking (i.e. smoking after a satisfying meal in a restaurant). The other half imagined a scenario that was in no way related to smoking (i.e. relaxing and enjoying the view from a window). For the language comprehension task, participants read sentences and answered true–false questions about them. The mental arithmetic task involved participants verifying complex addition problems. Participants who imagined the smoking scenario had stronger cigarette cravings and made more errors on both the sentence comprehension and mental addition tasks than those who imagined the nonsmoking scenario.

In another study, habitual chocolate cravers showed performance decrements on a working memory capacity task following a chocolate urge induction. Working memory capacity refers to the ability to actively store information while simultaneously processing other information, and was assessed by the operation span task. In this task, participants were required to remember a series of words (storage) while also verifying mathematical equations (processing). Chocolate cravings were elicited through a combination of deprivation and exposure to actual chocolate. Specifically, a random half of participants (craving group) were instructed not to eat chocolate for 24 h, and upon arriving at the laboratory, were presented with a selection of wrapped chocolate bars attractively presented in a basket. Participants were asked to choose their favorite chocolate bar, to unwrap it and place it and the wrapper on a small tray positioned in view below the computer monitor, and to indicate how much they liked the chocolate. Participants then performed the operation span task in the presence of the chocolate bars. The other half of the participants (control group) did not abstain from eating chocolate and were instead presented with a basket of similar sized colored wooden blocks and analogously asked to choose their favorite colored block and place it in view below the computer monitor. The results showed that participants in the craving group reported stronger chocolate cravings than those in the control group. More importantly, as predicted, they also both recalled fewer words, and showed slower mathematical equation verification times in the operation span task.

Why Do Cravings Disrupt Cognitive Performance?

Taken together, the findings from laboratory studies clearly show that cravings impair performance on a range of cognitive tasks, from simple (like reaction time) to complex tasks (like language comprehension). There are a number of different theoretical explanations for these adverse cognitive effects of craving. The most supported is that dealing with cravings requires mental effort. In other words, cravings take up cognitive capacity. Because our cognitive capacity is limited, there is then less available for competing cognitive demands, such as a reaction time task. Consequently, task performance suffers. In this way, the interference of cravings with concurrent cognitive tasks can be likened to a dual-task procedure. In a dual-task procedure, participants are asked to perform two tasks simultaneously. The aim is to determine the amount of cognitive capacity that is used by the secondary task (e.g. counting numbers) by measuring how much it disrupts performance on the primary task (e.g. proof reading). Thus, the greater the performance decrement on the primary task (proof reading), the more capacity is being consumed by the secondary task (counting numbers). As such, cravings behave like a secondary task, taking up limited capacity that is required for the performance of a concurrent cognitive task.

Theoretical accounts of craving suggest two possible general mechanisms for why cravings take up cognitive capacity. First, during craving episodes, individuals may direct cognitive capacity to processing craving-related cues. In other words, their attention is automatically drawn to these cues, and they are distracted by them. For example, they notice the cigarette advertisement on television, or someone smoking, or the smell of coffee. Or, alternatively, individuals may allocate

cognitive capacity toward inhibiting consumption behavior. Consumption behavior, such as smoking and eating, is itself automatic in the sense that it does not take up cognitive capacity. However, once such behavior is triggered, for instance by craving, cognitive capacity is required to inhibit it. Thus, individuals need to consciously try to stop themselves from smoking, or drinking, or eating, and this takes up cognitive capacity.

Cravings Interfere Specifically with Visual Tasks

As mentioned previously, instructing participants to create an image of a craved substance is an effective means of eliciting cravings in the laboratory. Converging evidence from a number of recent studies in fact points to mental imagery, particularly visual mental imagery, as playing a key role in cravings. First, anecdotal reports of naturally occurring craving experiences show that when people crave, they have vivid visual images of the craved substance. For example, smokers commonly experience images of "relaxing with a cigarette" or "having a cigarette to help cope with stress." Second, several studies have reported a positive correlation between the vividness of people's images and the intensity of their craving, such that stronger cravings are associated with more vivid images. Third, surveys of everyday cravings for various substances including alcohol, tobacco, and food show that respondents readily use imagery terms to describe their cravings. For example, in one study, respondents used phrases such as "I could picture the pizza in my mind, picture eating it" when asked to write a short paragraph describing a previous food craving episode. In addition, when presented with a list of descriptive statements, respondents strongly endorsed imagery-based descriptors as characteristic of their cravings. Imagery descriptors in the visual modality (e.g. "I am visualizing the food") in particular were rated highly. In contrast, auditory descriptors (e.g. "I can hear myself having the food") were not highly rated. Together, these lines of evidence led to the conclusion that mental imagery is a key element of cravings. They further indicate that the imagery component of cravings is predominantly visual rather than auditory or verbal in nature.

We know from more general cognitive psychological research that visual imagery interferes selectively with visual tasks. For example, holding a visual image in mind interferes specifically with the detection of visual signals, but does not interfere so much with an auditory task, such as detecting tones. Conversely, an auditory image will interfere more with an auditory task than a visual task. This modality-specific interference occurs because the visual (and auditory) system has limited capacity. Therefore, a visual secondary task interferes with a visual primary task because they both compete for the same limited capacity visual system.

In view of the visual imagery basis of cravings, it logically follows that cravings will interfere most with performance on a visual task. This was demonstrated in a study that specifically examined the impact of chocolate cravings on both a visual memory task and a comparison verbal memory task. Half the participants (craving group) underwent a chocolate craving induction protocol that involved a combination of deprivation and cue exposure. Specifically, participants abstained from eating chocolate for 24 h before the testing session. They then chose their favorite from a selection of fun-size wrapped chocolate bars, unwrapped it, and performed the memory tasks in the presence of chocolate. The other half (control group) were not deprived of, nor exposed to, chocolate. The verbal memory task consisted of the digit span task. In this task, participants are presented with random series of digits and asked to recall these in correct serial order. The visual memory task consisted of the Corsi blocks task. In this task, the experimenter points to a random selection of nine blocks irregularly positioned on a board; the participant's task is to repeat the presented sequence. The Corsi blocks task has been designed to be analogous to the digit span task, but in the visual domain. As predicted on the basis of the visual imagery nature of cravings, participants in the craving condition performed more poorly on the Corsi blocks task than control participants, but the groups did not differ on the digit span task. These results indicate that cravings selectively disrupt performance on visual tasks.

Real-World Implications

It needs to be noted that the cognitive effects of individual craving episodes are likely to be small. For example, across craving studies for different substances, responses on a simple reaction time task are on average 50–100 ms slower when people are craving than when they are not. In addition, accuracy in reading comprehension and mental arithmetic in smokers drops by about 10% when they crave a cigarette. Likewise, memory performance drops by about 5–10% when people crave chocolate.

Nevertheless, even small cognitive decrements have the potential to compromise the ability of people to perform their jobs and everyday cognitive tasks to an optimal level, particularly as such decrements are likely to be cumulative over time. For example, most work places are now smoke-free, so smokers cannot respond to their smoking urges while at work. But they do often have to process complex information as part of their work. Not being able to respond to cigarette cravings in this situation may reduce smokers' work efficiency.

Similarly, there is an abundance of food and eating cues (e.g. fast food outlets, television advertisements) in our contemporary environment that are likely to induce food cravings in vulnerable individuals. Such individuals will often be exposed to craving cues in situations in which they have to perform a cognitive task but cannot respond to their food craving, for example, a driver who sees an advertisement for a chocolate bar on a billboard.

More generally, there are situations where split-second responses are crucial, for example, when maneuvering through dense traffic or responding to a visual stimulus in real-world vigilance tasks, such as monitoring a radar screen or inspecting items on an industrial production line. Unsatisfied cravings in any of these situations have the potential to increase accidents.

CONCLUSION

Cravings can give rise to a range of negative consequences, including cognitive impairment. Research to date shows that cravings for cigarettes, alcohol, drugs, as well as food disrupt performance on a range of cognitive tasks, including reaction time, memory, language processing and mental arithmetic; thus people do not perform to their maximum. These adverse cognitive effects further highlight the need for interventions designed to reduce the occurrence of cravings.

Relation of Craving and Appetitive Behavior

Stuart G. Ferguson[*,$], *Saul Shiffman*[**]

[*]School of Pharmacy, University of Tasmania, Hobart, TAS, Australia, [$]Menzies Research Institute Tasmania, University of Tasmania, Hobart, TAS, Australia, [**]University of Pittsburgh, Pittsburgh, PA, USA

OUTLINE

The phenomenon of craving has been a core focus of dependence research for many decades. The push to understand and treat craving is born out of the prominence of craving in addicts' experience of their addiction, and the wealth of evidence that suggests that the experience of craving can motivate behaviors such as smoking, gambling, or eating, even in the presence of a conscious desire to avoid the behavior in question. The ability of cravings to induce or promote behaviors, seemingly against the initial intention of those who experience them, is the core characteristic of craving and the one that most attracts the attention of researchers and theoreticians. We also discuss some of the reasons why some studies may have failed to find a relationship between craving and behavior.

Arguably the most intensive investigations on the nature and function of craving have taken place in the context of drug dependence, the findings from which are the focus of this review. As we discuss in detail below, across substances of dependence, drug craving has consistently been found to motivate drug-seeking behaviors and, hence, to disrupt efforts by users to achieve and maintain abstinence. Below we explore the nature and experience of craving, starting with the definition and measurement of craving. The evidence relating to the role of craving in maintaining appetitive behaviors is then examined. Although we have chosen to focus on findings from the drug dependency literature, craving has also been documented in relation to appetitive behaviors that are not substance related (e.g. gambling). The principles and knowledge gleaned from studies of substance abuse are also likely to be applicable to the experience of craving in these fields.

CRAVING: DEFINITION AND CONCEPTUALIZATION

For a topic that has been the focus of such a wealth of scientific research over the last century across a broad range of behaviors – most notably in drug dependence – it is perhaps surprising to learn that scientists are yet to categorically define what is meant by the term craving. Across, and sometimes even within disciplines, the term craving has been defined and operationalized in many ways. Although not identical, the many available definitions of craving have core similarities; even though the words may be different, the individual definitions contain similar themes. Thus, rather than attempting to define the concept of craving here, we instead focus on describing these core overarching

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00049-8

concepts that appear to span the individual definitions that other researchers have utilized.

It is generally agreed that a craving is primarily a relatively intense need, urge, or strong desire to undertake a target behavior. Cravings vary in intensity, but at their most intense, are often described by those who experience them as being overwhelming, provoking to some degree a loss of control over one's reactions. Many definitions of craving often incorporate some component of perceived loss of control over one's behavior. One may desire an ice cream, for example, but unlike a craving, such desires do not generally rise to the level where they are disruptive to other facets of life.

Conceptually, craving is often thought of as a withdrawal effect; that is, simply a product of abstinence from a target behavior or substance. For example, a typical physiological model of drug craving would posit that dependent individuals have become tolerant to the presence of a drug, resulting in changes in the very physiology of the brain (e.g. through changes in the number and/or sensitivity of receptors) and, as a result of these changes, they experience craving when the drug is not available in sufficient quantities. Within such a framework, craving is thought to follow a similar time course to withdrawal symptoms during periods of abstinence. Typically, drug withdrawal symptoms increase with the duration of abstinence before peaking and then gradually returning to baseline levels (although researchers have identified a number of unique time profiles of withdrawal symptoms that do not follow this trajectory). Supporting such a conceptualization, there is strong evidence from numerous studies across many drugs of dependence that the experience of craving does vary predictably with abstinence (typically increasing within the hours following cessation of drug use before tapering back to baseline levels gradually over subsequent days and weeks).

However, unlike true withdrawal effects, researchers have also noticed that craving can be induced without manipulating abstinence; researchers have demonstrated that craving can be reliably invoked even during periods of drug satiation or after prolonged abstinence (when withdrawal effects should have disappeared). Using laboratory-based cue reactivity paradigms (discussed briefly below and in detail in other chapters), for example, researchers have demonstrated that intense cravings can be induced simply by exposing drug users to cues (or stimuli) that are associated with drug administration (e.g. a syringe or drug paraphernalia). Certain emotional states, such as emotional distress and negative affect, have also been shown to reliably provoke craving. Such moment-to-moment volatility in craving is difficult to adequately explain using a purely physiological/withdrawal-based model of craving: if abstinence were the only factor driving craving, then the experience of craving should follow a reliable, relatively consistent, and slow time course (as circulating levels of the drugs are cleared from a user's system). A further challenge to traditional withdrawal-based explanations of craving is the observation that craving continues to fluctuate even after circulating levels of the drug are completely exhausted. Withdrawal-based explanations of craving cannot explain why individuals can continue to experience fluctuations in craving months or even years after complete cessation was achieved.

Such findings beg the question: How can an intense craving for a drug be induced simply via exposure to certain stimuli or cue? The answer, most theorists argue, lies in the psychological concept of conditioned associations. Within this conceptual framework, the link between situational stimuli and craving is thought to be mediated by conditioned, or learned, association; that is, these cues have come to elicit craving through a history of repeated pairing with smoking. There are various accounts for how such relationships are established, but they all stress the importance of repeated pairing of stimuli with drug administration.

Thus, unlike traditional withdrawal symptoms, craving appears to be driven not only by abstinence, but also by exposure to drug-related stimuli. For this reason, researchers have found it useful to distinguish between two types of craving depending on how it is induced, namely abstinence-induced craving and cue-induced cravings. (Cues in this context may be external (sensory stimuli such as visual or olfactory reminders of a drug) or internal (strong emotions)). Abstinence-induced craving, also known as background craving, is akin to withdrawal symptoms and is characterized by its relationship to drug levels. Such craving is experienced as relatively steady, tonic states over the course of days or at least hours, fluctuating relatively slowly. Cue-induced cravings, on the other hand, are more volatile and subject to moment-to-moment variations in intensity. The example of hunger can be used to illustrate the distinction between these two types or conceptualizations of craving. If one has not eaten, one is likely to feel constantly hungry. Such hunger is akin to background craving (or withdrawal symptoms); craving that changes slowly over the course of days and or weeks depending on an individual's degree of abstinence. In contrast to the relatively steady experience of background craving, however, as discussed above, drug users also experience bouts of intense craving; episodic spikes or surges in craving that are seemingly independent of abstinence. Such cravings have been referred to as cue-induced cravings. Using the hunger analogy, consider the desire for food one experiences when seeing or smelling appetizing food. The mere presentation of food can result in intense, acute, hunger even when one is sated. In such circumstances, the

person is not hungry because they require sustenance in the traditional sense; rather they experience the sensation of hunger because they have seen that food is available.

Cue-induced cravings are experienced as acute episodes of intense craving overlaid on slowly varying levels of background craving. As discussed below, however, the measurement tools used to assess craving do not differ according to the type of craving being measured.

ASSESSING CRAVING

Unlike the measurement of physical properties (e.g. weight, blood pressure, heart rate, etc.) psychological concepts such as craving cannot be measured directly. Researchers have to either ask patients to self-report their levels of craving or measure secondary physiological properties that are believed to vary systematically with a patient's level of craving intensity (proxy measures of craving). As discussed briefly (and in more detail in other chapters), there are advantages and disadvantages to each of these approaches.

Craving is most commonly assessed through individual self-report measures. Patients are explicitly asked to report on their subjective level or intensity of craving. Such questioning is typically conducted using questionnaires, but it is also possible to have patients self-report their craving verbally or by turning a dial. Several forms of self-report assessments have been used in craving research. These include verbal reports, visual analog scales (individuals are asked to indicate their degree, or amount, of agreement with a statement by marking a position along a line between two anchors or end points), Likert-type scales (rating scales), and magnitude estimation scales, among others. Such measures range from single-item reports (e.g. "How much are you craving right now?") to multi-item questionnaires that use a variety of items to capture different aspects of craving, and either average across these items or produce a multifactorial measure of craving. As indicated by the range of different approaches, there is no universally accepted measure of craving, and the type of assessment used may be contingent on various factors, including study design, outcome of interest, and a number of other factors. Although relatively simple to use, self-report measures of craving are not without their problems, the most serious of which is that self-report measures are inherently subjective. It is impossible to know whether one person's experience of craving is the same as the next. For this reason, researchers have explored alternate ways to assess the experience of craving in the hope of developing more objective measures.

In an attempt to overcome the issues involved with self-reporting, researchers have developed many ostensibly more objective assessments of craving. These include psychophysiological measures, cognitive processing and performance (where craving is implied by decrements in cognitive speed and/or accuracy), behavioral indices, measures of facial expressions, startle response, and reinforcement proxies (e.g. delay discounting).

More recently, researchers have started to investigate whether craving can be reliably indexed using neuroimaging techniques such as functional magnetic resonance imaging. In such studies, researchers attempt to assess a patient's intensity of craving using patterns of activity in various regions of the brain. The brain areas most commonly activated across studies of cue-provoked craving include those associated with executive control, and emotional and cognitive learning and processing. Identification of these areas is important not only to understand the neural underpinnings of craving but also to begin to predict, understand, and perhaps eventually manipulate the neural underpinnings of successful regulation of craving. In the case of appetitive behaviors, the ability to regulate craving is likely vital to forestall relapse, lending importance to the investigation of such regulatory processes. Such a neurocognitive model of self-regulation seeks to understand the interactions between brain regions that have been identified as being important to the subjective experience of craving and can be applied to the study of either withdrawal or cue-induced craving. Of particular interest, findings from brain imagining studies across a range of dependence-producing substances suggest that cravings may be the same (or at least similar) regardless of the stimulus that provoked them. Across substances, similar patterns of brain activity are observed under conditions that generate cue-induced cravings, suggesting a shared circuitry for craving across substances. If this is indeed the case, it suggests the tantalizing possibility of the development of generic (i.e. behavior nonspecific) treatments for the successful regulation of craving in the future.

Such non–self-report measures of craving are typically viewed as correlates of craving or peripheral indicators of an individual's subjective experience of craving, meaning that although they may appear to be more objective, they are actually more distally related to the experience of craving and hence potentially poorer measures of the actual craving experience. For example, it may be difficult to know if brain activation in response to a stimulus in the laboratory is reflective of craving, the process of regulation of that craving, or a combination of the two. These methodological issues may become more pronounced during certain conditions (e.g. if the substance in question is readily available, thus tending to engender greater experience of craving) and in certain

subject populations (e.g. in abstinence-seeking substance users, who may tend to resist their craving). A further issue with using objective proxy measures of craving is that these measures are not uniquely related to craving. The objective measures noted above are all subject to variation that is unrelated to an individual's experience of craving; thus, it is difficult to tease apart whether observed fluctuations in these measures are true indications of changes in craving, or whether they are simply indexing variation in unrelated phenomena. Nevertheless, despite these limitations, given that self-report measures of craving are by no means a perfect index of the craving construct, such additional indirect measures may be viewed as interrelated components that comprise the phenomenon of craving.

The type of measure used (self-report or physiological) traditionally does not differ depending on the way that the experience of craving has been induced. Such an approach is born out of the belief (explicit or otherwise) that how craving is induced, be it via abstinence or via cue exposure, does not fundamentally change the nature of the craving itself. To put it more simply: all cravings are fundamentally the same regardless of how they are generated. However, the assumption that abstinence-induced and cue-induced cravings are simply just the same phenomenon induced through different mechanisms has not been extensively tested, although as noted earlier, recent brain research does suggest similarities to craving across substances of dependence, which is suggestive of a common experience of craving.

THE STUDY OF CRAVING: LABORATORY AND FIELD-BASED RESEARCH METHODOLOGIES

To truly understand craving, researchers need to develop methods to apply those tools in real-life situations where individuals experience craving in real time. While this can be, and indeed has been, conducted in real-world situations (i.e. in observational field studies), most of our understanding of the intensity, duration, and motivational significance of craving (i.e. its relationship to behavioral change) comes from detailed observations taken in laboratory settings.

Craving has been studied extensively in laboratory settings for decades. Such studies are generally referred to as cue reactivity studies because they traditionally utilize situational cues, or stimuli, to artificially invoke intense cravings under controlled conditions. The standard cue reactivity research paradigm is as follows: a participant undergoes a baseline assessment, which may include both psychological (e.g. cigarette craving before cue exposure, mood rating) and/or objective physiological (e.g. heart rate) measures. Next, the participant is exposed to a cue or stimulus that has been designed to induce craving. During and/or following this cue exposure period, the participant then again completes a battery of assessments similar to those administered at baseline. Differences in measures before and after exposure to the target cues are then used to calculate the magnitude of the craving induced, based on the assumption that exposure to the cues will influence the individual's level of craving. Exposure to a neutral cue may also be used in a separate session as a control.

The actual cue or stimulus used to induce craving obviously varies depending on the nature of the craving that one is trying to induce. If the participants are nicotine dependent, for example, the cue may be a lit cigarette. However, if the participants suffer from a gambling disorder, then researchers may choose to use a gambling-specific cue, such as poker chips or a pack of cards. Furthermore, researchers can choose whether to use physical or nonphysical stimuli. Examples of nonphysical exposure to stimuli that have been used include visual cues (e.g. showing participants pictures of relevant stimuli) or imagery (having participants imagine that they are in the presence of relevant stimuli). Some more recent laboratory studies have used virtual reality in an attempt to recreate the more complex environmental stimuli that individuals encounter in the real world (i.e. outside the laboratory setting). In general, nonphysical stimuli have been found to yield less robust increases in craving than physical ones, perhaps because physical stimuli are richer more detailed stimuli, but in general they are easier to use and make it possible to expose participants to a broader range of stimuli. In an attempt to make them more salient and hence more potent, some studies that utilize nonphysical cues have attempted to personalize these cues such that places or things that individuals identify as cues in their everyday lives can be incorporated into cue presentations within the laboratory. As discussed earlier, researchers have used two primary mechanisms for inducing craving in individuals: abstinence and cue exposure. Although cue exposure is the most commonly used laboratory cue induction strategy implemented, abstinence has also been used in some studies of craving using similar designs. The study of abstinence-induced cravings in laboratory settings, however, is less common due, in part, to the practical complications of conducting such studies. In the case of drug studies, for example, an abstinence induction procedure requires recruiting drug dependent individuals and then asking them to abstain from drug administration for a set duration of time; a procedure that is both uncomfortable for the participant and potentially time-consuming for the experimenter.

Cue reactivity studies have allowed researchers to closely explore topics such as the role of cues in

provoking craving, but their artificial nature means that it is difficult to know how well these findings generalize to real-world experiences. Furthermore, cue reactivity studies are limited practically in terms of the duration that craving can be monitored, meaning that they are generally unsuitable for the study of the extended time course of craving, or the effect of these patterns on behavior. For these reasons, researchers have also attempted to study such craving outside the laboratory, in natural real-world settings. Such longitudinal observation studies have the advantage of assessing the relationship between craving and target behaviors within the context in which they naturally occur; that is, within an individual's general day-to-day life.

One relatively recent development in the field-based study of craving has been the use of real-time measurement (e.g. ecological momentary assessment (EMA)). This approach avoids retrospective recall by having participants report their experience of craving as it is happening. Participants may be instructed to report their craving at particular milestones or events (e.g. when they are about to use a drug or about to relapse after changing their behavior), or their craving may be monitored by randomly sampling their craving state over the course of the waking day (e.g. by beeping them at random times to ask about their craving). This type of field-based real-time data allows for collection of rich data over time, in individuals' natural environments.

As discussed earlier, some cravings are believed to be induced through exposure to situational stimuli. Although this can and has been studied within a laboratory setting, in order to truly understand the behavioral significance of such craving, we need to observe them, and their consequences, under real-world conditions. However, accurately monitoring craving within a real-world setting is more complicated than doing so in a laboratory. Perhaps the most common method of assessing craving within a participant's natural environment is to use retrospective recall: that is, participants report how much craving they experienced, and/or how frequently they experienced craving, over a given period of time (e.g. the previous week). Asking a participant to report how they felt at some previous point in time, however, involves the process of recall: participants need to think back over the defined period to remember how much craving they experienced. Such an approach is problematic because recall has been found to be both fallible (i.e. people forget) and potentially biased (i.e. systematically incorrect).

In an attempt to overcome some of these issues, researchers have utilized diary methods, where participants complete daily (or more frequent) assessments of their craving. More sophisticated methodologies utilize handheld computers to administer surveys of craving in near real-time as described above, further removing the opportunity for recall bias to influence the study results.

Regardless of the data collection strategy used, field-based monitoring of craving allows for the measurement of the natural history of craving and the study of temporal patterns. Together with results gleaned from cue reactivity studies, these studies have helped researchers to better understand the relationship between craving and appetitive behaviors. An overview of the results from these studies is the focus of the next section.

RELATIONSHIP BETWEEN CRAVING AND BEHAVIOR

As discussed earlier, although the proposed mechanism of action differs, all theories of craving to some extent acknowledge their role in motivating, or driving, appetitive behaviors. Clinically, across drugs of dependence and appetitive behaviors in general, craving is one of the symptoms that most concerns dependent individuals who are interested in quitting and, understandably, is one of the symptoms that they commonly seek to ameliorate through treatment. A cornerstone of treatment for appetitive behavior is aiding individuals to strengthen their own ability to regulate craving during high-risk situations, such as stressful situations or situations involving relevant cue exposure. Typically, reaching this overarching treatment goal may be achieved through a combination of pharmacologic and behavioral therapy. From a research perspective, a better understanding of the process of craving – and self-regulation in the face of craving – is central to improving health across disease states. Thus, craving is an exemplary condition for study, because unchecked, it often leads to behavior and outcomes that are against a person's interest and often contrary to their plans (e.g. cigarette craving during a quit attempt may lead to relapse and the universally undesirable high risk of multiple diseases and or markedly premature death).

Findings from both observation field studies and laboratory-based studies suggest that a drug-dependent individual's concern regarding the experience of craving is well founded. Extant research suggests that increases in craving are associated with increased likelihood of engaging in a given behavior in real time. For example, real-time data collected via handheld computers have shown that day-to-day variation in craving during a smoking cessation attempt accurately predicts the likelihood of lapsing. There is some evidence that craving predicts cessation success even when the severity of withdrawal symptoms (such as negative affect) is accounted for; suggesting that craving is more than just simple drug withdrawal. In addition, during conscious

efforts to abstain, individuals often cite increased craving as a significant contributor to resuming use of the drug.

The relationship between craving and drug use is seen not only in observation studies but also under controlled laboratory conditions. For example, cue reactivity studies have shown that artificially induced increases in craving are associated with subsequent drug use in individuals not currently attempting to abstain.

Another source of evidence supporting the relationship between craving and behavior can be found in the success of pharmacotherapies that target, or purport to target, craving. A prime example of this is nicotine replacement therapy (NRT) for the treatment of nicotine dependence. NRT was developed to mitigate the loss of nicotine that occurs during cessation attempts, thereby reducing withdrawal symptom severity and craving and making abstinence more sustainable. Since its development, numerous studies have shown that NRT promotes abstinence and it reduces craving severity during a cessation attempt. The one study that directly tested whether the reduction in craving and withdrawal symptom severity did indeed account for the effect of NRT on cessation found some support for the proposed mechanism of action: although incomplete, NRT's ability to promote cessation was found to be partially mediated via its effects on craving. The fact that medications that aim to reduce craving have been found to promote cessation is further evidence of the relationship between craving and appetitive behavior.

This is not to say that the relationship between craving and behavior has always been clearly supported. Some field-based and laboratory studies have failed to show the hypothesized relationship. However, a number of methodological issues have been proposed that may explain some of these inconsistent findings. Being an abstract concept, craving is difficult to accurately measure, particularly in real-world situations. A growing number of studies have utilized EMA real-time data collection methods described above, but the majority of field-based evidence has relied on retrospective recall and hence is susceptible to recall bias and/or error, perhaps clouding a legitimate relationship between craving and appetitive behaviors.

In addition to the difficulties involved in the assessment of craving itself, a second methodological issue that faces researchers interested in exploring the role of craving in appetitive behaviors has been first identifying, and then controlling for, factors that may moderate the effect of craving. A good example of this is the effective use of coping strategies. If unmeasured, the successful use of strategies to resist craving can obscure the relationship, because they potentially allow high levels of craving to occur without increasing the probability of the target behavior occurring; the effect of craving on behavior is moderated by a third variable, in this case the use of coping mechanisms. Failure to first assess, and then account for, such moderating variables can account for some of the negative findings in this area.

A final methodological challenge for researchers is that there is some evidence that the relationship between craving intensity and behavior may not be completely linear in nature. There is evidence of a positive linear relationship between craving and the probability of drug use at lower levels of craving intensity but, once craving reaches a certain intensity or threshold, the relationship asymptotes, with further increases in craving not increasing the probability of drug use. The exact intensity of this threshold likely differs from person to person, and indeed likely even from situation to situation within the same individual. One important implication of this nonlinear response curve is that a relationship between craving and use will only be seen at low to moderate levels of craving. Once craving intensity reaches a threshold, increased craving is no longer associated with increased use. This may account for why some studies fail to observe a relationship between craving and use: craving studies often purposely focus on high levels of craving and thus are, in effect, studying the flat part of the curve in the relationship.

The question of whether cue-induced or abstinence-induced cravings are more important in maintaining appetitive behavior has not been well addressed to date. As noted earlier, it is standard practice to simply assess the level of craving irrespective of how it is induced. Findings from observational field studies suggest that cue-induced cravings may be particularly important in determining the outcome, or at least the failure, of a drug cessation attempt. The regular/timely drug dosing patterns observed when individuals are not interested in maintaining abstinence, however, suggest that abstinence-induced cravings may be more important in terms of maintaining the behavior during such periods. More work needs to be done in this area to determine whether there are functional differences between cue-induced and abstinence-induced cravings in terms of maintaining appetitive behaviors, or whether they are simply the same experience provoked via different mechanisms.

SUMMARY

Craving is an important, albeit nebulous, contributor to the maintenance of drug use and other appetitive behaviors. Its strict definition may be the subject of continued debate, but its role in driving behavior has been, and continues to be, upheld by both subjective reports and scientific reviews. Conceptually, craving can be seen as a final-common-pathway expression of motivations for such behaviors.

International Data on the Prevalence and Correlates of Comorbid Substance Use and Psychiatric Disorders

Katherine L. Mills and Christina Marel

University of New South Wales, Sydney, NSW, Australia

OUTLINE

The term comorbidity refers to the co-occurrence of two or more disorders or diseases in an individual within a defined period of time. Although the focus of this chapter is on the co-occurrence of substance use and mental disorders, it is important to note that there are many different types of comorbidity evident among individuals with substance use disorders (SUDs). Indeed, the most common form of comorbidity among people with SUDs is the occurrence of more than one SUD. Other conditions that are often found to co-occur with SUDs are physical health conditions (e.g. cirrhosis, hepatitis, heart disease, diabetes), intellectual and learning disabilities, cognitive impairment, and chronic pain.

The co-occurrence of mental disorders with alcohol, tobacco, and other drug disorders is not a new phenomenon; however, there has been an increase in awareness of this phenomenon due to the development of structured diagnostic interviews, and their use in large-scale epidemiologic surveys of mental health. Epidemiological surveys provide the opportunity to observe patterns of psychiatric comorbidity in the general population, providing valuable information about the need for services within that population. They also overcome biases inherent in studies of treatment-seeking samples.

Over the last three decades, a growing number of representative population surveys utilizing fully structured diagnostic interviews have been conducted around the world. These surveys have provided invaluable data on the prevalence and correlates of comorbid mental health and SUDs. The vast majority of research examining the population prevalence of comorbid mental health and SUDs has come from the United States, but studies have also been conducted in Australia

and New Zealand, and Europe (Table 50.1). In addition to these studies, a number of population surveys examining mental health and substance use have been conducted in other countries from the America, Africa, the Eastern Mediterranean, Europe, the Western Pacific, and South east Asia as part of the World Mental Health (WMH) Survey Initiative. At the time of writing, however, only data from the aforementioned countries had been published in relation to comorbidity. This chapter presents a summary of the major findings of these studies with regard to the prevalence and correlates of comorbidity. The strengths and limitations of these studies are also discussed, as well as future directions for research.

UNITED STATES

Five large-scale epidemiologic surveys have been conducted in the United States since 1980. These include the Epidemiologic Catchment Area (ECA) survey, the National Comorbidity Survey (NCS) and its replication, as well as Waves I and II of the National Epidemiologic Study of Alcohol and Related Conditions.

Epidemiological Catchment Area Survey

The first survey designed to derive population prevalence estimates of substance use and mental disorders was the landmark ECA survey. Participants were derived from households as well as institutional settings including long-term mental hospitals, nursing homes, and penal institutions, from five catchment areas in the United States. The diagnostic interview schedule (DIS) was used to estimate the prevalence of selected Diagnostic Statistical Manual Version III (DSM-III) mood disorders (mania, dysthymia, bipolar disorder, major depression, bipolar disorder), anxiety disorders (obsessive–compulsive disorder (OCD), phobia, panic), SUDs (alcohol and drug abuse and dependence), psychotic disorders (schizophrenia and schizophreniform), somatization, antisocial personality, and anorexia nervosa.

The ECA documented the high prevalence of substance use and mental health disorders, and substantial comorbidity between them. One-third of the sample met criteria for either a substance use or mental disorder during their lifetime, and 54% of those met criteria for more than one. The odds of having a comorbid mental disorder were 2.7 times higher among those with an SUD compared to the rest of the population. Over one-third (37%) of those with an alcohol disorder, and 53% of those with a drug use disorder, also met criteria for a mental disorder during their lifetime. Conversely, 29% of those with a mental disorder met criteria for an SUD (22% alcohol, 15% other drugs).

In terms of specific SUDs, mental disorder was most prevalent among individuals with cocaine, barbiturate, and hallucinogen use disorders (76, 75, and 69%, respectively), followed by those with opiate, amphetamine, marijuana, and alcohol use disorders (65, 63, 50, and 37%, respectively). Strong associations were observed with comorbid ASPD (odds ratios (ORs) 8.3–29.2), schizophrenia (ORs 3.3–13.2), affective (ORs 1.9–6.6), and anxiety disorders (ORs 1.5–5.0).

The ECA study pioneered epidemiologic research pertaining to mental health in many ways. However, as the sample was not nationally representative, there were concerns regarding the generalizability of the study findings to the broader population. These concerns were addressed a decade later, when the NCS was conducted.

National Comorbidity Survey

The first national representative epidemiologic survey to be conducted in the United States was the NCS. As the name suggests, one of the primary aims of the NCS was to examine patterns of comorbidity. The NCS interviewed a nationally representative noninstitutionalized sample of men and women from the 48 contiguous states. A modified version of the Composite International Diagnostic Interview (CIDI) version 1.1 was used to assess for the presence of selected Diagnostic Statistic Manual Version III Revised (DSM-III-R) mood disorders (major depression, mania, dysthymia),

anxiety disorders (panic disorder, agoraphobia, social phobia, generalized anxiety disorder (GAD)), SUDs (alcohol and drug abuse and dependence), and antisocial personality disorder (ASPD) during respondents' lifetime. Nonaffective psychosis (a category made up of schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, and atypical psychosis) was determined using a combination of the CIDI interview and structured clinical interviews. The past 12-month diagnoses were made in the subsample of respondents who qualified for the lifetime diagnosis and who reported at least one symptom in the 12 months prior to interview.

Like the ECA, the NCS documented high rates of comorbidity between substance use and mental health disorders. Forty-eight percent of the sample met criteria for at least one mental or SUD during their lifetime and 29% in the preceding 12 months. Just 21% of all the lifetime disorders occurred in respondents with a lifetime history of just one disorder, meaning that the vast majority of lifetime disorders in this sample (79%) were comorbid.

The strongest association observed was between substance use and antisocial personality disorder (OR 13.9). The likelihood of having a co-occurring affective or anxiety disorder in one's lifetime or in the last 12 months was 2–3 times higher among individuals with SUDs. Associations were particularly strong in relation to mania and GAD. The odds of receiving a lifetime diagnosis of nonaffective psychosis were 3.7 times higher among those with SUDs. All disorders were more strongly associated with dependence, rather than abuse. Associations also tended to be stronger in relation to drug use disorders as opposed to alcohol use disorders. Examination of the temporality of disorders revealed that among people with a history of both a mental and SUD, the mental disorder typically occurred first.

Examination of the correlates of comorbidity revealed that the likelihood of having three or more disorders within one's lifetime was positively associated with being female, of a younger age cohort, lower levels of education, and lower income. Conversely, African-American ethnicity was associated with a decreased likelihood of lifetime comorbidity. The same correlates were observed for current comorbidity, with the exception of race; current comorbidity was more likely to be present among individuals of Hispanic ethnicity. Current comorbidity was also more likely to occur among those living in major metropolitan areas.

National Comorbidity Survey-Replication

The NCS-R was conducted between 2001 and 2003, providing some of the most recent estimates of the prevalence and correlates of Diagnostic and Statistical Manual IV (DSM-IV) mental disorders in the United States. Using the WMH–CIDI, the NCS-R measured the lifetime prevalence of a wide range of mental health disorders, as well as the severity of these disorders, among a nationally representative sample of respondents from the contiguous states. The disorders included were anxiety disorders (panic, GAD, agoraphobia without panic, specific, social, post-traumatic stress disorder (PTSD), OCD, separation anxiety disorder), mood disorder (major depression, dysthymia, bipolar I or II), impulse control disorders (oppositional defiant, conduct, attention deficit/hyperactivity, intermittent explosive), and SUDs (alcohol and drug abuse and dependence). Like the NCS, past 12-month diagnoses were made in the subsample of respondents who qualified for lifetime diagnosis and who reported at least one symptom in the 12 months prior to interview.

The NCS-R estimated that 46% of the population met criteria for one or more DSM-IV disorders at some point in their lives, and 26% met criteria for a disorder in the preceding 12 months. The NCS-R found a strong association between substance dependence and mental disorders. The relationship between all mental disorders and any substance use was significant. The strongest association was with externalizing disorders (i.e. conduct disorder, oppositional defiant disorder, attention deficit-hyperactivity disorder, intermittent explosive disorder). After controlling for age, gender, and ethnicity, people with an externalizing disorder were over four times more likely to meet criteria for lifetime dependence on alcohol, nicotine, or other drugs. Individuals with mood and anxiety disorders were 2.5–3.5 times more likely to meet criteria for lifetime dependence. As in the NCS, associations tended to be stronger in relation to drug dependence as opposed to alcohol or nicotine dependence. Further, the onset of mental disorder was more likely to occur prior to the onset of dependence, particularly in relation to externalizing and anxiety disorders. Mood disorders tended to have their onset both before and after the onset of dependence.

Demographic correlates of comorbidity have received little attention in analyses of the NCS-R data to date. Similar to the NCS, however, comorbidity was positively associated with younger age cohorts. In regard to clinical correlates, the NCS has made an important contribution by examining the association between severity of illness and comorbidity. In particular, this study found that disorder severity was strongly associated with comorbidity, even though the temporally primary disorder was often relatively mild. Twenty-five percent of those with two disorders and one-half of those with three or more disorders were classified as having serious mental health disorders.

It should be noted that the version of the CIDI used in the NCS-R contained a serious fault in that respondents were required to meet criteria for abuse before being asked about dependence. This is of concern as this condition is not a requirement of the DSM-IV and a significant number of people have been shown to meet dependence criteria without meeting criteria for abuse. Thus, estimates of prevalence and associations between disorders may be biased.

National Epidemiologic Survey on Alcohol and Related Conditions

The National Epidemiological Survey on Alcohol and Related Conditions (NESARC) was conducted between 2001 and 2002 (Wave I), and a follow-up of the same respondents occurred between 2004 and 2005 (Wave II). NESARC was a nationally representative sample of those living in households or group quarters (i.e. boarding houses, non-transients hotels/motels, shelters, group homes) from all US states (contiguous and noncontiguous). The group quarters sampling frame captured important subgroups of the population with heavy substance use patterns that are often not included in general population surveys. With sample sizes of 43 093 and 34 653 in Waves I and II, respectively, the NESARC represents the largest comorbidity survey conducted to date.

The Alcohol Use Disorder and Associated Disabilities Interview Schedule-DSM-IV version (AUDADIS-IV) assessed for the presence of mood disorders (major depression, bipolar I and II, and dysthymia), anxiety disorders (panic with and without agoraphobia, social and specific phobia, GAD), and SUDs (alcohol and drug abuse and dependence). Full diagnoses were obtained for both lifetime and 12-month disorders. Personality disorders assessed on a lifetime basis at Wave I included DSM-IV avoidant, dependent, obsessive–compulsive, paranoid, schizoid, and antisocial. Additional personality disorders assessed at Wave II included borderline, schizotypal, and narcissistic personality disorders. NESARC was the first US population survey to examine the prevalence of personality disorders beyond ASPD.

Analyses of data from Wave I of the survey found that individuals with current alcohol use disorders were significantly more likely to meet criteria for a co-occurring mood, anxiety, or personality disorder, even after controlling for demographic characteristics and the presence of other comorbid psychiatric disorders (ORs 1.4, 1.3, and 1.4, respectively). After controlling for the aforementioned factors, individuals with drug use disorders were also more likely to meet criteria for a co-occurring mood (OR 1.8) or personality disorder (OR 2.2), but they were no more likely to experience an anxiety disorder. Similar ORs were observed with respect to the personality disorders assessed at Wave II. Again, comorbidity was more strongly associated with dependence than abuse, and with drugs as opposed to alcohol.

Unlike the ECA and the NCS surveys, the NESARC was able to differentiate between substance-induced and independent mood and anxiety disorders. It was estimated that 20% of individuals with an SUD met criteria for at least one independent mood disorder during the same 12-month period, and 18% met criteria for at least one independent anxiety disorder. Less than 1% of comorbid mood and anxiety disorders were classified as being substance-induced. Twenty-nine percent of those with an alcohol use disorder and 48% those with a drug use disorder met criteria for a personality disorder.

EUROPE

Netherlands Mental Health Survey and Incidence Study

The Netherlands Mental Health Survey and Incidence Study (NEMESIS) was a study of 7076 respondents from 90 Dutch municipalities in 1996. In keeping with the NCS, the NEMESIS used the CIDI version 1.1 to assess selected DSM-III-R disorders, including mood disorders (depression, dysthymia, bipolar), anxiety disorders (panic, agoraphobia, simple, social, GAD, obsessive–compulsive), SUDs (alcohol or drug abuse and dependence), eating disorders (anorexia and bulimia nervosa), and schizophrenia.

Forty-one percent of respondents met criteria for at least one mental or SUD during their lifetime: 23% in the past 12 months. Forty-five percent of those with a psychiatric disorder had suffered more than one. The overall population prevalence comorbidity between substance use and anxiety and/or affective disorders was estimated to be 2%. One-quarter of those with a current SUD had a comorbid disorder (15% mood disorder, 19% anxiety disorder). Conversely, 17% of those with a mood disorder and 13% of those with an anxiety disorder had a comorbid SUD.

The correlates of current comorbidity were similar to those observed in the NCS. The likelihood of having two or more disorders within the past 12 months was associated with being female, younger age cohorts, lower levels of education and income, being out of the workforce, and living in an urban area. Additionally, the NEMESIS found that comorbidity was more likely to occur among those whose parents had a history of psychiatric disorder and those with a history of abuse or neglect.

Further analyses were undertaken examining the correlates of specific comorbidities. Among those with

SUDs, comorbid mood and anxiety disorders were more likely to occur among females, those with lower levels of education, those whose parents had a history of psychiatric disorder, and those with a history of abuse or neglect. Comorbid mood disorders were also more likely to occur among those aged between 35 and 54 years and those who were unemployed.

European Study of the Epidemiology of Mental Disorders: Belgium, France, Germany, Italy, Netherlands, and Spain

The European Study of the Epidemiology of Mental Disorders (ESEMeD) was a cross-sectional community survey administered between 2001 and 2003 to 21 425 respondents across six European countries (Spain, Italy, Germany, Belgium, France, and Netherlands). It is the largest and most comprehensive population-based epidemiological study conducted in Europe to date. Similar to the other epidemiological studies discussed in this chapter, the ESEMeD used the WMH-CIDI to assess the prevalence of substance use and mental disorders. Current (past 12 months) comorbidity was examined in relation to selected DSM-IV mood (major depression and dysthymia), anxiety (GAD, social phobia, specific phobia, PTSD, agoraphobia, and panic disorder), and alcohol use disorders (abuse and dependence).

Twenty-three percent of those with an alcohol disorder also had a co-occurring mood or anxiety disorder, which translates into an overall population prevalence of 0.3%. Alcohol dependence was more frequently comorbid with other disorders (28%) than alcohol abuse (21%). Alcohol abuse and dependence were associated with an increased likelihood of most mood and anxiety disorders. Neither abuse nor dependence was associated with comorbid dysthymia or PTSD. Alcohol dependence was also not related to social phobia.

Demographic correlates of comorbid substance use and mental disorders were examined, however, no significant relationships were observed. This lack of difference most likely reflects a lack of statistical power to detect differences, rather than a true absence of differences.

AUSTRALIA

Australia has conducted two National Surveys of Mental Health and Wellbeing (NSMHWB). The 1997 survey examined the 12-month prevalence of selected International Classification of Diseases 10th revision (ICD-10) anxiety disorders (panic, agoraphobia, social phobia, OCD, PTSD, GAD), affective disorders (major depression, dysthymia, bipolar), and SUDs (alcohol and drug abuse/harmful use and dependence) using the CIDI version 2.1. The 2007 NSMHWB assessed for the lifetime prevalence of the same disorders using the CIDI version 3.0. Past 12-month diagnoses were made in the subsample of respondents who qualified for the lifetime diagnosis and who reported at least one symptom in the 12 months prior to interview.

In 1997, it was estimated that 23% of the population met ICD-10 criteria for a substance use or mental disorder, and approximately 25% of those met criteria for more than one class of disorder. Close to one-half (48%) of females and 34% of males with an alcohol use disorder had a comorbid affective or anxiety disorder. Two-thirds of both males and females with a drug use disorder met criteria for a comorbid affective or anxiety disorder. In terms of overall population prevalence, these figures translate to 3% of males and 2% of females meeting criteria for a comorbid substance use and affective and/or anxiety disorder within a 12-month period.

Similarly, the 2007 survey estimated the prevalence of any lifetime mental disorder to be 45% and the prevalence of any 12-month mental disorder to be 20%. One in four people (25%) with a 12-month mental disorder were diagnosed with more than one disorder. One in five (21%) of those with an SUD also met criteria for an affective disorder and one in three (33%) met criteria for an anxiety disorder. Analogous to the 1997 survey, the overall population prevalence of comorbid substance use and affective and/or anxiety disorder was estimated to be 3% for males and 2% for females.

In both surveys, females were more likely to experience comorbid anxiety and affective disorders, whereas males were more likely to experience these disorders in combination with a SUD. Further analyses of the demographic correlates of comorbidity in the 1997 survey found that having three or more disorders within the last 12 months was associated with younger age cohorts, being unmarried, and not in the workforce. Comorbidity was not associated with sex, level of education, ethnicity, or urbanicity. Analyses of the 2007 survey demonstrated a strong relationship between comorbid mental disorders and severity. More than half (54%) of those with comorbid classes of mental disorder experienced severe levels of impairment, compared to only 7% of those with one class of mental disorder.

NEW ZEALAND

New Zealand conducted its first nationally representative epidemiological study in 2003 as part of the World Mental Health Survey Initiative. The interview was based on the CIDI version 3.0, which assessed selected DSM-IV anxiety disorders (panic disorder, agoraphobia

without panic, specific phobia, social phobia, GAD, PTSD, and OCD), mood disorders (major depressive disorder, dysthymia, and bipolar disorder), SUDs (alcohol and drug abuse or dependence), and eating disorders (anorexia and bulimia). Like the NCS, the past 12-month diagnoses were made in the subsample of respondents who qualified for the lifetime diagnosis and who reported at least one symptom in the 12 months prior to interview.

Thirty-nine percent of the population met criteria for a lifetime mental health or SUD; 21% in the past 12 months. Close to one-half (49%) of those who met criteria for a disorder during their lifetime met criteria for more than one. The corresponding figure for the preceding 12 months was 37%.

Close to one-third (29%) of those with a 12-month SUD had a comorbid mood disorder; 40% had a comorbid anxiety disorder. SUDs were strongly and positively associated with all mood and anxiety disorders. In particular, strong associations were observed between drug dependence and dysthymia (OR 15.6), bipolar disorders (OR 10.6), and panic disorder (OR 10.4). Alcohol dependence was most strongly related to bipolar disorders (OR 11.8), OCD (OR 11.0), and panic disorder (OR 8.8).

There was a clear relationship between increasing numbers of disorders and case severity. Sixty percent of those with three or more disorders were classified as serious, as opposed to 12% of those with one disorder. There was also a clear association between comorbidity and suicidal behavior.

DISCUSSION

Understanding the prevalence and distribution of comorbidity is important for several reasons. Recognizing the clustering of disorders within individuals gives a greater appreciation of how and in whom the burden of psychopathology is concentrated. Estimates of current comorbidity provide important information regarding the treatment needs of the population at any given time and is essential for health service planning and delivery. An understanding of lifetime patterns of comorbidity provides opportunities for the prevention of the secondary disorders.

The data presented in this chapter demonstrate the substantial comorbidity experienced by individuals with SUDs. Direct comparisons between surveys are difficult due to differences in terms of the number and types of disorders assessed, the assessment criteria and survey instrument used, the reference timepoint, and the sampling procedures (to name a few). Despite these differences, individuals with SUDs were consistently found to be at greater risk of having comorbid mood (affective) and anxiety disorders around the world. Although measured less frequently, strong associations were also found in relation to personality disorders and psychosis.

Although the overall population prevalence of comorbidity appears to be relatively small (<3%), the burden attributed to this group is considerable, with more recent surveys consistently demonstrating strong positive associations between comorbidity, severity of illness, and disability. Thus, this seemingly small proportion of the population confers a substantial cost to the community.

The population surveys reviewed in this chapter indicate that between one-third and one-half of individuals with SUDs meet criteria for a comorbid mental disorder at some point in their lives, and 20–25% will experience these comorbid disorders in any 12-month period. Given that the majority of epidemiologic surveys have limited their focus to household populations and excluded population segments in which the prevalence of mental health and SUDs are known to be high (e.g. the homeless and those living institutions and treatment facilities), these estimates are likely to be conservative. Studies specifically targeting these populations have demonstrated that comorbidity among these groups is typically the norm rather the exception.

A further reason as to why these estimates are likely to be underestimates of the true prevalence is that, for logistical reasons, epidemiologic surveys of mental health focus only on selected mental disorders, rather than the full spectrum of possible mental disorders. Thus, many disorders are not taken into account. Indeed, the estimates presented in this chapter pertain largely to the co-occurrence of mood and anxiety disorders. It should also be borne in mind that while the focus here was on individuals who meet criteria for a diagnosis of comorbid mental health disorder, there are a large number of people with SUDs who may fall into the category of "diagnostic orphans": individuals who display a number of *symptoms* of disorders while not meeting criteria for a *diagnosis* of a disorder. Although these individuals may not meet full diagnostic criteria according to the classification systems, their symptoms may nonetheless impact significantly on their functioning and require intervention.

The fact that findings have been largely consistent across surveys conducted in different parts of the world using different methodologies is evidence of the robustness of the association between comorbid substance use and mental disorders. However, the breadth of countries in which comorbidity has been examined in nationally representative population surveys is relatively small, and restricted to nations from the developed world. It is unknown to what degree these findings can be generalized to the populations of other countries, particularly

those of the developing world. Estimates and associations may vary in countries where there are alternate health-care policies and health service delivery systems. Furthermore, differences in patterns of substance use, types of substances used, and cultural understandings of mental disorder may also lead to variations. Therefore, while studies conducted internationally may be informative to nations where local data are not available, it should be viewed with caution. Further research examining substance use and mental health comorbidity in other countries, in particular developing nations, would represent a valuable addition to the literature.

The knowledge base surrounding the association between mental disorders and particular types of SUDs could also be broadened. The predominance of research to date suggests that associations between comorbid mental and SUDs are stronger in relation to dependence as opposed to abuse, and among those with drug as opposed to alcohol use disorders. However, limited analyses have been conducted comparing the patterns and distribution of mental disorder between drug classes. Studies that do distinguish between drug type indicate that associations may be stronger in relation to drugs with a high dependence liability.

The finding that mental disorders tend to have their onset prior to SUDs highlights the importance of identification and early intervention in order to prevent the progression of primary disorders and the development of subsequent SUDs. Limited data are available with regard to the correlates of comorbidity more broadly, let alone with regard to comorbidity between substance use and mental disorders specifically. The data that are available nonetheless indicate that comorbidity is positively associated with female gender, younger age cohorts, unemployment, and lower levels of income. Findings regarding education, urbanicity, and ethnicity have been mixed. Consistent with research among clinical samples, a history of childhood abuse or neglect and parental psychiatric history appears to play an important role in the development of comorbid disorder. Further epidemiologic research identifying the correlates of comorbidity would be beneficial in informing the development of targeted interventions. Nonetheless, these findings point to the importance of interventions aimed at preventing primary disorders.

Needless to say, it is crucial that epidemiological information be as up-to-date and accurate as possible to reflect changes in nosology. An issue of concern for future epidemiologic surveys is the need for adequate response rates. As evident from Table 50.1, response rates have been declining in recent years. This phenomenon is not restricted to surveys of mental health and has been observed in relation to general population surveys more broadly. Declining response rates raise concerns regarding the validity of the estimates and associations derived, as the likelihood of response bias is increased (e.g. those with mental illness having higher survey refusal rate than those without or vice versa). It is therefore important that future epidemiologic surveys undertake measures to increase response rates so that the estimates and associations derived are representative of the population under investigation.

CONCLUSION

The epidemiologic surveys discussed in this chapter have provided crucial information about the patterns and distribution of comorbid mental health and SUDs in the United States, Europe, Australia, and New Zealand. Comorbidity between substance use and mental disorders is a common occurrence, but a relatively small group bears an especially heavy burden. Despite the frequent occurrence of comorbid mental disorders among people with SUDs, much remains to be understood about comorbidity. In particular, little is known regarding the patterns and distribution of comorbidity in countries outside of the developed world, and there is a notable lack of epidemiological research focusing explicitly on the demographic or clinical correlates of substance use and mental disorders. Further research in these domains would provide useful information for the recognition of at risk individuals, the planning of population health initiatives, and the provision of appropriate interventions.

Models of Relationships between Substance Use and Mental Disorders

[*]Dartmouth Medical School, Lebanon, NH, USA [$]Dartmouth Psychiatric Research Center, Concord, NH, USA

OUTLINE

Numerous studies have demonstrated an elevated prevalence of substance use disorders (SUDs) among individuals with psychiatric disorders. Strikingly, the odds of co-occurring disorders are elevated by 1.5–2 times the general population rate among individuals with depression and anxiety disorders in these samples, but the odds are elevated 3–6-fold for individuals with schizophrenia or bipolar disorder. This has motivated attempts to understand why such high risks for SUDs occur in this population.

Many explanations have been proposed for the increased risk of SUDs in people with serious mental illness. Four general models of increased comorbidity include secondary psychiatric disorder models, secondary SUD models, common factor models, and bidirectional models. According to secondary psychiatric disorder models, substance use contributes to the onset of mental illness in individuals who would otherwise not have developed these disorders. Secondary SUD models propose that serious mental illness increases the person's chances of developing a SUD. Different models may account for comorbidity in individual patients, and more than one model may apply for a given individual over time, or in relation to different substances.

Before reviewing these models we note that much of the data on the prevalence of SUDs in serious mental illness are drawn from clinical samples, including some of the data from the Epidemiologic Catchment Area study. According to Berkson's fallacy, estimates of comorbidity are inflated when samples are obtained from treatment settings, as opposed to the general population, because either disorder increases the likelihood that individuals will receive treatment. As a result, estimates of comorbidity may be inflated by sampling bias. However, it is unlikely that this factor is sufficient to explain the high rates observed.

SECONDARY PSYCHIATRIC DISORDER MODELS

The theory that substance abuse can lead to serious mental illness has focused primarily on stimulants, hallucinogens, and cannabis because of their

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00051-6

psychotomimetic effects. In contrast, there is less evidence that alcohol use can contribute to onset of schizophrenia or bipolar disorder, and some debate as to whether it can mask their onset.

Models proposing that psychotomimetic drug use can lead to long-term psychotic disorders build on the catecholamine hypothesis of schizophrenia or mood disorders. Animal research has shown that repeated or continuous stimulant administration can lead to increased sensitivity of response, or behavioral sensitization. Similarly, increased electrophysiological and behavioral responses can be induced by repeated electrical stimulation or stimulant administration, referred to as kindling. Behavioral sensitization and kindling due to substance use have been suggested as mechanisms by which drug use may precipitate serious mental illness.

McLellan et al. followed 51 male veterans with at least yearly hospitalizations for drug abuse over a 6-year period. Although there were no differences in psychiatric symptoms initially, by endpoint 5 of 11 stimulant users had developed psychosis, and 8 of 14 depressant users had developed severe depression. However, if substance type predicted psychiatric diagnosis, then different diagnostic groups would tend to abuse different types of substances, which is not the case. There is no consistent association between psychiatric diagnosis and the specific types of substances abused by people with serious mental illness. Indeed, polysubstance misuse is the most common pattern.

Several studies have compared people who develop long-term serious mental illness following drug abuse to matched controls without SUDs. Most of these researches have failed to find consistent differences between these groups. Furthermore, there are no consistent differences between people with co-occurring disorders whose SUD developed before versus after the mental illness.

CANNABIS AS A PRECIPITANT OF PSYCHOSIS

Interest in the potential role of cannabis as a precipitant of psychosis was triggered by the intriguing findings of a landmark study by Andréasson and colleagues. Andréasson et al. reported that in a large 15-year prospective follow-up study of young men conscripted into the Swedish army, there was a strong association between history of cannabis use at conscription and later diagnosis of schizophrenia. Although this association was reduced when other variables were statistically controlled, it nevertheless remained significant. No associations were found between use of other drugs and the subsequent development of schizophrenia. Additional analyses indicated that the cannabis users who developed schizophrenia had a more rapid onset of illness characterized by positive symptoms than nonusers who developed schizophrenia, which the authors interpreted as supporting an etiologically distinct subgroup.

Since this study, several other population-based studies have demonstrated a relationship between cannabis use and the development of schizophrenia, controlling for possible confounders. The relationship between cannabis use and schizophrenia is dose-dependent, is stronger for earlier cannabis use, and is not modified by other drug use. Furthermore, cannabis use is associated with an earlier age of onset of psychosis in this population. In addition, Caspi and colleagues reported that adolescent cannabis use elevated risk for subsequent schizophreniform disorder, with use by age 15 conveying even higher risk than use by age 18, but only among those with a genetic marker for schizophrenia risk (see Section Genetic Factors). These studies are consistent with the stress–vulnerability model of schizophrenia, in which substance use may trigger the psychotic disorder in people who are vulnerable because of genetic or neurodevelopmental risk, where substance abuse serves as just one of many potential influences.

Neurobiological hypotheses were proposed by Müller-Vahl and Emrich to explain the relationship between cannabinoids and schizophrenia. The authors suggested that cannabis could influence the onset of psychosis through either exogenous or endogenous mechanisms. The exogenous hypothesis proposed that cannabis abuse could alter the endocannabinoid system, resulting in the onset or exacerbation of symptoms associated with schizophrenia. The endogenous hypothesis proposed that a disrupted endogenous cannabinoid system could influence the degree of psychosis experienced by patients with schizophrenia. This would support the notion that cannabis is a risk factor for either new onset of psychosis or exacerbation of symptoms in genetically predisposed people. In both of these mechanisms, the dysregulation of the cannabinoid system has potential to modify or interact with other neurotransmitter systems. Evolving understanding of the role and functions of the endocannabinoid system may help to reconcile the "Cannabinoid Hypothesis" described above with the well-described glutamatergic and dopaminergic systems that are associated with schizophrenia.

A central question that this research raises is whether cannabis use precipitates an earlier age of schizophrenia onset in people who would have developed the illness at a later age, or whether it causes schizophrenia in some vulnerable people who would otherwise not have developed the illness. If cannabis use causes schizophrenia in some people, one might expect to see increase in the prevalence of schizophrenia in countries where cannabis

use has increased. Two studies that addressed this question in birth cohorts in Australia between 1940 and 1979, and in the United Kingdom from 1996 to 2005, failed to find such an association. However, questions about the reliability of the diagnosis of schizophrenia over the time periods studied means that a possible increase in the incidence of schizophrenia due to the growth of cannabis use in a population cannot be ruled out.

Hickman and colleagues took a different approach to exploring the public policy implications of the association between cannabis use and the onset of psychosis. These researchers addressed the question of how many cannabis users would need to be prevented in order to prevent a single case of schizophrenia or psychosis, based on data collected in England and Wales. The results indicated that for men between 1007 and 8416 (depending on age) heavy cannabis users would need to be prevented, and for women between 1408 and 22 732 heavy cannabis users would need to be prevented, to prevent one case of schizophrenia. Approximately four to five times more cases of light cannabis use would need to be prevented to prevent the onset of schizophrenia. The results of this study suggest that the public health importance of preventing cannabis use to prevent schizophrenia is not clear.

Although the role of cannabis use in the precipitation of psychosis is unclear, there is strong evidence that cannabis interacts with the course of the illness. A large study based in Suffolk County, New York, suggested that there was an association between cannabis use and an adverse course of psychotic symptoms in patients who were newly diagnosed with schizophrenia spectrum disorders. This study followed psychotic symptoms over a 10-year follow-up period and is the longest assessment of its kind to date. It included over 200 participants recruited from 12 regional inpatient facilities. There were several findings in this work that provide insight into the relationship between cannabis and positive symptoms of schizophrenia. Of note, a positive relationship was established between the severity of psychotic symptoms and cannabis use, consistent with other studies. The mathematical modeling in the Foti study revealed a bidirectional nature in predicting outcomes. That is to say, not only did patients with prior cannabis use have more severe psychotic symptoms at the next assessment interval, but more severe psychotic symptoms also predicted future use of cannabis. A further implication is that there may be a reduction in the severity of psychotic symptoms with successful cessation of cannabis use.

While support for a simple causal role for cannabis use in schizophrenia is inconclusive, evidence is stronger that substance use can precipitate schizophrenia in vulnerable individuals. Both people with schizophrenia that was preceded by SUD and those with only schizophrenia have stronger family histories of schizophrenia than people with only an SUD. In addition, drug abuse not specific to cannabis is associated with an earlier age of schizophrenia onset.

SUBSTANCE USE AND PRECIPITATION OF BIPOLAR DISORDER

Of the several comorbidities that have been associated with substance abuse, bipolar disorder has been shown to have the highest prevalence as a concurrent diagnosis. Swann and colleagues suggested that individuals who have co-occurring bipolar and SUDs tend to have a more severe course of bipolar disorder, defined as having an earlier onset of symptoms, having more frequent episodes, and resulting in more complications. The complications included more anxiety, aggressiveness, legal involvement, and suicidal behavior. The search for a shared mechanism to explain the correlation between the two diagnoses identified many common characteristics including impulsivity, susceptibility to behavioral modification, and poor modulation of motivation and response to stimulus.

Another study by Kemp et al. demonstrated an association between rapid cycling bipolar patients with a comorbid substance use disorder and poor treatment response to mood stabilizers. Having a substance abuse comorbidity also increased the likelihood of incurring serious medical problems. The ability to predict associated risks and therapeutic outcomes may guide treatment options for this increasingly common population of people with co-occurring disorders.

The strong evidence that substance use worsens the course of bipolar disorder raises the question of whether it can also precipitate onset of the illness. People whose alcohol use disorder developed before their bipolar disorder have been found to have a later age of onset of bipolar disorder than those whose alcoholism came second. Furthermore, lower familial rates of bipolar disorder have been found in people whose alcoholism antedated their bipolar disorder, as well as fewer affective episodes and a more rapid recovery, compared with those whose bipolar disorder came first. These findings suggest that alcohol misuse may precipitate first episodes of mania in some persons who might not otherwise develop the disorder, or may have developed it at a later age.

SECONDARY SUBSTANCE USE DISORDER MODELS

A variety of different models posit that serious mental illness increases individuals' vulnerability to developing

an SUD, including alleviation of symptoms/dysphoria, multiple risk factors, supersensitivity, and brain reward circuit dysfunction.

Alleviation of Symptoms/Dysphoria Model

The term "self-medication" to refer to people's use of substances to alleviate psychiatric symptoms or other negative mood states has been used in so many different ways that there is little consensus in the scientific community as to its meaning. To avoid confusion, we use the term "alleviation of symptoms/dysphoria model" for this broad set of explanations for high rates of SUDs in people with serious mental illness. One version of this model suggests that substances are selected by the individual based on their specific effects on symptoms. Although research indicates that people are aware of their initial psychological reactions to substances (Mueser et al., 1995), there is little evidence for substance selection related to specific diagnoses or internal states. Self-report studies find that people with co-occurring disorders report that alcohol and other substances alleviate social problems, insomnia, depression, and other problems across diagnoses, but rarely report that specific substances alleviate specific symptoms. Studies of clinical epidemiology show that individuals with serious mental illness use the same substances as others in society but at higher rates; substance selection is not related to diagnosis but is related to availability and market forces.

Another more general version of this model is that people with serious mental illness are prone to using substances in response to distress. In support of this, research shows that people with serious mental illness often experience dysphoria, and self-reports of people with co-occurring disorders indicate that the alleviation of unpleasant feelings is a common motive for using substances. Furthermore, there is some evidence that people with co-occurring disorders have higher levels of dysphoria than those with serious mental illness alone.

Multiple Risk Factors Model

Possible indirect mechanisms involve a variety of risk factors related to serious mental illness, such as social isolation, poor interpersonal skills, poor cognitive skills, school and vocational failure, poverty, lack of adult role responsibilities, lack of structured daily activities, association with substance-using subgroups, and living in neighborhoods with high rates of drug availability. This model is consistent with Kandel's work demonstrating that achievement of adult social roles and responsibilities was associated with discontinuation of substance use among young adults (role incompatibility theory). Little research has addressed multiple risk factor models, but self-reports regarding reasons for use are consistent with the identified factors.

Supersensitivity Model

This model is an elaboration of the stress–vulnerability model for schizophrenia, which proposes that environmental stress interacts with psychobiological vulnerability to precipitate the onset of serious mental illness or to trigger relapses. Because vulnerability is defined in terms of increased biological sensitivity to stress, it may also apply to the effects of alcohol and drugs. This sensitivity may render people with serious mental illness more likely to experience negative consequences from using relatively small amounts of substances.

A number of avenues of research provide support for this model. First, people with co-occurring disorders tend to misuse lower quantities of substances than those with primary SUDs, and are less likely than primary SUD populations to develop physical dependence. Second, in pharmacological "challenge" tests, people with serious mental illness are highly sensitive to low doses of psychoactive substances that produce minimal responses in controls. Third, people with serious mental illness are sensitive to negative clinical effects such as symptom relapses following use of small quantities of alcohol or drugs. Fourth, Drake and Wallach reported that fewer than five percent of people with serious mental illness were able to sustain symptom-free drinking over time without negative consequences, in marked contrast to approximately fifty percent of the general population who drink alcohol over time without developing a disorder, suggesting increased sensitivity to the effects of alcohol.

Brain Reward Circuit Dysfunction Model

A number of authors have noted overlap in the neural circuitry putatively involved in both SUD and schizophrenia. This has led to a model that theorizes that biological vulnerability to SUD is inherent to the neurobiology of schizophrenia. Substances of abuse activate dopaminergic mesocorticolimbic tracts involved in reward, and repeated use increases sensitivity to substance effects. The reward circuit regulates repetition of behavior. People with schizophrenia appear to have a dysregulation of this circuit, which results in blunted responses to rewarding stimuli. The hypothesis suggests that people with schizophrenia are vulnerable to SUDs because substances of abuse directly stimulate this circuit, creating relatively greater reward response and stimulating compulsive repetition of the behavior of substance use. Similar reward circuitry dysfunction hypotheses have been put forward to explain the

etiology of SUD in other contexts. The reward dysfunction argument is consistent with research showing that substances with abuse potential increase dopaminergic turnover in reward circuitry in both animals and humans, as well as data indicating abnormal reward circuitry responsiveness to drug cues in people with primary SUDs.

Several areas of research have provided indirect support for the hypothesis in people with schizophrenia. For example, people with schizophrenia do not show the normal increase in P300 event-related potential amplitude to stimuli associated with monetary reward, have abnormal hedonic and brain activation responses to odors, and have structural and functional brain abnormalities in their reward circuitry, including frontal lobe subregions, striatum, amygdala, and hippocampus. This model has been primarily been applied to schizophrenia, but may have relevance in bipolar disorder as well, to the degree that it shares neurobiologic underpinnings with schizophrenia.

COMMON FACTOR MODELS

Common factor models posit that high rates of comorbidity are the result of shared vulnerabilities to both disorders. To the extent that specific factors can independently increase the risk of developing both disorders, increased comorbidity can be explained. Two risk factors have been studied in some detail: genetics and antisocial personality disorder. Other factors have been identified but less thoroughly evaluated as reasons for increased rates of comorbidity, including socioeconomic status and cognitive impairment.

Genetic Factors

Family history and twin studies provide strong evidence that genetic factors contribute to the development of schizophrenia, bipolar disorder, and SUD, although single, common genetic causes of these disorders are unknown. The question is whether genetic vulnerability to one disorder also increases risk for another disorder. Research shows that people with comorbid disorders are more likely to have relatives with an SUD than similar people with only serious mental illness. These findings suggest that genetic vulnerability to SUDs plays a role in the development of some cases of comorbid substance use and serious mental disorders.

However, do such genetic factors account for increased comorbidity via susceptibility to both disorders? Research examining the rate of SUDs in the relatives of people with serious mental illness and the rate of serious mental illness in relatives of people with an SUD addresses this question. If shared genetic vulnerability to both serious mental illness and SUD accounted for increased comorbidity, higher rates of the other disorder would be expected in the relatives of persons with one of the disorders. There are at least two possible sources of shared genetic vulnerability in families. First, within individual family members, genetic vulnerability to one disorder could also be associated with increased vulnerability to the other disorder, with offspring at increased risk to developing both disorders from the genetic contribution of that individual parent. Second, if family members with one disorder were more likely to mate with individuals with the other disorder than would be expected by chance alone (i.e. cross-trait assortative mating), the offspring would be at increased risk to developing comorbid disorders, due to the genetic contributions from each parent.

Some research provides evidence against a simple genetic model. Several studies indicate that genetic risk to schizophrenia or bipolar disorder is not associated with an increased risk of SUD in relatives, or vice versa. However, one recent investigation of bipolar and SUD comorbidity described an association of serotonin and dopamine gene polymorphisms. This linkage study used a genomic database with 278 bipolar patients to evaluate candidate genes in dopamine and serotonin pathways that are associated with substance use and bipolar disorders. Seven dopamine receptor and serotonin receptor transporter genes were targeted for closer scrutiny. After statistical analysis was completed on the genetic data of the bipolar patients, a potential association between the 5HT2C serotonin transporter gene and substance abuse comorbidity was identified.

More complex genetic models of the relationship between co-occurring schizophrenia and SUD have been proposed. For example, Caspi et al. reported that a genetic variation in the COMT gene moderated the effect of adolescent cannabis use on the later development of psychotic symptoms or schizophrenia. Adult cannabis use did not have the same effect, highlighting that the effect of substance use on the developing brain may be different and more deleterious than the effect of substances on adult brains. This research also exemplifies that genetic risk for co-occurring disorders may be enacted via gene–environment interactions, whereby substance abuse acts as an environmental stressor on the developing brain.

Genetic susceptibility for these disorders accumulates across a multitude of genes regulating various aspects of brain function. Another line of preliminary research has examined genetic variations of the dopamine D3 receptor (DRD3) and its moderators. D3 receptors are expressed in the mesocorticolimbic dopaminergic system and are increased in postmortem studies of individuals with schizophrenia. The DRD3 receptor is highly expressed

in the nucleus accumbens, where reward, including substance-induced reward, is mediated. The DRD3 receptor modulates dopamine movement in this structure when substances are used. Although studies have been mixed, some research has shown that homozygosity in a polymorphism in the DRD3 was associated with co-occurring addiction in schizophrenia.

Antisocial Personality Disorder

Another possible common factor is antisocial personality disorder. Extensive research has shown that antisocial personality disorder and its childhood precursor conduct disorder, are strongly related to increased vulnerability to SUD, and a more severe course of addiction. In addition, similar associations have been reported between antisocial personality disorder and serious mental illness. Specifically, symptoms of conduct disorder in childhood, such as repeated fighting, truancy, and lying, have been found to be predictive of the later development of schizophrenia, and to a lesser extent, bipolar disorder. Furthermore, increased rates of antisocial personality disorder have been reported in both schizophrenia and bipolar disorder.

The strong associations between conduct disorder, antisocial personality disorder, and SUDs, and the increased prevalence of antisocial personality disorder in persons with serious mental illness, suggest a role for antisocial personality disorder as a common factor underlying increased comorbidity. More direct support is provided by evidence of people with serious mental illness and past conduct disorder or antisocial personality disorder are more likely to have comorbid SUD than similar people without antisocial personality disorder. Finally, among persons with co-occurring disorders, the additional diagnosis of conduct disorder or antisocial personality disorder is associated with a more severe course of SUD and a stronger family history of SUD, consistent with research on antisocial personality disorder in persons with primary SUD.

Thus, moderately strong evidence suggests that antisocial personality disorder is a common factor that may contribute to the increased rate of SUDs in a subset of people with serious mental illness. Further work is needed to evaluate the role of temperament and to rule out other common factors related to antisocial personality disorder that could account for its relationships with SUD and serious mental illness.

BIDIRECTIONAL MODELS

Bidirectional models suggest that ongoing interactions between serious mental illness and SUD account for increased rates of comorbidity. For example, substance abuse could trigger serious mental illness in biologically vulnerable individuals, which is subsequently maintained by continued substance use due to socially learned cognitive factors, such as beliefs, expectancies, and motives for substance use. Consistent with this model, there is evidence that SUD worsens the course of serious mental illness, and that worsening symptoms are related to heavier substance use. Despite the intuitive appeal of bidirectional models, limited research has evaluated whether bidirectional interactions lead to greater psychiatric SUD comorbidity.

CONCLUSIONS

This chapter has reviewed the evidence supporting various models that attempt to explain the elevated prevalence of SUDs among individuals with psychiatric disorders. Much work remains to be done to clarify, refine, and test these hypotheses to develop a clear understanding of the psychoneurobiology of co-occurring disorders. We conclude with an important caveat and an agenda for future research. The secondary psychiatric disorder and secondary SUD models reviewed herein are focused on understanding the high rates of comorbidity, but do not imply that treatment of the "primary" disorder is adequate care. Clinical studies consistently find that treatment approaches that deliver care for both the psychiatric and the SUDs in an integrated fashion, treating both disorders as primary with simultaneous interventions designed to minimize risks to exacerbate the other disorder, achieve superior treatment outcomes. The notion of a primary–secondary relationship between psychiatric disorders and SUDs (defined in treatment studies by the chronologic order of onset in an individual's life), in which one disorder would resolve once the other is adequately treated, is not supported by available evidence, at least when each disorder is well established.

Recent advances in the understanding of neuroplasticity and epigenetics may inspire innovation in future research into the disparity between these models of comorbidity and related clinical treatment trials. We now have access to concepts and tools that have the potential to allow an increasingly sophisticated inquiry into the relationships between psychiatric and SUDs. Such inquiry might address the challenge of understanding how a disorder that may appear to have its origins in response to another disorder of earlier onset in an individual's life course can evolve into a fully established, independent disorder that requires specific, primary treatment.

List of Abbreviations

DRD3 dopamine D3 receptor
SUD substance use disorder

Glossary

Berkson's fallacy the observation that estimates the comorbidity of any two disorders are inflated when samples are obtained from treatment settings (such as a hospital or outpatient program) than from the general population (such as a household survey) because either disorder increases the likelihood that individuals will receive treatment.

Comorbidity the co-occurrence of two or more disorders, such as psychiatric and substance use disorders.

Supersensitivity hypothesis a hypothesis that some of the high comorbidity between serious psychiatric disorders and substance use disorders is due to the increased biological sensitivity to the effects of substances on people with psychiatric disorders.

Substance Use and Mood Disorders

Frances Kay-Lambkin[*,$], *Amanda Baker*[$]

[*]National Drug and Alcohol Research Center, University of NSW, Sydney, NSW, Australia

[$]Center for Brain and Mental Health Research, University of Newcastle, Callaghan, NSW, Australia

OUTLINE

In 2007, the second National Survey of Mental Health and Wellbeing (NSMHWB) was conducted in Australia, and confirmed the results of similar population-based epidemiological studies in the United Kingdom and the United States. The lifetime rates of mental disorders was 46%, 20% experienced a mental disorder in the past 12 months, and 1 in 10 met criteria for a current mental disorder, within the month prior to interview. The three most common mental disorders were anxiety, mood, and alcohol/other drug (AOD) use disorders, occurring at rates of 14, 6, and 5%, respectively, in the previous 12-month period. Over one-fifth (22%) of survey respondents identified as current tobacco smokers.

Mounting pressure is exerted on the health system by the increasing prevalence of mood and substance use disorders (SUDs). For example, depression and alcohol use disorders were ranked 3 and 17 in contribution to the global disease burden in 2008, with depression elevated to first place and alcohol use to fifth among middle-high income countries. These disorders frequently co-occur and together are associated with significant disability, premature death and morbidity on a global scale.

THE PREVALENCE OF ALCOHOL, TOBACCO, AND OTHER DRUG USE PROBLEMS

Consistently, population surveys in Western countries reveal that the most commonly used substance among adults is tobacco, followed by alcohol, marijuana, and psychostimulants (such as cocaine and methamphetamines). The focus of this chapter is alcohol and illicit drugs: issues related to tobacco will be only briefly covered.

Typically, epidemiological data exploring the prevalence of AOD use problems focuses on the formal AOD use disorders of substance abuse and/or substance dependence. For example, the US Epidemiological Catchment Area (ECA) study reported lifetime prevalence rates of alcohol abuse/dependence at around 14%, with 6% lifetime

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00052-8

prevalence of other drug abuse/dependence. Australian data indicate that one in 15 adults meet criteria for an alcohol use disorder in a 12-month period, and one in 45 adults report other drug use disorders over the same period. Marijuana was the most commonly used illicit drug in both the ECA and NSMHWB surveys, and in Australia accounted for 2% of the other drug use disorders reported by the sample. The NSMHWB attempted to estimate the prevalence of harmful/hazardous AOD use, with data indicating that in the past 12 months, 3% of respondents reported using alcohol at harmful levels, 0.6% reported harmful cannabis use, and 0.9% reported harmful use of any drug (excluding alcohol).

AOD use disorders are more common among males than females. For example, the NSMHWB revealed that the rates of alcohol dependence in the past 12 months were more prevalent in males (2% versus 1%), and rates of other drug use disorders were reported among 1% of males and 0.4% of female respondents. Despite this, rates of help-seeking for AOD use disorders are generally higher among females than males, with around 39% of women in the NSMHWB seeking help for alcohol-related problems, compared with 23% of men. The pattern of smoking tobacco that is most harmful to health is daily smoking, and the great majority of smokers do so every day. In Australia, as with AOD, males are more likely to be daily smokers (18%) than females (15%).

Aside from gender, the prevalence of AOD use disorders is affected by various other sociodemographic variables such as employment, marital status, and age. To use the NSMHWB as an example, being single and unemployed were factors associated with higher rates of alcohol use disorders, as was decreasing age of survey respondents. The same patterns were found for other drug use problems. Smoking has been found to be more common among people who are unemployed, living in areas with the least socioeconomic resources or living in remote areas. Indigenous Australians are more likely to smoke than other Australians (34 and 19% respectively). These differences are also observed in epidemiological studies internationally. For example, the National Epidemiological Survey on Alcohol and Related Conditions (NESARC) conducted in the United States revealed that younger people (aged 18–29) were 13 times more likely to report an alcohol use disorder in the 12 months prior to survey than were their older counterparts, and that single respondents and those who were currently widowed, divorced or separated were around two times more likely to report a 12-month alcohol use disorder than were their married/cohabiting equivalents. This survey also revealed that Native Americans were at increased risk of lifetime alcohol dependence, who reported double the risk of Black, Asian, and Hispanic survey respondents.

THE PREVALENCE OF MOOD DISORDERS

Mood, or affective, disorders encompass a range of symptoms and diagnoses where the underlying feature is a disruption to the person's general mood and emotions. Two groups of mood disorders are commonly recognised, depressive disorders and bipolar disorders, which are distinguished from each other by the presence of manic episode(s). A depressive episode is characterized by depressed mood and/or loss of interest or pleasure in life activities for at least 2 weeks, during that time the person also experiences at least five other key depressive symptoms. A manic episode is a period of abnormally and persistently elevated, expansive, or irritable mood lasting for at least 1 week, and accompanied by three or more key symptoms. Whilst depressive or manic episodes are not codeable disorders on their own, a major depressive disorder is diagnosed when a person experiences a single or recurrent (two or more) depressive episode in the absence of a manic episode. If periods of mania have been experienced, then a bipolar disorder is likely to be present. Bipolar disorders are further categorized according to whether the dominant feature of the illness is mania (or daily cycling between manic and depressive episodes, bipolar I disorder) or recurrent depressive episodes (with hypomanic episodes, bipolar II disorder).

Within each of these mood disorder categories, people can experience subthreshold symptoms that do not meet formal diagnostic criteria, but continue to cause significant impairments in functioning and quality of life for the individual. For example, chronic depressive disorder (dysthymia) refers to the presence of a depressed mood for a period of 2 years or more, along with two of the symptoms of a depressive episode during that time. Similarly, cyclothymic disorder is a state of cycling between hypomanic (where manic symptoms are observed by others, but symptoms are not as severe) and depressive episodes that do not meet the criteria for a diagnosis of bipolar disorder. Importantly, both depressive and bipolar disorders may be classified as substance-induced; that is, a disturbance that meets full criteria for the relevant mood disorder. However the symptoms occur or develop within a month following severe intoxication or withdrawal from alcohol/other drugs, and do not persist for more than a month following the cessation of the substance.

Epidemiological research suggests that, aside from AOD use disorders, affective disorders (namely depression) are among the most common mental disorders experienced in the general population. For example,

population studies conducted in the United States indicate that the lifetime prevalence of mood disorders is 21%.

In Australia, the NSMHWB indicated that mood disorders occurred in 6% of the study population in the previous 12 months, supporting previous population-based surveys of mental disorders conducted internationally. Depressive episodes were reported by 4% of participants in the previous 12 months, and bipolar disorders by 2% of NSMHWB respondents. Internationally, bipolar I disorders generally occur in 0.8% of the general population, and 1.1% meet criteria for bipolar II disorder in a given 12-month period.

In general, depressive disorders are more common in females than males, and tend to decrease with age, declining markedly after 55 years of age. There are also gender differences in the experience and prevalence of bipolar disorders. The onset of bipolar disorder is often later in women than men, and women tend to experience more depressive episodes and rapid cycling than do men, with bipolar II disorder appearing more commonly in females. In addition, unemployed people report higher rates of mood disorders and rates are higher if people do not complete secondary school, are separated or divorced and if they currently live alone. For example, in the NSMHWB, rates of depression rose to 11% for those people without housemates in the year prior to the survey. These patterns were not observed among people with anxiety disorders.

Health service utilisation is typically low for people with mood disorders. Because of the gender differences in the presentation of bipolar disorders, women tend to experience a delay in the diagnosis of bipolar disorder and hence in gaining access to appropriate treatment. Depression accounts for the most disability of the high prevalence disorders, with respondents to the NSMHWB indicating on average that for almost 12 days of the past 4 weeks, they were completely unable to carry out their usual activities owing to their symptoms. Further, of the 13% of disability-adjusted life years attributable to mental disorder, mood disorders alone accounted for 33%, and depression was responsible for 12% of the total burden of nonfatal global disease. Bipolar disorder accounts for more disability-adjusted life years than all forms of cancer, epilepsy, and Alzheimer's disease. This is despite effective psychological and pharmacological treatments being available for the mood disorders.

THE PREVALENCE OF COMORBID ALCOHOL/OTHER DRUG USE AND MOOD DISORDERS

As noted in other chapters in this volume, a reliable finding across population-based surveys is the common co-occurrence of mental disorders, referred to as "comorbidity." The presence of a mental disorder seems to increase the risk of developing additional mental disorders. For example, the Australian NSMHWB reported that one-quarter of people with a mental disorder experienced more than one class of mental disorder. Comorbid conditions may meet criteria for diagnostic-level disorders, according to standard clinical classification systems. However symptoms do not necessarily need to meet standard diagnostic criteria in order for comorbidity to be present, and for this comorbidity to impact significantly on a person's functioning across many domains. However, epidemiological data tend to report on disorder-level comorbidity. For example, based on data from the US National Comorbidity Survey, males who smoked cannabis were 1.6 times more likely to develop a major depressive episode than were nonusers. Similarly, females were at 2.6 times the risk of a major depressive episode if they smoked cannabis, even at nondependent levels. In research conducted among 2000 Australians aged 14–21 years, the association between marijuana use and symptoms of depression and anxiety was examined. Young adult females who used cannabis daily, had five-fold higher rates of depressive and anxiety symptoms, after controlling for the effects of other substance use. Weekly cannabis use as a teenager predicted a two-fold higher rate of depression and anxiety in females in young adulthood after controlling for baseline mental health and other potential confounders. By contrast, depression and anxiety symptoms in adolescence did not significantly predict later cannabis use.

The ECA study revealed that the rate of alcohol use disorders among people with mental disorders was 22%, compared to 11% of their counterparts without mental disorders. Rates of other drug use disorders among people with mental disorders were around 15%, relative to a rate of 4% of the remaining survey respondents. Taken together, these findings suggest that adults with lifetime mental disorders are twice as likely to experience alcohol use disorders and around four times more likely to have a drug use disorder than are their counterparts without mental disorders.

Equally, studies have indicated an increased rate of psychiatric disorder is likely among people using AOD. Although rates of some acute mental disorders among AOD users are comparable to the general population, a consistent finding has been that rates of depressive disorders are elevated among AOD users, particularly those with alcohol abuse and dependence. For example, in the US NESARC, 20% of people with an AOD use disorder had a co-occurring mood disorder, and 20% of people with mood disorder also had a SUD. Major depression occurred in 10% of national survey respondents identified as having a current or past year

alcohol use disorder, and around 21% of people in the same survey with major depression also reported an alcohol use disorder over the previous 12-month period. Rates of comorbid SUDs are highest amongst people with bipolar disorders, with as many as 60% of people with bipolar I disorder reporting lifetime SUDs. In the United States, data indicate that people with cannabis dependence are twice as likely to have experienced clinically significant depression, and that current users are also twice as likely to have a concurrent mood disorder. Cannabis abuse has been associated with four times the risk of developing a subsequent depression. Generally, alcohol use disorders are most prevalent amongst people with mood disorders, followed by marijuana, amphetamines, and cocaine.

Service-based research suggests that levels of comorbidity and associated problems may be more pronounced in treatment-seeking populations. The ECA study reported that rates of AOD use disorders within mental health services were twice that of people with mental disorders not engaged in treatment, and rates of mental disorder were even higher among people engaged in AOD treatment. In general, mood disorders occur in 40–42% of people engaged in addiction treatment services. Depressive disorders can occur in as many as 60% of treatment seekers for cocaine dependence, as evidenced in a US-based survey of people recruited to research studies over a 16-month period, whereby 53% ($n = 184$) reported lifetime use of cocaine and of these, 89% met criteria for lifetime major depressive disorder.

ETIOLOGICAL MODELS OF ALCOHOL/OTHER DRUG USE AND MOOD PROBLEMS

Given the frequency with which mood and AOD use problems co-occur, population-based surveys have been used to more closely examine the various environmental, genetic, and neurobiological factors that may explain this particular type of comorbidity. As a result, several different models have been proposed to explain the co-occurrence of any mental health and AOD use problem and these can be applied to the relationship between mood and AOD use problems, with a view toward planning treatment approaches for these comorbid conditions. Figure 52.1 displays the following models:

1. Primary AOD use models propose that the problematic AOD use preceded the first problematic mood symptoms, and AOD is considered the major determinant of the symptoms experienced by the person. Often, mood symptoms would occur only within reasonably close proximity (1 month or less) to AOD intoxication, withdrawal or cessation. In this case, treatment would target the primary problem (AOD use), assuming that upon abstinence, the mood symptoms would also remit.
2. Primary mood models suggest that AOD use commenced after the development of mood problems, as a means to self-medicate symptoms, or to cope with distress related to symptom development. Mood symptoms would also be experienced in the absence of any AOD use, or over a sustained period (greater than 1 month) following AOD cessation. According to this model, the mood problem would be the target of treatment, under the assumption that relief of negative mood and associated distress would lead to a remission of AOD use.
3. Bidirectional models state that low mood acts as a trigger and maintaining factor for harmful AOD use, and vice versa.
4. Common-factor models suggest that one or more factors, such as genetic predisposition, antisocial personality disorder, social difficulties, stressful events, etc., contribute to an increased risk of both mood and AOD use problems.
5. Artifact models suggest that mood and AOD use problems are unrelated, and the high co-occurrence of these problems could simply represent sampling biases in population and/or clinical studies, or the overlap in diagnostic classification systems for major depression and AOD abuse, dependence, and withdrawal syndromes.

Little firm evidence exists to support the adoption of one of the above models over another, and each model has inherent problems when applied to individuals in real-world clinical settings. For example, while longitudinal studies of the comorbidity of marijuana use and depressive symptomatology support a primary marijuana use model, cross-sectional surveys indicate that a primary depression model better accounts for the dysphoria experienced with marijuana abuse in adulthood. Further, while the US-based ECA study revealed that rates of alcohol use disorders were 35% more likely in relatives of people with major depressive disorder, indicating a relationship between the two disorders, a second study found no such association.

We need large-scale follow-up studies of epidemiologically defined cohorts of adults to examine relationships between comorbid disorders. The recent 3-year follow-up of incident disorders in the NESARC cohort and their relationship to baseline disorders provides a good illustration of the potential value of this approach. In this study, 34 653 persons who were interviewed in the first wave of the NESARC study were followed up after 36 months and reassessed for

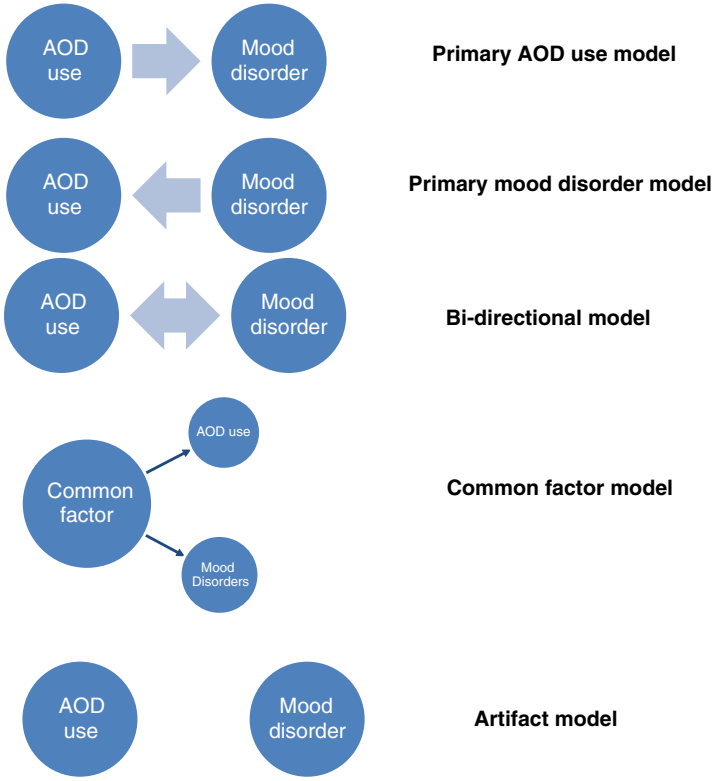

FIGURE 52.1 Proposed models of etiology of AOD and mood disorders.

symptoms of a wide range of common mental and SUDs. The sample size was large enough to examine relationships between demographic characteristics and mental disorders at the baseline assessment and incident disorders during the 3-year follow-up period. The disorders with the highest incidence rates (per 100 person years) were alcohol dependence (1.7), alcohol abuse (1.0), major depressive disorder (1.5), and generalized anxiety disorder (1.1). The demographic predictors of these disorders were unsurprising: alcohol and drug use disorders were more common among young males; and major depressive disorder was more common among young females.

The presence of some mental disorders at baseline did predict incident disorders during the 3-year follow-up (after controlling for demographic variables). Alcohol abuse and dependence were strong predictors of each other, as were drug abuse and drug dependence. By contrast, alcohol and drug use disorders at baseline did not predict an increased incidence of mood disorders; mood disorders at baseline, specifically bipolar and panic disorders, did predict an increased risk of drug and alcohol abuse at follow-up, as did borderline personality disorder.

The US NESARC did attempt to quantify the prevalence of self-medication among people with SUDs and mood disorders. Results indicated that one-quarter of the participants with mood disorders used alcohol/other drug to relieve their symptoms. The highest prevalence of self-medication was among people with bipolar I disorder, with 41% of participants indicating relief of symptoms as their primary reason for use of alcohol/other drugs. Further, men in this study were twice as likely as women to report self-medication of their mood disorder with alcohol/other drugs. In a 20-year study of mood and SUDs, researchers in the United States further revealed that the presence of manic symptoms in people with bipolar disorders was predictive of the development of subsequent alcohol use disorders, cannabis use disorders, and benzodiazepine use disorders. Bipolar II disorder was associated with later development of alcohol use disorders and benzodiazepine use disorders, with major depressive disorders associated with the later development of benzodiazepine use disorders. The self-medication model of substance use and mood disorder comorbidity assumes that a specific mood disorder would lead to abuse or dependence on a specific drug type that targeted the required symptom relief. The finding that, at least for bipolar disorders, multiple substances were associated with the presence of this disorder indicates that perhaps the self-medication model of comorbidity may not be an appropriate global etiological model of comorbid mood and SUDs.

Other researchers have suggested that the primary/secondary distinction between mood and AOD use disorders is immaterial once the two disorders have surfaced. This assertion is supported by studies indicating that the primary/secondary distinction, at least for alcohol use problems and depression, is not predictive of treatment outcomes. For example, in a 5-year follow-up of 97 Americans with concurrent affective disorder and alcohol use problems, levels of depression and alcohol use were equivalent for primary depressive and primary alcohol use conditions.

Clinical practice suggests that the relationship between AOD use and mood disorders may change over time. For example, depression may trigger alcohol use at some times and the reverse may occur at others. In a 10-year follow-up of people with alcohol-related problems, results indicated that there was a bimodal association between depression and transition to higher levels of drinking, perhaps indicating more than one developmental pathway. That is, respondents who progressed from low-level drinking to higher levels appeared to be drinking to relieve tension and distress (self-medicating their depression), while those who were already drinking at high levels at baseline seemed to have already developed chronic drinking patterns that contributed to their current depressive episode, rather than the reverse. This may be indicative of the clinical situation where initially, an individual may be drinking to relieve negative mood and other symptoms of depression (the depression is primary), however over time, the drinking may develop into a chronic problem in its own right, leading to depressive episodes. In this case, if treatment was based on the primary depressive condition, the independent alcohol use problem may not receive appropriate treatment.

Different etiological models may apply for men and women who experience comorbid mood and AOD use disorders. In a study of 2945 people with alcohol use problems, 15% were classified as having primary depression and a further 26% as having secondary (or alcohol-induced) depression. This study reported that there was a significantly higher proportion of men than women in the secondary depressed group (70% versus 30%), whereas the gender ratio was roughly equivalent for those in the primary depression group (48% men versus 52% women). Epidemiological studies additionally suggest that AOD use problems are more prevalent among men than women, with affective and anxiety problems more commonly reported among women. One implication of this pattern may be that it is more acceptable for males to report problems with drugs and alcohol than to admit to problems with their mood, emotions, or feelings. The reverse is likely to be true for females. This could lead to underreporting of affective states in men and of drug and alcohol use in women in survey-based research, further confounding the issues.

There are also practical problems in reliably establishing the temporal relationship between mood and AOD use problems, and using client self-report to establish the primary condition is often imprecise. This is especially true if both conditions have been present for many years, and if the primacy of each condition has changed over time. As such, a reliance on treating coexisting mood and AOD use problems according to the primary/secondary model may be inadequate. Further, the pattern of depressive symptoms in primary and secondary depression (coexisting with AOD use problems) is often so similar that it is difficult for clinicians to use the presence of certain key depressive symptoms as indicators of primary and secondary depressive conditions. Thus, clinicians may not be able to identify from the outset which clients are more likely to have a mood disorder that persists beyond abstinence from AOD use problems.

THE IMPACT OF COMORBID ALCOHOL/OTHER DRUG USE AND MOOD DISORDERS

Despite the difficulties in determining the etiological relationship between mood and SUDs, it is well known and accepted that people with this type of comorbidity experience significant and multiple adverse consequences of their comorbidity. For example, in one of the few AOD treatment studies that did not specifically exclude people with comorbid issues, a clinical profile of people presenting for treatment for marijuana use disorders was established. Results indicated that 83% experienced marijuana-related health problems, such as respiratory distress (e.g. asthma, coughing), problems with relationships, and psychological symptomatology (e.g. depression). Financial difficulties, criminal activity, and use of multiple drugs in addition to cannabis over their lifetime were high.

The severity, impact, and patterns of comorbidity of mood and SUDs are similar across international borders. Consistently, this type of comorbidity is associated with significantly more severe clinical symptoms, elevated suicidal behaviors, and poorer clinical course and outcome than for people without comorbidity. For example, compared with patients with bipolar disorder alone, those with bipolar disorder and substance use disorder comorbidity experience earlier onset of mood symptoms; higher rates of anxiety disorders, suicide attempts, accidents, hospitalizations, and rapid cycling; more depressive episodes; and lower treatment compliance. At a population level, the presence of comorbid depression and AOD use disorders has been associated

with high levels of disability, days out of role, and a significant contribution to the total burden of disease. In addition, epidemiological research suggests that there is a consistent association between suicidality, mood, and AOD use disorders. For example, in an analysis of the US Multiple Cause of Death Data, comorbid AOD use disorder with mood disorders (both depressive and bipolar) was associated with between 1.5 and 9.5 times the likelihood of death by suicide and other unnatural causes than for mood disorders alone. Data from this study also indicated that people with comorbid mood and SUDs died 12–34 years sooner than did people without this comorbidity.

Using data from NSMHWB, those respondents with comorbid alcohol use disorders and anxiety or depression experienced around twice as many days out of role in the previous 4-week period relative to their counterparts with alcohol use disorder alone. A higher proportion of the comorbid group than the alcohol use only group was younger, never married, unemployed, and separated or divorced. People in the comorbid group were four times more likely to have seen a specialist health professional for their problems, and slightly more likely to have seen any health professional in the previous 12 months. At entry to treatment, those participants with comorbid anxiety and depressive disorders reported more disability and higher levels of alcohol use than did those with alcohol use alone. Other research indicates that levels of depression are associated with higher rates of AOD use (such as tobacco) upon presentation to treatment services.

Service-based data indicate that, among people presenting for treatment for methamphetamine use problems, up to 70% concurrently experience at least moderate levels of depression, and that comorbid mood disorders are associated with significantly higher methamphetamine use, abuse and dependence, and significantly greater use of benzodiazepines, tobacco, and use of multiple substances.

A small body of research exists that attempts to examine the relationship between depression and AOD use and treatment utilization and outcome. The focus here has been almost exclusively on depression and comorbid alcohol use disorder. For example, people with comorbid depressive and alcohol use disorders are also suggested to require inpatient hospitalization more frequently than their counterparts without problematic alcohol use. In a large-scale US study of people with affective disorders, 3% also had a diagnosis of alcohol use disorder and reported increased rates of recurrent depressive episodes over the follow-up period, as measured by re-admission rates over 23 years.

The presence of mood problems at entry to treatment for alcohol dependence has also been associated with premature treatment dropout, more frequent relapses to alcohol use, and subsequent addiction treatment if left unaddressed. Antidepressant and other psychiatric medication can also be less effective when people are drinking alcohol at harmful levels. For example, in a study of people with major depressive disorder, levels of alcohol, tobacco, and caffeine use were assessed prior to commencement of an 8-week course of the antidepressant, fluoxetine. At the conclusion of treatment, levels of alcohol use at baseline were positively correlated with levels of depressive symptoms, suggesting a poorer response to the antidepressant.

Comorbid alcohol use and mood disorders additionally place people at increased risk of criminality. The same is likely true for drugs in addition to alcohol. For example, among a sample of 1016 methamphetamine users in the United States, levels of psychiatric disorder were high, with around one-third of the sample reporting depressive symptoms in the month prior to the study. Twenty-seven percent of the sample reported suicide attempts in their lifetime, and assault charges and other criminal activity were also high.

Despite these findings, other researchers suggest that the effect of a comorbid depressive disorder on AOD use characteristics is not clear-cut, as several researchers have failed to show a demonstrable effect of depression on AOD use and vice versa. For example, in a study of 54 undergraduate students in China, risk-taking tendencies were significantly reduced after induction of a negative mood, relative to positive and neutral moods. Although not directly tested in this study, one implication of this result may be that drug use, arguably a "risky" behavior, may be reduced in severity or frequency in the presence of depressive symptoms.

In a sample of 75 people with alcohol abuse/dependence, depressive symptoms present at the initial assessment were not related to quantity or frequency of drinking at baseline, nor to levels of alcohol consumption at the 3-month follow-up assessment. This study also suggested that depression may indeed enhance motivation to reduce drinking behavior, by increasing the alcohol-related costs/losses incurred by the individual. According to the stages of change model, behavior change will likely to occur when these personal costs for drinking outweigh any benefits the person perceives are associated with continuing to drink. Results of this study supported this hypothesis, with higher levels of depressive symptoms being significantly associated with the action stage of change for alcohol.

Levels of lifetime and current major depressive disorder were used to predict rates of relapse to problematic alcohol use following a brief intervention among 99 men with moderate to severe alcohol dependence. At the 6-month follow-up, 58% of the sample had relapsed to drinking. However, no differences existed between

relapsers and non-relapsers in terms of levels of depression at baseline, nor presence of lifetime major depressive disorder.

In summary, it is acknowledged that comorbid mood and SUDs present a set of unique difficulties and risks than would on either condition present on its own. However, little firm evidence exists to clearly suggest how these might apply to drugs in addition to alcohol, nor about the characteristics and needs of people within these populations who are seeking treatment. More research needs to examine these issues in more detail.

SMOKING AND MOOD DISORDERS

Results of the NSMHWB showed that 32% of current smokers had a mental disorder in the previous 12 months, which was twice the prevalence of 12-month mental disorders of those who had never smoked (16%). Compared to never smokers, current smokers also experienced four times the prevalence of 12-month SUDs (12% versus 3%), almost three times the prevalence of affective disorders (12% versus 5%) , and twice the prevalence of 12-month anxiety disorders (22% versus 11%). People with histories of depression or anxiety have been found to be heavier and more frequent smokers and have lower quit rates (although this is controversial) and higher dependence compared to people without such histories.

The relationship between smoking and mental disorders is thought to be complex, as mental disorders are a risk factor for smoking. Depressive mood increases the risk of smoking and vice versa. Commonalities in genetic and environmental factors probably underlie the comorbidity of depression and smoking.

SUMMARY

Mood and AOD use disorders commonly co-occur, and researchers and clinicians find it difficult to agree on how to best categorize and treat these concurrent conditions. This is a concern given that on a global scale, mental and AOD use disorders contribute 20% to the total burden of disease borne by society, and evidence from some studies indicates that comorbidity is associated with poorer functioning, higher risk of relapse, and increased symptom severity. When tobacco smoking is added to this scenario, the comorbidity between smoking, mood, and AOD use disorders becomes even more burdensome and associated with higher rates of mortality in addition to worsened morbidity.

Substance Use in Response to Anxiety Disorders

Jennifer A. Robinson, James M. Bolton

PsycHealth Centre, Winnipeg, MB, Canada

OUTLINE

Those who choose to use substances in response to an anxiety disorder typically do so in an attempt to ameliorate anxious symptoms. This behavior was first described in the scientific literature over 50 years ago, and was labeled the tension-reduction theory. Since then, a large body of research has accumulated to describe and define various aspects of this process currently known as self-medication. Edward J. Khantzian's formulation of the self-medication hypothesis (SMH) is based on two primary assumptions: (1) substance use is effective in reducing psychiatric symptoms and (2) the particular substance chosen for self-medication purposes corresponds to an individual's particular symptomatology. For instance, those with anxiety disorders are more likely to use alcohol to alleviate distressing symptoms than cocaine, given that alcohol is a central nervous system depressant and cocaine is a stimulant. Although evidence exists to support both of these claims, the former rests on a more solid empirical grounding than the latter.

A more recent formulation of the SMH makes three main assumptions: (1) psychiatric symptoms must precede substance use, (2) substance use is effective in relieving these symptoms, and (3) continued and excessive use of the substance is promoted by symptom relief. Support exists for each of these assumptions, but results

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00053-X

can vary depending on the particular anxiety disorder in question. Furthermore, examination of these processes has often been compromised by studies with methodological limitations. For example, many have been limited to cross-sectional samples, which prevent investigations of the central temporal claims of the SMH.

This chapter focuses specifically on the use of substances for the amelioration of anxiety symptomatology. Clinically and scientifically important questions to ask about this behavior include the following:

- What are the risks of self-medication?
- Who is most likely to engage in this behavior and when?
- Does substance use actually reduce anxiety? If so, how does it do this?
- How does this behavior affect treatment for anxiety?

Empirical investigations are ongoing, and in some cases these questions have only just begun to be examined. However, an attempt is made to highlight the major points in the body of knowledge that exists on the use of substances as an attempt to relieve anxiety (self-medication).

IMPORTANCE OF SELF-MEDICATION

Self-medication is an important and popular topic of scientific study, largely because this process is thought to (at least partially) account for the high comorbidity seen between substance use and anxiety disorders. Simply put, those who utilize substances in response to symptoms of anxiety are at higher risk for developing a comorbid substance use disorder, which can then lead to further mental health consequences. The prevalence and consequences of comorbidity are discussed as a basis for understanding the importance of clarifying the mechanism(s) behind this comorbidity.

Prevalence of Anxiety and Substance Use Disorder Comorbidity

Epidemiologic Studies

In the Netherlands Mental Health and Incidence Study, 13% of those with anxiety had comorbid substance use disorders, and 18.9% of those with substance use disorders had comorbid anxiety. Similar rates were found with the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC). In this national survey of the US adult population, 15% of those with anxiety disorders had comorbid substance use and 17.7% of those with substance use had comorbid anxiety disorders. These rates were noticeably higher than the prevalence rates of the pure disorders found in the general population (which are approximately 9.4% for substance use disorders and 11.1% for anxiety disorders). Using the same sample, it was found that meeting criteria for a substance use disorder was associated with an almost twofold risk of also meeting criteria for an anxiety disorder.

Analysis of two more population samples – the National Comorbidity Survey and the Ontario Health Survey, from the United States and Canada, respectively – revealed that problem drinking was significantly associated with social phobia, simple phobia, agoraphobia, panic, and generalized anxiety disorder (GAD). A study that utilized four general population samples from different locations found that individuals with alcohol use disorders were more than twice as likely to receive a diagnosis of an anxiety disorder compared with those without an alcohol use disorder. These results indicate that substance use and anxiety disorders are substantial risk factors for each other and frequently co-occur in the general population.

With regard to specific anxiety disorders, among those with GAD in the general population, roughly half have a comorbid substance use disorder. Those with panic disorder and obsessive compulsive disorder are also significantly more likely to be diagnosed with an alcohol use disorder, and social phobia is consistently associated with high drug and alcohol use disorder comorbidity. One estimate reported that approximately 20% of those with social phobia also have an alcohol use disorder and 15% of those receiving alcoholism treatment met criteria for social anxiety disorder.

Clinical Studies

Comorbidity rates in clinical samples tend to be substantially higher than rates in general population samples. Among a sample of individuals receiving treatment for alcohol use disorders, 69% experienced anxiety-related problems. Among those being treated for anxiety disorders, an estimated 16–25% met the criteria for comorbid alcohol use disorders.

Individuals who present for treatment in a clinical setting may be experiencing a greater amount of psychological distress than those in the general population who are not currently seeking treatment. This increased severity may account for the higher comorbidity rates generally seen in treatment samples. Research in support of this confirms that comorbid anxiety and substance use are associated with increased rates of treatment seeking in a number of international locations.

Consequences of Anxiety and Substance Use Disorder Comorbidity

In both clinical and population samples, comorbidity has been associated with a number of serious negative health consequences that often exceed those of

individual or pure disorders. For instance, comorbid individuals tend to utilize mental health services at greater rates, have more severe symptomatology and disability, and have longer duration of illness compared with a noncomorbid cohort. These factors signify the importance of uncovering and studying mechanisms that can lead to this comorbidity in order to prevent its occurrence. Many researchers have attempted to investigate (using various methodologies and assumptions) whether self-medicating behavior is responsible for this comorbidity, as well as how and when it arises. These investigations are discussed subsequent to an exposition of the prevalence and consequences of self-medication in both epidemiologic and clinical samples.

Prevalence of Self-medication

Epidemiologic Studies

Prevalence rates for self-medication have been calculated using a variety of different samples, with results varying as a function of the particular anxiety disorder in question, sample characteristics, as well as the operationalization of terms such as anxiety and self-medication. A general population study calculated that self-reported self-medication was present in approximately 20% of respondents who met criteria for any anxiety disorder. This figure is roughly in accordance with other epidemiologic studies. Self-medication is typically assessed within these studies as a single self-reported item. In the National Epidemiological Survey on Alcohol and Related Conditions (NESARC), for example, after endorsing symptoms of panic disorder, the respondent is asked "did you ever drink alcohol to keep from having panic attacks?" Self-report items from other surveys are comparable with this.

Within the individual anxiety disorders, analysis of the National Comorbidity Survey revealed rates of self-medication ranging from 7.9% (social phobia, speaking subtype) to 35.6% (GAD). A different population study found the highest rates of self-medication with alcohol among those with social phobia (14.9%), with GAD following closely behind (14.1%). In a comparison of those with GAD and a substance use disorder with those with GAD and no substance use disorder, those with GAD and a substance use disorder were found to be 5 times more likely to self-medicate with alcohol and 14 times more likely to self-medicate with drugs.

Self-reported measures of self-medication may be prone to recall errors. More robust methods of assessing self-medication would involve assessment as self-medication was occurring, rather than asking about it after the fact. However, given its high prevalence in substance use and anxiety disorders, self-medication may play an important role in the maintenance of comorbidity. The use of drugs for self-medicating anxiety generally has a much lower prevalence than self-medication with alcohol, with rates ranging from about 1 to 5% among those with anxiety disorders.

Clinical Studies

Clinical samples are generally characterized by much higher rates of self-medication than community-based samples. In a sample of individuals with agoraphobia, 41% self-reported self-medication. Among those with comorbid alcohol abuse and agoraphobia, 91% self-medicated with alcohol. All of those with comorbid alcohol dependence and agoraphobia or social phobia said that alcohol was useful in coping with fears, and 33% intentionally used it for such purposes. In a different sample, 74% of socially phobic individuals reported using alcohol to reduce fears related to socialization. Given such high rates of self-medication with alcohol, particularly in response to social anxiety, it is not surprising that the empirical literature is focused on the comorbidity of these two disorders to the near exclusion of other substance and anxiety disorders. However, research is emerging to suggest that increased focus on other substances of abuse and other anxiety disorders (particularly GAD) may prove to be clinically and empirically relevant.

Consequences of Self-medication

In cross-sectional population-based studies, self-medication has been associated with extremely high odds of a number of different substance use disorders (such as alcohol, cocaine, stimulant, and marijuana dependence).

Besides potentially leading to comorbid substance use disorders, self-medication for anxiety may have a number of other negative health consequences. Cross-sectionally, this behavior is strongly associated with mood and personality disorders. Comparisons between self-medicating with alcohol and self-medicating with drugs have revealed that the risk of other comorbidities is higher among those self-medicating with drugs than with alcohol. Mental health-related quality of life is lower in those self-medicating with alcohol, and even lower among those self-medicating with drugs compared with those with anxiety disorders who do not self-medicate. Most concerning is that people who engage in self-medication are at increased risk of suicidal ideation and suicide attempts compared with those who do not self-medicate, indicating that this behavior may be a worrisome marker of safety concerns. These relationships hold even after adjustments are made for a range of potentially confounding variables, including comorbid

psychiatric diagnoses. Although it is known that comorbidity can have serious negative consequences (as described above), the results of these studies suggest that even in the absence of comorbidity, self-medication is an important clinical target for the prevention of important health consequences.

EVIDENCE FOR SELF-MEDICATION

Order of Onset

Researchers who support the premise that self-medication for anxiety disorders leads to a subsequent alcohol or substance use disorder must show that anxiety disorders precede substance use. This premise has proved somewhat difficult to investigate, largely due to the lack of prospective studies that have examined this question, combined with potential recall bias and the failure to examine different anxiety disorders separately. However, results seem to indicate that anxiety generally precedes alcohol or substance use disorders with, as we will see later, the possible exceptions of panic and generalized anxiety disorder.

A nationally representative dataset was examined to determine the retrospective age of onset of various disorders among comorbid individuals. Interesting differences emerged depending on the particular disorder examined. For instance, whereas both social and specific phobia tended to precede the onset of alcohol use disorders, panic and generalized anxiety disorder tended to follow them. The phobias were five times more likely to precede than to follow alcohol use disorders, with GAD four times more likely to follow alcohol use disorders. The findings regarding social phobia and panic accord fairly well with the established scientific literature on anxiety–substance use disorder comorbidity, whereas findings regarding GAD are at odds with some of the literature. One clinical study reported that 67% of comorbid cases of GAD and alcohol use disorders had an onset of GAD prior to the alcohol use disorder. This difference might be accounted for by the differences in sampling techniques. In other words, in the general population, GAD may be more likely to follow alcohol use disorder, whereas the reverse may be true in clinical samples. Further investigation on this issue is needed to clarify the order of onset for GAD and alcohol use disorder. In terms of panic disorder, there is evidence to suggest that the use of alcohol can condition and kindle panic attacks, supporting the finding that panic should more frequently follow than precede alcohol use disorders. Many studies consistently find that social phobia is a risk factor for the development of alcohol use disorders, which also fits with the above results.

In general, prospective studies show that baseline anxiety disorders present an increased risk for development of subsequent alcohol use disorders, and vice versa. A substantial amount of this longitudinal work has been unable to examine different anxiety disorders individually, and has focused primarily on alcohol use disorders as an outcome as opposed to other drug use disorders. A recent longitudinal study found that panic, social phobia, and GAD predicted the onset of substance use disorders, and substance use disorders predicted these same three anxiety disorders. All types of substance use disorders (alcohol abuse and dependence, and drug abuse and dependence) predicted the onset of GAD, whereas only alcohol dependence and drug abuse predicted the onset of panic disorder. However, this study did not examine mechanisms, such as self-medication, that might underlie this comorbidity.

Although it is possible that self-medication in response to anxiety disorders subsequently leads to the development of substance use disorders via increasing amounts of substance use to remedy anxiety, a slightly more complex, although inherently plausible model is also important to consider. This model is sometimes termed the feed-forward model, and suggests that self-medication of subthreshold anxiety symptoms can not only exacerbate substance use problems but can also increase anxiety symptomatology. Although immediately anxiolytic, over longer periods of time, substance use may become anxiogenic. One study of patients with phobias found that although the phobia typically preceded alcohol use disorders, it was most severe after alcohol use. Furthermore, withdrawal symptoms – especially withdrawal from alcohol – can mimic anxiety symptoms, leading to further self-medication. It is likely that these processes occur in many self-medicating individuals, and that continued self-medication for anxiety would promote the emergence of both disorders.

Anxiety reduction through extinction may also be prevented due to substance use. In other words, the use of alcohol prevents the experience of anxiety from occurring fully, which prevents learning that the situation is less frightening than imagined through exposure. This, combined with the negative reinforcement of immediate anxiety reduction through substance use, perpetuates both anxiety and substance use.

A major strength of this model is that it does away with questions about order of onset of disorders. Self-medication cannot be assumed simply because an anxiety disorder happens to have begun prior to a substance use disorder. Moreover, certain disorders are more likely to occur at different points along an individual's developmental trajectory simply due to the nature of the disorder. Overall, whether self-medication begins in response to subthreshold anxiety or to a full-blown anxiety disorder, it is likely that

among those with comorbidity, each disorder serves to reinforce the other.

Does Alcohol Reduce Anxiety?

Experimental studies aiming to examine whether alcohol actually decreases anxiety have been somewhat ambiguous up to this point. This can be contrasted with subjective reports among self-medicators, who typically report decreased anxiety as a result of alcohol use. Discrepancies within the experimental literature may be due to factors that were not accounted for, such as individual personality and sociodemographic characteristics. Therefore, it may be the case that alcohol use decreases subjective anxiety only in certain individuals. This notion has been supported by other studies examining factors potentially leading to alcohol and substance use in response to anxiety, and are discussed in more detail later. It has also been postulated that experimental studies that have not found an anxiety-reducing effect may not have allowed subjects to consume a sufficient amount of alcohol to generate the effect. Moreover, these studies have varied in the anxiety-provoking task given to participants. Differences seen in the effectiveness of alcohol to reduce anxiety may be the result of differences in baseline anxiety as a result of the particular task given.

In general, most experts agree that anxiety can be temporarily reduced by sufficient alcohol consumption, due to the pharmacological effects of ethanol, although this should not imply that alcohol use does not also increase anxiety (as delineated in the feed-forward model above). The effect of alcohol on anxiety reduction, as well as one's propensity to use it for these purposes, is likely to be the result of a number of factors including age, gender, expected effects, and other individual characteristics. In experimental studies that induce panic- and phobic-like symptoms, the use of alcohol has often been found to be anxiety reducing, although this is not the case for all studies.

Unequivocally, a large number of individuals with comorbid anxiety and substance use disorders report the use of substances as a means to cope with anxiety, and a large percentage of those with anxiety disorders report self-medication in both clinical and community samples. These subjective self-reports of anxiety reduction among self-medicating individuals is more consistent than reports in the experimental literature noted above. Anxiety reduction is the prominent affective consequence reported by self-medicators; the results from the experimental literature (which has examined those with and without propensities to self-medicate) are somewhat more ambiguous.

How Does Alcohol Affect Anxiety?

There are a number of potential mechanisms through which alcohol can have anxiolytic effects in anxious individuals. Alcohol affects the brain in ways that are similar to substances known to reduce anxiety, such as benzodiazepines and opiates. These substances operate by increasing the activity of γ-aminobutyric acid (GABA), a neurotransmitter that contributes to the inhibition of central nervous system activity. As many of the symptoms of anxiety are manifestations of increased autonomic arousal, the sudden muted activity in the nervous system may be perceived as a reduction of subjective anxiety.

Moreover, alcohol limits the production of norepinephrine, a substance that activates the central nervous system's fight or flight response, causing increases in blood pressure and heart rate. Another suggestion is that alcohol intoxication works to reduce anxiety by diverting attention away from anxiety-inducing stimuli, in what has been termed the attention allocation model. This prevents extinction from occurring and may lead to increased substance use as an avoidance strategy. Over 20 years ago, it was proposed that the expectation that alcohol will reduce anxiety leads individuals to self-medicate and to experience less anxiety, primarily due to a placebo effect. This notion has received increased attention in the research literature over the past decade or so and is discussed in greater detail below. Alcohol's anxiogenic effects often occur following a period of heavy drinking. While initially anxiety reducing, alcohol can often serve to increase anxiety in the longer term.

MEDIATORS AND MODERATORS

Alcohol Outcome Expectancies

Some findings indicate that alcohol itself does not decrease anxiety, but rather the mere belief that one has consumed it does. It is more likely that the belief that alcohol will reduce anxiety interacts with the anxiolytic depressant properties of ethanol. Alcohol outcome expectancies (AOEs) can be defined as an individual's evaluation of the anticipated effects of alcohol prior to its consumption. AOEs are a frequent topic of discussion in this body of scientific literature, particularly as they relate to social anxiety disorder. Because those who do not expect alcohol to reduce anxiety often report no anxiety reduction following drinking (at least in an experimental setting), AOEs may be important considerations when treating a client who is self-medicating for anxiety. Many reports indicate that the expectation that alcohol will reduce anxiety predicts increased consumption of alcohol, as well as the use of alcohol for the specific purpose of self-medicating symptoms.

Moreover, coping-related alcohol use is associated with greater problems related to alcohol use.

There is some evidence that among those who do not expect alcohol to reduce anxiety, those with higher levels of social phobia are less likely to consume alcohol compared with those with lower levels of social phobia who also do not expect alcohol to reduce anxiety. This may be the result of differences in avoidance behavior. For instance, those with higher social anxiety may be less likely to engage in social situations where alcohol is available. Conversely, those with lower social anxiety may be more likely to attend social gatherings, but to do so with fear and trepidation. Another possibility is that instead of anxiety reduction, these people may believe that alcohol will lead to disinhibition and greater risk for social embarrassment, which will therefore lead to less alcohol intake among those with more significant social phobia. Among those who did expect alcohol to reduce anxiety, no difference has been found between those with high or low social anxiety; both groups use alcohol for self-medication.

In general, the more a person believes that alcohol will reduce anxiety, the more likely they are to utilize it for such purposes. This belief may be maintained and perpetuated by popular notions that alcohol will "take the edge off" after a difficult day or help one "loosen up" at parties. Although this may be true, it can also lead to the development of substance use disorders and other psychiatric problems in vulnerable individuals. In considering the particular types of situations in which self-medication is most likely (which is examined in greater detail later), alcohol consumption is reduced in situations where performance may be impeded, such as before giving a public lecture. Despite its immediate anxiolytic effects, the awareness of increased anxiety subsequent to a perceived below par performance may prevent self-medicating in these specific situations.

Sociodemographic Variables

Gender

In the general population, men and women report roughly equal rates of self-medication with alcohol in response to anxiety, however, men are more likely to self-medicate with drugs. This is particularly important given findings that self-medicating with drugs may pose a greater risk of other comorbidities than self-medication with alcohol alone. The use of drugs to cope with anxiety can be considered a marker of clinical severity, particularly in individuals using illicit substances rather than misusing prescription medications.

In longitudinal studies, women with social phobia are at greater risk of developing subsequent alcohol use disorders than are men with social phobia, with family support moderating this relationship. Whether this gender difference exists in those with anxiety disorders other than social phobia remains to be seen. There are a number of possible explanations for this finding, including increased social acceptability of drinking in men, or greater physiological effects of alcohol in women. Further research is needed to clarify the underlying mechanisms at work.

Gender differences have also been found in terms of AOEs. Men with high AOEs experience greater anxiety reduction after being given a placebo alcoholic beverage than men with low AOEs. This difference was not seen in women. It may therefore be especially important to assess AOEs in male patients.

Age

Self-medication for anxiety is most prevalent in the 30–44 years age group, especially when considering self-medication with drugs. Those over the age of 65 years report very low rates of self-medicating behavior.

Marital Status

Married individuals make up the majority of the group self-medicating with alcohol (60%); the rates are roughly equal among those who are married, separated, or single when considering self-medication with drugs.

Education

In any type of self-medicating behavior (either with alcohol or drugs), the majority of self-medicators have attended college at minimum. Those who did not complete high school, or completed high school and did not pursue further education, reported less self-medication. This finding may be the result of sampling bias, because the majority of individuals in the sample were those who had some college education.

Income

Interesting differences have been reported in terms of self-medication and income. Higher income categories (US$60 000+) represent the majority of those who self-medicate with alcohol. Lower income categories (US$0–19 999) represent the majority of those who self-medicate with drugs.

To summarize, it appears that those self-medicating with alcohol, but not with drugs, may represent a higher sociodemographic bracket. These individuals tend to be married, educated, and have higher household income levels. This profile is somewhat contrary to that often seen among those with psychiatric disorders; such individuals tend to be representative of the lower income and educational categories, and they are often single. Whether or not this is the cause or consequence of mental illness is not a subject of debate in this chapter, we merely

wish to point out – particularly to clinicians working with self-medicating individuals – that a different sociodemographic profile may define this group.

Specific Situations

In general, people at risk for self-medication tend to drink less alcohol prior to a performance task, likely because they do not want to impede performance. However, these individuals are at risk for self-medication following the task, and in other types of anxiety-provoking situations. Self-medication has a greater probability of occurring in situations that the individual chooses to endure with fear rather than avoid, which may explain the dearth of research on self-medication for specific phobias, as well as the low prevalence of this behavior in populations of individuals with specific phobias. Simply put, those with a pure specific phobia may choose to – and be able to – avoid the feared stimulus rather than endure it, precluding any need or benefit from self-medication. In the few population studies that have looked at specific phobias, the results are consistent in that this disorder has the lowest prevalence of self-medication compared with the other anxiety disorders. Conversely, socially phobic individuals are less able – and may be less willing – to avoid interactions with people. They are more likely to choose to endure feared situations rather than avoid them and use alcohol to allow them to endure feared social situations. Those with GAD are also less able to cope with fears through avoidance strategies, given that they are generalized to a wide variety of situations, which may explain the high prevalence of self-medication in these individuals.

Among those with social phobia specifically, anxieties about being observed or being scrutinized (such as when performing or giving a speech) tend to predict the onset of alcohol use disorder over and above anxieties related to social interaction. However, other research has indicated that self-medication is more common in situations where an individual has to interact socially than in those where they must perform. From these somewhat contradictory findings, it can be concluded that although self-medicating for social interactions is more common, it is specifically drinking to cope with observation that puts one at risk for the development of an alcohol use disorder. More research is needed to clarify the specific conditions under which anxiety can lead to substance use disorders in order to improve specificity in identifying at-risk populations. Research on other anxiety disorders, such as those with high prevalence of self-medication (e.g. GAD), is also likely to have substantial clinical benefits.

In summary, those at higher risk of self-medication may be those who have high expectations that alcohol will reduce anxiety, are not about to engage in a performance task, and are male. Self-medication poses a risk of subsequent alcohol use disorders in those with social phobia, and particularly those with observation-based fears.

OTHER QUESTIONS ABOUT SELF-MEDICATION

Why Do Some Choose Self-medication and Others Do Not?

In one of the original formulations of the self-medication hypothesis, it was proposed that individuals who engage in this behavior have a reduced ability to tolerate negative affect. In other words, self-medicating made difficult affective states easier to bear for vulnerable individuals who were compelled to reduce symptoms immediately. Other individuals may experience a significant amount of anxiety, but for other reasons are more able or willing to tolerate it, thus reducing their risk of self-medication. It is also possible that those who choose to self-medicate may have more severe manifestations of anxiety disorders and comorbidities than those who do not. Simply meeting criteria for an anxiety disorder may not increase the risk of self-medication; other factors may need to be in place. These factors may include ones that have already been discussed such as male gender, decreased tolerance of anxiety, and specific feared situations. Others are likely to include elements such as poor coping skills, family history of substance use, low resilience, environmental factors, as well as the perceived stigma of seeking more conventional treatments (such as psychotherapy). At this early stage in the research, it is extremely difficult to determine who is at risk for self-medication and who is not among those with anxiety disorders. It is known that engaging in this behavior can be harmful and risky, but it is not entirely known why some choose this coping strategy over others. This is an extremely important area for future research to pursue in order to develop strategies for the prevention of comorbid anxiety and substance use disorders, as well as to prevent other detrimental consequences of self-medication.

How Does Self-medication Lead to Comorbidity?

Individuals who self-medicate are known to be at increased risk for the development of comorbid substance use disorders. This may occur as a result of anxiety and substance use exacerbating each other. Attempts to self-medicate with alcohol, for instance, may be negatively reinforced initially. However, as this behavior continues it is likely to cause more anxiety as a result of neurochemical effects on the brain as well

as failure to appropriately process, and gain exposure to, the root cause of the anxiety. This increased anxiety is then likely to lead to increasing attempts to self-medicate, and symptoms thus progress in an upward spiral. Recent studies indicate that among those who endorse self-medication, the amount of alcohol consumed moderates the relationship between social anxiety and incident alcohol use disorders.

GAPS IN THE LITERATURE

Although recent epidemiologic studies have aided in determining the prevalence and consequences of self-medication in the general population, and experimental studies have furthered our understanding of AOEs and efficacy of self-medication, there are many existing gaps in the scientific literature that need to be addressed.

First, the vast majority of the literature is focused on social phobia and alcohol use. This is somewhat justified given the high rates of self-medication with alcohol in social phobia, yet further research is needed to examine the impact of the use of drugs on those with social phobia. This includes the use of illicit drugs and the misuse of prescription medications. Self-medication with drugs, although not as common as self-medication with alcohol, is still a prevalent and potentially serious behavior in those with social phobia. This is especially important given the increased negative consequences of drug use compared with alcohol use.

Second, more attention should be focused on the use of substances to relieve anxiety in those with other anxiety disorders, specifically GAD (given the high prevalence of this behavior in GAD and its potentially serious consequences).

The amount of substances used to self-medicate is another important consideration for future investigations. This is especially important when considering findings showing that self-medication – in the absence of a substance use disorder and after adjusting for comorbidity – is associated with important negative health consequences (e.g. suicidality, decreased quality of life). In these findings, the amount of alcohol consumed may be driving the associations rather than whether it constitutes self-medication. Longitudinal research aimed at addressing the finer details of the temporal association between substance use and anxiety, as well as the perceived efficacy and outcome expectancies of self-medication will also likely prove to be a fruitful avenue for future investigations.

TREATMENT CONSIDERATIONS

There is recognition that many individuals may not present for treatment. Self-medication may be an ingrained behavior in some individuals that has developed over a long period of time. The person may believe it to be an effective coping mechanism and thus not feel the need for formalized treatment. Furthermore, some individuals may not even recognize their substance use behavior to be problematic, or their anxiety to be distressing. Thus, there will likely remain a large group of people who engage in self-medication who are beyond the reach of treatment efforts. This underscores the importance of public health campaigns directed at anxiety, drug and alcohol use, and their interplay. Enhancing understanding of these conditions at the societal level will hopefully expand the effectiveness of treatment efforts.

Conversely, given the substantial comorbidity and negative consequences associated with self-medication, increased treatment seeking may be observed in a subset of people. In reviewing the literature, it seems, at least preliminarily, that self-medication is associated with greater rates of treatment seeking compared with those with anxiety disorders who do not self-medicate, when examined in an epidemiologic sample. Those who self-medicate are more likely to have seen a professional (e.g. a counselor or psychiatrist) and to have been prescribed medications than they are to present in an emergency room or to have been hospitalized. Treatment providers therefore need to be aware of self-medication in order to effectively care for these individuals who do present for help.

General Principles

Perhaps the most important treatment consideration of self-medication is its recognition, as well as an understanding of its consequences. Specifically, treatment providers need to have a high index of suspicion of self-medication among individuals with anxiety symptoms and disorders, given its high prevalence in this population. Care providers should directly ask all people with anxiety whether they use alcohol or illicit drugs, or misuse prescription drugs, to reduce their anxiety. If they endorse self-medication, the treatment provider needs to recognize that this person is at greater risk of alcohol and drug use disorders (if they have not yet developed), psychiatric comorbidity, poor quality of life, and suicidal behavior, compared with their anxious counterparts who do not self-medicate.

Self-medication implies a preexisting anxiety disorder, and therefore clinical guidelines for the treatment of anxiety disorders should be followed. Likewise, if the person has developed a comorbid substance use disorder, established guidelines for alcohol and drug use disorders should be followed. A review of specific treatment approaches for anxiety disorders and substance use disorders is beyond the scope of this

chapter; this review focuses on treatment approaches specific to self-medication.

In recent years, there has been a greater emphasis on the importance of treating co-occurring disorders simultaneously, with a developing evidence base for this approach. Co-occurring treatment initiatives lead to better outcomes compared with approaches that separate the treatment of anxiety and substance use disorders. Self-medication patients should be referred to such programs if they exist in the region. If not, treatment providers should make every effort to align their treatment as closely as possible to co-occurring disorder treatment guidelines.

Medications: The Use of Benzodiazepines

Caution should be used in the prescription of benzodiazepines to individuals who are at risk for self-medication. Research indicates that these individuals tend to shift their usage of benzodiazepines from an as-prescribed to an as-needed basis, which can lead to addiction. In general, prescription of benzodiazepines should be confined to agents with the least amount of abuse potential wherever possible. If their benefit is deemed to outweigh the potential risks associated with their use, benzodiazepines with longer half-lives, dosed regularly rather than as-needed, may reduce the likelihood of misuse and dose escalation. It is important to realize that even if the use of benzodiazepines does not lead to a comorbid substance use disorder in at risk individuals, simply misusing these medications for self-medication purposes may be associated with some of the other harmful outcomes of self-medicating behavior. It is also important for clinical practitioners to be aware of the potential for harmful drug interactions when they are considering writing a prescription for an individual who has been self-medicating.

Psychotherapy

Psychoeducation and cognitive behavioral therapy are two psychotherapeutic modalities that are likely to be effective in the treatment of people who engage in self-medication. They both alert patients to the knowledge that experiencing anxiety, rather than numbing it or avoiding it through substance use, is the best way to overcome anxiety in the long run. Psychoeducation can help people identify their problematic coping strategies, as well as understand the negative consequences associated with self-medication.

AOEs may prove to be a fruitful target for cognitive behavioral therapy in individuals with anxiety disorders prone to self-medication, as well as in comorbid individuals. For instance, beliefs that alcohol will be anxiety reducing may be challenged (given that alcohol produces greater anxiety over the longer term). This is important, given findings that high AOEs predict increased use of alcohol for coping, and that many socially phobic individuals hold such beliefs. Cognitive restructuring regarding whether anxiety can be endured will likely also prove beneficial, since many self-medicating individuals are likely to believe that they must immediately reduce anxiety in order to avoid serious negative consequences. In general, thoughts that promote and maintain self-medication should be uncovered and challenged through cognitive behavioral techniques.

Behavioral experiments can be easily devised to help reduce anxiety as well as reliance on substances to deal with it. For example, during later stages of therapy, a patient might choose to attend a party and not consume alcohol in order to test out how much they actually need it to control their anxiety. This might work best in patients who do not concurrently meet criteria for a substance use disorder, because withdrawal symptoms may need to be dealt with primarily in these individuals. The effectiveness of cognitive behavioral therapy on self-medication requires further study, ideally in the form of randomized controlled trials.

SUMMARY

The use of substances in response to anxiety (self-medication) is a fairly common and risky behavior. It is associated with increased comorbidity and suicidality, as well as decreased quality of life. The majority of research in this area has focused on the use of alcohol in response to social anxiety disorder, but there is evidence to suggest that the use of other substances, and in response to other anxiety disorders, is an important topic for both clinicians and researchers to consider. AOEs, gender, and the particular anxiety disorder in question are important considerations for determining the risk of self-medication, but more work is needed to uncover other variables likely to be relevant. Systematic studies of treatment efficacy in self-medicating and comorbid individuals are missing from the research literature. Traditional cognitive behavior therapy and client-centered techniques are likely to be effective for self-medication but require formalized intervention studies. Given the significant consequences that self-medication can have on an individual, their families, and society at large (in terms of the economic burden of comorbidity), it is an extremely important topic for both clinicians and researchers.

Glossary

Benzodiazepines a category of psychiatric medications that increase the effect of the γ-aminobutyric acid (GABA) neurotransmitter, resulting in the reduction of anxious symptomatology.

Comorbidity the presence of two or more psychiatric disorders occurring in the same individual at a given time.

Cross-sectional measured at one time point.

Epidemiologic referring to large-scale population-based sampling methods used to determine health patterns in the general population.

Longitudinal measured over two or more time points.

Self-medication the use of alcohol or drugs as an attempt to reduce psychiatric symptomatology; drugs may be either illicit or prescription (if used in a manner other than as directed by a physician).

Self-medication hypothesis the proposal that self-medicating behavior is the primary causal explanation for co-occurring substance use and anxiety disorders.

OUTLINE

INTRODUCTION

Over the past several decades, epidemiological studies in developed countries have consistently found associations between regular cannabis use and psychotic symptoms and disorders in the general population. Clinical studies have also reported higher rates of heavy cannabis use among new and chronic cases of schizophrenia. In this article, we address the following important questions raised by these findings:

1. What do these associations and other evidence indicate about the role of cannabis use in the onset of serious psychiatric disorders like psychosis with symptoms of delusions, hallucinations, and cognitive and social impairment?
2. How does cannabis use affect the course and outcome of psychoses like schizophrenia?
3. Is there similar evidence that cannabis use may increase the risk of developing bipolar disorders?
4. What implications does this evidence have for responding to young people with psychoses who use cannabis; warning young people of the mental health risks of cannabis use; social policies toward recreational cannabis use by young people?

CANNABIS USE AND SCHIZOPHRENIA ONSET

The inference that cannabis use is a contributory cause of psychosis requires that there is an association between cannabis use and psychosis; that chance is an unlikely explanation of the association; that cannabis use preceded the psychosis; and that plausible alternative explanations of the association can be excluded.

There is now good evidence from prospective studies that cannabis use and psychosis are associated, that chance is an unlikely explanation of the association,

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00054-1

and that cannabis use often precedes the development of psychosis. The major challenge has been in excluding two other explanations of the relationship: (1) that it is due to other uncontrolled factors, such as other drug use (e.g. amphetamines and alcohol), or a genetic predisposition that increases the likelihood of developing schizophrenia and using cannabis and (2) that the direction of the causal relationship is from psychosis to cannabis; that is, that persons with psychoses use cannabis to self-medicate the symptoms of their disorder.

The first good evidence that cannabis use may precipitate schizophrenia came from a 15-year prospective study of cannabis use and schizophrenia in 50 465 Swedish conscripts. This study investigated the relationship between self-reported cannabis use at age 18 and a diagnosis of schizophrenia in the Swedish psychiatric case register during the next 15 years. Those who had tried cannabis by age 18 were 2.4 times more likely to receive a diagnosis of schizophrenia than those who had not. The risk of a diagnosis of schizophrenia increased with the number of times cannabis had been used by age 18 (compared with those who had not used cannabis) from 1.3 times among those who had used cannabis 1–10 times, 3 times for those who had used between 10 and 50 times, and 6 times for those who had used more than 50 times. These risks were substantially reduced after statistical adjustment for having a psychiatric diagnosis at age 18, and having parents who had divorced (as an indicator of parental psychiatric disorder) but the relationships remained statistically significant.

Zammit et al. reported a 27-year follow-up of the Swedish cohort study, covering most of the risk period for the onset of psychotic disorders. This study provided better statistical control of a larger number of potential confounding variables that included other drug use, IQ, and known risk factors for schizophrenia and social integration. It was also able to distinguish between cases that occurred in the first 5 years and later. Zammit et al. also found that cannabis use at age 18 predicted an increased risk of schizophrenia during the follow-up period in a dose–response way and these relationships persisted after statistically controlling for the effects of other drug use, other potential confounders, and psychiatric symptoms at baseline. The relationship was a little stronger during the first 5 years, probably reflecting the decline in cannabis use that occurs with age. They estimated that 13% of cases of schizophrenia could be averted if all cannabis use were prevented.

Van Os and colleagues reported a 3-year study of the relationship between self-reported cannabis use and psychosis in a community sample of 4848 people in the Netherlands. Subjects were assessed at baseline on cannabis and other drug use and psychotic symptoms were assessed using a computerized diagnostic interview and a diagnosis of psychosis validated by a telephone interview with a psychiatrist or a psychologist. A consensus clinical judgment was made on whether individuals with psychotic disorder needed psychiatric care.

Van Os et al. replicated and extended the findings of the Swedish cohort study. Cannabis use at baseline predicted the risk of psychotic symptoms during the follow-up period in individuals who had not reported psychiatric symptoms at baseline. There was a dose–response relationship between the frequency of cannabis use and the psychotic symptoms during the follow-up period, and these relationships persisted when they statistically controlled for the effects of other drug use. The relationship between cannabis use and psychotic symptoms was stronger in persons with more severe psychotic symptoms who were judged to be in need of psychiatric care. Those who reported any psychotic symptoms at baseline were more likely to develop schizophrenia if they used cannabis than were individuals who did not. Van Os et al. estimated that cannabis use accounted for 13% of the psychotic symptoms and 50% of the psychotic disorders that needed treatment.

The Swedish and Dutch findings were replicated in a 4-year follow-up of 2437 adolescents and young adults between 1995 and 1999 in Munich. The subjects were assessed at baseline on cannabis use and psychotic symptoms were assessed in early adulthood using the Computerised International Diagnostic Interview. They found a dose–response relationship between self-reported cannabis use at baseline and psychotic symptoms. Young people who reported psychotic symptoms at baseline were much more likely to report psychotic symptoms at follow-up if they used cannabis than were peers who did not have such a history.

Arsenault et al. reported a prospective study of the relationship between adolescent cannabis use and psychosis in a New Zealand birth cohort ($N = 759$), whose members had been assessed intensively on risk factors for psychotic symptoms and disorders since birth. Psychotic disorders were assessed according to DSM-IV diagnostic criteria, with corroboration from family members or friends. Psychotic symptoms were first assessed at age 11, *before* the onset of cannabis use. They also examined the specificity of the association between cannabis use and psychosis by conducting analyses of the effects of (i) other drug use on psychotic symptoms and disorders and (ii) cannabis use on depressive disorders.

Arsenault et al. found a relationship between cannabis use by age 15 and an increased risk of psychotic symptoms by age 26 that persisted after controlling for other drug use. The relationship was no longer statistically significant after adjustment for

psychotic symptoms at age 11, but this probably reflected low statistical power given the small number of psychotic disorders in the sample. The measurement of cannabis and other drug use was crude (viz, none, 1–2 times, and 3 or more times). There was no relationship between other drug use and psychotic disorders and between cannabis use and depression. Earlier onset of cannabis use was more strongly related to psychotic symptoms and there was a suggestion that there was a higher risk of psychosis among cannabis users who reported psychotic symptoms at age 11.

Fergusson, Horwood and Swain-Campbell reported on a longitudinal study of the relationship between cannabis dependence at age 18 and psychotic symptoms at age 21 in the Christchurch birth cohort in New Zealand. They assessed cannabis dependence using DSM-IV criteria and psychotic symptoms by 10 items from the Symptom Checklist 90. Fergusson et al. were able to adjust for a large number of potential confounding variables, including self-reported psychotic symptoms at the previous assessment, other drug use, and other psychiatric disorders. Cannabis dependence at age 18 predicted an increased risk of psychotic symptoms at age 21 years (RR of 2.3) that remained significant after adjustment for potential confounders (RR of 1.8). Fergusson and colleagues also examined the association between cannabis and psychotic symptoms until age 25 years, using structural equations modeling to account for observed and nonobserved confounding factors. The association between cannabis and psychosis was not explained by confounding factors, and the direction of the relationship was from cannabis use to the symptoms of psychosis rather than vice versa.

McGrath and colleagues conducted a similar analysis of an Australian birth cohort in Brisbane. They examined the association between the duration of self-reported cannabis use (collected at age 21) and the likelihood of reporting psychosis-related outcomes (as assessed by the Peters et al. Delusions Inventory) in a cohort of 3801 young adults. They found that the number of psychosis-related symptoms reported increased linearly with the duration of cannabis use and that the relationship persisted when controlling for potential confounders. They were also able to replicate these relationships within 228 sibling pairs in the sample, thereby controlling for the effects of unmeasured confounders (such as shared genetic risk and family background).

In all these longitudinal studies, there have been consistent associations between self-reported cannabis use in adolescence and psychotic symptoms in early adult life. There was, however, some uncertainty about the timing of the first cannabis use because participants were assessed yearly or less often about their cannabis use during the preceding year or years.

Verdoux and colleagues addressed this issue by studying the more fine-grained temporal relationships between cannabis use and psychotic symptoms using an experience sampling method. They asked 79 college students to report on their drug use and psychotic symptoms at randomly selected time points, several times each day over 7 consecutive days. Subjects made their ratings when prompted by randomly programmed signals to a portable electronic device. Participants included high-level cannabis users ($N = 41$) and some ($N = 16$) who had reported one or more psychotic symptoms in the past month in a personal interview. Users reported more unusual perceptions and less hostility in periods after cannabis use, and cannabis use was more strongly associated with unusual perceptions in vulnerable individuals.

Henquet and colleagues have recently replicated these results using a similar sampling method to study the relationship between cannabis use, mood, and psychotic symptoms over 6-consecutive study days in 42 patients with psychotic disorders and 38 normal controls who were regular cannabis users. They found that cannabis use predicted short-term increases in positive mood and longer-term increases in hallucinations in both groups. The patients were more sensitive to both these effects of cannabis than the controls.

IMPACT OF CANNABIS USE ON THE COURSE OF SCHIZOPHRENIA

Clinical reports suggest that patients with schizophrenia who continue to use cannabis have more psychotic symptoms, respond poorly to neuroleptic drugs, and have a worse clinical course than those patients who do not. Prospective studies have reported similar findings. Jablensky and colleagues, for example, reported that patients with schizophrenia who used cannabis and cocaine had more psychotic symptoms and hospitalizations in a 2-year follow-up of 1202 first episode schizophrenic patients in a 10-country WHO Collaborative study. Martinez-Arevalo et al. reported that continued use of cannabis during a 1-year follow-up of 62 DSM-diagnosed schizophrenic patients predicted a higher rate of relapse and poorer compliance with antipsychotic drug treatment.

Linszen and colleagues reported a prospective study of 93 psychotic patients whose symptoms were assessed monthly over a year. Twenty-four of their patients were cannabis users (11 were less-than-daily users and 13 were daily users). Cannabis users relapsed to psychotic symptoms sooner, and had more frequent relapses in the year of follow-up, than the patients who had not used cannabis. Daily users relapsed earlier, and more often, than the less-than-daily users who, in turn, relapsed sooner, and more often, than the patients who did not

use cannabis. These relationships persisted after statistically controlling for premorbid adjustment and alcohol and other drug use during the follow-up.

These results were replicated in a larger sample of patients with schizophrenia followed by Degenhardt and colleagues monthly over a 10-month period. There was a small association between cannabis use in 1 month and psychotic symptoms in the following month that persisted after controlling for baseline symptoms and other drug use. Foti et al. have recently confirmed these results in a 10-year follow-up of 162 incident cases who were interviewed during their first admission, and then 6 months, 2, 4, and 10 years later. Cannabis use in the previous year predicted an increased likelihood of psychotic symptoms that persisted after adjustment for confounders. There was also some evidence that the experience of psychotic symptoms increased the likelihood of cannabis use in the following year.

Some uncertainty remains about the role of confounding factors, such as premorbid differences between patients who do and do not use cannabis in personality, family history, and other characteristics that predict a poorer outcome. The other challenge has been in separating the contributions that cannabis, alcohol, and other drug use may make to any exacerbation of schizophrenic symptoms. A 2008 meta-analysis of 13 longitudinal studies by Zammit and colleagues concluded that most studies were underpowered statistically and had not adequately controlled for baseline differences in the severity of disorder or for the effects of alcohol and other drug use.

INTERVENTION STUDIES

Intervention studies that reduce cannabis use among patients with schizophrenia who use cannabis could reveal whether symptoms of their disorders improved. The major difficulty with this strategy is that we have not been very successful in treating cannabis use disorders in persons with schizophrenia. There are very few controlled outcome studies of cannabis abuse treatment in schizophrenia and these studies have showed modest treatment effects and have rarely treated a large enough number of patients to detect any positive impacts of abstinence from cannabis on the course of schizophrenia (*see* chapter Treatment for Co-occurring Substance Abuse and Mental Health Disorders for more details).

BIOLOGICAL PLAUSIBILITY

The major psychoactive ingredient of cannabis, delta-9-tetrahydrocannabinol (THC), acts upon a specific cannabinoid receptor (CB_1) in the brain. D'Souza and colleagues have also shown in a double-blind provocation study that intravenous THC provokes positive and negative psychotic symptoms in a dose-dependent way in healthy volunteers and persons with schizophrenia. There is increasing evidence that the cannabinoid system may be involved in schizophrenia and related disorders. For example, CB_1 receptor knockout mice show behavior consistent with some of the symptoms of schizophrenia, such as reduced goal-directed activity and memory for temporal representations. Elevated levels of anandamide, an endogenous cannabinoid with similar effects to that of THC, have also been found in the cerebrospinal fluid of persons with schizophrenia.

AN OVERALL EVALUATION

The evidence reviewed points strongly in the direction of cannabis use playing a causal role in the precipitation and exacerbation of schizophrenia and other psychoses. Two other explanations need to be excluded before drawing these conclusions.

The first is that young people with psychoses use cannabis to self-medicate the symptoms of their disorders. The evidence for his hypothesis is weak. The reasons that most persons with schizophrenia give for using alcohol, cannabis, and other illicit drugs are similar to those given by peers who do not have schizophrenia, namely, to relieve boredom, provide stimulation, feel good, and socialize with peers. They also use the same drugs as their peers: tobacco, alcohol, and cannabis. Some persons with schizophrenia report using cannabis to relieve negative symptoms and depression, but prospective epidemiological studies have generally not found any relationship between early psychotic symptoms and an increased risk of later cannabis use, as required by the self-medication hypothesis. Moreover, neither Verdoux and colleagues nor Henquet and colleagues found a temporal relationship between reporting unusual experiences and the use of cannabis, as would be the case if self-medication was involved.

The other major alternative to a causal explanation of the association between cannabis use and psychosis is that it is due to uncontrolled residual confounding. The most plausible confounders are (1) the use of other drugs that can produce psychotic symptoms, such as, psychostimulants and alcohol and (2) a genetic vulnerability to develop a psychosis that also increases the risk of using cannabis or the susceptibility to its effects. The strongest epidemiological studies have addressed these forms of confounding by statistically adjusting for other drug use, personal characteristics that predict psychosis risk, and a personal history of psychotic symptoms. The number of confounding variables that have been assessed has varied between studies, as have the specific

variables that have been statistically controlled for. One recent study used fixed effects regression to control for *unmeasured* confounders.

In most of these studies, the relationship has persisted after adjustment for potential confounders. We accordingly agree with Moore and colleagues in their review of the literature that it is unlikely that the association is due to confounding. Those who continue to argue for uncontrolled confounding need to identify *plausible* confounding variables that have not been adequately controlled in studies to date so that they can be controlled in future studies. We also give weight to the evidence on the biological plausibility of a causal relationship between cannabis use and psychosis. For these reasons, we think it is more likely than not that cannabis use precipitates schizophrenia in persons who are vulnerable because of a personal or family history of schizophrenia. This hypothesis is consistent with the stress-diathesis model of schizophrenia that schizophrenia arises from the effects of stress acting on individuals with a preexisting vulnerability (arising from family and personal history) to develop the disorder.

This explanation is also consistent with the following facts: the relative risk of developing schizophrenia among regular cannabis users is modest (RR of around 2–3); the incidence of treated schizophrenia does not appear to have substantially increased during the period when cannabis use has steeply increased among young adults in Australia, North America, and the United Kingdom, and the onset of these disorders is, on average, at an earlier age among those who have used cannabis.

It is also noteworthy that heavy alcohol and amphetamine use have been accepted as causing psychoses on the basis of weaker evidence than that for cannabis. For example, the evidence that heavy alcohol use causes psychosis largely consists of case series of *delirium tremens* in severely alcohol-dependent people undergoing alcohol withdrawal. There is one experimental study, which showed that *delirium tremens* could be induced by abruptly stopping alcohol after several weeks of sustained heavy drinking in a hospital ward.

The evidence that heavy amphetamine use can induce a psychosis was initially based on Connell's 1958 series of 200 case studies of heavy amphetamine users who developed paranoid psychoses after sustained heavy amphetamine use and whose disorders remitted after abstinence. These case series were supported by small-scale experimental reproductions of psychoses in amphetamine users and normal volunteers. More recently, epidemiological studies have found associations between the frequency of amphetamine injection and the severity of psychotic symptoms in illicit amphetamine users. A causal explanation is supported by animal evidence that amphetamine and cocaine affect dopaminergic neurotransmission.

CANNABIS USE AND BIPOLAR DISORDER

Like schizophrenia, bipolar disorders also often have begun in late adolescence and early adulthood during the peak periods for initiation of cannabis use. Persons with bipolar disorders also have high rates of comorbid cannabis use disorders and there is some evidence that heavy cannabis use may also precipitate symptoms of these disorders. Henquet and colleagues reported a 3-year longitudinal study of the relationship between self-reported cannabis use and symptoms of mania in the NEMESIS sample of 4848 people in the Netherlands. Cannabis use at baseline predicted an increased risk of manic symptoms during the follow-up period in individuals who had not reported symptoms at baseline; there was a dose–response relationship between the frequency of cannabis use at baseline and the risk of manic symptoms during the follow-up; and these relationships persisted when they statistically controlled for the effects of personal characteristics and other drug use.

There is similar evidence for an adverse impact of cannabis use on the course of bipolar disorders. A North American study by Strakowski of 144 bipolar patients, 69 of whom had cannabis use disorders, found poorer outcomes in cannabis users but this difference disappeared after adjustment for confounders. The effects of cannabis use on outcome were also much less pronounced than the effects of alcohol use disorders in the same cohort. Different results were reported in a European study of the outcomes of bipolar disorder after a 12-month follow-up in 3459 patients. In this study, cannabis users showed poorer treatment compliance, higher levels of overall symptoms of disorder, and of mania and psychotic symptoms; and all of these relationships persisted after controlling for demographic and clinical confounders.

Overall, the evidence suggests that there are similar relationships between cannabis use and bipolar disorder as between cannabis use and schizophreniform psychoses, namely, early and regular use increases manic symptoms, and patients with bipolar disorders who are regular cannabis users are more likely to experience symptoms of the disorder. The evidence is not as strong as that for schizophrenia, but is reasonable enough to warrant similar policy responses, a topic to which we turn now.

WHAT ARE THE POLICY IMPLICATIONS OF THE EVIDENCE?

A Public Health Case for Prudence

How strong does the evidence for a causal relationship between cannabis and psychosis need to be before

we are justified in taking action? If the standard of proof required for action was "beyond reasonable doubt," then we would find it difficult to take *any* public health policy decisions. If, however, we are prepared to act on the "balance of probabilities" (more likely than not), then policy action can be justified on prudential grounds.

In deciding on a policy in the face of uncertainty, we need to consider the likely costs and benefits of different courses of actions. Prudential reasoning arguably supports the efforts to discourage young people from using cannabis. The public health gain from discouraging use, if the relationship is causal (perhaps a 10% reduction in schizophrenia incidence), would arguably offset the foregone pleasure among those young people who either did not use cannabis, or delayed using cannabis until young adulthood. In principle, a reduction in cannabis use among incident cases of psychosis would also provide evidence for the effectiveness of this policy but it has been difficult to decide if the increased use of cannabis by young Australians has increased the incidence of schizophrenia. Recent epidemiological modeling in the United Kingdom by Hickman and colleagues also suggests that a very large number of young people would need to be prevented from becoming heavy cannabis users (2018–4530) in order to prevent a case of schizophrenia. Four to five times as many young people would need to be deterred from even light cannabis use in order to prevent one case of schizophrenia.

The case for attempting to discourage cannabis use by young people is strengthened by the evidence that regular cannabis use in adolescence predicts the development of cannabis dependence, poor educational outcomes, an increased risk of using other illicit drugs, an increased risk of depression, and a lower quality of life and poorer social relations in early adulthood. There are similar debates on the causal interpretation of these associations, but the fact that cannabis use is associated with so many indicators of poor psychosocial outcomes makes it unlikely that confounding explains them all.

Responding to Cannabis Use among People with Psychosis

The implications of the evidence are probably least controversial for mental health services that treat young people with psychoses, among whom there are high rates of regular cannabis use. Given the evidence that people with psychoses who are regular cannabis users have more positive symptoms, more frequent relapses, and require more hospitalization, it is prudent to encourage young people with psychotic disorders who use cannabis to stop or reduce its use. The major challenges are finding ways of persuading persons with schizophrenia to stop doing something that they enjoy and helping those who want to stop using cannabis but find it difficult to do so.

Recent evaluations of psychological interventions for cannabis dependence in persons *without* psychoses have found only 20–40% abstinence rates at the end of the treatment and there are substantial rates of relapse thereafter. The treatment substantially reduces cannabis use and problems among those who do not succeed in quitting. Many persons with schizophrenia have characteristics that predict a poor treatment outcome, namely, they lack social support, are cognitively impaired, unemployed, and may not adhere to treatment. A Cochrane review of 25 RCTs found that there was no compelling evidence to support one psychosocial treatment over another in treating people with serious mental illnesses who used cannabis. This finding was confirmed in a recent review by Baker and colleagues who identified CBT and motivational interviewing as the most promising approaches to explore.

INFORMING YOUNG PEOPLE ABOUT THE MENTAL HEALTH RISKS OF CANNABIS USE

A major challenge is finding effective ways of persuading young people that cannabis use is a contributory cause of psychosis and that regular cannabis use can increase poor psychosocial outcomes. This task is complicated by the polarized views on the risks of cannabis use expressed in the public policy debates about whether cannabis use by adults should continue to be a criminal offense. Publicly expressed differences of opinion about the evidence make it easier for young people to discount the evidence of harm.

We need to be realistic about the likely impacts of health education on drug use. Well-conducted school-based drug education can produce statistically significant reductions in cannabis use, but these effects are modest. The primary effect is on knowledge rather than behavior change and this is more likely to occur among less frequent users rather than the heavier users who are at greater risk of psychotic symptoms and other adverse effects. The nature and delivery of the advice will need to differ for different groups facing different levels of risk. The best way to deliver the advice will depend upon good research on the preexisting views of young people and the most effective ways to change them.

Education on the risks of cannabis use should be part of the general health education on drug use and mental health. It should explain the mental health risks of regular intoxication with alcohol and cannabis; and define the known high-risk groups such as those with

a family history of psychosis and those who have had bad experiences with cannabis and alcohol. It also needs to equip young people to identify peers who are adversely affected by cannabis use and to encourage them to cease using or seek help.

A major challenge will be framing the magnitude of the psychosis risks from cannabis use. If cannabis use increases the incidence of psychosis among those who use it regularly, then the risk for regular cannabis users increases from around 7 in 1000 to 14 in 1000, arguably still a low incidence rate. If this risk is multiplicative with family history, then in persons with an affected first-degree relative, the risk could increase from 1 in 10 among those who do not use cannabis to 1 in 5 or 1 in 3 among those who use cannabis. The consequences for those individuals who develop the disorder are serious. The temptation for parents and health educators is to play up the risk, arguing that everyone is at risk because it is difficult to predict which young people are most vulnerable. We think this a doubtful strategy that may undermine the credibility of the message by being seen to exaggerate the risk.

POLICIES TOWARD RECREATIONAL CANNABIS USE

The evidence on cannabis and psychosis is clearly relevant in societal decision making about cannabis policy because psychoses are serious disorders that adversely affect the lives of the young people affected by them. Nonetheless, this health effect cannot and should not be the sole basis for social policy. It does not follow that cannabis use should be prohibited because it harms some users. If it did, we would be morally obliged to prohibit alcohol and tobacco use, not to mention motor cars and motorbikes. Those who advocate for cannabis prohibition need to provide additional arguments that criminal penalties are the best way to discourage cannabis use and reduce the harms that it causes. As a society, we also need to consider the social costs of using the criminal law to deter people from using cannabis; that is, informed policy requires evidence on the harms caused by cannabis use, and the social consequences of policies that aim to discourage its use, including criminal penalties for possession and use (*see* more detailed discussion in Drug Decriminalization and Legalization on legalisation).

SUMMARY

There is consistent epidemiological evidence of a causal relationship between cannabis use and psychosis, namely, the two disorders co-occur in the population and clinical populations; cannabis use often precedes psychotic symptoms in prospective studies, and the association does not appear to be explained by plausible confounding variables. A causal relationship is also biologically plausible because the cannabinoids interact with dopaminergic neurotransmission, the cannabinoid system may be disturbed in psychosis, high doses of THC provoke psychotic symptoms in people without psychosis, and persons with psychoses who continue to use cannabis have more severe symptoms and poorer outcomes than those who do not.

We should accordingly discourage cannabis use among young people who have developed mental health problems. This could be done by screening all patients with psychotic symptoms, and advising those who use cannabis to stop, or at the very least, to reduce their use. More research is needed on (1) how best to persuade them to stop and (2) better ways of assisting those who would like to stop, but find it difficult to do so.

There is an ethical imperative to inform young people of the probable mental health risks of cannabis use, especially early and frequent use of cannabis. The challenge will be finding credible and persuasive ways of doing so.

We should avoid making the common assumption that if the relationship between cannabis use and psychosis is causal, then we should continue to criminalise cannabis use. Accepting a causal relationship weakens the simplest case for liberalization – the absence of any harmful effects of cannabis. Given the seriousness of the psychotic disorders for the life chances of the young people who are affected by them, this evidence increases the case for caution in liberalizing cannabis laws in ways that may increase young people's access to cannabis, decrease their age of first use, or increase their frequency of cannabis use. But the effect of the law on young people is not the only outcome we should consider in framing cannabis policies. A considered decision about a policy toward cannabis requires an analysis of the social harms caused by current policy, as much as the harms caused by cannabis use.

SEE ALSO

Marijuana Use and Abuse

Glossary

Bipolar disorder a serious mood disorder defined by one or more episodes of abnormally elevated mood (mania) and depression. Either type of episode can be accompanied by psychotic symptoms such as delusions and hallucinations.

Cannabinoids they comprise drugs derived from the cannabis plant, such as THC or CBD, and the synthetic substances that act on cannabinoid receptors in the brain.

Cannabis any product of the *cannabis sativa* plant, namely, marijuana (the flowering tops of the plant) and hash, the compressed resin.

Cannabis dependence marked distress resulting from impaired control over cannabis use as indicated by difficulty in ceasing use and continued, usually daily use, despite harms caused by such use.

Delusions fixed and false or fanciful beliefs that often involve being persecuted by others or having special talents and attributes. These beliefs are firmly sustained despite not being believed by anybody else and in the face of strong disconfirming evidence. They are not accepted by other members of the person's culture.

Hallucinations perceptions that occur in the absence of appropriate stimuli in a conscious and awake state. They are vivid and perceived as veridical perceptions by the person experiencing them. They can occur in any sensory modality, but auditory and visual hallucinations are most common.

Provocation study an experimental study in which participants (e.g. persons with or without schizophrenia) are exposed to a putatively causal substance (e.g. cannabis) or placebo to see if the substance provokes a specific response (e.g. psychotic symptoms).

Psychotic symptoms symptoms of serious mental illness (such as schizophrenia and bipolar disorder) that include hallucinations and delusions.

Schizophrenia a serious mental illness that typically begins in early adulthood. It is characterized by impaired thinking, loss of contact with reality, and emotional unresponsiveness. Among its most common symptoms are auditory hallucinations, delusions, disorganized speech and thought, blunted emotional expression, and significant social and occupational impairment.

Schizophreniform psychosis a psychotic disorder that shares some of the symptoms of schizophrenia such as delusions and hallucinations.

Tetrahydrocannabinol (THC) the chemical substance in cannabis plants that is primarily responsible for the psychoactive effects sought by cannabis users, namely, euphoria, relaxation, increased sociability, and so on.

OUTLINE

CAUSES OF COMORBIDITY

While comorbidity between substance use disorders (SUDs) and severe mental disorders is common, the interaction between disorders is generally seen as one of mutual influence. There are a number of possible explanations for the frequent co-occurrence of mental disorders and SUDs. The explanations have differing consequences for the impact of SUDs on severe mental disorders and we cover them below. The causes include:

- The presence of a mental disorder may lead to an SUD, or vice versa (known as the direct causal hypothesis).
- There may be an indirect causal relationship (i.e. the role of an intermediary causal agent).
- There may be factors that are common to both the substance use and mental disorder, increasing the likelihood that they will co-occur.

Direct Causal Hypothesis

The Substance Use Disorder May Be a Consequence of the Mental Disorder

In some cases of substance use in individuals with mental disorders, the substance use occurs in an attempt to relieve mental health symptoms. If this happens repeatedly, over time an SUD is likely to develop. This is often described as the "self-medication hypothesis," in that substances are used in an attempt to medicate mental health symptoms. In these

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00055-3

circumstances, mental health conditions may become more apparent after the substance use has ceased. Certain mental health conditions may also impair a person's ability to make sound judgments regarding his or her substance use. For example, individuals with some personality characteristics or cognitive impairments relating to a mental disorder may have difficulty identifying social cues about appropriate use. This may lead the person to use in greater quantities or with greater frequency, increasing the likelihood of developing an SUD.

The Mental Disorder May Be a Consequence of Substance Use

Alternatively, substance intoxication and withdrawal can induce a variety of mental health symptoms and disorders, such as depression, anxiety, and psychosis. For example, alcohol use and withdrawal can induce symptoms of depression or anxiety; manic symptoms can be induced by intoxication with stimulants, steroids or hallucinogens; and psychotic symptoms can be induced by withdrawal from alcohol, or intoxication with amphetamines, cocaine, cannabis, Lysergic acid diethylamide (LSD) or Phencyclidine (PCP). In the majority of cases, these effects subside and eventually disappear with abstinence. For some, however, psychiatric symptoms may continue even after they have stopped drinking or using drugs.

Indirect Causal Relationship

An indirect causal relationship is said to exist if one condition has an effect upon an intermediary factor that, in turn, increases the likelihood of developing the second condition. For example, research has shown that the presence of early onset of substance use reduces the likelihood of completing high school, entering tertiary education, and completing tertiary education. This poor level of education may lead to later life difficulties (e.g. unemployment) that may predispose an individual to the development of other problems, such as depression. Similarly, the reverse is possible, whereby a mood disorder may lead to difficulties in completing study and work commitments, which may in turn lead to difficulties finding employment, increasing the risk of substance misuse.

Common Factors

The co-occurrence of two conditions may also come about due to the presence of shared biological, psychological, social, or environmental risk factors. That is, the factors that increase the risk of one condition may also increase the risk of another. For example, both substance and mental health conditions have been associated with lower socioeconomic status, cognitive impairment, the presence of conduct disorder in childhood, and antisocial personality disorder. It is also possible that a genetic vulnerability to one disorder may increase the risk of developing another disorder.

THE NEUROBIOLOGY OF SUBSTANCE USE IN SEVERE MENTAL DISORDERS

A growing body of evidence from basic science and translational studies implicates common neurobiologic pathways and abnormalities involved in addiction and a number of mental disorders. Using a neurobiologic framework, several hypotheses can be postulated to explain comorbidity: (1) addiction and other mental disorders are different symptomatic expressions of similar pre-existing neurobiologic abnormalities; (2) repeated drug administration, through neuroadaptation, leads to biologic changes that have common elements with the abnormalities mediating certain mental disorders.

One of the bridging constructs between mental disorders and SUDs involves the role of stress in SUDs and other psychiatric disorders. Corticotrophin releasing factor (CRF), one of the key hormones involved in the stress response, has been implicated in the pathophysiology of anxiety, affective and addictive disorders. Stress stimuli that activate CRF circuits are also known to potentiate mesolimbic dopaminergic reward pathways in laboratory animals. Similarly, human laboratory studies have shown that emotional stress and negative affect states increase drug craving in drug-dependent individuals. Evidence of an association between severity of depressive symptoms in patients with major depression and the subjective reinforcing effect of an acute dose of dextroamphetamine suggests dysregulation of reward systems with increasing level of distress in major depression. In this case, the addition of substance use to major depression has been shown to lead to a poorer course for the depression. The mechanism for this poorer course is dysregulation of reward systems. Animal models of early life stress and chronic stress result in long-term changes in stress responses which can alter the sensitivity of the dopamine system to stress and increase susceptibility to self-administration of substances of abuse. This may provide the neurobiologic underpinnings of the well-established relationship between early life adversity and SUDs in adolescents and adults and for the well-documented poorer course for severe mental disorders in those with SUDs

DOES CAUSALITY MATTER?

In the past, there has been a focus on establishing the relative order of onset of mental disorders and SUDs to identify which is the primary disorder. As, indicated earlier in this chapter, disorders may occur in any order, or they may develop at the same time. The evidence regarding the typical order of onset of disorders is not consistent. Establishing the order of onset of conditions can be useful in understanding the relationship between conditions. It is important to note however, that once both a mental disorder and substance misuse have been established, it is most likely that the relationship between them is one of mutual influence rather than there being a clear causal pathway, and both conditions may serve to maintain or exacerbate each other. For example, a person may engage in substance use to reduce symptoms of depression, however, research suggests repeated use may lead to increased depression. It is also possible that the relationship between disorders may change over time. For example, depression may trigger alcohol use on some occasions, while it may be the result of alcohol use on others.

WHAT ARE THE COMMON COMORBID DISORDERS AND WHAT IS THEIR IMPACT?

For many individuals with severe mental disorders and a comorbid disorder, a poorer disorder course is often the consequence. It is also the case that some substance use is more common among some mental disorders. Before examining course for each disorder, we will briefly outline the common comorbidities so as to set the research on course in perspective.

The most informative methodology for examining course of disorder is a longitudinal cohort study. These are, however, rare in individuals with severe mental disorders. The main source of information is long-term follow-up from clinical populations, usually following treatment. Research on the course of disorders, therefore, is very heavily reliant on treatment outcome rather than natural course.

SCHIZOPHRENIA

Prevalence

It has been approximated that 40–50% of those with schizophrenia will, at some point in their lives, also be diagnosed with an SUD; however, rates vary tremendously in published studies from as low as 10% to as high as 70%. The Epidemiologic Catchment Area (ECA) study of individuals from both community and institutional settings found 47% of all persons with a lifetime diagnosis of schizophrenia or schizophreniform disorder met criteria for some form of substance abuse or dependence (33.7% for alcohol disorder and 27.5% for another drug abuse disorder). Persons with schizophrenia were 4.6 times more likely to have a substance abuse diagnosis compared to the rest of the population (three times more likely for alcohol disorders, and six times more likely for other drug disorders). The moderating effects of demographic (e.g. gender, age) and population (e.g. clinical or nonclinical, in- or out-patient treatment) characteristics, along with other factors such as geographic location and heterogeneity in diagnosis/assessment techniques, are often cited as the reasons for such variability. Individuals with schizophrenia are, nevertheless, more likely to use substances than members of the wider community. As with many other forms of co-occurring conditions, the highest rates of comorbidity tend to be among those in treatment, the homeless, and the incarcerated.

Individuals with schizophrenia in particular have extremely high rates of smoking, ranging from 58 to 90%, with most studies suggesting it is almost universal. In addition, a recent review of 42 studies from 20 countries found that heavy smoking and high nicotine dependence were more frequent in smokers with schizophrenia than in smokers in the general population.

Clinical data suggest that cigarette smoking in individuals with schizophrenia may represent an attempt to self-medicate some symptoms of the illness. Studies suggest that individuals with schizophrenia have a primary deficit in brain nicotinergic systems that leads to abnormal sensory gating, and smoking cigarettes may be an attempt to overcome this deficit. Consistent with this theory, several studies indicate particular neuropsychological performance deficits in schizophrenia appear to be improved by nicotine administration and argue this may be one of the reasons for the high rates of nicotine smoking within this population.

With the exception of nicotine dependence, there is little evidence to suggest that persons with schizophrenia choose specific drugs to reduce specific symptoms and negative states. Other than nicotine, alcohol tends to be the drug most frequently associated with abuse or dependence in this population, followed by cannabis (and in some regions, cocaine). In general, the rates of types of substance use vary and tend to follow general population and geographic trends.

There has been much investigation and discussion surrounding the link between cannabis and psychosis. It is generally accepted that although there is little evidence to suggest that cannabis use per se causes psychosis, it appears that the drug exacerbates the

illness and may precipitate an earlier onset of illness in vulnerable individuals. In a recent meta-analysis of data from 83 studies, researchers found that cannabis users experienced psychosis almost 3 years earlier than nonusers, while for those with broadly defined substance use this onset was 2 years prior to that of nonusers. Cannabis and cocaine use have also been linked to psychotic relapses, while the role of alcohol is less clear. It has been suggested that individuals who use cannabis to ameliorate distressing symptoms of schizophrenia (rather than those for whom cannabis might be a predisposing factor to the disorder) report less negative symptoms than non-abusers. There may, however, be alternate explanations which, may better explain this finding.

Course

In assessing the impact of substance misuse on the course of mental disorders, there is a lack of clarity in the literature for a number of reasons, including inconsistencies in information concerning the primacy of disorders, restriction of samples to clinical populations, and differing treatments and rates of service use.

Overall, the impact of substance use on the course of schizophrenia appears to be detrimental across a range of outcomes. Generally persons with schizophrenia and comorbid substance use disorders have more psychotic symptoms than those without substance use. This link with psychosis may be mediated by treatment noncompliance among those with SUDs, as a number of reports indicate that persons with schizophrenia who abuse substances are more likely to be medication noncompliant. This medication noncompliance may be one explanation for the increase in psychotic symptoms.

There have been many studies highlighting the high rates of relapse and readmission to hospital and medication/treatment noncompliance among this comorbid population. Indeed, reports indicate that a decrease or cessation of substance use significantly increases the probability of remission from psychosis, while persistent use substantially reduces this likelihood. Although it is fair to assume these individuals with both schizophrenia and SUDs have a more complex clinical profile, recent evidence on treatment outcomes for people with co-occurring disorders indicates greater optimism is warranted, at least during the first 1–2 years. In the past, attempts to treat the disorders sequentially were largely unsuccessful and arguably to blame for these poorer outcomes. Currently, an integrated approach to treatment is recommended and integrated treatment programs have been rapidly emerging. Evidence suggests that if consistently applied, individuals in integrated treatment programs achieve positive recovery and more stable outcomes across substance use and schizophrenia as well as improved social and emotional outcomes and quality of life (*see* Treatment for Co-occurring Substance Abuse and Mental Health Disorders).

Recent studies into long-term recovery outcomes for this group are equally encouraging. At 3-year follow-up, one study found that participants with comorbid substance use and schizophrenia improved steadily in terms of reduced alcohol and drug use, schizophrenia symptoms, hospitalization and homelessness, as well as increased employment outcomes, contact with non-substance abusers, and overall life satisfaction. At 10-year follow-up, each of these areas showed steady and often significant improvement with the most dramatic functional improvements in the area of competitive employment. Participants also reported greater satisfaction with their lives overall. While most participants had not achieved the clinical cutoffs taken as indicators of recovery in several areas at the 3-year follow-up assessment, by 10 years a majority had achieved these levels on at least four of six recovery outcomes.

In terms of pharmacotherapeutic interventions in those with comorbid schizophrenia and SUDs, some studies suggest first-generation (typical) antipsychotic medications are less helpful than in non-comorbid individuals. There are even several reports suggesting that substance use may increase in such individuals when these antipsychotics are used. There is evidence, however, that the newer, second-generation (or atypical) antipsychotics (e.g. Clozapine) may be highly efficacious in individuals with schizophrenia and co-occurring SUDs and may have a positive impact on substance use in some individuals. Nevertheless, these benefits must be weighed against the heightened metabolic side effects of these medications.

Individuals with schizophrenia and substance use also tend to have increased mortality and higher rates of serious infection and medical problems, such as HIV and hepatitis C when compared to those without use. Because of the high rates of smoking among individuals with schizophrenia, this population is also at higher risk for many tobacco-related diseases compared to the general population. With these increased complications surrounding treatment response, relapse, and physical illness it is not surprising that hospitalization and crisis care expenses are also higher in this group when compared to individuals with schizophrenia without drug and alcohol problems.

Comorbid substance use has also been associated with a range of psychosocial problems. As with individuals with SUDs in general, those with schizophrenia and SUDs have been found to be at higher risk for violent behavior, suicide, and legal issues. One study found that individuals with schizophrenia and polysubstance use were more than 12 times more likely to be violent during a 3-month period when using and more than

four times more likely to be violent in the subsequent 3 months when compared to nonusers. Interestingly, cannabis or alcohol use alone did not predict violence. Consequently, these comorbid individuals are more likely to be incarcerated, while conversely, they are also more likely to be victims of violence themselves.

Issues surrounding stability of accommodation and homelessness have been shown to be more pronounced in this comorbid group compared to individuals with schizophrenia without SUDs. This comorbid group has also been found to benefit less from community outreach programs for the homeless. High rates of homelessness and unstable accommodation are arguably linked to the finding that substance use is associated with low levels of satisfaction with family relationships among persons with severe mental illness.

MAJOR DEPRESSIVE DISORDER

Prevalence

Like all prevalence data, a range of methodological, demographic, and population factors lead to variation in findings regarding the rates of SUDs in individuals with major depressive disorder. In the general population however, rates of current SUDs in this group range from 8.5 to 21.4%, with a lifetime prevalence of comorbid SUDs ranging from 27 to 40%. The ECA study found 27.2% of all persons with a lifetime diagnosis of major depression met criteria for some form of SUD (16.5% for alcohol disorder and 18% for another drug abuse disorder). Persons with depression were 1.9 times more likely to have a substance abuse diagnosis compared to the rest of the population (1.3 times more likely for alcohol disorders, and 3.8 times more likely for other drug disorders). Similarly, the National Comorbidity Study (NCS) indicated that those with major depressive disorder were twice as likely to be dependent on alcohol, twice as likely to be dependent on drugs and 1.6 times more likely to abuse drugs than those without major depression. The National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) found that, among those in the general population with major depressive disorder, 19.2% had an SUD in the prior 12 months, 14% had a 12-month alcohol use disorder, and nearly 5% had a 12-month drug use disorder, while among those with lifetime major depressive disorder, this rate was 40 and 17% for alcohol and drug use disorders, respectively.

In clinical populations, the prevalence of concurrent SUDs in those with major depressive disorder tends to be higher than the general population. This is consistent across mental disorders as the presence of multiple disorders increases the likelihood of seeking treatment. In clinical populations, the rate of 12-month SUDs ranges from 8.6 to 25% and the lifetime prevalence ranged from 30 to 42.8% of treatment-seeking patients with major depressive disorder.

The types of SUDs most commonly found in those with major depressive disorder generally mirror those of the general population, with particularly high rates of alcohol use disorders. A recent meta-analysis of 35 studies revealed a median prevalence of current alcohol problems in depression of 16% (ranges 5–67%) and lifetime rates of 30% (ranges 10–60%). In contrast, the general population figures of these disorders were 7% for current and 16–24% for lifetime alcohol problems.

Course

The course of major depressive disorder in those with an SUD tends to be more complex than in those without this comorbidity. Recent epidemiological data has shown that among populations with lifetime drug or alcohol dependence and major depressive disorder, past year substance dependence remission was associated with an approximate three-fold reduced risk of depression. Compared with those without the comorbid condition, individuals with major depressive disorder and concurrent SUDs are more likely to be younger, male and either divorced or never married. They also tend to attribute greater functional impairment to their illness. Similarly, it has been reported that compared with those with major depressive disorder alone, those with comorbid SUDs have greater depressive symptomatology, more frequent concurrent anxiety disorders, poorer functioning (particularly social functioning), and an earlier age of onset of depression. Despite this finding, there have been no randomized controlled trials regarding comorbidity interventions targeting this younger population. A longitudinal study of disorder course in adolescents found that although an increase in substance use is not necessarily accompanied by an increase in depressive symptoms, decreases in substance use severity are associated with decreases in depressive state. Similarly, stable substance use rates, either at a low or a high level, tend to be associated with low or high levels of depression, respectively.

Much of the literature on course of major depressive disorder is found in the treatment literature. Longitudinal follow-ups of depressed patients indicate poor long-term outcomes for severe depressive disorders. These chronic outcomes are compounded by co-occurring substance use. Treatment outcome studies have consistently found that individuals with co-occurring major depressive disorder and SUDs have poorer treatment outcomes than those with one disorder alone, however, the nature of this relationship is contentious.

Among opiate-dependent populations, current mood disorders are associated with poorer treatment response and higher rates of relapse. Analogous findings have been observed among alcohol- and cocaine-dependent patients. The presence of an alcohol use disorder has also been shown to reduce the likelihood of depression remission, while the immediate treatment of the SUDs can reduce depressive symptoms. Meanwhile, a recent meta-analysis reported mixed findings regarding the effects of alcohol problems on depression course in terms of risk of relapse and likelihood of recovery, the authors conclude that current, but not lifetime, alcohol problems increase health care utilization. More generally, individuals with a range of comorbid SUDs and major depressive disorder have been shown to use health services more frequently and at greater cost compared to persons with one disorder. All these findings indicate both the negative impact comorbid substance use has on the course of depression and the positive effect associated with the treatment of these disorders.

There is growing evidence that antidepressants improve depression outcomes in persons with SUDs. Some studies have also found that antidepressant treatment can also improve drug use outcomes in comorbid individuals, but these effects are strongest in those individuals who report improvement in the symptoms of depression, suggesting that the improvement in SUDs outcomes may be influenced by the improvement in depression. It is generally observed that pharmacological intervention is not a stand-alone treatment, and concurrent therapy directly targeting the addiction is also indicated.

A recent meta-analysis has found only limited evidence for the effectiveness of cognitive behavioral therapy (CBT) either alone or in combination with antidepressant medication for the treatment of co-occurring depression and substance use, over and above that of other psychotherapies. There is, however, consistent evidence of improvements in both depression and substance use outcomes, regardless of the type of treatment. The authors suggest more specific forms of CBT be developed for this comorbid population. In light of this finding a number of integrated cognitive behavioral therapies have been developed with promising results both on substance use and depression outcomes.

Perhaps unsurprisingly, considering the high rates of suicide in the disorders respectively, individuals with major depressive disorder and a comorbid SUD have been found to have higher rates of suicidal ideation and attempts than in individuals without this comorbidity. Furthermore, evidence suggests, at least with alcohol use disorders, that this may be true of not only concurrent comorbidity, but also those with any history of alcoholism. Conversely, individuals with major depressive disorder and current suicidality have been shown to have higher rates of current SUDs than those without.

Evidence suggests that interpersonal and social functioning is often impaired in depressed patients with comorbid SUDs. Reports indicate that compared with individuals with major depressive disorder, only those with co-occurring alcohol problems have impaired relationships with their spouses, as well as a higher rate of divorce and living alone. Less evidence exists concerning the impact of other drugs on interpersonal and social impairment in major depressive disorder, however, limited data suggests similar patterns of poorer functioning.

BIPOLAR DISORDER

Prevalence

SUDs are common in individuals with bipolar disorder. Three epidemiologic studies conducted in the United States over the last 30 years have all concluded that individuals with bipolar disorder are at greatly enhanced risk for the development of SUDs as compared to the general population. In the ECA study, 56% of individuals with bipolar disorder had a lifetime SUD. The NCS found that individuals with bipolar disorder were approximately seven times more likely to have an SUD when compared to the general population. In both the ECA and NCS, bipolar disorder was the Axis I disorder associated with the highest risk for a co-occurring SUD. More recently, the NESARC also found that bipolar disorder was highly and significantly related to SUDs. Studies in clinical samples also support the high co-occurrence of bipolar disorder and SUDs.

There is little evidence to suggest that individuals with bipolar disorder choose specific drugs depending on their mood states. Alcohol is the drug most frequently associated with abuse or dependence in this population. In general, the rates of types of substances used by individuals with bipolar disorder vary and tend to follow general population and geographic trends.

Course

A number of studies suggest that the presence of an SUD has an impact on the age of onset and course for individuals with bipolar disorder. While several studies have found that the onset of bipolar disorder at an early age is associated with co-occurring SUDs, others have noted a later onset of bipolar disorder in alcohol-dependent bipolar patients. It has been hypothesized that there are subtypes of individuals with bipolar-SUDs comorbidity. The early onset group has more severe

bipolar illness that includes the development of subsequent SUDs, whereas the patients with SUDs that precede the onset of their mood disorder may have a less severe illness that required the presence of substance abuse to initiate the bipolar disorder. Several studies have found that mixed manic states and rapid cycling bipolar disorder are more common in bipolar individuals who have SUDs than in those who do not. This is important because both mixed episodes and rapid cycling disorder are associated with treatment resistance and a slower time to recover from an index episode. Along these lines, several studies have found that individuals with co-occurring bipolar disorder and SUDs have increased health service utilization including more emergency room visits and hospitalizations, more suicide attempts, and greater medication noncompliance.

Longitudinal studies have indicated that even a remitted SUD may be associated with poorer acute treatment response, a longer time to remission of their acute mood episode, and a greater percentage of time with subthreshold, but clinically significant, depression and manic symptoms over follow-up compared to those without this comorbidity. This poorer course of illness could not be fully explained by subsequent substance abuse during follow-up. However, a recent study found past or current SUD did not predict time to recovery from a depressive episode relative to no substance use comorbidity. Rather, those with current or past SUD were more likely to experience a switch from depression directly to a manic, hypomanic, or mixed state. These contrasting findings may be the result of differing forms of therapy or severity of substance use.

Much of the evidence on course of disorder in those with bipolar disorder is from long-term follow-up of treatment samples. Lithium is often considered the standard medication treatment for bipolar disorder, however, co-occurring SUDs may be a predictor of poor response to lithium. There is some data suggesting that anticonvulsant mood-stabilizing agents may be a better choice in individuals with SUDs. In particular, one recent trial investigating lithium plus valproate as compared to lithium plus placebo in subjects with alcohol dependence and bipolar disorder found better alcohol-related outcomes in those who received valproate. There have also been some promising pilot studies investigating the use of naltrexone and disulfram in individuals with co-occurring alcohol dependence and bipolar disorder. Recent investigations of psychotherapeutic treatments specifically targeting SUDs in individuals with bipolar disorder also show promise. All individuals with bipolar disorder should be assessed for substance use and counseled concerning the negative impact of substance use and risk for developing dependence.

CONCLUSION

The issue of substance use in those with serious mental disorders is gaining increasing attention from researchers and clinicians with strong evidence that it complicates the natural course of the disorder and is associated with a range of negative outcomes. These negative outcomes relate to a myriad of areas such as general health, psychosocial problems, functional impairment, greater symptomatology, earlier age of onset and treatment. While we have excellent evidence on the epidemiology and prevalence of these co-occurring problems, there remains very little guidance as to evidence-based practice for individuals with more than one disorder.

Glossary

Comorbidity refers to the co-occurrence of an SUD with one or more mental health conditions. The terms "comorbid" and "co-occurring" are used interchangeably throughout this chapter.

Mental disorder refers to the presence of a mental disorder (other than a SUD) as defined by the DSM-IV. Severe mental disorder, for the purposes of this chapter we focus on schizophrenia, major depressive disorder, and bipolar disorder.

Substance use disorder (SUD) refers to the presence of a drug and/or alcohol use disorder as defined by the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV). This includes abuse and dependence.

Developmental Risk Taking and the Natural History of Alcohol and Drug Use among Youth

Jennifer L. Maggs, Laura Wray-Lake$, John E. Schulenberg***

*The Pennsylvania State University, PA, USA $Claremont Graduate University, CA, USA

**The University of Michigan, MI, USA

OUTLINE

The 2010 Monitoring the Future national survey of high school seniors reported that 71% of adolescents had consumed alcohol by the 12th grade, 42% had tried cigarettes, 44% had used marijuana, and 25% had consumed an illegal drug besides marijuana. These rates suggest that substance use is a common but not universal experience during adolescence. Adolescence is a developmental period characterized by risk-taking behavior, and risk taking is heightened in adolescence for various reasons including biological development and identity exploration.

NORMATIVE DEVELOPMENT OF RISK TAKING

Biology

By late adolescence, most individuals have fully developed in terms of height and reproductive capacity, and by the early 20s, individuals typically reach peak physical functioning in heart and lung strength and athleticism. These physical changes impact adolescents' tolerance of substances, making it possible for youth to recover from negative physical effects, such as hangovers, more quickly. In conjunction with pubertal development, adolescents often look older and desire to be older than they actually are. As alcohol use is a status and privilege of adulthood, the desire to look and act older may prompt initiation of alcohol use.

The adolescent brain offers capacity for heightened sensation seeking and may allow adolescents to derive greater physical pleasure from substance use. It is now recognized that brain development continues beyond adolescence into young adulthood. In particular, higher-order reasoning and cognitive processing capacities continue to develop. Until these capacities fully mature, youth are increasingly likely to engage in excessive substance use and other risk-taking behaviors. Still

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00056-5

developing brain functions can be negatively affected by heavy substance use during adolescence, putting youth at risk for later life repercussions.

Identity

Identity exploration is a fundamental developmental task for adolescents and young adults. This exploration entails recognizing and solidifying one's personal interests, values, goals, commitments, and overall sense of self. As part of identity exploration, adolescents often question assumptions and beliefs that they previously took for granted, including beliefs about substance use. Over the past few decades, US youth have increasingly delayed careers, marriage, and parenthood, and as a result, identity exploration extends beyond adolescence and into young adulthood. These years of prolonged exploration are referred to by some as "emerging adulthood." Although identity exploration is necessary, normal, and healthy, it may sometimes involve experimentation with substance use. Despite the short-term and long-term health risks of the behavior, substance use (and alcohol use in particular) can serve developmental functions such as making friends, testing boundaries of independence, and exploring one's sense of self. Thus, some youth view substance use as a natural pathway to identity formation.

Developmentally Limited Substance Use

Adolescence is a time of rapid development and simultaneous transitions across multiple domains, and this confluence of changes sets the stage for heightened risk-taking behavior. Risk-taking behavior extends to behaviors beyond substance use such as reckless driving, unsafe sex, and extreme sports. Although many youth drink heavily and a sizeable proportion experiment with drugs, only a small number of youth advance to long-term difficulties with substance use including abuse and dependence. As youth grow into adults and take on corresponding responsibilities, experimentation with substance use typically tapers off. Thus, the substance use of most youth is *developmentally limited*. This term refers to substance use that may be heavy during adolescence or young adulthood but is not sustained over time; instead, patterns reflect "aging out" or maturing out of use. Even when youth engage in substance use for a limited period, however, alcohol and drug use can be a highly risky and tragic experience. Moreover, for an important minority of individuals, alcohol and drug use does not decrease. Continued use sets the stage for substance use and abuse problems as well as difficulties in other life domains.

INITIATION OF ALCOHOL AND DRUG USE

The onset of substance use is important to understand because adolescence is a time of greatest risk for the development of substance use disorders. Initiating alcohol use in childhood or early adolescence is a clear marker for problematic patterns of alcohol or drug use in adolescence and adulthood. Age of initiation is defined as the age at which alcohol is first consumed. In measuring alcohol initiation, some researchers exclude sips or tastes, and some only include regular alcohol use. The age cutoff that defines "early" alcohol initiation varies widely across studies. Some researchers define early as use before age 13, whereas others put the cutoff at age 14, 15, or even 18. Regardless of definitional differences, early alcohol initiation consistently predicts later substance use problems. For example, early initiation of alcohol use predicts greater likelihood of drunk driving; more blackouts after use; and increased tolerance, dependence, and substance abuse. Risks increase in correspondence with earlier initiation.

Although a consistent negative link between age of initiation and subsequent alcohol use and disorders has been documented, there is a considerable disagreement over the interpretation of this finding. Some researchers argue that early alcohol use is a cause of later use. In other words, using alcohol in childhood or early adolescence puts individuals on a trajectory toward heightened use and misuse. Prevention efforts consistent with this view seek strategies to delay onset of alcohol use. Taking a different view, other researchers posit that both early and late use stem from the same underlying susceptibility to alcohol problems. Genetic risks for alcohol problems, family environment, or mental illness are some suggested factors that may serve as common causes for initiation and persistence of alcohol use. Proponents of this perspective argue that delaying onset of alcohol use would not reduce problem drinking; rather, prevention efforts should focus on halting the progression from initiation to problem use and abuse. More rigorous research is needed to specify the causal processes involved in the initiation and maintenance of alcohol use in order to determine the most effective prevention efforts.

These two explanations for alcohol initiation are also relevant to understanding the initiation of drug use. Moreover, early alcohol use is a known risk factor for illicit drug use. Middle adolescence is the typical time that individuals start to use marijuana, and late adolescence is a peak time for initiating use of other illicit drugs. Alcohol can serve as a gateway drug, meaning that exposure to alcohol may increase the likelihood that adolescents try other substances and engage in other risk-taking behaviors.

DEVELOPMENTAL TRAJECTORIES

Understanding age-related patterns in alcohol and drug use is necessary from a developmental perspective. A cross-sectional study is a common way to examine substance use at different ages in research; this method compares age groups at a single point in time. While relatively inexpensive to conduct, cross-sectional studies offer incomplete information about how a person's substance use changes as he or she gets older. Long-term longitudinal studies, which follow the same individuals over a period of time, allow researchers to predict individuals' substance use based on their past or present use. These studies chart developmental trajectories, which are patterns that reflect the course of substance use over a number of years. Examining trajectories can help researchers determine why some individuals do not follow patterns that seemed likely based on previous behavior. There are two important types of trajectories: *Average trajectories* demonstrate the overall mean-level developmental pattern for a group of people as a whole, and *multiple trajectories* identify several distinct subgroups of individuals who share the same developmental patterns.

Average Trajectories

Examining average patterns in substance use across adolescence and young adulthood is important for documenting normative developmental changes in use, with normative referring to patterns that describe average change across individuals in a society. Several US longitudinal studies, including Monitoring the Future and the National Longitudinal Survey of Youth, have reported similar average patterns in substance use. Alcohol use increases during adolescence and peaks in the early 20s, at around ages 21–22. This pattern is evident regardless of whether alcohol use is measured as use in the past year, use in the past 30 days, or heavy episodic drinking in the past 2 weeks. Another term for heavy episodic drinking is binge drinking, historically defined in this age group as consuming five or more drinks in a row on a single occasion; binge drinking follows the similar pattern of increasing right after high school, peaking in the early 20s, and then decreasing.

Substance use, and particularly alcohol use, is intertwined with the cultural experience of becoming an adolescent and young adult. Attending college is one such experience that carries high risk for heavy episodic drinking. During high school, adolescents who plan to attend college have *lower* rates of alcohol and other drug use than their peers with no college plans. After high school, *higher* rates of alcohol use and heavy drinking are found among college students compared to their non college-bound peers. However, youth not attending college report higher rates of illicit drug use compared to college attendees.

Studies have also examined trajectories in marijuana use. On average, marijuana use remains relatively stable in the years immediately following high school (ages 18–19) and gradually decreases across the early 20s. Over half of US young adults have reported ever trying marijuana, and 25% have engaged in marijuana use across ages 18–24. However, frequent use is relatively low: In 2008, 5% of US 12th graders reported daily marijuana use, as measured by using marijuana on 20 or more days in the month prior to the survey. Rates of other illegal drugs also tend to peak in late adolescence.

Following the early 20s, substance use steadily declines across young adulthood and beyond. This decline corresponds with the adoption of adult roles. For example, levels of alcohol use, problem drinking, and marijuana use decline in conjunction with marriage, and to a lesser extent with full-time employment and parenthood. Thus, the normative developmental pattern is likely a consequence of shifts in freedoms and responsibilities experienced during adolescence and young adulthood. Adolescence is characterized by freedom and autonomy, whereas the 20s and beyond often involve adult responsibilities. Whether transitions into adult roles cause reduced substance use or vice versa is a matter for debate: Longitudinal research has shown that declines in substance use actually foreshadow marriage, suggesting that the young adults most likely to marry are also those less inclined to use substances.

When examining developmental trajectories, it is important to recognize that substance use is embedded in changing historical contexts. Drugs can change in popularity or availability over time, impacting youth's initiation and use of substances. For instance, nonmedical use of prescription drugs (e.g. OxyContin and Vicodin) and over-the-counter medications (e.g. cough suppressants) have increased in popularity in recent years. As older drugs fall out of favor, new drugs tend to replace them. Alcohol, however, is a mainstay with adolescents. Trends in alcohol use have been relatively stable across several decades, suggesting that risks associated with drinking are prevalent and alcohol use is developmentally relevant regardless of historical time.

The average trajectory approach to examining substance use has several limitations. For example, long periods between measuring substance use in most longitudinal studies can omit important information and lead to overgeneralizations about the simplicity of the overall pattern. Also, as described below, not everyone follows a uniform developmental pathway. Despite these limitations, average developmental trajectories can inform universal prevention efforts, which are aimed at reducing substance use among the population of adolescents. Normative patterns of substance use also

give us valuable insights into youth development and suggest that substance use may serve important developmental functions.

Multiple Trajectories

Rather than identifying a single overall pattern, the multiple trajectory approach focuses on unique subgroups of individuals who follow similar patterns. This approach is useful because it offers the potential for better understanding the origins of substance use disorders and improving early identification of problems. Moreover, individuals follow many different life paths, and substance use patterns likely diverge as a consequence of diverse experiences.

Regarding alcohol use, the most common trajectory subgroup found for adolescents and young adults across several studies is a *low-risk group*. Individuals in this group tend to abstain from drinking, drink small amounts, or consume alcohol rarely across adolescence and young adulthood. Although the exact definition of this group varies across studies, this group engages in very little use and defines one-fifth to two-thirds of adolescents and young adults. In addition, about one-third of adolescents and young adults fall into a *stable-moderate drinker group*. These individuals tend to initiate alcohol use in late adolescence (e.g. age 17 or later); they engage in some heavy drinking over time, but do not increase or decrease use dramatically. These two groups comprise relatively low-risk drinkers and represent the drinking patterns of a large proportion of youth. Thus, the vast majority of youth are not drinking at problematic levels.

Several more problematic patterns in alcohol use have been identified. *Chronic heavy drinkers* tend to initiate heavy drinking early (typically by middle adolescence) and maintain high use in their 20s. *Late onset drinkers* initiate alcohol use later (by middle to late high school), and then steeply increase drinking levels in the late adolescence and young adulthood. Both of these groups are defined by the age at which individuals begin to drink heavily. Because the way researchers define this age varies across studies, these two groups can be difficult to identify or compare across studies.

Another potentially problematic trajectory is exhibited by *fling drinkers*. These individuals tend to engage in heavy drinking during a brief period, typically peaking in adolescence and declining in early adulthood. Fling drinkers make up approximately 10% of adolescents and young adults.

Decreasers reflect a subgroup wherein individuals begin drinking heavily at an early age such as during middle school, looking similar to chronic drinkers. Unlike chronic heavy drinkers who maintain early high levels, this group significantly decreases alcohol consumption during late adolescence and early adulthood. An estimated 10% of adolescents and young adults comprise this group. It is interesting to note that by their mid-20s, however, decreasers not only look different from chronic drinkers in their substance use, but also decreasers are more likely to be married, parents, employed full-time, and financially independent.

Marijuana use trajectories have also been identified in youth aged 18–24. Much like the drinking subgroups, there are two groups of *low-risk marijuana users*: those who abstain and those who report rare and infrequent use across all occasions. *Chronic users*, *fling users*, and *decreasers* are also typical developmental patterns in marijuana use. The vast majority of young people fall into low-risk, decreaser, or fling categories, reflecting either no use or developmentally limited marijuana use. A group of *increasers* display patterns of marijuana use similar to late onset drinkers: these youth report no use or infrequent use in late adolescence which escalates to frequent use in the early 20s. Thus, the multiple trajectory approach has identified very similar alcohol and marijuana use subgroups.

Trajectories in binge drinking and marijuana use across young adulthood vary according to the number of developmental transitions experienced. Typical indicators of young adult developmental transitions include movement into post-secondary education, work, marriage, and parenthood, and out of the parental home. Longitudinal research indicates that experiencing many developmental transitions is associated with a decreasing pattern of substance use; however, experiencing too few developmental transitions is associated with a high, stable developmental pattern of substance use across young adulthood. Although direction of effects was not the focus of the research, findings imply that postponement of developmental transitions is related to higher substance use.

In summary, not everyone experiences the same developmental pathway, and the multiple trajectory approach describes variability in substance use patterns. Identifying unique subgroups based on substance use trajectories can greatly assist researchers and clinicians in pinpointing the most problematic patterns and the best course of prevention or treatment. Both average and multiple trajectory approaches are limited by individuals dropping out of longitudinal studies (called attrition). If attrition is high among the heaviest substance users, then studies will underestimate problems.

RISK AND PROTECTIVE FACTORS

After identifying the developmental patterns in substance use, an important next step is to understand risk and protective factors related to substance use in

adolescence and young adulthood. Risk factors are variables that predict a higher likelihood that a negative outcome will occur, and protective factors refer to anything that reduces or prevents the likelihood of a negative outcome. Risk and protective factors for adolescent alcohol and drug problems have been grouped into at least 17 different categories. Some are distal, contextual factors such as state laws about substance use or ease of obtaining substances in a community. Other risk factors stem from an adolescent's proximal environment, such as experiences in one's family (e.g. conflict with parents), school (e.g. academic failure), and peer group (e.g. rejection). Risk and protective factors can also be person characteristics such as cognition and personality. Elsewhere, scholars have extensively reviewed risk and protective factors; here, we overview a few key domains of developmental significance during adolescence and young adulthood and highlight risk and protective factors found within these domains.

Cognition

A myriad of cognitive changes occur during adolescence that are related to risk for substance use. For example, the capacity to think abstractly and take the perspective of others increases. As adolescents become more independent in their thinking and more likely to question authority, parents', teachers', and other adults' ideas become only one of many possible perspectives. Thus, adults' warnings to avoid alcohol and drugs may be just one of the perspectives that adolescents consider following. In relationships with peers, adolescents become able to view themselves from the perspective of others, and this perspective-taking creates a keen awareness of how actions may impact image and popularity. Adolescents who drink often say they do so to increase their popularity. In fact, with adolescents' increased ability to consider costs and benefits of risky behaviors such as substance use, adolescents become increasingly aware of the potential benefits of substance use and less convinced of its costs. Adolescents' alcohol expectancies, or the expectations that individuals have for positive and negative outcomes of drinking, represent a major risk factor for alcohol use and misuse. When adolescents have more positive attitudes toward alcohol and drug use, they tend to have higher levels of use.

These cognitive risk factors do not imply that adolescents lack cognitive capacity for logical decision making. On the contrary, adolescents' abilities to assess risk and consequences in hypothetical scenarios are equivalent to adults' capabilities by the time adolescents reach age 15. The consensus among researchers is that adolescents use different social and emotional cues when making decisions related to risk behavior. Moreover, certain cognitions serve protective functions: for example, perceived risks to using alcohol or drugs and perceived disapproval of substance use are related to lower likelihood of substance use.

Relationships

Relationships with parents, siblings, peers, and romantic partners can serve as risk or protective factors for substance use. As children become adolescents, they experience more autonomy and increasingly seek independence from parents. As part of this transition, adolescents spend less time with parents and more time in contexts outside of the family. Adolescents tend to increase alcohol use as they become more independent from parents and parents monitor their activities less intensely. Likewise, parental involvement is related to lower substance use for adolescents regardless of gender, ethnicity, or age. Older siblings can also influence substance use. Siblings can be behavioral models by using alcohol or drugs themselves, and they may offer younger siblings access to alcohol or drugs.

Outside of the family, peers represent one of the most important contexts for adolescent development. The majority of youth substance use occurs in the presence of peers, and several different kinds of peer influences can increase risk for alcohol and drug use during adolescence and young adulthood. Unsupervised time spent with friends during adolescence and having friends who get drunk increase the likelihood of substance use. Susceptibility to peer pressure is heightened during transition periods such as transitions to high school and college. At these times in particular, young people are more willing to follow peers' suggestions, which may include using alcohol or other drugs. Adolescents and young adults (particularly college students) tend to overestimate the prevalence of substance use among peers. Perceptions of group norms can encourage heightened drinking as a way to fit in with the peer group. As active agents in their own development, individuals tend to seek out friends with similar interests, values, and behaviors. These similarities among friends can facilitate continuity in behavioral patterns over time. For example, adolescents whose friends use marijuana are more likely to have their own use reinforced in their peer group.

Although less studied, peers can also be positive influences on adolescents, and having peers who exhibit prosocial behaviors is a protective factor. Positive relationships with non-parental adults and greater involvement in social institutions can also serve protective functions against substance use. For example, students who attend church and report high religiosity are less likely to drink heavily or use marijuana across adolescence and young adulthood.

As pubertal development converges with social expectations, adolescents begin to seek romantic and sexual relationships. A range of early sexual experiences are associated with alcohol use during adolescence, and there are several explanations for this co-occurrence. Beliefs in social and sexual enhancement functions of alcohol and other drugs constitutes one possible reason that adolescents are motivated to use substances. In addition, youth may search for social situations where drinking or drugs are present based on a desire to meet new romantic partners. Alcohol consumption can make sexual behaviors more risky by reducing inhibitions and analysis of consequences.

Gender

Gender differences are important for understanding risk and protective factors for substance use. Males have a higher likelihood of belonging to a heavy drinking subgroup and displaying chronic or increasing patterns of marijuana use during adolescence and young adulthood. Adolescent boys are more likely to exhibit externalizing behaviors such as aggression or delinquency, behaviors that are risk factors for substance use. Women are less likely to be in the chronic and late-onset user groups, and are more likely to be represented among abstainers or low-risk users of alcohol and marijuana. Despite level differences, men and women show similar developmental patterns in use. One exception is that women show more dramatic decreases in marijuana use across early adulthood compared to men. Gender differences in substance use seem to develop during middle to late adolescence. At earlier ages, there are generally no gender differences in substance use, and in a few studies, early adolescent females have higher rates of substance use than their male peers.

Race/Ethnicity

White youth tend to be overrepresented in heavy drinking and frequent marijuana use groups compared to ethnic/racial minority youth, and African American and Hispanic American youth are most likely to abstain from substance use. Some evidence suggests that developmental trajectories for binge drinking differ by race/ethnicity, with the pattern of binge drinking for African Americans being flat across ages 18–24, whereas White youth display the overall pattern described above. Overall, however, there are more similarities than differences across ethnic groups in the developmental risk factors and processes related to substance use. Cross-nationally, remarkably similar patterns of alcohol initiation have been found across Western countries, despite wide-ranging laws and adult prevalence rates. This international similarity demonstrates the importance of developmental transitions, which are relatively comparable in Western nations, for understanding substance use.

Achievement

Successful adaptation in educational and occupational roles is a defining feature of healthy development. On the other hand, difficulties in navigating transitions to school and work can exacerbate substance use and related health risks. Therefore, school and work contexts can function as risk or protective factors. Difficulties in transitioning to middle school or high school can put youth at risk for substance use, and truant youth tend to report higher substance use levels across adolescence and young adulthood. On the protective side, high school students with higher GPAs are more likely to abstain from substance use during adolescence and across young adulthood. Positive interactions with family and at school may work together to protect adolescents from health-risk behavior. For example, parental involvement is related to higher school success, which in turn, relates to lower adolescent substance use. Thus, there are important interrelations between protective and risk factors across domains.

In transitioning to college, desires to form social networks and participate in the mythical college party culture may create social motivation to drink heavily. As noted above, college students have higher rates of alcohol use compared to their non-attending peers. In particular, college students are more likely to exhibit patterns of increasing substance use and fling drinking. Stress associated with the academic demands of college may encourage students to turn to heavy drinking or drug use. Living away from home and fraternity or sorority participation represent risk factors for substance use in college; these youth are more likely to display chronic, increasing, or fling patterns. Fraternity members report higher alcohol, marijuana, and other illicit drug use compared to college men not in fraternities. Being in a sorority increases one's risk of using alcohol and marijuana, but does not increase risk of other drug use. Importantly, longitudinal research has revealed that differences between fraternity and sorority members and their peers exist prior to college, suggesting that college-bound youth with a tendency to use substances seek out these experiences through fraternities and sororities. Developmental patterns are also affected: fraternity and sorority members tend to experience greater increases in heavy drinking and marijuana use over time.

Regarding paid work, research findings have consistently shown that working more hours during high school is associated with greater alcohol and other drug use. For example, adolescents who work 16 hours per week or more tend to report more frequent marijuana use. The reason for this finding is controversial,

however. A "third variable" such as disengagement from school may be responsible for causing both increased work hours and substance use. Alternatively, stress from balancing work and school may lead to substance use, or substance use may arise from experiences at work such as exposure to older peers with access to substances. On the protective side, adolescents who set future goals and hold higher occupational aspirations are less likely to engage in substance use.

Developmental Processes of Risk and Protection

A developmental perspective calls for understanding how risk and protective factors interrelate. Some scholars believe that risk and protective factors represent opposite ends of a single continuum. For example, high parental warmth in parent–child relationships can be a protective factor against substance use, whereas low parental warmth can be a risk factor. An alternative view is that protective factors are activated when risk factors are present. In this case, protective factors may counteract effects of risk factors. For example, a supportive family context may be most important in protecting adolescents against substance use only when adolescents are also experiencing negative peer influences. A third possibility is that protective factors function by reducing a risk factor; for example, a supportive family context reduces negative peer influences by improving adolescents' choice of friends.

A developmental perspective on risk and protective factors is needed because these factors change across a person's lifespan and may also change in the way they predict substance use for certain people at certain times. Longitudinal studies make it possible to understand why many individuals do not develop substance use problems despite exposure to documented risk factors. Likewise, a developmental perspective can help explain why individuals without great exposure to risk factors do develop substance abuse or disorders. Multifinality and equifinality are useful concepts in this regard.

Multifinality refers to the idea that any given risk or protective factor can lead to a diversity of outcomes. For example, family history of alcoholism predicts heightened likelihood of alcohol problems in some people, yet reduced likelihood of problems in others. In other words, individuals with the same high-risk background are more likely to become substance use dependent or abstainers. *Equifinality* refers to diverse combinations of risk and protective factors that can result in the same outcome. For example, among heavy-drinking individuals in late adolescence, some individuals may have initiated early due to personality characteristics and antisocial tendencies; other adolescents may exhibit the same behavior, yet experience a short-term heavy drinking episode in response to peer pressures.

Furthermore, timing of risk and protective factors is important for understanding the development of substance use. Early experiences can be useful in predicting substance use and abuse, yet at the same time, some early experiences may be erased or even reversed by later experiences, particularly when a major transition is involved. For example, an individual may have a multitude of early protective factors (e.g. supportive family environment, high self-esteem) that set them on a low-risk path, yet that individual may become a heavy substance user upon transitioning to college and affiliating with substance-using peers. Certain risk and protective factors are stable and robust, meaning that they predict current and future substance use, whereas others are emergent (i.e. predicting future substance use but not current behavior) or concurrent (i.e. only predicting current behavior). In many cases, risk and protective factors that are concurrently related to substance use are not predictive of future behavior.

DEVELOPMENTAL TRANSITIONS

Developmental transitions refer to important changes in individuals' lives that are embedded in cultural contexts. Transitions provide a structure that moves individuals from childhood to adolescence and from adolescence to young adulthood. For example, society holds age-related expectations regarding the timing at which individuals obtain a driver's license or graduate from high school, and societal norms also guide the timing of marriage and parenthood. However, there is considerable diversity in the timing and individuals' experiences of transitions, particularly in the United States. Developmental transitions can vary based on gender, class, and historical period, and individuals can differ in when and how they experience a transition depending on personal goals and life situations. Although all adolescents and young adults do not follow a single developmental pathway, the successful negotiation of transitions in at least a few areas is likely to benefit individuals' health and well-being.

Processes of Transitioning into Substance Use

Transitions help to describe the ways in which alcohol and drug use become a part of developmental experiences. Early initiation and use of alcohol and drugs relates to various negative health and social consequences later in life, yet little is known about what occurs in the interim period between adolescent substance use and later life consequences. Several conceptual models explain how transitions can serve as intervening mechanisms in the development and progression of substance use.

The Overload Model takes the view that alcohol and drug use result from experiencing many developmental transitions over a short period of time. When multiple transitions are experienced simultaneously, stress can accumulate and overwhelm the capacity to cope with the circumstances. In response, individuals may turn to alcohol or drugs as an alternative coping strategy. For example, an adolescent who simultaneously enters college, starts a full-time job, and experiences parental divorce may turn to alcohol or drugs as a way to cope with the stress of multiple transitions.

The Developmental Mismatch Model notes the importance of the fit between individuals and their contexts. For optimal development, individuals' developmental needs should be appropriately matched to opportunities provided by their environments. Some transitions can reduce alcohol and drug use by improving the match between person and context. Other transitions can make the person–environment match less optimal and can adversely affect health. The relationship between work hours and substance use during adolescence supports this model: An adolescent's job may likely be mismatched with the developmental stage in that he or she may be experiencing an increasing need for autonomy yet the job thwarts this goal by not offering opportunities for individual autonomy and being boring or monotonous rather than engaging skills or interests. This mismatch may result in increased substance use.

The Increased Heterogeneity Model argues that difficult transitions intensify individuals' existing strengths and weaknesses. According to this model, individual differences may be exacerbated at critical developmental transitions. During significant transition points, youth who are already experiencing difficulties may have more problems with navigating the new transition, and these difficulties may be reflected in maladjustment, including increases in substance use. Supporting this model, research suggests that individuals who have emotional or academic difficulties tend to experience the transition to college as an immensely stressful event.

The Transition Catalyst Model builds on the idea that a certain degree of risk-taking is a normative developmental experience during adolescence and young adulthood. This model argues that risk-taking behaviors such as alcohol use serve to facilitate healthy development as well as hinder successful transitions. Adolescents may experiment with substance use in order to succeed at certain developmental tasks, such as building bonds with peers, exploring one's identity, or gaining independence from parents. Heavy drinking during the transition to college can help individuals achieve social goals such as new friendships and popularity. At the same time, substance use could turn into a destructive behavior, impede one's developmental goals, or threaten safety and well-being over the short and long term.

In summary, these models, which are examples of some of the more common ones, are important because they reflect the complex and diverse constellation of associations between developmental transitions and substance use patterns. The models are not mutually exclusive, meaning that they could provide overlapping explanations for pathways to substance use and abuse. Furthermore, these models are not the only explanations for the processes by which developmental transitions can facilitate or reduce substance use. Focusing on developmental transitions highlights the role of proximal contexts in providing opportunities as well as constraints for engaging in substance use during adolescence and young adulthood. A developmental perspective recognizes that individuals play an active role in charting their life courses. Individuals choose activities and seek out opportunities based on their personal characteristics, and in these ways, actively shape their own transitions and experiences. In turn, developmental transitions are potential turning points that offer opportunities for increased well-being or risks for negative adaptation.

IMPLICATIONS FOR HEALTH AND PREVENTION

Substance use during adolescence and young adulthood can have harmful effects on health and well-being. Consequences of substance use have biological and social implications, as well as costs to communities and society. These effects can be temporary or long-lasting. Examples of short-term consequences of heavy substance use include an immediate impact on one's judgment and performance, injuries and accidents, and sexual risk-taking. Substance use is likely to lead to long-term negative consequences to the extent that substance use is utilized as a strategy to cope with difficult developmental transitions, use is heavy and sustained over time, or substance use is responsible for a negative life-changing event. Compared to non-heavy drinkers, adolescents who are chronic heavy drinkers have heightened risk for obesity, hypertension, mental illnesses such as depression and anxiety disorders, and substance use and dependence problems in adulthood. These patterns hold even after accounting for important personal characteristics and background factors. Social consequences of heavy substance use include lower likelihood of obtaining a higher education degree and greater criminal behavior such as theft and violence.

Prevention

To counter the numerous serious consequences of substance use during adolescence and young adulthood, a range of prevention efforts are aimed at reducing or eliminating substance use problems. Substance use

prevention efforts are most effective when they are developmentally relevant. Thus, intervention programs should consider the normative developmental change in substance use for the population. A developmental perspective requires taking a long-term view of intervention effects. Changing developmental patterns and the potential for reversal of risk or protective factors emphasize the need to continue assessing individuals who have been involved in a prevention program. It is useful and important to show positive short-term effects of substance use prevention programs, and long-term positive effects are arguably even more important. A prevention program may not demonstrate any short-term improvement, yet long-term effects may accumulate gradually over many years.

The multiple pathways into substance use suggest that a single prevention approach could never fit everyone's unique needs. Instead, multiple approaches to prevention are needed that correspond with unique needs of different subgroups. For instance, chronic heavy drinkers may need intensive early interventions to prevent the escalation of substance abuse and dependence as well as negative health consequences. Fling drinkers may not need intense personalized interventions, and may instead benefit from programs offering high-quality diversions or promoting responsible behaviors. Prevention programs may be successful if focused on strategies to cope with difficult transitions to adulthood, because fling and increasing marijuana users tend to report using marijuana to cope with life difficulties.

Substance use is a leading cause of preventable death among college students. The transition to college comes with multiple developmental tasks including achieving success in academics, romantic relationships, identity, and social life. Given college students' unique needs, high school prevention strategies would not likely translate directly into successful college prevention programs. Programs aimed at easing stresses of the college transition and improving the match between individual expectations and the environment may help youth transition successfully without heightening substance use. Given that alcohol use is heavily embedded into college life, no program is likely to produce sharp reductions in alcohol use, at least in the short term. Thus, harm reduction programs are also important. These programs focus on reducing rather than eradicating heavy drinking behaviors and providing strategies that help young people manage risk behaviors and avoid harmful consequences. Examples of harm-reduction techniques include preventing drunk driving, helping youth know their limits in terms of use, and encouraging accountability among friends at bars or parties. Reducing substance use among fraternity and sorority members is also an important avenue for prevention.

Beyond targeting developmental transitions, prevention programs that target broader social and environmental risk factors have been shown to reduce substance use among adolescents and young adults. For example, changing social norms, heightening penalties for substance use violations, and changing marketing practices can be effective solutions for communities with heavy alcohol use. Overall, despite three decades of prevention research aimed at reducing adolescent substance use, the effectiveness of interventions is mixed. In particular, alcohol use has been stable over historical time and resistant to various local and national efforts to prevent excessive use. The most promising prevention programs operate at multiple levels, targeting, for example, problem-solving skills, peer relationships, social norms, the family environment, and school context. Prevention efforts should also recognize individual and cultural variation in substance use and related risks.

CONCLUSIONS

Adolescence and young adulthood constitute critical transition periods during which initiation and escalation of heavy drinking or drug use can set the stage for problems across the lifespan. Utilizing a developmental perspective entails analyzing risk and protective factors and modeling various functions of developmental transitions. This approach can help us understand initiation of substance use, normative and person-specific developmental patterns, and strategies for preventing destructive patterns of use. Given that risk-taking is a broader phenomenon during adolescence, underlying processes related to the development of substance use are likely applicable to a host of problem behaviors and should also inform optimal development across the lifespan.

Glossary

Attrition the proportion of individuals who drop out of later waves in longitudinal studies.

Average trajectory an overall mean-level developmental pattern for a group of people as a whole.

Developmentally limited substance use substance use during a time-limited period of the lifespan, typically adolescence or young adulthood, which is later reduced.

Equifinality diverse combinations of risk and protective factors that can result in the same outcome.

Heavy episodic drinking another term for binge drinking, which has historically been defined in adolescence and young adulthood as consuming five or more drinks in a row on a single occasion.

Multiple trajectories several distinct subgroups of individuals who share the same developmental patterns, typically identified by statistical methods.

Multifinality any given risk or protective factor can lead to a diversity of outcomes.

Epidemiology of Adolescent and Young Adult Alcohol, Tobacco, and Drug Use and Misuse in the United States

Vivian B. Faden, Patricia A. Powell

National Institute on Alcohol Abuse and Alcoholism, Bethesda, MD, USA

OUTLINE

It is now widely recognized that addiction is a developmental disorder with its roots in childhood and adolescence. Adolescents and young adults are among the heaviest users of alcohol, tobacco, and other drugs in the US population. This chapter will provide information on the prevalence of alcohol, tobacco, and other drug use by age and grade, trends in substance use over time, associated consequences, and some thoughts about what all this may mean for the development of America's children. Although the primary focus of this chapter is substance use by adolescents and young adults in the United States, a limited amount of information is also provided about substance use among 15–16-years-olds in 35 European countries and regions based on the 2007 European School Survey Project on Alcohol and Other Drugs (ESPAD).

BACKGROUND

The developmental period encompassing adolescence and young adulthood is one characterized by dramatic changes across multiple biopsychosocial domains. Children are transformed physically, emotionally, and socially as they mature into adults. The extent of change during this transformation is important to keep in mind as one considers the epidemiology of substance use across these life stages, as is the variability in the timing and tempo of these changes across individuals.

Life Stages

Adolescence

The term "adolescence" is often used to describe the period between the onset of puberty and the assumption of adult roles and hence encompasses a broad range of physical, cognitive, and emotional development; grades in school; and levels of independence and responsibility. Not only are adolescents' bodies and brains developing, but they are also experiencing transitions between schools, changes in friends, and peer groups, and adjustments in the way they interact with the world at large. Adolescence is a time of trying new things, as individuals figure out who they are and where they fit in. For many, this includes experimenting with one or more substance. Accordingly, alcohol, tobacco, and drug use typically begin and escalate during this stage of life.

Young Adulthood

Young adulthood, which follows adolescence, is the life stage in which individuals generally settle on a career, choose a life partner, become more financially independent and, for some, start a family. In previous generations, individuals typically married and had children in their late teens or early twenties; over the past 50 years, more and more people are postponing marriage and parenthood until at least their late twenties, and spending their late teens through their mid-twenties in self-focused exploration as they try out different personal relationships and work options. Therefore, in the United States what most people experience during the years from age 18 to 29 has changed dramatically. Essentially, a new developmental stage has been created between adolescence and young adulthood. Jeffrey Arnett has coined the phrase "emerging adulthood" to describe this phenomenon. Unlike in the past, when alcohol and drug use decreased as people took on more adult responsibilities, this relative freedom from responsibility may prolong heavier use of substances throughout a person's twenties.

Substances

This chapter will address the use and abuse of the following substances: alcohol; tobacco; marijuana and hashish; cocaine and specifically crack; heroin; hallucinogens overall and specifically lysergic acid diethylamide (LSD), Phencyclidine (PCP), and ecstasy; inhalants; and nonmedical use of any psychotherapeutic overall, specifically pain relievers (in particular oxycontin), tranquilizers, stimulants (in particular methamphetamine), and sedatives. These substances are considered individually and/or by category depending on the analysis.

Data Sources

This chapter uses data from three US nationally representative surveys conducted in 2009: the National Survey on Drug Use and Health (NSDUH, public use data base), the Monitoring the Future (MTF) survey, and the Youth Risk Behavior Survey (YRBS). Binge drinking is defined in these surveys as drinking five or more drinks on an occasion or in a row.

The NSDUH is an annual, general population, household survey conducted throughout the year by the Substance Abuse and Mental Health Services Administration (SAMHSA) that collects information on individuals 12 years and older. For a number of substances the NSDUH asks questions that parallel the *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition (DSM-IV) diagnostic criteria for substance abuse and dependence permitting estimation of the prevalence of certain substance use disorders (SUDs) in the general population beginning at age 12.

MTF is a nationally representative school-based survey that has been conducted every spring since 1975 by the University of Michigan Institute for Social Research under a grant from the National Institute on Drug Abuse (NIDA). The study has collected substance use information from 12th graders since its inception and began collecting information from 8th and 10th graders in 1991. In addition to collecting data on substance use, this survey asks respondents about their perceptions of harm and availability of specific substances.

The YRBS is a biennial school-based survey of high school students (9th, 10th, 11th, and 12th graders) conducted by the Centers for Disease Control and Prevention (CDC) since 1991. This survey covers a wide range of risk behaviors, providing a better understanding of how various risk behaviors relate to one another. The Youth Risk Behavior Surveillance System (YRBSS) monitors six categories of health-risk behaviors among youth: (1) behaviors that contribute to

unintentional injuries and violence; (2) tobacco use; (3) alcohol and other drug use; (4) sexual behaviors that contribute to unintended pregnancy and sexually transmitted diseases, including human immunodeficiency virus (HIV) infection; (5) unhealthy dietary behaviors; and (6) physical inactivity. YRBSS includes the national school-based YRBS conducted by CDC and state and local school-based YRBSs conducted by state and local education and health agencies.

EXTENT AND NATURE OF SUBSTANCE USE BY ADOLESCENTS AND YOUNG ADULTS

This section draws on data from the NSDUH, MTF, and the YRBS. NSDUH and MTF data are used for overall prevalence and for information about substance use by basic demographic variables. Past month (or past 30 days in the case of MTF) is emphasized due to the sporadic, or opportunistic, nature of substance use among youth. Some lifetime prevalence data is presented to provide information about the extent to which individuals in various age groups have any experience at all with various substances. Finally, this section draws on data from the YRBS about the relationship of substance use to other risk behaviors.

Lifetime Substance Use among Adolescents and YoungAdults

Table 57.1, based on data from the 2009 NSDUH, presents the lifetime prevalence of substance use by age. This table is useful for understanding the extent to which individuals of various ages have any experience at all

TABLE 57.1 Percentage of Lifetime Substance Use by Age, NSDUH 2009

	Age					
Substance	**12–13**	**14–15**	**16–17**	**18–20**	**21–25**	**26–34**
Tobacco products	9.8	25.0	44.6	63.6	73.6	76.2
Cigarettes	7.2	20.2	37.8	56.7	68.6	71.4
Alcohol any	14.3	37.6	60.7	79.1	90.7	90.6
All illicit drugs	13.6	25.0	40.4	53.8	61.5	59.3
Marijuana/Hashish	3.0	14.6	31.8	47.7	55.9	52.8
Illicit drugs other than marijuana	11.9	17.6	24.1	32.1	40.7	40.6
Cocaine	0.3	0.9	3.6	9.7	18.4	18.4
Crack	0.1	0.1	0.5	1.4	3.9	4.7
Heroin	0.1	0.2	0.5	1.1	2.2	2.1
Hallucinogens	1.2	3.3	7.3	15.1	22.2	23.7
LSD	0.2	0.6	2.0	4.5	8.9	14.5
PCP	0.2	0.4	0.7	0.7	1.9	2.2
Ecstasy	0.6	1.7	4.3	9.5	14.9	15.9
Inhalants	8.1	9.8	9.5	8.9	12.3	13.6
Nonmedical use of psychotherapeutics	5.1	10.5	17.7	25.4	32.1	29.0
Pain relievers	4.3	9.0	15.4	21.5	26.5	22.5
Oxycontin	0.1	1.3	3.2	5.3	7.1	4.5
Tranquilizers	0.6	2.4	5.1	10.7	14.6	12.9
Stimulants	0.8	2.2	3.8	7.8	12.8	12.2
Methamphetamines	0.3	0.7	1.0	2.8	5.7	7.9
Sedatives	0.6	0.7	1.3	1.3	1.8	1.9

Data from the public use data set of the National Survey on Drug Use and Health conducted by the Substance Abuse and Mental Health Services Administration.

with a number of substances. It also provides a background context for considering the 30-day (or monthly) data that follows and which is typically a better indicator of current substance use for youth populations.

An examination of Table 57.1 indicates that 14.3% of US youth ages 12–13 reported having used alcohol, 9.8% reported having used a tobacco product, and 13.6% reported having used an illicit drug; 37.6% of youth ages 14–15 reported having used alcohol, 25.0% reported having used a tobacco product, and 25.0% reported having used an illicit drug; 60.7% of youth ages 16–17 reported having used alcohol, 40.4% reported having used a tobacco product, and 44.6% reported having used an illicit drug, at some point in their lives. Among those ages 18–20, those rates were 79.1, 63.6 and 53.8%. These increasingly high numbers across adolescence speak to the fact that trying substances at some point during this developmental period is normative among youth in the United States.

Prevalence of Substance Use among Adolescents and Young Adults

Table 57.2, based on data from the 2009 NSDUH, presents the prevalence of 30-day use of various substances by age. An examination of Table 57.2 indicates that while adolescents and young adults use many different substances, the most commonly used substances by far are alcohol, tobacco, and marijuana, followed by psychotherapeutics (nonmedical use of pain relievers, tranquilizers, stimulants, and sedatives), hallucinogens,

TABLE 57.2 Percentage of Past-Month Substance Use by Age, NSDUH 2009

	Age					
Substance	**12–13**	**14–15**	**16–17**	**18–20**	**21–25**	**26–34**

Oxycontin	0.0	0.3	0.6	0.6	0.5	0.4
Tranquilizers	0.2	0.5	1.1	1.7	2.0	1.1
Stimulants	0.2	0.6	0.8	1.2	1.3	0.7
Methamphetamines	0.1	0.2	0.1	0.1	0.3	0.4
Sedatives	0.2	0.1	0.2	0.2	0.3	0.2

Data from the public use data set of the National Survey on Drug Use and Health conducted by the Substance Abuse and Mental Health Services Administration.

and cocaine. Interestingly, the prevalence rates for marijuana and illicit drug use are highest among 18–20-year-olds and decrease substantially among those ages 26–34, from 20.1 to 9.4% for marijuana, and from 22.5 to 12.1% for illicit drugs overall. The prevalence rates for past 30-day tobacco (legal for those 18 and older) and alcohol (legal for those 21 and older) use, by contrast, are highest among 21–25-year-olds at 43.5% for tobacco and 70.4% for alcohol use before dropping off slightly to 39.5 and 64.3% among 26–34-year-olds, respectively.

Importantly, examining the data in Table 57.2 also allows an appreciation of the ramp up in the use of substances across adolescence and into young adulthood. Figure 57.1 presents this dramatic increase graphically for tobacco, alcohol, and marijuana, the substances used by the greatest numbers of adolescents and young adults, and for illicit drugs other than marijuana as a group.

Table 57.3, based on data from the 2009 MTF survey, presents data on the prevalence of past-month use (past 2 weeks for binge drinking) for 8th, 10th, and 12th graders as well as for college students and for non-college students ages 19–28. The substance categories are similar but not identical to those from NSDUH, reflecting differences in the surveys themselves; however, overall the data are remarkably similar. An examination of this table also shows that tobacco, alcohol, and marijuana are the most widely used substances and illustrates the ramp up of substance use with increasing age across adolescence and into young adulthood.

Looking at Substance Use in Adolescence and Young Adulthood by Gender

Table 57.4, based on data from the 2009 NSDUH, presents the prevalence of 30-day use of various substances by sex for various age groups. Interestingly, rates for girls ages 12–13 and 14–15 are higher than or equal to those for boys on most of the measures of substance use reported in the table. On the other hand, once youth are 16–17 years old, males exceed females on all the measures in the table and this is true for all the older age groups as well. One likely explanation is that some younger girls are associating with older boys and are being exposed to substances by them. This notion is supported by studies indicating that early physical maturity in girls is a risk for substance use because of their association with older boys.

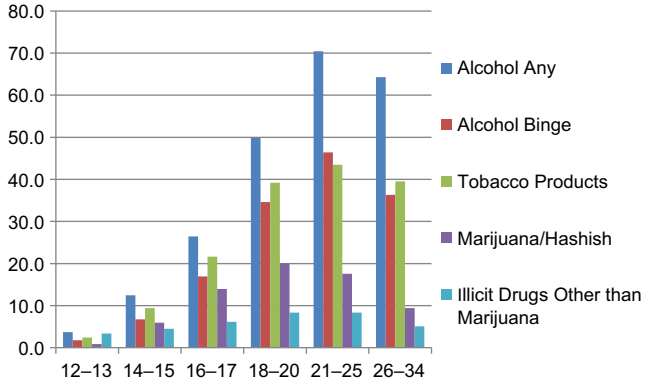

FIGURE 57.1 Substance use increases dramatically during adolescence. *Data from 2009 National Survey on Drug Use and Health conducted by the Substance Use and Mental Health Administration.*

Data from the public use data set of the National Survey on Drug Use and Health conducted by the Substance Abuse and Mental Health Services Administration.

Looking at Substance Use in Adolescence and Young Adulthood by Race/Ethnicity

Table 57.5, based on data from the 2009 NSDUH, presents the prevalence of 30-day use of various substances by race/ethnicity. At all ages and for most substances, the highest prevalence rates are seen among Whites and American Indians or Alaska Natives. In addition, the biggest differences among race/ethnic groups tend to occur for alcohol and tobacco.

Looking at Substance Use in Adolescence and Young Adulthood by County Type[1]

Table 57.6, based on data from the 2009 NSDUH, presents the prevalence of 30-day use of various substances

[1]Counties were grouped based on the "Rural/Urban Continuum Codes" developed by the US Department of Agriculture (2003). Each county is in either a metropolitan statistical area (MSA) or outside of an MSA (also see Butler and Beale, 1994). Large metropolitan (large metro) areas have a population of 1 million or more. Small metropolitan (small metro) areas have a population of fewer than 1 million. Nonmetropolitan (nonmetro) areas are outside of MSAs and include urbanized counties with a population of 20 000 or more in urbanized areas, less urbanized counties with a population of at least 2500 but fewer than 20 000 in urbanized areas, and completely rural counties with a population of fewer than 2500 in urbanized areas. Estimates based on county-type information presented in this report use the 2003 revised definition of an MSA; estimates for 2002 in this report, therefore, are not directly comparable with those presented in the 2002 NSDUH report (Office of Applied Studies (OAS), 2003).

by county type. While there is some variation in substance use across county type (nonmetropolitan, small metropolitan, and large metropolitan) and age group, no clear generalizations can be made.

Long-Term Trends in Adolescent Substance Use

MTF which has surveyed 12th grade students in the United States since 1975 provides an excellent opportunity to look at long-term trends in 12th grade substance use.

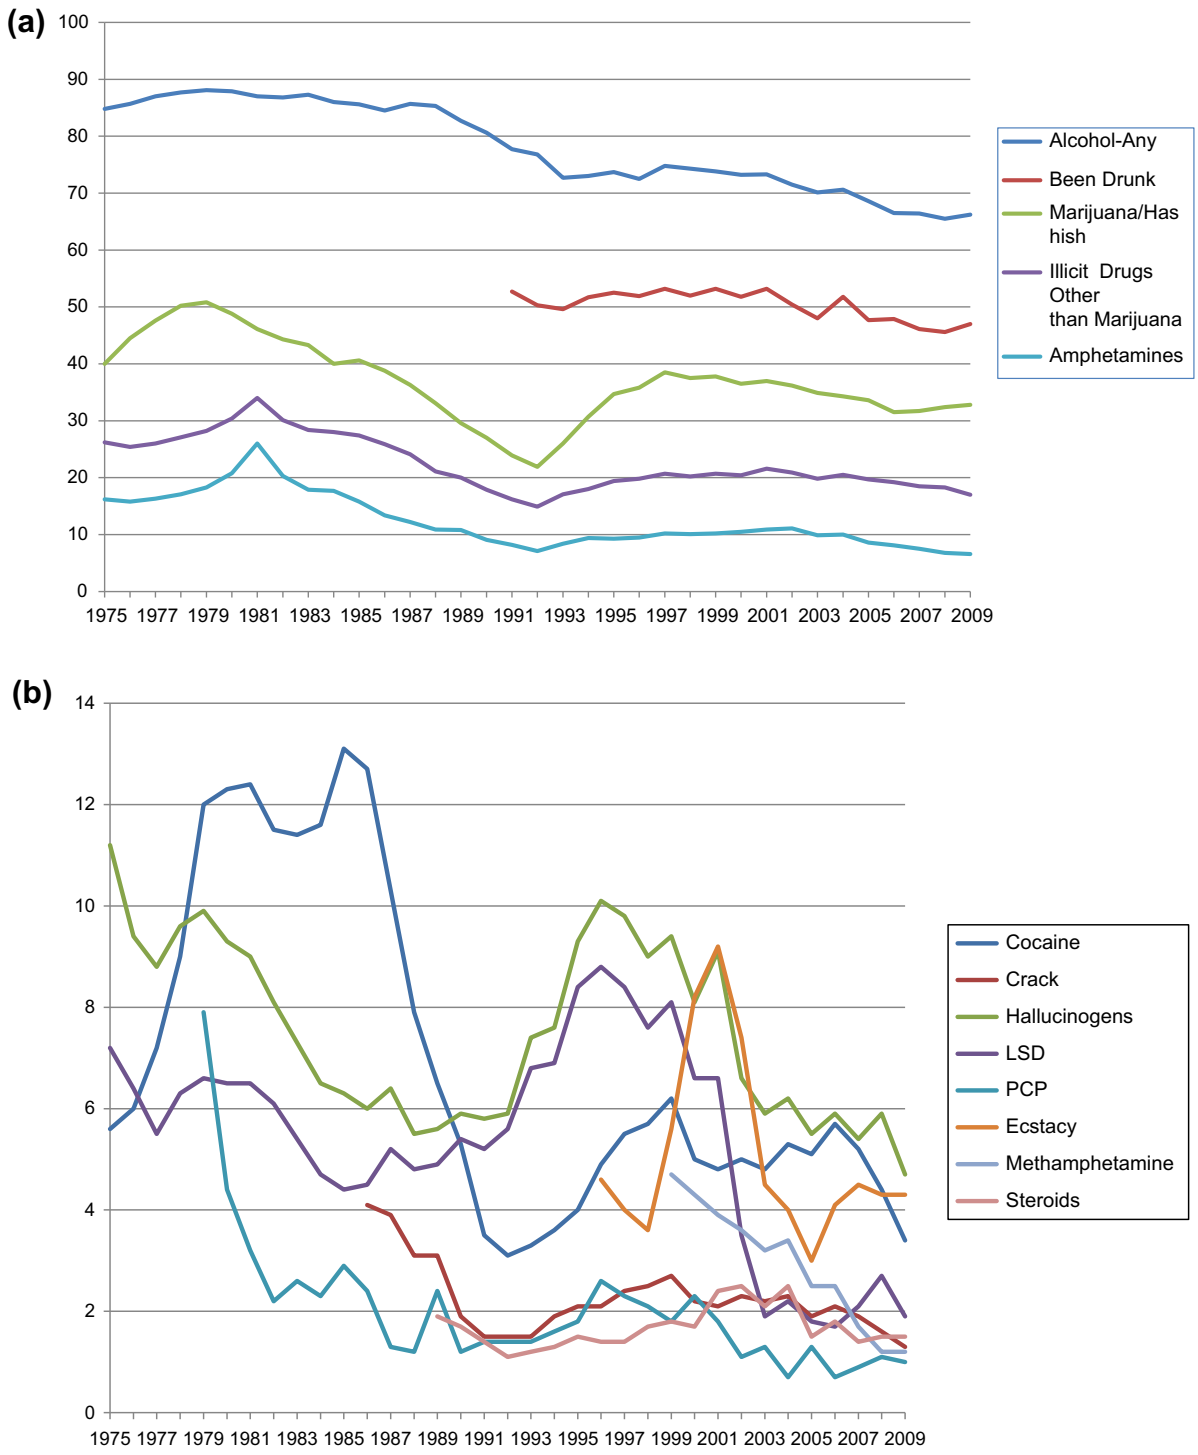

FIGURE 57.2 (a) Trends in annual substance use by 12th graders 1975–2009 – Higher prevalence substances. (b) Trends in annual substance use by 12th graders 1975–2009 – Lower prevalence substances. *Data from Monitoring the Future survey conducted by the University of Michigan under a grant from the National Institute on Drug Abuse.*

Figures 57.2a and b present data illustrating how the prevalence rates of use of various substances have changed across the period from 1975 until 2009. An examination of Fig. 57.2a, which illustrates trends in those substances that are used by more young people, shows that more youth have experience with alcohol and being drunk followed by the use of marijuana/hashish, illicit drugs other than marijuana, and amphetamines. This ranking of use

has remained consistent across the entire period for which data were collected. Of note, use of all substances in this figure declined between 1985 and 1992. Whereas the prevalence of marijuana use by 12th graders increased substantially between 1992 and 1997 before leveling off and then declining slightly, the prevalence of use of the other substances in this figure remained relatively constant or declined somewhat from 1992 to 2009.

Figure 57.2b depicts similar information for less widely used substances and allows an appreciation of the fads in drug use among young people over time. In fact, for some of the substances shown, data collection does not span the entire time period but rather was initiated as a result of the increased popularity of these substances. For other substances, such as ecstasy and cocaine, the figure captures both the steep rise and fall in their use by 12th graders. The figure also illustrates that different substances were popular at different times; for example, cocaine use peaked in 1985 whereas ecstasy use peaked in 2001.

Relationship of Substance Use to Other Risk Behaviors

Data on risk behaviors from the 2009 YRBS allow an examination of the concurrent use of various substances as well as the relationship between substance use and other risk behaviors. The data from 9th, 10th, 11th, and 12th graders were collapsed to provide an overview for purposes of this chapter. Table 57.7a presents the relationship among use of five substances: alcohol (binge drinking one or more times in the past 30 days), smoking (smoked cigarettes on 20 or more of the past 30 days), marijuana (used or smoked one or more times in the past 30 days), cocaine (ever used any form), and methamphetamines (ever used). Not surprisingly, there is a strong association between use of the five substances. Binge drinking is strongly associated with marijuana use and vice versa; and both binge drinking and marijuana use are similarly associated with regular smoking (20.9 and 25.7% respectively), with cocaine use (18.0 and 21.4% respectively) and with methamphetamine use (10.8 and 13.2% respectively). Among those who ever used cocaine or methamphetamine almost 75% have also used marijuana, about 70% binge drink, and 40% smoke regularly.

Table 57.7b presents the relationship of the use of the same five substances with a number of non-substance high-risk behaviors. In general, of the five substances analyzed, ever having used cocaine or ever having used methamphetamine are more strongly associated with the non-substance high risk behaviors in the table than are binge drinking, regular smoking or marijuana use.

Attitudes about Substance Use among Adolescents

MTF collects information from 8th, 10th, and 12th graders about perceived risk of using various substances. Importantly, trends in use often reflect changing attitudes. For example, Fig. 57.3a shows the dramatic inverse relationship between 12th graders' attitudes about perceived harm from marijuana use and the prevalence of its use between 1975 and 2009.

As perceived risk increases, a decline in use often follows, and similarly as perceived risk decreases, a rise in use often follows, albeit sometimes with a slight time lag. Figure 57.3b presents perceived risk among 12th graders over time (early 1990s to 2009) for some of the most frequently used substances. For 8th and 10th graders (data not presented) use of all substances is generally lower and perceived risk is generally higher than for 12th graders, but trends in attitudes and use over time are similar. Perceived risk for alcohol and

Used cocaine 1+ times in life	64.8	45.4	22.9	46.8	46.3	51.4	28.9
Used meth 1+ times in life	64.7	54.6	30.6	53.0	46.1	56.1	36.7

Data from the Youth Risk Behavior Surveillance System conducted by the Centers for Disease Control and Prevention.

tobacco use have been stable or increased slightly over the past few years while perceived risk for illicit drug use has declined. Correspondingly, alcohol and tobacco use have decreased slightly while the use of a number of illicit substances has increased somewhat in recent years.

Information about the perceived availability of a substance (how easy they think it would be to get that substance) by youth is also collected by MTF. As was seen with attitudes, trends in use of different substances track perceived availability. This may in part reflect increased opportunity to obtain various substances from greater numbers of friends who are using them.

CONSEQUENCES OF UNDERAGE AND YOUNG ADULT SUBSTANCE USE

The consequences of underage and young adult substance use are many and varied. Depending on the substance, they include social, academic, and vocational problems; unwanted, unintended, and/or unprotected sexual activity; unintentional injuries including from car crashes and falls; involvement with the criminal justice system; truancy; the potential for possible irreversible, adverse effects on the developing brain; increased risk for HIV/AIDS; compromised present and future health; the development of SUDs as a teen or young adult; increased risk for substance dependence in later life; and deaths from a substance overdose. Some of the more readily available prevalence estimates of consequences are highlighted below.

It is estimated that each year approximately 5000 people in the United States under the age of 21 die as a result of drinking alcohol. This includes about 1900 deaths from motor vehicle crashes, 1600 as a result of homicides, 300 from suicides, as well as hundreds from other injuries such as falls, burns, and drownings. In addition, early initiation of alcohol use is associated with increased risk for developing alcohol dependence at some point later in life, as well as developing dependence more quickly and at younger ages.

Many sources including the NSDUH and MTF have documented high levels of drinking and binge drinking among college students. Thus, it is not surprising that there are a high number of negative alcohol-related consequences that occur among college students including date rapes, assaults, and unintentional injuries. It is estimated that about 1800 alcohol-related deaths among college students ages 18–24 occur each year (*see* Costs and Consequences (Morbidity and Mortality) Associated with Adolescent and College Drinking and Related Problems).

Use of other substances clearly poses risks as well. For example, the use of tobacco by underage and young adult individuals increases the likelihood of nicotine addiction and the devastating physical illnesses that results from chronic tobacco use, such as lung cancer and emphysema.

Use of illicit drugs and nonmedical use of prescription drugs can result in drug overdose. According to the CDC, in 2007 about 93% of the 29 846 unintentional poisoning deaths that occurred in the United States were unintentional drug (illegal, prescription or over-the-counter drug) overdoses. Using this overall percentage to estimate the number of drug overdoses among 12–17, 18–20, 21–25, and 26–34-year-olds from the reported number of unintentional poisonings in these age groups translates to approximately 300, 891, 2322, and 4751 drug overdoses in each age group, respectively.

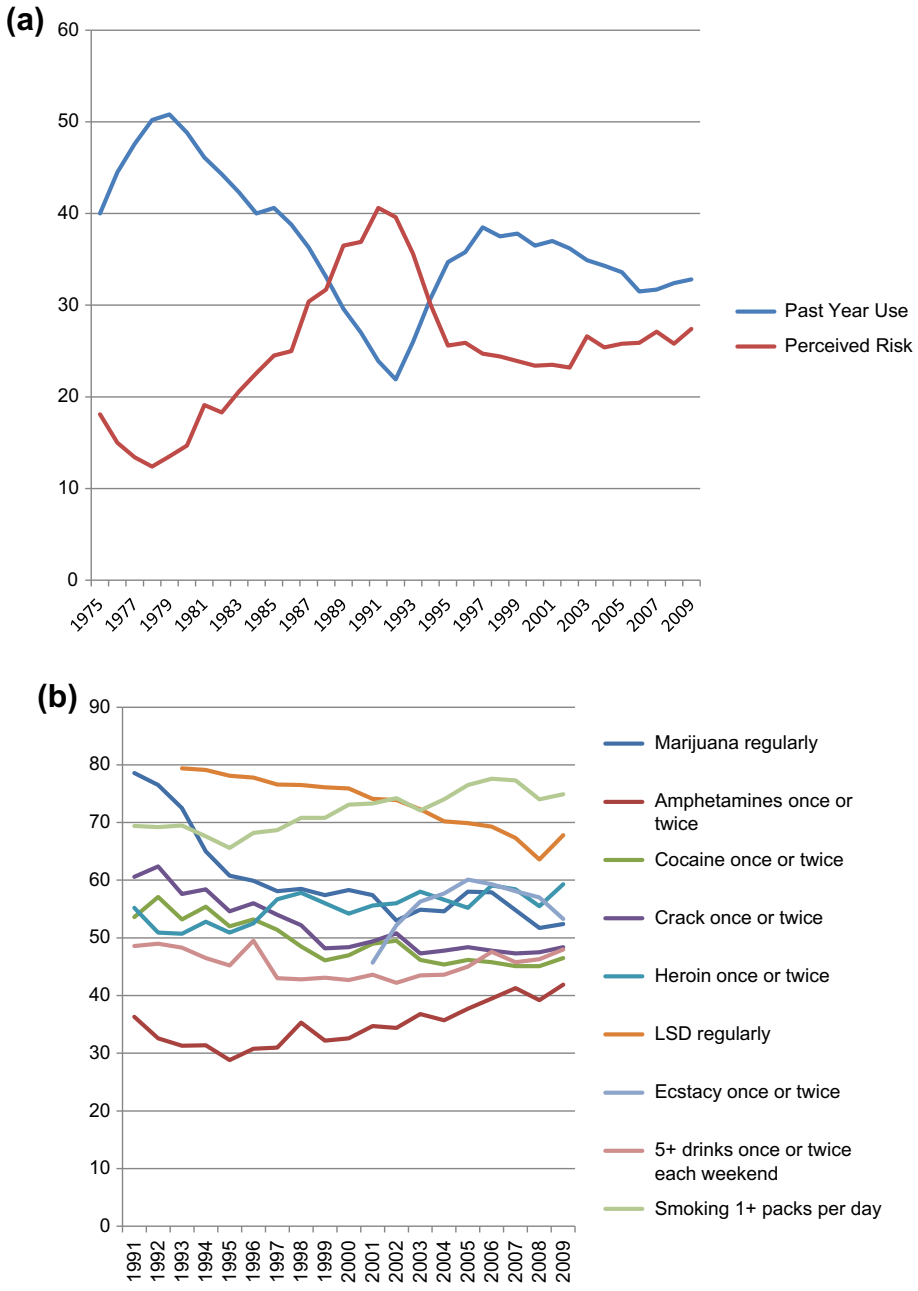

FIGURE 57.3 (a) 12th graders' past-year marijuana use versus perceived risk of occasional marijuana use, 1975–2009. (b) 12th graders' perceived risk of use of various substances 1991–2009. *Data from Monitoring the Future survey conducted by the University of Michigan under a grant from the National Institute on Drug Abuse.*

EXTENT AND NATURE OF SUDs AMONG ADOLESCENTS AND YOUNG ADULTS

The development of an SUD is an important risk of substance use by adolescents and young adults. The sections below discuss the epidemiology of SUDs in this population, their comorbidity with other psychiatric disorders, and the receipt of treatment by those who develop an SUD.

The Prevalence of Substance Abuse Disorders in Adolescence and Young Adulthood

Table 57.8a, based on data from the 2009 NSDUH, presents the prevalence of SUDs among adolescents and young adults in the general US population by age and substance. An examination of this table reveals that more individuals are addicted to nicotine (by far the highest number) and to alcohol, than to other substances.

TABLE 57.8A Percentage of Past-Year Abuse and Dependence by Substance and Age, NSDUH 2009

Abuse and dependence	Substance	12–13	14–15	16–17	18–20	21–25	26–34
Abuse	Illicit drugs	0.6	1.9	3.4	3.0	1.9	1.2
	Marijuana/Hashish	0.2	1.4	2.9	2.6	1.3	0.8
	Nonmedical use of psychotherapeutics	0.3	0.5	0.8	0.6	0.5	0.3
	Alcohol	0.4	2.5	4.7	9.1	9.9	5.8
	Both illicit drugs and alcohol	0.1	0.3	1.0	1.0	0.6	0.4
	Illicit drugs or alcohol	0.9	4.1	7.2	11.1	11.2	6.5
Dependence	Illicit drugs	0.6	1.8	4.4	6.1	5.1	2.8
	Marijuana/Hashish	0.3	1.4	3.6	4.6	3.2	1.4
	Nonmedical use of psychotherapeutics	0.2	0.5	0.7	1.7	1.6	1.0
	Alcohol	0.3	1.7	3.6	5.6	7.2	5.9
	Both illicit drugs and alcohol	0.1	0.4	1.0	1.6	1.4	0.8
	Illicit drugs or alcohol	0.8	3.2	6.9	10.1	10.9	7.9
	Nicotine (past month)—NDSS	0.3	1.3	3.7	9.6	12.7	12.9
	Nicotine (past month)—FTND	0.5	1.9	4.5	10.7	13.3	13.2
	Nicotine (past month)—either NDSS or FTND	0.5	2.3	5.8	13.8	17.0	17.0
Abuse or dependence	Illicit drugs	1.1	3.7	7.8	9.1	6.9	3.9
	Marijuana/Hashish	0.5	2.8	6.6	7.2	4.5	2.1
	Nonmedical use of psychotherapeutics	0.5	1.0	1.5	2.3	2.1	1.3
	Alcohol	0.7	4.3	8.3	14.7	17.1	11.7
	Both illicit drugs and alcohol	0.4	1.5	3.5	4.5	3.4	1.9
	Illicit drugs or alcohol	1.4	6.5	12.6	19.3	20.6	13.7

Data from the public use data set of the National Survey on Drug Use and Health conducted by the Substance Abuse and Mental Health Services Administration.

Table 57.8b, based on data from the 2009 NSDUH, presents the percentage of current users of a substance who meet the criteria for a diagnosis of abuse or dependence for that same substance which likely reflects the addiction liability of that substance. This table indicates that addiction liability (likelihood of having a SUD given that one uses the substance) is highest for nicotine for all age groups. There is some variability by age, but in general the next highest percentages are for illicit drugs, followed by marijuana, psychotherapeutic drugs used nonmedically, and then alcohol.

These tables considered together indicate that addiction risk is highest for nicotine and quite high for illicit substances, and that alcohol and nicotine affect the largest numbers of people.

Comorbidity of SUDs and Other Psychiatric Conditions in Underage and Young Adult Populations

Understanding the relationship of SUDs and other psychiatric disorders, including other SUDs, is very important as those youth/young adults who have more than one disorder have more complex prevention and treatment needs.

TABLE 57.8B Percentage of Past-Year Abuse and Dependence by Substance and Age, among Respective Substance Users, NSDUH 2009

Abuse and dependence	Substance	12–13	14–15	16–17	18–20	21–25	26–34
Abuse	Illicit drugs	6.6	10.1	11.2	7.7	5.3	5.4
	Marijuana/Hashish	7.7	11.3	11.8	7.7	4.4	4.7
	Nonmedical use of psychotherapeutics	7.7	6.6	6.6	3.6	3.5	3.6
	Alcohol	4.2	8.6	9.4	12.8	11.7	7.2
	Both illicit drugs and alcohol	1.8	2.5	3.9	2.6	1.7	1.8
	Illicit drugs or alcohol	6.1	11.6	13.0	15.1	13.1	8.1
Dependence	Illicit drugs	6.7	9.9	14.2	15.8	14.5	12.9
	Marijuana/Hashish	13.0	11.3	14.6	13.4	11.0	8.3
	Nonmedical use of psychotherapeutics	7.1	7.1	6.0	11.2	11.1	10.7

	Both illicit drugs and alcohol	4.3	3.3	3.9	4.4	4.3	3.9
	Illicit drugs or alcohol	5.2	9.0	12.6	13.7	12.7	9.7
	Nicotine (past month)—NDSS	18.1	17.3	22.1	28.8	33.7	38.1
	Nicotine (past month)—FTND	28.9	26.0	27.0	32.0	35.1	39.2
	Nicotine (past month)—either NDSS or FTND	34.4	31.5	34.4	41.3	45.0	50.4
Abuse or dependence	Illicit drugs	13.2	20.0	25.5	23.4	19.8	18.3
	Marijuana/Hashish	20.7	22.6	26.4	21.1	15.5	13.0
	Nonmedical use of psychotherapeutics	14.9	13.6	12.6	14.7	14.5	14.3
	Alcohol	7.7	14.5	16.5	20.7	20.3	14.6
	Both illicit drugs and alcohol	13.2	11.8	13.7	12.3	10.1	9.1
	Illicit drugs or alcohol	9.7	18.4	22.8	26.3	24.1	16.9

Data from the public use data set of the National Survey on Drug Use and Health conducted by the Substance Abuse and Mental Health Services Administration.

As is seen among adults, for certain youth substance use problems are related to psychiatric comorbidity. These can include, for example, depression, anxiety, conduct disorder, and various personality disorders. The NSDUH provides information on the co-occurrence of major depression, both lifetime and past year, and dependence on various substances. Table 57.9, based on data from the 2009 NSDUH, illustrates that in the adolescent and young adult population, many who have an SUD also have experienced a major depressive episode within the past year; the data indicate that the prevalence of a lifetime depressive episode in this population is even higher. Table 57.9 also shows that among adolescents and young adults, just as the use of one substance is associated with the use of other substances (see Table 57.7), so too is dependence on one substance associated with dependence on other substances.

Receipt of Treatment for Substance Use Problems by Adolescents and Young Adults

In spite of the high prevalence of alcohol and other substance use problems among underage and young adult populations in the United States (as determined in nationally representative surveys), only a small proportion of those with such a disorder receive treatment. Table

TABLE 57.9 Percentage of Major Depressive Episode and Substance Use Dependence, Age, NSDUH 2009

	Major depressive episode		Dependence			
Age	**Lifetime**	**Past year**	**Illicit drugs**	**Marijuana/Hashish**	**Nonmedical use of psychotherapeutics**	**Alcohol**
Dependence—Alcohol						
12–17	36.8	27.3	27.4	19.1	10.2	100.0

18–20	25.4	17.6	100.0	74.5	28.5	26.4
21–25	32.7	22.6	100.0	64.0	31.9	28.5
26–34	33.2	19.1	100.0	49.4	35.3	28.8

Data from the public use data set of the National Survey on Drug Use and Health conducted by the Substance Abuse and Mental Health Services Administration.

57.10, based on data from the 2009 NSDUH, illustrates the receipt of treatment in the past year and lifetime treatment for those individuals who had past year abuse or dependence. It clearly shows that, at all ages, just a fraction of those who need treatment actually receive it, even among dependent individuals.

Beyond the United States – Youth Substance Use in Europe

The information presented in this section is from the 2007 ESPAD which collects data from 15 to 16-year-old students in 35 European countries and regions.[2] Given the ESPAD survey's similarity to MTF, comparisons can be made between youth substance use in the United States and Europe. For comparability, data for the United States in this section is from the 2007 MTF.

For past 30-day alcohol use as well as for past 30-day cigarette use among 15-to 16-year-old students, the United States is in the bottom three countries along with Iceland and Armenia. With respect to having been drunk, youth in Denmark report by far the highest rates. Students in the United Kingdom, Austria, Ireland, the Slovak Republic, and Spain report the next highest levels. The middle group of countries includes the United States and many of the Eastern European and Northern European nations as well as France. The lowest rates of having been drunk are reported by students in many of the Southern European countries as well as Sweden, the Netherlands, and others. With respect to illicit drugs, the United States tops the list in

[2]Data from Spain is from a separate national survey.

Data from the public use data set of the National Survey on Drug Use and Health conducted by the Substance Abuse and Mental Health Services Administration.

perceived availability of cannabis. However, the students in Spain and the Czech Republic report the highest 30-day use of marijuana or hashish. Reporting the highest levels of lifetime illicit drug use other than marijuana and hashish are the students from the United States (18%) and the Isle of Man (16%) followed by France, Austria, and Latvia (all at 11%).

A CONTINUAL CHALLENGE – RECENT AND EMERGING ISSUES

While substance use and abuse among adolescents and young adults is not a new phenomenon, what substances are used and how they are used often reflects what is popular among youth at a particular moment in time. Examples include drinking games, the custom of drinking 21 shots to celebrate one's 21st birthday, and the unprescribed use of medication for attention deficit hyperactivity disorder to enhance academic performance. Fishing/pharming parties are a relatively new and particularly dangerous practice in which partiers contribute whatever is available from the medicine cabinet at their home to a common "punch" bowl and everyone downs a fistful of pills. Drug and drug/alcohol interactions may be a particularly lethal combination that results.

Recently and of increasing concern, the prevalence of prescription drug abuse in the adolescent and young adult population has been increasing. This is reflected, for example, in the fact that the number of emergency department visits related to nonmedical use of opioid pain relievers increased by nearly 80% for 17-year-olds and more than doubled for 18–20 and 21–24-year-olds from 2004 to 2008 (NSDUH, data not shown).

WHAT DOES IT ALL MEAN? SUMMARY AND FINAL THOUGHTS

We know from this overview that many adolescents in the United States use some substances at some point during their development, the majority continue this use into young adulthood, and many adolescents and young adults not only use substances but also do so frequently and/or at high levels.

While we can list many of the potential consequences of substance use, we know far less about the actual numbers of specific consequences that do occur. Especially difficult to measure are the effects on long-term outcomes. For example, it is virtually impossible to enumerate how many downstream problems are set in motion by substance use or to determine the number of individuals for whom substance use has either temporarily or permanently interfered with their developmental trajectories.

What we can take away from this epidemiologic overview is some sense of the complexity of substance use among young people and the extent to which it is intertwined with development in general, and with psychiatric and other problems, and risk behaviors, specifically. Clearly, substance use is a significant problem among adolescents and young adults, affecting both boys and girls, and young people of every ethnicity, no matter where they live. One can also readily appreciate that far too many youth and young adults have experience with substances, sometimes more than one, and that they are suffering the consequences of that use including dependence. We as a society need to change attitudes so that substance use among young people becomes far less acceptable to young people themselves, as well as to the rest of us. This will be difficult as long as substance use is seen as a statement of maturity and/or identity, as central to socializing, or as a way to escape difficulties. The ultimate goal is to help young people navigate the transition from childhood to adulthood without the use of substances which can hijack promising young lives.

INTRODUCTION

Lesbian, gay, bisexual, and transgender (LGBT) populations are at elevated risk for substance use and abuse compared to their heterosexual counterparts. This chapter focuses on alcohol and drug use, abuse, and dependency among LGBT populations with a particular emphasis on the developmental period of youth and young adults. We begin by defining sexual orientation and gender identity, discuss the unique life challenges faced by LGBT individuals, and describe how these challenges are linked to substance use, abuse, and dependency for LGBT populations in general. We proceed to discuss some of the challenges that are particular to LGBT youth and young adults, provide details about the use and abuse of specific substances in LGBT youth populations, and discuss potential explanations for elevated use in this population. We conclude the chapter with an overview of substance abuse treatment issues specific to this high-risk population.

OVERVIEW OF LGBT POPULATIONS

Definitions and Dimensions of Sexual Orientation

Sexual orientation is a complex, multidimensional construct for which definition and measurement can vary across studies and settings. However, there is a growing consensus that sexual orientation includes cognitive, affective, and behavioral dimensions. *Sexual identity,* the cognitive dimension of sexual orientation, is the term typically used to refer to an individual's own self-identification as lesbian, gay, or bisexual (LGB). In contrast, behavioral definitions of sexual orientation focus on the sex of an individual's sexual partners. Research using behavioral definitions sometimes refers to participants as MSM (men who have sex with men) or WSW (women who have sex with women). Sexual attraction, the affective component of sexual orientation, can also be assessed. Individuals may be emotionally and sexually attracted to men, women, or both. Although these three dimensions of sexual orientation are related, there is not complete overlap among them. Indeed, research that assesses all three dimensions of sexual orientation reveals a surprising lack of congruence, particularly among youth and women. For example, HIV and AIDS researchers must contend with the fact that some men identify outwardly as heterosexual yet may engage in sex with other men covertly. Similarly, some women may experience attractions to both women and men yet identify as lesbian because of the stigma associated with a bisexual identity in lesbian communities.

Gender Identity

Gender identity is a term used to refer to an individual's internal identification with being male or female. In contrast to sexual identity, gender identity is focused on one's view of oneself, rather than one's attractions to others. Although it is often conflated with sexual identity in the literature, gender identity is a distinct construct. *Transgender* is an umbrella term that encompasses a range of variations in gender identity, including transsexuals (individuals who identify as or desire to live and be accepted as a member of the sex different from the one they were assigned at birth), transvestites (individuals who cross-dress), and individuals whose gender identity lies outside of the traditional binary categorization of gender (e.g. genderqueer, two-spirit). Transgender individuals may include male-to-female (MTF) and female-to-male (FTM) individuals. Transgender individuals may identify their sexual identity as LGB, or heterosexual.

Terms for this Chapter

Although gender and sexual identity are distinct constructs, there is much overlap in the types of discrimination, prejudice, and stigma faced by lesbian, gay, bisexual and transgender people. As a result, the term "LGBT" is often used to refer to the community of sexual and gender minority people. To facilitate readability, we will use this term throughout the chapter when discussing the field more generally. However, research studies may use varying definitions of sexual minorities such as men who have sex with men (MSM) or may include only LGB (but not transgender) participants. In order to report the findings of these studies accurately, we use these terms in describing the results of specific studies. Additionally, throughout the chapter we use the following terms for racial/ethnic identities: White, Black, Latino, Native American/American Indian, Asian American, and Asian American/Pacific Islander (wherever applicable).

The Coming Out Process: Development and Milestones

One of the most central experiences for LGBT individuals is the process of *coming out,* a term used to describe the process of developing and disclosing an identity as an LGBT person. Individuals often progress through a series of milestones during this process, including awareness of same-sex attractions, self-identification as LGB, disclosure of sexual identity to others, engaging in same-sex sexual exploration, and entering into same-sex relationships. The coming out process for bisexuals may be more complex, as individuals develop

awareness of both same- and opposite-sex attractions. For transgender individuals, coming out involves awareness of gender identification, disclosure of this identification to others, and for some, changing one's outward gender expression and/or physical body. An important step in the coming out process is seeking and finding support from other LGBT individuals and communities. The timing and sequence of coming out milestones can vary greatly according to the individual's social and cultural context as well as their own individual characteristics and personal history. It is also important to note that disclosure of sexual orientation is an ongoing process over the lifespan, with each new interpersonal encounter presenting challenges of when and how to come out. Individual's degree of "outness" may also vary according to context; for example, a gay man may decide not to disclose his sexual orientation at work, but may be very open with his friends and family about his identity and relationships.

OPPRESSION OF LGBT PEOPLE

The term "homophobia," which refers to the irrational fear, hatred, and intolerance of homosexuality, has historically been used when describing the oppression faced by LGBT people in society. However, the recognition that prejudice is a social-level phenomenon, rather than an individual pathology, has led to the more common use of the term "heterosexism," which refers to the ideological denial, denigration, and stigmatization of sexual minorities. Despite much progress over the past few decades, heterosexist laws, policies, attitudes, and behaviors are still widespread in the United States. For example, federal law does not protect employees from discrimination based on sexual or gender identity, and several states do not include these identities in hate crime laws. Same-sex couples are still unable to marry or form legal unions in most parts of the United States; over two dozen states have recently changed their constitutions to restrict marriage to one man and one woman. Such legislation legalizes unequal treatment of LGBT individuals and families and exacerbates their stigmatized status.

The impact of the heterosexist social context on the individual LGBT person has been conceptualized as "minority stress," a term used to describe the additional stress exposure experienced by members of minority groups. Minority stress for LGBT people includes actual experiences of victimization and discrimination, expectations of rejection, concealment of identity, and internalized negative beliefs about being LGBT. LGBT people may also encounter minority stress due to multiple oppressed identities; for example, ethnic minority LGBTs may encounter negative attitudes regarding homosexuality in their ethnic communities, while encountering racism and rejection from other LGBT people.

A growing body of literature has documented that minority stressors are indeed common for LGBT people. A recent national probability sample of LGB adults indicated that 20% reported having experienced a person or property crime based on their sexual orientation, about half had experienced verbal harassment, and more than 1 in 10 reported having experienced employment or housing discrimination. Numerous studies have also documented that LGBT people are at elevated risk for experiences of physical and sexual violence over the lifespan. These external experiences, along with more internal minority stress processes such as internalized heterosexism (internalized negative attitudes about one's own sexual orientation), have been linked empirically to psychological distress, depression and anxiety disorders, smoking, and substance use. Indeed, minority stress has been posited to be the primary explanatory factor driving health disparities between LGBT and heterosexual populations.

SUBSTANCE USE IN LGBT POPULATIONS

Early research on LGBTs and substance use focused on lesbians and gay men; this research consistently found higher rates of substance use, abuse, and dependency relative to heterosexual adults. Because of the difficulty of finding a hidden and stigmatized population for research, these studies relied on gay bars as a venue for research recruitment, thereby introducing a confound into research findings. For example, some early studies suggested that over one-third of lesbians and gay men abused alcohol. Subsequent studies using more representative sampling methods have tempered these initially disturbing statistics. Still, population-based and other large studies of LGBTs suggest that this population does indeed use alcohol and drugs more than the general population, although these differences are greater for women than for men. It is important to note that these differences are relative and that the majority of LGBT people do not experience substance abuse or dependence.

Sexual Orientation Differences by Substance

Literature on substance use among LGBT populations has most often focused on alcohol; however, the extent to which LGBT populations differ from heterosexual populations may vary for different substances. Below we describe what is known about specific substances

and their use among LGBT populations. The majority of studies focus exclusively on LGBs, with very little empirical research on transgender populations. Additionally, samples for these studies are typically predominantly White; thus, we know relatively little about risk for substance use among ethnic minority LGBT people.

Alcohol

Alcohol may be the most commonly used and abused substance among LGBT people. Differences between LGBT and heterosexual populations are most dramatic among women. Lesbian and bisexual women use alcohol more frequently, consume greater quantities, and report higher rates of alcohol-related problems than heterosexual women. One study found that 15% of lesbians did *not* consume alcohol compared with 35% of the heterosexual women in their sample, and that lesbians were almost three times more likely to report alcohol use problems than their heterosexual peers (23% versus 8%). According to the National Lesbian Health Care Survey, 25% of a sample of 1925 women reported drinking alcohol several times a week and 6% self-reported daily drinking. Whereas hazardous drinking typically peaks in young adulthood for heterosexual women, lesbian and bisexual women continue to drink heavily into their 30s and 40s. Although early research focused primarily on lesbians, recent studies indicate that bisexual women show the highest risk for hazardous drinking.

Findings regarding gay and bisexual men's alcohol use are mixed, with most studies showing similar levels of consumption and alcohol-related problems compared to heterosexual men. However, a few studies have found high rates of abuse and dependence among gay and bisexual men. For example, one large survey of men who have sex with men (MSM) in four large metropolitan areas found that 85% reported alcohol use within the past 6 months, 12% reported three or more alcohol-related problems, and 8% reported heavy–frequent alcohol use. In comparison, the 2005–2007 National Health Interview Survey reported 67% of male respondents were current drinkers (alcohol use within the past year); DHSS data suggest that approximately 9% of men drink heavily frequently. Similarly, analyses from the National Epidemiologic Survey on Alcohol and Related Conditions (NESARC), gay men had significantly higher odds than heterosexual men of alcohol dependence within the past year.

Marijuana

Marijuana is the most commonly used and abused illicit drug in the United States, and may be even more commonly used among LGBT populations. Studies have found rates of marijuana use among lesbian and bisexual women between 14% and 38% for past year and 58% and 76% for lifetime. Comparisons with heterosexual women have revealed a greater likelihood of recent and lifetime use. Gay and bisexual men also have a greater likelihood of recent use compared to their heterosexual counterparts; however, their rates appear similar to heterosexual men for lifetime use (65.6% versus 52.3%). Lesbian, gay, and bisexual men and women in the 1996 National Household Survey on Drug Abuse (NHSDA) were more likely to meet criteria for marijuana dependence syndrome than heterosexual men and women. Similar to findings with alcohol, recent research suggests that bisexual women may be the highest risk group for marijuana use and abuse.

Methamphetamines

Research on methamphetamine use and dependency has generally focused on gay men and men who have sex with men (MSM). The past decade has seen a major surge in methamphetamine use in this population of men, with estimates of use in the United States ranging from 25% to 29%, a rate approximately 10 times higher than in the general population of men. Methamphetamine use is much less common among lesbian and bisexual women, although surveys of lifetime use indicate that lesbian and bisexual women are more likely to have tried this substance than their heterosexual counterparts.

Other Substances

LGBT individuals are also more likely to use and abuse other illicit drugs. According to 1996 NHSDA, lesbian and bisexual women reported higher lifetime rates of cocaine and hallucinogen use and abuse compared to heterosexual women. Similarly, gay and bisexual men reported elevated levels of sedative, tranquilizer, cocaine, GHB, and illicit prescription pain medication use than other men. However, research on other illicit substances is a new area of study, and thus is hampered by some of the sampling problems encountered by early research on alcohol use (e.g. recruitment of men at gay bars for research).

SUBSTANCE USE DIFFERENCES ACROSS RACE/ETHNICITY IN LGBT POPULATIONS

Though much of research on substance use in LGBT populations has utilized predominantly White samples, there has been a surge of research dedicated to individuals who are both racial/ethnic and sexual minorities. The majority of studies have addressed substance use in Black and Latino gay and bisexual men. Studies have indicated that the substances used by Black gay and bisexual men are alcohol, methamphetamine, and

crack cocaine and that Latino gay and bisexual men are more likely to use cocaine, methamphetamine, and ecstasy more often than other substances. With regard to racial/ethnic comparisons, two studies have found elevated risk among Black gay and bisexual men relative to their Latino and White counterparts, with one study focusing on illicit drug use and the other on quantity of alcohol consumption. Latino gay and bisexual men have been reported to use cocaine more often than White gay and bisexual men within the past 4 months. Other studies have indicated a higher recent (4–6 months) and lifetime rates of marijuana and crystal methamphetamine by White gay and bisexual men than Black and Latino gay and bisexual men. There are, however, a growing proportion of Black gay and bisexual men who have used methamphetamine at least once in their lifetime, and likelihood of lifetime and current (past 30 days) use has been associated with racism within predominantly White gay communities.

Substantially less is known regarding differences in substance use by race/ethnicity in lesbian and bisexual women. The majority of these studies have focused on alcohol consumption. Limited research has indicated that Black and Latina lesbians' drinking patterns are more similar to non-Latina White lesbians than to Black and Latina heterosexual women. One study assessing differences in alcohol consumption found no significant differences between Latino/Latina and non-Latino White women. There were a few differences between Black and White lesbians: Black lesbians (15.4%) were more likely to be heavy drinkers than non-Latino White women (3.8%) and were more likely to have experienced adverse consequences from drinking (e.g. driving while intoxicated, fights with family or others) within the past year.

SUBSTANCE USE IN TRANSGENDER POPULATIONS

Although public health surveillance surveys have gradually begun to include questions about sexual identity and/or same-sex sexual behavior, to date there are very few surveys that include questions pertaining to gender identity, with most surveys assessing gender as only "male" or "female." The few studies that have specifically examined transgender individuals include samples of MTF sex workers and primarily focus on HIV risk and related behaviors. Not surprisingly, rates of alcohol and illicit drug use in this population are high. However, we know much less about substance use among MTF individuals who are not sex workers, FTM individuals, and other transgender individuals (e.g. those who do not identify as either male or female).

A meta-analysis suggested sizeable use of substance use for MTFs with regard to alcohol (44%), marijuana (20%), and other illicit drugs (26.7%), but a low rate of injecting drugs such as heroin or crack. Findings are mixed with regard to FTMs: whereas two studies have indicated no injection drug use among FTMs in their small research samples, three other studies have found that 4–21% of participants reported injecting substances at least once in their lifetimes. A sample of 48 transgender youth and adults revealed that participants believed stimulants and psychedelic drugs to be the most frequently used substances in transgender communities; other research has also suggested a high rate of stimulant use by transgender populations.

CORRELATES OF SUBSTANCE USE IN LGBT POPULATIONS

Given the consistent findings of relatively high levels of substance use, abuse, and dependency among LGBT populations, recent scholarship has begun to focus on identifying potential explanations for this disparity. Many risk factors may be similar to those in the general population (e.g. familial substance abuse); higher rates of these risk factors among LGBTs may account for some of their disparities in substance use. Other risk factors, described below, may be unique to LGBT populations.

Minority Stress

Stress exposure is an important predictor of substance use in the general population. In addition to general stressors, LGBT people are subject to unique minority stressors that may lead to substance use. Perceived discrimination and harassment based on sexual orientation have been linked empirically to substance use and substance use disorders (SUDs) among LGB adults. Further, there is some evidence that internalized heterosexism may be related to hazardous drinking among lesbian and bisexual women. Substance use may be an attempt to cope with psychological distress caused by both external and internal minority stressors. Although more research is needed to better understand these causal pathways, one recent longitudinal study found that the relationship between discrimination and problem drinking was indeed mediated by both negative effect and coping motives in stigmatized populations, including women, racial/ethnic minorities, and LGB individuals.

Victimization

As previously noted, LGBTs consistently report alarmingly high rates of physical and sexual abuse and

assault over the lifespan. Men and women with victimization histories in the general population are at elevated risk for substance use and abuse, and this appears to be true for LGBT people as well. A recent analysis of data from NESARC indicates that childhood victimization may be the strongest predictor of SUDs in adulthood for LGB people. Additionally, childhood victimization is a risk factor for victimization in adulthood. This phenomenon is referred to in the literature as *revictimization* and is often used to refer to experiences of both childhood sexual abuse and adulthood sexual assault. Evidence suggests that individuals who experience revictimization are at even greater risk for substance use than those with only one type of victimization, and this is equally true for LGB individuals. Causal pathways between substance use and victimization may be bidirectional. For example, substance use may be an attempt to numb oneself to the psychological aftermath of victimization; at the same time, substance use may place individuals in situations and contexts in which victimization is more likely to occur.

Mental Health Problems

Mental health disorders such as depression and anxiety are highly comorbid with SUDs in the general population, particularly among women. It is not surprising, then, that these comorobidities also occur in LGB populations. Numerous studies have documented small but significant elevations in rates of mental health disorders and levels of psychological distress among LGB people. Mental health disorders may manifest differently among LGB people; for example, there is evidence that LGBs are even more likely to have more than one mental health or SUD in their lifetime, and are also more likely to have mental health disorders that persist over time.

LGBT-Specific Factors

Factors such as mental health problems and stressful events are hypothesized to lead individuals to "self-medicate" with substance use. However, this hypothesis does not account for substance use and abuse among individuals who are not experiencing psychological distress. Substance use, particularly alcohol use, is seen as normative in many segments of US society, including LGBT communities. Historically, gay and lesbian bars were the only public place where LGBT people could go to socialize, meet potential friends and dating partners, and freely express their identities without fear of retribution. Even with decreasing societal stigma and the resulting increase in opportunities for meeting other LGBT people, bars remain a primary socializing outlet for many LGBT people. This may be particularly true for lesbian and bisexual women, who have been documented in research to spend more time in bars than heterosexual women. Indeed, one study found that reliance on bars as a primary social venue was a predictor of substance abuse among lesbians. More recently, circuit parties (large, multi-day dance parties) have become commonplace as a socializing venue for gay and bisexual men, particularly in large cities. These events are characterized by use of multiple substances including MDMA, ketamine, methamphetamines, and cocaine. In addition to higher overall rates of illicit substance use, attendees of these parties also commonly ingest multiple substances simultaneously, including combinations of methamphetamines, ketamine, and GHB as well as combinations of club drugs with viagra. A recent study conducted in San Francisco reported a median number of drugs to be four per individual. Importantly, variation exists in individuals, wherein substance may be considerably low during non-circuit party weekends and considerably higher during circuit party weekends.

The prevalence of heavy substance use contexts in LGBT communities not only provides further opportunity to use alcohol and other drugs, but may also influence individual perceptions of social norms. LGBT people may view alcohol and other drug use as commonplace among others who share their minority status. Perceived social norms have been documented to be a strong predictor of substance use in the general population. Although there is little research on social norms in LGBT communities, preliminary evidence suggests that these norms may indeed play a role.

Another difference between LGBT and heterosexual populations that may affect substance use is life roles and transitions. The majority of heterosexual men and women marry and have children, and these life transitions are typically associated with reduction in use of substances. Although many LGBT people form and maintain long-term, intimate partnerships, legislation prohibiting same-sex marriage as well as the stigma associated with same-sex relationships serve as barriers to doing so for some LGBT individuals. Further, although the past two decades have witnessed a "gayby boom" in which more out LGBT people are choosing to become parents, the majority of LGBT people are still childless. This may be a particularly relevant factor for lesbian and bisexual women, given the sharp decreases in alcohol use typically seen among heterosexual women as they begin to have children.

In general, substance use is seen as more normative for men than for women. Hence, nontraditional gender roles and gender expression among lesbian and bisexual women may also be associated with substance use. Indeed, in one of the few studies to examine this

hypothesis, butch-identified lesbians (i.e. those adhering to a more masculine gender role and identity) were more likely to use and abuse substances than femme-identified women (i.e. those adhering to a more feminine gender role and identity). Additionally, in a recent study of gay men, those who conformed to traditional masculine gender roles were more likely to abuse alcohol and use tobacco and illicit drugs than gay men with lower masculinity. Thus, it may be that identification with traditional constructions of masculinity may be a risk factor for both men and women.

HIV

A recent study indicated that HIV-positive individuals appear to use alcohol and drugs more frequently than HIV-negative individuals in general, though other research has indicated that HIV-infected populations tend to reduce the frequency of injection drug use post-diagnosis. HIV-positive gay and bisexual men appear to be more susceptible to both risky sexual behaviors and substance use behaviors and disorders than HIV-negative gay and bisexual men. Specifically, HIV-positive men have been found to have elevated rates of heroin, crack, cocaine, and marijuana use and abuse and to be more likely to use injection drugs. Substance use in HIV-positive populations has been linked to problems with HIV treatment adherence.

SUBSTANCE ABUSE TREATMENT FOR LGBT POPULATIONS

Given their relatively high risk for substance use problems over the lifespan, it is not surprising that LGBT people are overrepresented among treatment-seekers. For example, research indicates that lesbians are more likely than heterosexual women to have engaged in treatment for alcohol and drug use problems: approximately half of lesbian and bisexual women substance users have sought professional help for their drug/alcohol problems at least once. Though research has suggested that gay and bisexual men are less likely to receive treatment relative to lesbian and bisexual women, gay and bisexual men are up to three times more likely to be receiving treatment for substance use than heterosexual men. Another study revealed that approximately 16% of gay and bisexual men reported having received treatment at some point in their lives relative to 2% of heterosexual men.

Despite demonstrated interest and need, there are relatively few programs specifically tailored for LGBT clients. Although the substance abuse field has increasingly been adapting services for culturally diverse clients, these efforts typically do not include a focus on LGBT issues. A recent study of substance abuse treatment programs in the United States and Puerto Rico found that only 11.8% provided services specifically for LGBT individuals, and only 7.3% offered tailored programs to meet their unique needs. Surveys of substance abuse treatment providers and staff reveal little to no formal education regarding the needs of LGBT clients. Moreover, these surveys reveal that many providers harbor negative or ambivalent attitudes toward LGBT clients. These attitudes do not go unnoticed; indeed, a survey of LGB adults in recovery found that most had experienced nonaffirming behaviors from treatment providers. Thus, although many LGBT people seek substance abuse treatment, it is likely that the lack of availability of culturally tailored treatment and culturally sensitive providers may hamper treatment retention and effectiveness.

Greater efforts to adapt and develop specialized services that are culturally appropriate for LGBT populations is greatly needed, considering that preliminary research has found that LGBT specialized treatment programs may be more effective than traditional, general programs for this population. Further, many LGBT individuals who use substances report a preference for an LGBT-only and/or culturally adapted treatment program.

LGBT YOUTH AND YOUNG ADULTS

The remainder of this chapter will focus on the unique factors pertaining to substance use for LGBT people in adolescence and young adulthood. This developmental period is characterized by the opportunity for identity exploration across multiple domains, including romantic relationships, academic and vocational interests, and sense of self. For many LGBT people, this is the period in which they first become aware of and disclose their LGBT identity and initiate same-sex relationships. This identity exploration and formation occurs against a backdrop of the more typical stressors faced by youth.

Youth and young adulthood is also a period characterized by increased vulnerability to substance use and abuse. Indeed, this phase represents the highest risk period for lifetime diagnoses of SUDs. Youth and young adults are particularly vulnerable to negative outcomes associated with substance use. For example, alcohol use is the largest contributor to preventable deaths in this age group, associated with the three leading causes of mortality: accidents, homicide, and suicide. LGBT youth, who face additional developmental tasks and challenges during this period, are even more vulnerable to substance use and its consequences.

It is important to note the methodological challenges inherent in studying substance abuse among LGBT youth. Although public health surveys of adults have begun to add questions assessing sexual orientation, the inclusion of such questions in surveys of youth is often met with political resistance, resulting in fewer opportunities to obtain data on this population. Similar to adults, LGBT youth and young adults are a stigmatized population and thus may be difficult to recruit for research. Recruitment at this developmental phase may be further limited by the fact that many LGBT youth still reside at home and their families may not know about their sexual orientation. Additionally, many youth and young adults who will eventually identify as LGBT may still be questioning their identity and may not have disclosed to others. Accordingly, many surveys of LGBT youth and young adults focus on attractions, rather than identity or behavior, to classify this group.

Substance Use in Heterosexual and LGBT Youth and Young Adults

In most cases, LGBT youth (18 years or younger) and young adults (19–25 years old) appear to be more vulnerable to substance use, abuse, and dependency than their heterosexual peers. Research has indicated sexual orientation differences in alcohol, marijuana, methamphetamines, and other illicit drugs. In particular, bisexual and questioning youth may be particularly vulnerable to using specific substances, as discussed below.

Sexual Orientation Differences by Substance

Alcohol

Alcohol is the most frequently studied substance when comparing LGBT and heterosexual youth and young adults. Among middle and high school students living at home, those who are not exclusively heterosexual (i.e. bisexual, questioning, and mostly heterosexual) are more likely to use alcohol (e.g. 61.2% versus 51.1%), use alcohol earlier in life, and do so more frequently than their heterosexual peers. Lesbian and bisexual young women are more likely, for instance, to have consumed a whole alcoholic drink before they enter college. Another longitudinal study found that while lesbians consumed more alcohol than their heterosexual peers during high school, gay men increased their alcohol use at greater rates than heterosexual men during the initial transition to college. Among college students, LGBT individuals have reported greater use of alcohol as well as greater frequencies of binge drinking and drunkenness at the beginning of their college career. Bisexual men and women appear to be particularly likely to report binge drinking and to consume large amounts of alcohol.

Marijuana

Marijuana is the most frequently used substance among youth and young adults in the general population; recent findings among high school students suggest that it may be used even more frequently than alcohol. LGB high school boys and girls are more likely to use marijuana (73.3%) than heterosexual peers (37.2%); additionally, those who use do so more frequently. Similar differences have been found among college students, with differences between LGB and heterosexual students increasing over time. Similar to findings among adults, bisexual youth and young adults may be the highest risk group for marijuana use.

Methamphetamines

LGBT youth in the United States appear to use crystal meth and other amphetamines more often than heterosexual adolescents in the past 3 months, 6 months, and over their lifetimes. For example, a pilot study using a convenience sample found that the odds of LGBT youth having ever using crystal meth was 26% higher than for heterosexual adolescents.

Other Substances

Although there is relatively less research on other illicit drug use, there is some evidence that LGBT adolescents are more likely to inject drugs, use cocaine crack, and take hallucinogens and ketamine than their heterosexual counterparts. Use of other drugs such as heroin, peyote, or GHB has not been found to be more highly prevalent among LGBT youth. Similarly, club drug use among young adults does not seem to differ by sexual orientation.

Sub-Group Differences Within LGBT Youth and Young Adult Populations

Similar to adult LGBT populations, substance use differences between LGBT and heterosexual youth and young adults are most dramatic and common among females. Lesbian and bisexual girls and young women are more likely to report alcohol use and alcohol-related risk behaviors, and have a drug abuse diagnosis than their heterosexual counterparts. Findings regarding sexual orientation disparities in substance use for boys and young men have been mixed. While some studies have found elevated rates of alcohol use among gay and bisexual young men, others have failed to detect differences from heterosexual young men. There is relatively little empirical information about transgender youth and young adults. This developmental phase is

considered to be particularly relevant for transgender individuals, as physical changes associated with puberty, which may further enhance discrepancies between self-identity and physical appearance, may lead to intense distress and risk for substance use problems.

Another important subgroup is those who identify as bisexual, questioning, or mostly heterosexual. A number of studies have documented elevated use of substances among these youth who do not identify as exclusively lesbian or gay. These youth have additionally been noted to display a unique pattern of substance use wherein they use substances more often at the time of first initiation and are more likely to binge drink.

Among general populations, Black and Latino youth have generally been found to consume less alcohol and use drugs less frequently than their White counterparts. The few studies that have examined racial/ethnic differences in LGBT youth and young adolescents have revealed similar patterns. For instance, in one study, White LGB youths reported more frequent consumption of alcohol relative to Black, Latino or other LGB youth and young adults of color. Although there is little research examining sexual orientation differences within racial/ethnic minority groups, one study found that Asian/Pacific Islander LGB adolescents had use patterns more similar to their White LGB counterparts than to heterosexual API adolescents.

Correlates of Substance Use in LGBT Youth and Young Adults

Victimization

LGBT youth and young adults experience elevated risk for victimization across multiple contexts that likely accounts for some of their substance use and abuse. In particular, victimization and bullying in school settings has been associated with both psychological distress and substance use. One study of high school students in the United States found that individuals who experienced homophobic teasing were more likely to use alcohol and marijuana than individuals who did not experience homophobic teasing. Interestingly, students who were questioning their sexual identity and experienced high levels of homophobic teasing also reported the highest levels of substance use, suggesting that these youth may lack some of the supports that individuals with a more clear sexual minority identity experience.

Coming Out and Minority Stress

Youth and young adults who are exploring and disclosing their identities as LGBT may be subject to unique minority stressors. Unlike adults, who have more relative control over their social and work environments, most youth have little personal choice over these environments and are often subject to home, school, and community environments that do not support their LGBT identities. Indeed, research has shown that earlier timing of awareness and disclosure of LGBT identity is a predictor of substance use, perhaps reflecting the greater vulnerability to minority stressors at younger ages. Additionally, even in families that will eventually be accepting of LGBT identities, initial reactions to disclosure are often negative, and such reactions have been linked empirically to alcohol and marijuana use in several studies. Not surprisingly, internalized heterosexism has also been linked to binge and heavy drinking among gay and lesbian youth.

Family of Origin

For all youth and young adults, parental support can serve as a buffer against the effects of life challenges. This may be particularly true for LGBTs; indeed, parental support has been documented to play an important role for those who encounter sexual orientation-based victimization. For instance, according to the Growing Up Today Study, LGB students who experienced a moderate frequency of homophobic teasing and the greatest amount of parental support reported less substance use than those who received the highest frequency of homophobic teasing and had the lowest amount of parental support. Another large-scale study indicated that substance use differences between LGB and heterosexual youth may be accounted for by lower parental support among LGB youth.

Homelessness

LGBT youth are disproportionately represented among homeless youth populations, comprising an estimated 40% of adolescents living on the street. LGBT youth may run away or be asked to leave their family home due to conflict with parents over sexual orientation. Homelessness is a known risk factor for substance use, abuse, and dependency, and this may be particularly true among LGBT youth. One study found that having recently left home was associated with higher alcohol or drug use for LGB youth.

Social Norms and Peer Relationships

Peer relationships and social norms have been found to be the strongest predictors of substance use in general youth and young adult populations, due to the importance of peer influences during this developmental phase. Peers may play a particularly important role for LGBT youth, who are seeking connection with other LGBT people in the face of rejection by family, friends, and communities. Paradoxically, by seeking this support and connection, LGBT youth may expose themselves to greater risk. For example, frequency of participation in

LGBT events and perceived connection to LGBT communities have been found to be among the strongest predictors of substance use among LGB youth, both cross-sectionally and longitudinally. Similarly, a study of college students found that those attending schools with more LGB resources engaged in more drinking. Further, a retrospective study of lesbians found that exposure to heavy drinking contexts during the coming out period was an important risk factor for later drinking behaviors.

Social norms may also play an important role for LGBT youth and young adults. Research with general samples has found that perceived norms for drinking behavior are often inflated in this age group, and that it is perceived norms, rather than actual norms, that most strongly influence drinking behavior. Indeed, a few studies of college students have found perceived levels of drinking among others to play an important role in alcohol consumption and binge drinking for lesbian and bisexual women.

Prevention and Treatment with LGBT Youth and Young Adults

Clearly, many LGBT youth and young adults would benefit from substance abuse services, both preventive and treatment-oriented. However, a number of barriers exist that may limit access to these services for this high-risk population. LGBT youth and young adults may harbor concerns about heterosexism from health care and treatment providers and may avoid disclosing their LGBT identity as a measure of self-protection. One recent study of high-school LGB youth found that only 35% had disclosed their sexual identity to their primary care physician, and even fewer bisexual youth had disclosed. When asked what physicians might do to increase the likelihood of disclosure, the majority of youth indicated that simply asking about sexual orientation would be sufficient.

Although specialized services are nonexistent in most regions of the United States, some US cities now have health centers that provide services targeted to LGBT youth. Many of these services focus on the most vulnerable segments of the LGBT community, such as homeless youth. Little or no research has examined the acceptability and effectiveness of substance abuse services for LGBT youth, either tailored or nontailored. Both SAMSHA and the Centers for Disease Control (CDC) offer guidelines for assessment and treatment with LGBT youth. These suggestions include asking questions at intake to assess all three dimensions of sexual identity as well as gender identity, assessing social environments and social contexts, and emphasizing safety and support in treatment.

Importantly, research on substance use among LGB youth suggests that prevention efforts aimed at reducing use during this phase could have long-lasting effects that extend into young adulthood. Prevention efforts, along with treatment approaches, should take into account the factors that have been found to influence substance use in this population, including victimization, minority stress, disclosure, family support, and peer norms. Additionally, it is critical that providers who work with LGBT youth in general health care and social service settings continually assess for substance use and abuse and make referrals when necessary.

SUMMARY AND CONCLUSIONS

In sum, LGBT youth and young adults are a population with elevated risk for substance use, abuse, and dependency. In addition to the typical developmental tasks of this life period, these youth face additional challenges that can influence their substance use behavior and set the stage for later problems with alcohol and drugs. More research is needed on subgroups such as bisexual, transgender, and LGBT ethnic minority youth. Additionally, it is important to understand why and how some LGBT youth resist substance use during this crucial developmental period. Further, it will be very important to identify ways to increase access to preventive and treatment services and to develop and test programs to address substance use in this population.

Glossary

CDC Centers for Disease Control.

Coming out the process of becoming aware of and disclosing one's identity as lesbian, gay, bisexual, or transgender.

FTM female-to-male transgender person: an individual who was born female but identifies as male.

Gender identity an individual's internal identification as a male or female.

Heterosexism ideological denial, denigration, and stigmatization of sexual minorities.

Homophobia irrational fear, hatred, and intolerance of homosexuality.
Internalized heterosexism internalized negative beliefs about one's own sexual identity as lesbian, gay, or bisexual.
LGB lesbian, gay, bisexual.
LGBT lesbian, gay, bisexual, transgender.
Minority stress the additional burden of stress experienced by members of minority groups because of their devalued or stigmatized social identity.
MTF male-to-female transgender person: an individual who was born male but identifies as female.
MSM men who engage in sexual behaviors with men.
NHSDA National Household Survey on Drug Abuse.
NESARC National Epidemiologic Survey on Alcohol and Related Conditions.
Revictimization victimization experiences in both childhood and adulthood.
Seropositive a person whose body is producing antibodies for a disease, such as HIV.
Sexual identity an individual's self-identification as lesbian, gay, bisexual, heterosexual, or other.
Sexual orientation an individual's sexual identity, attraction to, and/or sexual behavior with members of the same and/or opposite sex.
SUDs substance use disorders.
Transgender umbrella term for individuals whose gender identity does not strictly correspond with the sex they were assigned at birth.
Two-spirit a term used in some Native American/American Indian communities to refer to a gender and/or sexual identity outside of traditional male and female heterosexual identities.
WSW women who engage in sexual behaviors with women.

Athletes and Substance Use

Matthew P. Martens
University of Missouri, Columbia, MO, USA

OUTLINE

Substance use among athletes receives a considerable amount of attention in many nations, including the United States. This is presumably due to a number of factors, including the cultural importance of sport, high-profile alcohol and/or drug-related incidents involving famous athletes, and ethical issues associated with the use of performance-enhancing drugs. The impact of sport on many societies and cultures is considerable. In the United States, for example, youth and adolescent sport is pervasive, athletes are considered role-models by many, collegiate and professional sport are multibillion dollar industries, and there are dozens of television channels devoted exclusively to athletics. Considering this context, it is not surprising that substance-related issues among athletes can become magnified in terms of their overall societal impact. This impact includes tragedies such as alcohol- and drug-related deaths among famous athletes and the explosion in recent years of revelations of steroid and other performance-enhancing drug use (e.g. the large number of major league baseball players linked to steroids and human growth hormone; drug-related scandals associated with the Tour de France bicycle race). This state of affairs and the publicity afforded to substance-related issues among athletes creates the impression that substance use is rampant among this group. The reality of the situation, though, is more complex, including what drugs athletes are more likely than others to use and abuse, why it is that athletes use certain substances, and how to effectively intervene with athletes who do experience substance-related problems. Therefore, the purpose of this chapter is to review the prevalence rates of substance use among athletes, explanations for such use, and what is known about effective ways to prevent or reduce substance use in this population.

PREVALENCE AND REASONS FOR SUBSTANCE USE AMONG ATHLETES

Alcohol

The most frequently studied substance among athletes is alcohol, with the largest and most comprehensive studies occurring among college athletes in the United States. There have been three nationally representative studies that have compared drinking rates between college athletes and nonathletes, all of which have shown

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00059-0

that athletes are more likely than other college students to report heavy drinking. These studies have shown that between 53% and 57% of college athletes reported a heavy drinking or "binge" episode (defined as 5+ drinks in one sitting for men and either 4+ or 5+ drinks in one sitting for women) in the preceding 2 weeks, compared to 36–43% of nonathletes. These studies also found that athletes were more likely than nonathletes to engage in frequent heavy episodic drinking (3+ occasions in the preceding 2 weeks) and one study found that, on average, athletes consumed approximately 3.5 drinks per week more than nonathletes (7.57 drinks versus 4.12 drinks). These studies also showed that athletes were more likely than nonathletes to experience numerous negative alcohol-related consequences, such as having impaired academic performance, getting into trouble with the authorities, and experiencing unplanned or unwanted sexual encounters due to their drinking. It is therefore clear that participating in college athletics is a risk factor for excessive alcohol consumption and resulting negative consequences.

There have also been studies that compared alcohol use rates between athletes and nonathletes at the youth/high school level. In general, the findings are mixed regarding differences in alcohol consumption between youth athletes and nonathletes, although more recent studies suggest that athletes in that population drink more than nonathletes. One study of approximately 45, 000 8th, 10th, and 12th grade students in the United States found that participating in an athletic team was associated with more frequent alcohol use and increased likelihood of binge drinking. Another study using a nationally representative sample of US high school students found that participating in sport as a sole school-related activity was associated with a greater acceleration in problem alcohol use over time. However, participating in both school and academic activities was associated with a slower acceleration in problematic alcohol use. Another large-scale study among Norwegian adolescents found athletes were initially less likely than nonathletes to report being intoxicated over the previous 12 months, but experienced a greater growth than nonathletes in likelihood of intoxication over time. This effect was limited only to athletes who participated in team sports, as athletes participating in endurance sports actually had a decrease in intoxication over time relative to nonathletes. Other studies have suggested that certain subgroups of youth or high school athletes are more at risk for problematic alcohol consumption than other students, such as those with a high athletic identity and those with risk factors such as aggression and other problem behaviors.

There has been very little research examining alcohol use among athletes at the professional or other "elite" level, so little is known about the drinking habits of that group and how it compares to relevant population norms. Anecdotal reports in the popular press often suggest that professional or other elite athletes are frequently socializing and drinking heavily, but at this point there is little evidence to either support or refute this contention. There is some evidence to suggest that college students and adults participating in "nonelite" sports like intramurals or club teams are at risk for heavy alcohol use.

A few studies primarily conducted among college athletes have also shown that athletes tend to report drinking less during their competitive seasons than during the off-season. In the only longitudinal study examining this issue, the researchers found that male and female athletes reported a 69% and 58% higher rate, respectively, of typical drinks per week during the off-season in comparison to the in-season. These findings suggest that athletes are particularly at risk for heavy alcohol use and its resulting negative consequences when they are not active in their competitive seasons. It is possible that during a team's competitive season coaches are more likely to have specific rules that prohibit or limit alcohol use and teammates may be more likely to formally or informally discourage heavy drinking among their peers.

Based on this information on prevalence rates of alcohol use among athletes and nonathletes, it is important to understand why it is that some groups of athletes are more at risk relative to their nonathlete counterparts for excessive alcohol consumption and related negative consequences. Athletes are as susceptible as anyone else to the large number of risk factors associated with problematic alcohol consumption, but it is also possible that there are factors specific to sport itself that make athletes particularly at risk for heavy alcohol use. There are two main ways that researchers and theorists have attempted to explain these differences. One explanation is that athletes possess internal characteristics that make them more likely than others to engage in heavy alcohol use. The second is that athletes are susceptible to unique environmental or contextual influences that result in excessive alcohol consumption.

Personality Characteristics

An internal characteristic that may explain differences between athletes and nonathletes in their use of alcohol is differences in personality traits associated with excessive drinking. Such differences may suggest a genetic or biological risk factor for heavy alcohol consumption that is more common among athletes than nonathletes. For example, a number of researchers have shown that the personality trait of sensation seeking, which is typically conceptualized as a propensity toward enjoying exciting and/or risky activities, is associated with elevated levels of alcohol consumption. Different groups of researchers

have shown that athletes are more likely than nonathletes to report engaging in various risky behaviors and to score higher on measures of sensation seeking. Athletes in many sports experience a great deal of excitement and risk as a result of their athletic participation, which could explain why one finds higher levels of sensation seeking among athletes than others. It is therefore possible that for many athletes a personality predisposition that in part draws them to athletics also makes it more likely that they will engage in other "risky" behaviors such as excessive alcohol consumption.

Excessive Stress

A second internal characteristic that might explain drinking differences between athletes and nonathletes, which would pertain mostly to athletes at the collegiate level, is that some athletes drink heavily in response to excessive stress associated with balancing the demands of being both a student and an athlete. There is no doubt that many college athletes face a unique set of pressures, such as concerns about playing time or athletic performance and balancing academic work with 20+ h per week of sport-related commitments. Although theorists have speculated for some time that excessive stress levels are associated with alcohol use among athletes, research does not seem to suggest this is in fact the case. Studies have shown that few college athletes endorse coping-related motives as a primary reason for using alcohol and one study showed no athlete–nonathlete differences on a measure of drinking to relax. Athletes who do drink for coping-related reasons, like nonathletes who also do so, may be more at risk for significant alcohol-related problems than those who drink for reasons such as enjoying a party or experiencing pleasant feelings. But, using alcohol as a means of coping with excessive stress has not been shown to be an important reason for heavy drinking among athletes.

Social Opportunities

Relatively more attention has been given to environmental or contextual factors unique to sport that might explain higher rates of alcohol use among athletes, and it is possible that these factors interact with internal characteristics like personality traits in causing elevated risk for alcohol use among athletes. One unique environmental factor that may in part explain heavy alcohol use among athletes is the existence of more social opportunities than their peers. In many settings, such as the collegiate and high school environments, athletes are afforded a great deal of popularity and notoriety. This popularity may result in more social opportunities relative to the typical nonathlete, which for some results in excessive alcohol consumption. Athletes at the college level may be more likely than others to be invited to parties, bars, clubs, etc., where other students are interested in buying/providing them drinks due to their popularity and notoriety. Additionally, athletes on many teams have a built-in social network with teammates that can lead to opportunities for heavy drinking, especially at the collegiate level where athletes clearly drink more than other students. These social characteristics, especially if one possesses internal characteristics that make it more likely he or she will drink alcohol, could promote excessive alcohol consumption among some groups of athletes.

Athletic Team-Related Factors

Another unique environmental factor that could be associated with excessive alcohol use among some athletes is the influence of the athletic team. Social norms theory suggests that the more an individual perceives that others drink alcohol or the more permissive the attitudes others have toward drinking, the more the individual him- or herself will drink. A number of research studies have supported this contention, such that perceiving that one's peers drink heavily and/or have favorable attitudes toward drinking is associated with more alcohol use among the individual in questions. Research has also shown that the more salient or important the group that one is using in the social norms comparison (e.g. other students at one's university versus college students in general), the stronger the relationship between these perceived norms and personal alcohol use. In many instances, an athlete's teammates serve as important social influences over his or her life, so if an athlete perceives that heavy drinking is normal or encouraged by his or her teammates it is more likely that he or she will also drink heavily. Teammates may also influence each others' drinking through more overt means, such as formal or informal drinking-related competitions. Some theorists have speculated that the competitiveness that athletes display with both their teammates and opponents on the practice and playing field translates to the drinking arena as well. One study found that college athletes were more likely than other students to report engaging in drinking games, which are associated with heavy overall alcohol consumption. Drinking games involve competitions where the loser is required to drink a certain amount of alcohol. For example, in a game like beer pong one has to drink if his or her opponent successfully hits the ping pong ball into the designated cup. Thus, in an effort to "win" formal or informal competitive drinking competitions with their teammates some athletes may engage in risky drinking practices such as consuming large amounts of alcohol over a short period of time.

Other Cultural Factors

More recently researchers have begun to examine the association between broad cultural factors like alcohol

industry sponsorship of sport and its potential impact on the drinking behaviors of athletes. In Europe, pubs have been associated with sporting events for several hundred years and have historically played an important role in promoting sport. Currently, it is fair to say that alcohol companies are major sponsors of professional sports throughout the world, and in some cases have even owned professional teams or leant their names to professional stadiums. For example, the St. Louis Cardinals baseball team was owned by the Busch family for almost half a century and stadiums in places like St. Louis, Denver, and Montreal are named after beer companies. It is not clear how something like broad industry sponsorship of sport might impact the drinking behaviors of athletes themselves, but one possibility is that those who participate in sport have been influenced by advertising messages about their association at a greater intensity than others in the population. It is also possible that for some athletes this sponsorship link impacts their perceptions of what behaviors are normal or encouraged as part of being an athlete. In some cases a more direct relationship might exist between alcohol sponsorship and individual drinking behaviors. For example, one large study of athletes in New Zealand found that almost half of the athletes were sponsored by the alcohol industry, almost half of those sponsored reported receiving free or reduced price alcohol-related products, and those receiving alcohol industry sponsorship reported more problematic alcohol use than those not receiving sponsorship. In sum, there are a host of factors that might explain excessive alcohol use among athletes. It is important that researchers interested in understanding the phenomenon of alcohol use among athletes consider embarking upon high-quality studies designed to address topics reviewed in this section.

Tobacco

Research has shown that athletes generally report less cigarette use than nonathletes. National studies of US college students indicate approximately 15–18% of students overall report smoking cigarettes at least once in the past 30 days, whereas national studies of college athletes have shown only 9% report past 30-day use. Further, these studies show that the majority of college athletes who report using cigarettes indicate they do so only on social occasions with friends, whereas almost 50% of college students in general who smoke cigarettes do so daily. A national study among US high school athletes reported a similar pattern of findings, with female athletes 29% less likely and male athletes 36% less likely to smoke regularly than their nonathlete peers. Studies among other groups of athletes including Greek adolescents, French elite student-athletes, and English recreational athletes have shown that athletes were less likely than nonathlete comparison groups to report cigarette use.

One type of tobacco athletes are more likely to use, at least among some sports in the United States, is smokeless or spit tobacco. Approximately 12% of US college athletes report smokeless tobacco use in the past 30 days, compared to only 4% of college students in general. Smokeless tobacco use among athletes occurs disproportionately among certain types of sports. For example, approximately 40% of US collegiate baseball players and 30% of football players report past year smokeless tobacco use, compared to only 10–12% of those participating in basketball or track and field. Among US high school athletes, a national survey found that female athletes were 83% more likely and male athletes 41% more likely to use smokeless tobacco than nonathletes.

These findings represent an interesting discrepancy in tobacco use among athletes. The fact that cigarette use is relatively low among athletes is not surprising, due in part to the fact that athletes are more likely than others to be concerned about the health-related risks of cigarette use and/or its impact on their ability to perform as athletes. In contrast, many athletes do not seem to share the same concerns regarding smokeless tobacco. One explanation for this discrepancy is the cultural link between smokeless tobacco and certain types of sports. For example, one only need to watch a major league baseball game on television to see multiple instances of players using smokeless tobacco either on the bench or when actually playing in the game. Many US college athletes report that a member of their coaching staff or other athletic department personnel uses smokeless tobacco, which may lead to increased perceptions of permissiveness among one's coaches. Finally, athletes may be more comfortable using smokeless tobacco in comparison to cigarettes because they do not perceive it to have as strong of a negative impact on their athletic performance. Fortunately, researchers have shown that spit tobacco interventions that include dental examinations and behavioral counseling are effective at reducing tobacco use among adolescent athletes.

Illicit Recreational Drugs

The largest studies of recreational drug use among athletes have been conducted by the National Collegiate Athletic Association (NCAA). Their most recent study involved almost 20, 000 college athletes at universities across the United States. Results from the study indicated that in the past year 20.3% of college athletes reported using marijuana, 2.5% reported using hallucinogens (excluding ecstasy), 2.1% reported using cocaine,

and 1.2% reported using ecstasy. These figures are either comparable or lower to prevalence rates obtained from national surveys of the general college student population. For example, one national survey conducted in the same year as the aforementioned NCAA study found past-year prevalence rates of 33.3% for marijuana and 5.7% for cocaine among the general college student population. Additionally, a national study comparing marijuana use among college athletes and nonathletes found that male athletes were less likely than nonathletes to report marijuana use in the past 30 days, while rates were similar for female athletes and nonathletes. Findings from studies on other groups of athletes have generally reported a similar pattern of results. Studies of youth athletes in both the United States and other countries have usually shown that those participating in athletics are either less likely or as likely as those not participating in athletics to report recreational drug use, and the limited research on athletes at the professional or elite level also suggests that such individuals are less likely to use recreational drugs than nonathletes. Thus, in contrast to the findings that some groups of athletes use more alcohol than their nonathlete counterparts, research suggests that the opposite pattern occurs for recreational illicit drugs.

Even if athletes are at less or comparable risk than others for utilizing recreational drugs like marijuana, cocaine, or hallucinogens, it is still important to understand the factors associated with their use (or lack of use) specifically among athletes. In addition to the negative consequences associated with illicit drug use that can be experienced by anyone abusing a substance, some athletes who choose to use such substances experience a unique set of negative consequences associated with their participation in sport. For example, college athletes who are on scholarship risk suspension or expulsion from their sport as a result of a positive drug test, which could impact their academic futures. Athletes who have the talent to participate at a higher level, such as high school athletes wishing to participate in college athletics or college athletes wishing to compete at the professional level, may find their opportunities limited if they are known to have used illegal substances. Finally, professional athletes who are caught using illicit drugs face suspensions and other punishments that can impact their future employment and earnings potential in the form of less lucrative contracts and loss of endorsement opportunities.

One clear deterrent to recreational drug use among some athletes is random drug testing. Drug testing is commonplace among professional, college, and other elite athletes, and is instituted in some cases at the high school level. The frequency of drug testing an athlete is subjected to will vary across sport and competitive level, and even within competitive level when considering college athletes. Some colleges and universities (approximately 40%) do not engage in any internal drug testing, whereas others (generally those with more resources) will consistently randomly test their athletes. Testing is also conducted by governing organizations like the NCAA, often during championship events. Unfortunately, the effect of drug testing on athletes' substance use has not been extensively examined. One study conducted among high school athletes found some positive effects for a random drug testing program, but findings were not consistent enough to make strong conclusions about the program's effectiveness. Other studies have shown athletes are generally in favor of drug testing programs. Whether these programs are effective at preventing drug use among athletes at different competitive levels, though, awaits further study.

A second factor that may deter athletes from engaging in recreational drug use is health-related concerns. In the aforementioned survey of NCAA college athletes, the most commonly cited reason for not using recreational drugs was concerns about negative health-related consequences. This same concern was the most commonly cited reason for not using alcohol as well, but the percentage of athletes citing it as a deterrent from alcohol use as opposed to other drug use was considerably smaller. Most athletes are health-conscious, and it is possible that drugs other than alcohol are perceived by athletes as having a greater negative impact on one's health. Interestingly, concerns about a substance's negative impact on athletic performance were not frequently cited as the main reason for avoiding its use. It is therefore possible that a primary deterrent to drug use among athletes is a perception that using such substances will have considerable negative health-related outcomes.

Performance-Enhancing Drugs

Unlike alcohol and illicit recreational drug use, performance-enhancing drug use among athletes involves ethical considerations regarding competitive fairness. Competitive sport is built on principles of rules and fair play, so behavior on the part of an athlete that is deemed to create an unfair competitive advantage is often looked down upon by those involved in athletics. Even though such principles are sometimes applied unfairly and hypocritically (e.g. stealing signs in baseball is considered "part of the game" while steroid use is generally condemned), it is fair to argue that without such principles sport may cease to exist. Understanding performance enhancement drug use among athletes is therefore of interest not just because of potential health risks to the athletes who take such substances, but because of concerns about the impact of such use on the integrity of sport itself.

The consensus seems to be that performance-enhancing drug use, particularly steroids and human growth hormone, has increased over the past quarter century, and public perception may be that a large percentage of athletes use performance-enhancing drugs. Research, however, suggests that a relatively small percentage of athletes in fact use performance-enhancing drugs. The most recent NCAA study found that only 1.2% of college athletes had used steroids in the past year. A small percentage of students also reported using amphetamines (4.1%) and ephedrine (2.5%) in the previous year, but only 9.7% of those who used amphetamines and 27.3% of those who used ephedrine stated that the main reason they did so was to improve the athletic performance. There were differences across sports in terms of performance-enhancing drug use, but rates were still low among sports where one might think its use is relatively prevalent. For example, prevalence rates among baseball and football players were 2.3%, compared to 0.8% for track and field athletes and 0.3% for tennis players. Some smaller studies conducted in single universities have found higher prevalence rates of performance-enhancing drug use among college athletes than nonathletes, but overall it appears that a relatively small percentage of college athletes report using such drugs.

Studies among high school students have reported similarly low rates of steroid use among athletes, and one national study of over 16, 000 high school students found no differences between athletes and nonathletes on steroid use. No large studies have examined performance enhancement drug use rates among professional or other elite athletes. Such use is clearly occurring among some professional athletes, as evidenced by suspensions that occur each year in major professional sports and from international sporting governing bodies, and various estimates of use have been put forth in the popular press. But the actual rates of performance-enhancing drug use among professional and other elite athletes await further study.

Explaining the reasons for performance-enhancing drug use among athletes is presumably more straightforward than for other substances, in that the primary reason is to improve one's athletic performance. For example, the most commonly cited reason for steroid use among NCAA athletes was to enhance athletic performance, while assisting in recovery from injury was the second most common reason. It is possible that a number of sport-related variables serve as risk factors for steroid use among athletes, including permissive norms among teammates and coaches, a "win at all cost" mentality that is promoted within a team or organization, and believing that one is at risk for losing a spot on a team or in a starting lineup. Unfortunately, few research studies have attempted to address the role such factors might play in understanding steroid use among athletes.

TREATING AND PREVENTING SUBSTANCE USE AMONG ATHLETES

When thinking about treating and/or preventing substance use specifically among athletes, one must first consider the larger knowledge base regarding effective interventions among the general population. Substance abuse interventions can range from universal prevention strategies that are designed to be applied to an entire population in an effort to delay or inhibit the initiation of substance use to intensive treatments designed for those experiencing considerable substance-related problems. How interventions across this entire spectrum may be applied to athletes is described below.

One of the most commonly used universal prevention intervention models involve social norms marketing. This intervention has been frequently implemented on college campuses in the United States. The purpose of this type of intervention is to correct misperceptions regarding the actual rates of drinking behavior among a target population. Research has consistently shown that most college students overestimate the amount of alcohol that other students drink. Presumably, some students are in part motivated to drink in order to "fit in" with the perceived behaviors of other students. Thus, correcting this normative misperception may result in reduced drinking among those who had overestimated the amount of alcohol consumed by the typical college student. The effectiveness of social norms marketing campaigns has been the subject of some debate, and the research evidence is hampered by the existence of only a handful of well-designed studies that have addressed the issue. One large clinical trial did provide some support that these types of interventions, when implemented properly, can have small population-level effects.

Social norms marketing interventions can be targeted toward specific population groups, including college athletes. For example, instead of providing normative drinking rates for college students in general, the campaigns could use norms specific to college athletes or include information about misperceptions regarding the negative effects of alcohol use on athletic performance. Ideally these data would be specific to the location(s) where the intervention was being conducted, because research has shown a positive association between the salience of the normative reference group and personal substance use. For example, if a targeted social norms intervention were being developed for use at a specific high school, it would be best if the norms regarding perceived drinking rates, actual

drinking rates, and other related variables were collected from athletes at that high school.

Only a few studies have examined targeted social norms campaign among athletes, but there is some evidence that the interventions may be effective. One study examined the efficacy of a targeted social norms campaign among college athletes at a Northeastern university. The authors reported a decrease in alcohol use among student-athletes at the university over a 2-year follow-up after the campaign was implemented. They also found that students who reported more exposure to the targeted campaign also reported less alcohol use. Unfortunately, the study did not contain a control condition, thereby making conclusions about causality impossible. Nonetheless, a targeted social norms intervention may have promise as a universal prevention intervention among college athletes.

Effective interventions have also been developed for individuals who may be experiencing some problems associated with a substance but are not yet in need of more intensive treatment (i.e. indicated prevention). One well-studied intervention that has been applied in an indicated prevention framework involves providing an individual with personalized feedback regarding his or her substance use, sometimes in the context of a brief (15–50 min) one-on-one meeting with a facilitator. These interventions are rooted in Motivational Interviewing philosophy in that they are designed to increase motivation to change behavior by developing discrepancy between current behaviors and one's goals or values and overcoming ambivalence or resistance toward change. When delivered in a one-on-one session facilitators of these types of interventions use a number of techniques such as open-ended questions, reflective listening, and effective summaries to promote change talk within the session. Personalized feedback is often used to guide the content of these sessions, or in some cases is used as an intervention in and of itself. This feedback is developed based on an individual's responses to substance-related questionnaires, and often contains information such as how one's substance use compares to a relevant norm (e.g. how a college student's average drinks per week compares to a national or campus average for college students), a summary of negative consequences experienced as a result of substance use, other negative outcomes such as alcohol-related calories consumed or dollars spent on substances over a specific time period, and use or nonuse of strategies that have been shown to be associated with less substance use and fewer substance-related problems. Because this information is personalized, it is presumably more effective than general educational information in motivating people to change their behavior. A number of studies among groups such as college students, primary care patients, and emergency room patients have shown that these types of interventions are effective at reducing substance use. The majority of these studies have been in the area of alcohol use, although positive effects for substances like marijuana have also been demonstrated.

These personalized feedback-based interventions may be particularly appealing for use among athletes in part because the content of the intervention can be targeted specifically for the population. One group of researchers have shown that a standard personalized feedback-only intervention (i.e. one that was not targeted specifically toward athletes and did not involve a one-on-one meeting with a facilitator) was effective at reducing alcohol use among samples of college athletes over a 3-month period. In one of their studies, the authors reported that among athletes who had recently engaged in binge or heavy episodic drinking, those who received the personalized feedback intervention reported an average decrease of 32–46% in alcohol use (depending upon the specific alcohol use measure), whereas those in the control condition reported an average increase of 6–11%. A different group of researchers examined whether targeting personalized feedback specifically for college athletes would be more effective than more general personalized feedback that could be applied to all college students. They found that the targeted personalized feedback was more effective than the general personalized feedback and an education-only control condition at reducing alcohol use, particularly in terms of peak blood alcohol content on one occasion over the past month. A third group of researchers found that an intervention that utilized personalized normative feedback that was specific to college athletes was associated with decreased alcohol use, although the design of the study precluded causal conclusions. Finally, another group of researchers reported that an intervention that combined a brief one-on-one personalized feedback-based intervention with an intervention designed to facilitate parental communication about alcohol use was effective at reducing alcohol use among high school athletes making the transition to college. Together these studies suggest that personalized feedback-based interventions can be effective at reducing alcohol use among athletes, and that targeting the contents of interventions to be more relevant for athletes may yield additional benefits.

There are several treatments available for athletes who are experiencing significant problems with substance use and may require more intensive interventions than those used in the context of indicated prevention. The efficacy of these treatments has not been specifically examined among athletes, but there is no reason to suspect that the treatments would not generalize to the athlete population. Cognitive-behavioral and behavioral treatments that focus on factors such as developing social environments that do not reward

substance use and skills for avoiding or minimizing substance use, and contingency management treatments that provide tangible rewards for not engaging in substance use, have been shown to be effective at reducing alcohol and/or drug use. Additionally, therapies designed to facilitate the 12-step approach and marital/family treatments have been shown to reduce substance use, and pharmacological therapies like naltrexone and acamprosate have received some support. Thus, there are a number of empirically supported options that exist for the athlete who is in need of formal treatment for a substance use disorder.

When considering any type of intervention program that will be implemented or evaluated among a sample of athletes, it is important to consider several factors associated with athletic teams and organizations. First, many athletic teams, departments, and/or organizations are fairly closed systems and can be distrustful of outsiders, particularly when it comes to sensitive topics like substance use. This suggests that those interested in intervening in such a system may have to initially spend time gaining the trust of those in charge of the system (e.g. athletic directors, head coaches). Second, it is important to recognize that in most teams a coach wields a considerable amount of power and influence over his or her athletes. In many cases coaches can make arbitrary decisions regarding things like playing time, starting status, and even membership at all on a team. Although researchers have not yet examined this premise, it may be possible to work with coaches to establish clear policies and expectations regarding a team's behavior with respect to prohibition or responsible use of alcohol. Finally, considering the importance of successful athletic performance and avoiding injury to most athletes, any intervention modality may benefit by linking excessive substance use to poor athletic performance and/or increased injury risk. For example, in one recent study the researchers provided estimates of how long a single or back to back binge drinking episode might impact their athletic performance (3 days for a single binge; 5 days for back to back binges).

SUMMARY

Researchers have established that for some substances, like alcohol use, certain groups of athletes are more at risk for using the substance than their nonathlete peers. It is fairly well-established that college athletes on an average drink more than students not participating in athletics, and there is evidence to suggest that a similar pattern occurs among high school athletes. For tobacco and recreational drugs, though, evidence suggests that athletes use the substances at rates that are similar to or less than their nonathlete counterparts. In general, little is known about the prevalence rates of substance use among professional or other "elite" athletes.

The reasons that athletes drink alcohol more than others or use illicit drugs in the face of potential sanctions such as suspension and possible loss of income are complex. Certainly athletes are susceptible to the same factors that influence substance use in the general population. It is also possible that certain factors unique to sport, such as the cultural association between alcohol and athletics or a normative team-related environment that promotes alcohol use, in part cause some athletes to drink at high rates.

There currently exist a number of empirically supported treatment and preventive interventions in the substance abuse arena. Although most of these interventions have not been tested specifically among athletes, there is no reason to suspect that they would not be effective among them. Researchers have recently examined the effects of interventions that contain information targeted specifically for athletes, with findings that are promising.

CHAPTER

60

Cultural Influences on Youth Alcohol and Drug Use

Sharon Hsin Hsu

Center for the Study of Health & Risk Behaviors, University of Washington, Seattle, WA, USA

OUTLINE

Recent statistics suggest that ethnic minority population in the US is increasing. For example, according to US Census Bureau, by the year of 2050, it is expected that the Hispanic and Asian populations will triple and non-Hispanic whites (individuals who identify as white but not of Spanish/Hispanic/Latino origin) will represent about 50% of the total population. Figure 60.1 displays a distribution of the current US population by ethnicity and Hispanic origin and projections for 2050. According to a 2003 Census report, ethnic minority youth accounted for a large percentage of the total youth population. For example, Hispanics were the most likely to be preschoolers relative to other racial and ethnic groups; more than 10% (or 4.2 million) of its total population is in this age group. Native Hawaiians and other Pacific islanders reported the highest percentage (18%) of elementary-school age youth. American Indians, Alaska natives, native Hawaiians, and other Pacific Islanders had the highest percentage (8%) of high school age youth. Taken together, with the increase in population, it is imperative for federal and state agencies to allocate resources for service and research dedicated to addressing health-risk behaviors among ethnic minority youth.

In 1993, the National Institute on Drug Abuse (NIDA) composed a report to summarize research advancement, methodological issues, as well as new direction for research in understanding drug abuse by ethnic minority youth. In the introduction statement, De La Rosa and colleagues posited,

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00060-7

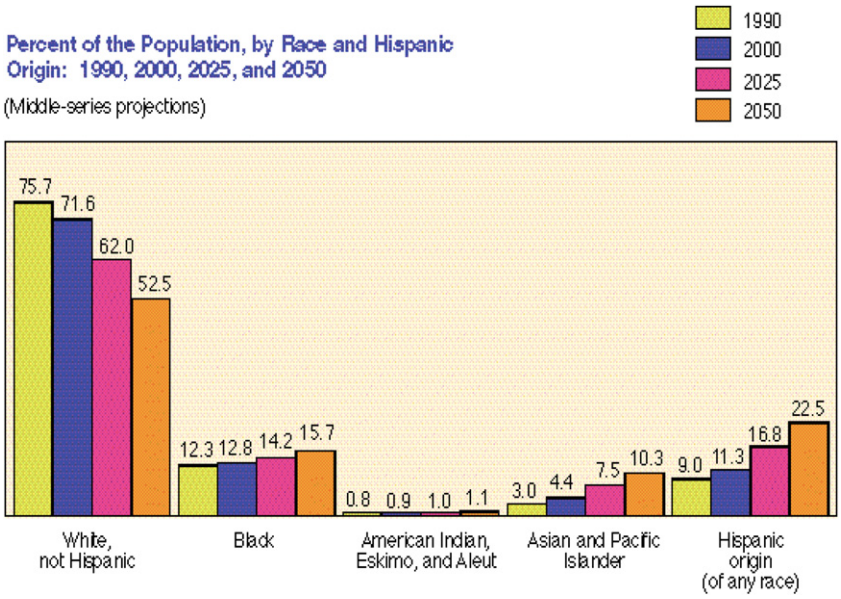

FIGURE 60.1 Percent of the population, by race and Hispanic origin reported by the US Census Bureau.

> *"The limited literature suggests that, because of* cultural influences, *unique economic situations, and formal and informal social network systems, the drug-using behavior of minority youth may vary significantly from that of non-minority youth. There is an urgent need for etiologic research that investigates the interactive roles of intrapersonal, interpersonal, familial, cultural community, and other larger societal factors on the onset, casual use, escalation to use, maintenance, development of dependence, cessation of use, and relapse to use of licit and illicit drugs among minority youth. Studies are also needed that would investigate protective factors among minority children who are at risk but have refrained from using drugs or from escalating to abuse from initial limited exposure (pp. 1)."*

This statement highlights the potentially important role of culture in substance use. In addition, several researchers, such as Castro and colleagues, have indicated that the "culturally blind" approach is not sufficient given that it ignores the service needs of racial/ethnic minority individuals, especially for those who are relatively traditional and/or low in level of acculturation. Thus, Catro and colleagues suggest that the examination of cultural variables may enhance the cultural relevance, efficacy, and effectiveness of prevention and treatment programs designed to serve racial/ethnic minority people.

This chapter will examine recent studies that have tested cultural variables as risk or protective factors among ethnic minority youth in the US Ethnic minority youth are 24 years of age or younger and include Asian American and Pacific Islander youth; Hispanic youth; African American youth; and American Indian and Alaska Native youth. These definitions are adapted from the NIDA monogram published in 1993. A greater proportion of the chapter will be dedicated to Asian American and Pacific Islander youth and Hispanic youth given that there has been a significant advancement in the literature with regard to these two ethnic groups. We will also discuss research on youth outside of the US in a later section.

INCLUDING CULTURAL VARIABLES IN SUBSTANCE USE RESEARCH

According to the US Department of Health and Human Services (DHHS), culture has been defined as a "common heritage or set of beliefs, norms, and values, shared group attributes and a system of shared meaning.". Castro and Hernández-Alarcón suggest that culture is both an environmental and a behavioral variable, and therefore can be divided into two basic types: environmental elements and psychological elements. The environmental elements consist of local environment and cultural creations (i.e. works of art, buildings, and community norms). The psychological elements consist of beliefs, attitudes, expectations, values, and family norms. Specifically, cultural beliefs refer to a historically shaped manner of "viewing the world" and the way in which people "interpret the meaning of objects and events." These beliefs also offer problem-solving strategies, including prescribed approaches of managing stress. Although this conceptualization is helpful, Kitayama and Cohen suggest that it is important to be aware that there are other ways to define culture.

In the context of substance abuse research, Castro and Hernández-Alarcón suggest that cultural variables are generally in the domains of interpersonal relations and

personal traits. The interpersonal relations domain includes variables such as familism, individualism–collectivism, and *tui lien* (loss of face). The personal traits domain includes variables such as acculturation, enculturation, ethnic identity, and biculturalism. For a complete list of variables, please refer to Castro and colleagues' original article. In the current chapter, we will focus on variables that have been tested frequently in the empirical literature. A brief overview of acculturation and cultural identification is provided, as these constructs have received the most attention from the research community.

Acculturation

Snowden and Hines posited that acculturation is broadly defined as the degree to which members of an ethnic group participate in the cultural traditions, values, and practices of the dominant society. This definition has been used in empirical research frequently. Acculturation is frequently measured by multiple indices. Some examples include nativity (i.e. US-born versus foreign-born), the length of time an immigrant has lived in the US, age at immigration, language abilities, and the context in which the language is used (e.g. home). Generally, the US-born individuals are considered to be more acculturated than foreign-born individuals. The longer an immigrant stays in the new country or the younger the age at immigration, the more acculturated they are likely to be. Higher ability to speak English tends to indicate higher level of acculturation. Indeed, Zane and Huh-Kim suggested that speaking English has often been considered to be the strongest acculturation measure linked to different health outcomes. Theoretical models proposed by many scholars have frequently regarded acculturation as a cause of stress and impaired mental and behavioral health among ethnic minorities. Conversely, Wolsko and colleagues pointed out that *enculturation* has been considered as a positive influence through providing a coherent, connected, and grounded identity. It has often been regarded as part of a healthy lifestyle and a buffer for the negative effects of stress.

Cultural Identification

According to Oetting, cultural identification is defined as "a persistent, long-term underlying characteristic that organizes cognitions, emotions, and behaviors." Individuals with high identification with a particular culture tend to recognize themselves as adapted to that culture. They will make evaluative judgments about people and events that are based on cultural beliefs and choose behaviors that are culturally congruent. This in turn will make them successful in participating in activities in such a cultural context. Oetting also posited that cultural identification is a personality trait and the development and maintenance of cultural identification are based on interactions with the environment.

RATES OF SUBSTANCE USE AMONG ETHNIC MINORITY YOUTH IN THE US

The Substance Abuse and Mental Health Substance Administration (SAMHSA) is an excellent resource for information on the latest trends of substance use and abuse among ethnic minority youth in the US. Below is a brief summary of substance use and abuse trends and treatment data by ethnicity. Most of the citations can be found electronically on the SAMHSA website.

Asian American and Pacific Islander Youth

Asian American youth aged 12–17 were less likely to have used alcohol or engaged in binge drinking during the past year, relative to Hispanic, White, or American Indian/Alaska Native (AI/AN) youth. According to the National Institute on Alcohol Abuse and Alcoholism, binge drinking is defined as consuming five or more alcoholic beverages within a 2-hour period. Additionally, a study conducted by SAMHSA indicates that there are subgroup differences in substance use patterns. Filipino youth had the highest rates of past year alcohol use (29.5%), followed by Korean youth (24.9%), Japanese youth (22.2%), Chinese youth (19.6%), and American Indian youth (16%). Based on these figures, Filipino youth were more likely to have reported alcohol consumption during the past year than Chinese or Asian Indian youth. In terms of binge drinking, Another SAMHSA study indicates that Filipino youth reported the highest rates of past year binge drinking (5.8%), followed by Asian Indian youth (5.4%), Japanese youth (4.5%), Korean youth (3.5%), and Chinese youth (1.1%). Additionally, there is a gender difference in alcohol consumption: female Asian youth (19%) were less likely to use alcohol in the past year compared to their male counterparts (26%).

Epidemiology research also suggests that older Asian youth may be at risk for developing alcohol use disorders. For instance, according to Grant and colleagues, the rate of Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV) alcohol abuse among Asian females between the ages of 18 and 29 years old increased significantly between 1991/1992 and 2001/2002. Rate of DSM-IV alcohol dependence among Asian males of the same age group also increased significantly over the 10-year period. Young adult Asian males have

been identified as an emerging high-risk group for developing alcohol use disorders.

Based on the most recent available statistics provided by SAMHSA, substance abuse treatment admissions for Asian and Pacific Islander youth aged 12–17 increased by 52% between 1994 and 1999. Most admissions were first treatment episodes (75%). Primary substances of abuse among Asian youth were marijuana, alcohol, and stimulants, with marijuana being the leading substance. Youth were more likely to enroll in treatment through self- or individual referrals or school referrals relative to the total youth treatment population.

Cigarette smoking among Asian youth has received a fair amount of attention in the empirical research literature. For example, Chen and colleague examined patterns of smoking behavior among 7–12 grade Asian American youth ($N = 1810$) in California. Data was extracted from the 1990–1996 California Tobacco Survey and the California Youth Tobacco Survey. Subgroup differences in lifetime smoking prevalence were found, with Filipinos (18.9%) reporting the highest smoking rate, followed by Japanese (17.3%), Koreans (16.3%), other Asian American youth (13.7%), and Chinese (11.0%). A similar pattern of subgroup difference was also found in the 30-day smoking rate. Gender by subgroup analyses revealed that for Chinese and Koreans, smoking prevalence was higher among males (13.4 and 18.8%, respectively) than females (8.3 and 15.9%, respectively). However, for Japanese and other Asians, smoking prevalence was higher among females (18.6 and 19.3%, respectively) than males (14.3 and 13.1%, respectively). Age of smoking onset differed among subgroups, with Japanese males (14.4%) and females (13.6%) reporting the latest onset relative to other subgroups.

Hispanic Youth

Similar to Asian American youth, Hispanic youth in the US are of diverse background. It is estimated that most Hispanic youth are Mexican (71.2%), followed by Puerto Rican (11.8%), Central or South American (10.9%), Cuban (3.0%), and other Hispanic (3.1%); the majority of them (77.8%) were born in the United States. Similar to patterns among Asian American youth, there are differences in patterns of substance use among Hispanic subgroups. With regard to alcohol use, a SAMHSA study suggests that Cuban youth aged 12–17 had the highest rates of past month alcohol consumption (21.2%), followed by Central or South American youth (17.1%), other Hispanic youth (16.8%), Mexican youth (16.5%), and Puerto Rican youth (14.3%). With regard to drug use, a study conducted by SAMHSA suggests that Puerto Rican youth had the highest rates of past month drug use (13.7%), followed by Mexican youth (10.9%), other Hispanic Youth (8.9%), and Central or South American youth (7.2%). Rates of past month alcohol use, binge alcohol use, and past month illicit drug use were similar between Hispanic male and female youth.

According to SAMHSA, among Hispanics of all ages admitted to substance abuse treatment, alcohol, opiates, and marijuana are the most common primary substances of abuse. The majority of these admissions were male (78%). Some subgroup differences in primary substance of abuse were found: While Puerto Rican admissions most commonly reported opiates as the primary substance of abuse, other Hispanic admissions most commonly reported alcohol.

AI/AN Youth

Alcohol use is an important health concern in the AI/AN community. SAMHSA research indicates that AI/AN youth were more likely than youth of other ethnicity/race to have a past year alcohol use disorder (8.5% versus 5.8%). AI/AN individuals of all ages who enter substance abuse treatment were more likely to indicate alcohol as their primary substance of abuse (63%) compared to admissions of other race/ethnicity (42%). Another important concern among AI/AN youth is tobacco use. AI/AN youth (12–17 years old) have the highest rate of current cigarette use when compared to youth of other race/ethnicity. Although available statistics typically do not examine within-group differences, Beauvais suggests that substance use patterns among AI/AN youth may be influenced by study region (e.g. tribal versus non-tribal) and tribal diversity.

African American Youth

Empirical literature indicates that African American youth have lower rates of alcohol consumption relative to Caucasian youth. Nevertheless, according to Turner and Wallace, drinking-related problems are more severe among African American youth, relative to other populations. SAMHSA research suggests that marijuana use is another concern for African American youth. Marijuana was the primary substance of abuse for 66% of all African American youth entering treatment, indicating a higher percentage than youth of other ethnic/racial backgrounds. Males comprised of 82% of all African American youth marijuana admissions. SAMHSA research also indicates that cigarette smoking may also be of concern for African American youth. Among all age groups (i.e. persons aged 12 and older), African Americans between 21 and 25 years old had the highest past month smoking rate (31%). Male youth were more like to smoke cigarettes than female youth in the

following age groups: 16–17, 18–20, and 21–25. Smoking rates were similar between males and females for younger age groups (i.e. persons aged 12–13 and 14–15).

SUMMARY OF RESEARCH REGARDING CULTURAL INFLUENCES ON SUBSTANCE USE IN THE US

Asian American and Pacific Islander Youth

Empirical literature has indicated a positive relationship between acculturation and substance use among Asian American youth. For instance, as mentioned earlier, Chen and colleague examined smoking behavior and its relation to acculturation among 7–12 grade Asian American youth ($N = 1810$) in California. The study includes a diverse sample of Asian American youth; 33% were Filipino, 19% were Chinese, 13% were Korean, 8% were Japanese, and 26% other Asian American. Acculturation status was assessed by English usage, language spoken at home, and age at immigration to the United States. Results indicate that among all youth in the sample, greater levels of acculturation were linked to greater smoking prevalence rates and earlier age of smoking onset.

Although the literature in general indicates a positive relationship between acculturation and substance use, one study found the opposite pattern. Among a sample of Korean American college students attending a large public university ($N = 108$), Hendershot and colleagues found that acculturation serves as a protective rather than risk factor as it predicted decreased drinking. Acculturation was measured by the Suinn-Lew Asian Self-identity Acculturation Scale developed by Suinn and colleagues. The measure assesses different domains of acculturation such as food and language preference and generational status. Findings in this study highlight the importance of a potential within-ethnic effect between acculturation and alcohol use. Additionally, it may be important to consider the cultural norms of substance use in the ethnic versus dominant culture. For instance, according to the World Health Organization (WHO), the annual average consumption for pure alcohol per capita is 8.4 l in the US for people 15 years and older, and this figure is higher for the Republic of Korea (11.8 l) but lower for China (4.2 l). Thus, while entering the US culture (a culture with lower consumption) may be a protective factor for Korean youth (a culture with higher consumption), it is a risk factor for Chinese youth (a culture with lower consumption).

To further explore the relationship between acculturation and substance use, Hahm and colleagues conducted two studies examining moderators and mediators for the relationship between acculturation and alcohol use among Asian American youth. In both studies, the sample was extracted from the National Longitudinal Study of Adolescent Health, containing Asian American adolescents in 9th–12th grade ($N = 714$). About 44% were Filipino, 31% were Chinese, 7.3% were Japanese, 4.9% were Korean, 3.1% were Vietnamese, 2.8% were Asian Indians, and 16.4% were other Asians. In the first study, acculturation was measured by an index of summing the following three variables: English use at home, place of birth, and length of residency in the United States. Findings indicate that acculturation was positively associated with levels of binge drinking. Thus, contact with the US culture for youth from cultures with lower alcohol consumption is a risk factor. Indeed, according to a WHO report, China, Japan, Vietnam, Philippines, and India all have lower annual alcohol consumption per capita than the US South Korean is the only country with higher annual consumption per capita. Serving as the mediator, friends' alcohol and tobacco use explained the relation between acculturation and binge drinking. These findings are consistent with research on the powerful role of peer influence suggested by Oetting and Beauvais. Connection with peers who use substances is the primary direct socialization influence on Asian American youth's involvement in substance use.

In the second study, Hahm and colleagues examined the moderating effect of parental attachment. Participants were divided into four groups based on their acculturation level, ranging from the high to low: (1) English use at home, US-born; (2) English use at home, foreign-born; (3) no English use at home, US-born; and (4) no English use at home, foreign-born. Results indicated that for youth with low parental attachment, the likelihood of drinking was 11 times greater in the highly acculturated group relative to the least acculturated group. However, the likelihood of alcohol use for youth with moderate or high degrees of parental attachment did not differ across levels of acculturation. This finding supports the family interaction theory proposed by Brook and colleagues. Strong parent–child attachment results in the parents having a greater influence on the youth and therefore is a powerful protective factor for preventing Asian youth drug use.

Hahm and colleagues' research demonstrates the powerful role of parental influence on substance use among Asian American youth. Indeed, based on the National Household Survey on Drug Abuse, Asian youth were more likely than youth from other racial/ethnic groups to believe that their parents would strongly disapprove of their consuming one or two drinks nearly daily. Related to this topic, an intriguing empirical question is how parents communicate to youth about substance use within the context of Asian culture. Empirical literature has indicated ethnic

differences in parent communication for other health-risk behavior among adolescents. Markus and Kitayama suggested that this difference may be attributed to how culture shapes parent–child communication. For example, Kim and Ward found that Asian parents tend to use indirect (e.g. implicit and/or nonverbal), rather than direct communication to discuss condom use. Building on prior research, Hsu and colleagues explored potential ethnic differences in parent communication. The study sample ($N = 1{,}104$) was extracted from a gambling study in a large public university. Participants' average age was 19.5 years old (SD = 2.2) and about one-third of them were Asian. Results indicated that, consistent with findings in the prior research, Asian youth reported having less direct communication (e.g. "My parents ask how much I drink"), relative to their Caucasian counterparts.

Another factor that may influence alcohol use and related problems among Asian American youth is Collective Self-Esteem (CSE). Developed by Luhtanen and Crocker, CSE refers to the value one places on being a member of a social group (e.g. gender, ethnicity). CSE contains four domains: membership self-esteem (i.e. judgment of one's worth as a member of their ethnicity), private collective self-esteem (i.e. evaluation of the worth of one's own ethnicity), public collective self-esteem (i.e. evaluation of how others view the worth of one's ethnicity), and importance to identity (i.e. how important being a member of one's ethnicity is to one's self-concept). Hsu and colleagues examined the roles of acculturation and CSE in drinking-related problems among Asian youth ($N = 442$), extracted from the baseline survey for an alcohol intervention study. Participants were from a large public university and the average age was 20.06 years (SD = 1.40). Results indicated that domains of CSE differentially predicted drinking problems among Asian youth. Furthermore, after controlling for alcohol consumption and sex, the relationship between CSE and alcohol-related problems was moderated by acculturation, measured by the S-L ASIA. Findings suggest that lack of adaptation for the worldview and living styles in the US, compounded by lower evaluation of how others view the Asian ethnicity or how well one functions as a member of the Asian ethnicity, strongly predicted alcohol-related problems. It is possible that participants with lower acculturation and lower levels of these CSE factors experienced "marginalization," marginalized individuals are isolated from both their culture of origin and the dominant society. Additionally, findings suggest that lack of adaptation for the worldview and lifestyle in the US, coupled with high regard for Asian ethnicity, also strongly predicted alcohol-related problems. Findings may be attributed to a potential within-ethnic effect not assessed in this study. Some scholars have suggested that for a particular Asian ethnic group (e.g. Korean American), feeling good about belonging to the ethnic group is related to consuming alcohol, if the culture of the ethnic group accepts or promotes drinking.

Hispanic Youth

A recent report based on the National Survey of Drug Use and Health indicates that US-born Hispanic youth were significantly more likely to have used illicit drugs in the past month than foreign-born Hispanic youth. Indeed, this positive association between acculturation and substance use among Hispanic youth has been found by a number of prior studies.

Related to acculturation is stress occurred in the process of adapting to the worldview and way of living in the host society. An earlier study conducted by Vega and colleagues indicated that drinking may be a coping strategy in response to perceived acculturation stress. To further explore this issue, Gil and colleagues examined factors associated with patterns and consequences of early alcohol involvement among male Latino immigrants ($N = 1051$) and US-born individuals ($N = 968$) attending middle schools in South Florida. Youth and their families were mostly Cuban (40%) and Nicaraguan (13%). An important strength of the study was the ability to examine how nativity may influence the longitudinal relations among variables including acculturation, familism, and alcohol involvement. Familism refers the tendency to live close by the family, as well as the use of family network as a source of emotional and social support. Using structural equation modeling, Gil and colleagues found that acculturation and acculturative stress influence alcohol use mainly through "deterioration of Latino family values, attitudes, and familistic behaviors." (pp. 443) For immigrant youth, the process of acculturation decreases problems related to mastery of the English language, which is an essential tool for survival. At the same time, this process of acculturation increases other aspects of acculturative stress (e.g. perceived discrimination; acculturation conflicts within the family). Among youth born in the US, elevated acculturation decreases acculturation stress. At the same time, acculturation among US-born youth also decreases values of familism and parental respect. Taken together, these findings suggest that depending on youth's nativity (US- versus foreign-born), acculturative stress influences alcohol use via different pathways.

In addition to nativity, researchers have used other methods to assess acculturation; one of which is language use and the context in which the language is spoken. In three studies, Epstein and colleagues demonstrated the role of linguistic acculturation and substance use using the same dataset, including Hispanic 6th and 7th graders in 22 New York City schools with low

socioeconomic status. This sample was predominantly Puerto Rican (47%) and Dominican (17%) youth. According to the WHO, both countries have lower annual alcohol consumption per capita for people 15 years and older compared to the US (6.8 and 7.3 l of pure alcohol, respectively), indicating contact with the host culture may be a risk factor. Results confirmed this hypothesis. A greater proportion of youth who spoke both English and Spanish with their friends tried alcohol and consumed two or more drinks per occasion than those who only spoke English with their friends. Additionally, for boys only, a higher proportion of students who spoke English and Spanish with their parents had tried alcohol and had been drunk, than students who spoke only Spanish with their parents.

In another study, Epstein and colleagues expanded the scope of their research by examining the relation between linguistic acculturation and polydrug use (i.e. cigarette smoking, alcohol use, and marijuana). Frequency of marijuana smoking was higher among youth who spoke English with their parents than those who spoke Spanish with their parents. By their second year in middle school, frequency of polydrug use was greater among youth who spoke English with their parents and bilingual students who spoke both English and Spanish with their parents than those who spoke only Spanish with their parents. Taken together, these two studies suggest that bilingual Hispanic youth may be a high-risk group to develop problematic substance use.

In the last study, to investigate the underlying mechanisms of the relationship between linguistic acculturation and substance use, Epstein and colleagues examined the following variables as mediators: perceived peer smoking norms, perceived peer drinking norms, and psychological distress. Results indicate that relative to students who spoke Spanish with their parents, bilingual students perceived that a higher proportion of their peers drank. This higher perception of peer drinking norm was linked to greater polydrug use when linguistic acculturation was controlled. Thus, peer drinking norms mediated the relationship between linguistic acculturation and polydrug use while peer smoking norms and psychological distress were not factors that explain the relation between linguistic acculturation and substance use.

Several scholars have postulated that cultural identification also plays an important role in substance use among Hispanic youth. In a recent study, Casas and colleagues examined the relationship between level of cultural identification and tobacco use among 1672 Mexican American youth (6th, 8th, 10th, and 12th graders) attending public schools located in a predominantly agricultural community in California within 100 miles of the United States–Mexico border. Some students were from migrating families, others reported having parents who were settled migrants and did not migrate across the border or to any other part of the United States. The Orthogonal Cultural Identification Scale (OCIS), developed by Oetting and Beauvais, was used to assess level of cultural identification with the following: (1) Mexican American/Spanish, (2) American Indian, (3) Anglo/White American, and (4) other. Here is a sample item: Some families have special activities or traditions that take place every year at particular times (such as holiday parties, special meals, religious activities, trips, or visits). How many of these special activities did your family have when you were growing up that were based on…culture? Results indicate that relative to youth with high Mexican American/Spanish cultural identity, youth with lower identification were more likely to use cigarettes on the daily basis. Additionally, youth who identified highly with the Anglo/White American culture were more likely to use cigarettes daily. Youth from non-migrant families or who identified with a traditional Mexican American/Spanish culture were more likely to perceive tobacco use on a regular basis as harmful.

AI/AN Youth

As indicated previously, tobacco use is an important health concern in the AI/AN community. A number of studies have investigated the relationship between culture and tobacco use among AI/AN youth and the findings have been mixed. For example, following predictions in the problem behavior theory developed by Jessor and Jessor and the social ecological theory developed by Bronfenbrenner, Yu and colleagues examined how mental health (e.g. conduct disorder) and environmental factors, including family, social, and cultural domains, were associated with American Indian youth tobacco use. A stratified random sample of reservation ($N = 205$) and urban American Indian ($N = 196$) youth residing in a Southwestern area participated in the study. 65% of the reservation youth and 53% of the urban youth reported lifetime tobacco use and this difference was statistically significant. Cultural factors, including cultural pride and engagement in cultural activities, were measured by a modified version of the OCIS. While mental health and environmental factors in the family and social domains were predictive of tobacco use, cultural factors and living setting (reservation versus urban) were not significant predictors of tobacco use in this sample of adolescents.

Although LaMaster and Yu have obtained nonsignificant findings in their studies, a recent study found an interesting pattern between cultural identification and smoking. Wolsko and colleagues surveyed a large sample of Yup'ik residents in the Yukon-Kuskokwim

Delta region of Alaska. Participants ($N = 853$) included both youth and adults, ranging from 14 to 94 years old. The OCIS was used to assess level of identification with White and Yup'ik cultures. Findings indicated that prevalence of smoking was quite high for youth aged 14–19: About 35% reported smoking any type of tobacco and about 40% reported using Smokeless Tobacco (SLT). Younger participants in the study tended to smoke cigarettes more, as well as to use both cigarettes and SLT more. In the overall sample, SLT users identified more with a Yup'ik lifestyle and less with a White lifestyle, speaking their traditional language more frequently, and consuming more traditional food and medicine. This in turn suggests enculturation as a risk factor for SLT, given that the use of SLT is consistent with the traditional culture of Yup'ik. Conversely, cigarette smokers tended to identify less with a Yup'ik lifestyle and reported using drugs and alcohol as means of handling stress. This in turn suggests acculturation as a risk factor for cigarette smoking. Theoretical models proposed by O'Nell and others have frequently described acculturation as a predictor or a cause of profound stress and impaired mental and behavioral health among ethnic minorities. Wolsko and colleagues' findings challenge the existing conceptualization of enculturation as a protective factor for substance use and researchers must carefully evaluate expressions of enculturation before designing intervention and prevention programs.

African American Youth

It has been suggested that African American is typically viewed as a racial group rather than an ethnic group, thus little research has tested the relationship between conventional cultural variables (e.g. acculturation) and substance use among African American youth. Available research has examined the relationship between ethnic identity and substance use among African American youth and some protective effects of ethnic identity were found by several studies. Among high school age youth, Cladwell and colleagues examined the influence of racial identity and parental support on alcohol use among a sample of 488 "academically at risk" African American youth entering high school in a Midwestern city. Academically at risk was defined as having an overall GPA 3.0 or below when youth were in the 8th grade. Two dimensions of racial identity were measured: (1) racial centrality, defined as the significance that one places on race in defining oneself ("Being Black is a major part of my identity."); and (2) private regard, defined as the extent to which one feels positively about Black people ("I am proud of Black people."). These subscales were derived from the Multidimensional Inventory of Black Identity, developed by Sellers and colleagues. Results indicate that private regard and perceived support from a father were associated with less alcohol consumption for these youth after controlling for age and gender. Private regard was also associated with less alcohol consumption for youth who considered race as a more central part of their identity.

Among college age youth, Pugh and Bry examined the influence of ethnic identity on alcohol and marijuana use among Black university students ($N = 167$). Ethnic identity was measured by one subscale in the Multigroup Ethnic Identity Measure-Revised (MEIM-R). A sample item includes, "I have a clear sense of my background and what it means for me." After accounting for year in school, sex, and friends' substance use, ethnic identity score negatively predicted beer/hard liquor use, wine use, and marijuana use, accounting for approximately 31, 6, and 4% of the variance, respectively.

SUBSTANCE ABUSE TREATMENT FOR ETHNIC MINORITY YOUTH

The above review demonstrates the important role of culture in substance use among ethnic minority youth. Given these findings, Castro and Hernández-Alarcón prevention and treatment programs that ignore cultural issues may be ineffective when administered to racial/ethnic minority youth. To address this important public health concern, a number of programs have been developed for ethnic minority populations or a specific ethnic population. In a systematic review of evidence-based treatment for ethnic minority youth, Huey and Polo suggested that Multidimensional Family Therapy (MDFT) developed by Liddle and colleagues, is the only efficacious treatment for drug-abusing ethnic minority youth. MDFT is a multicomponent program that addresses the multiple systems (e.g. family, school, work, peer) that contribute to the development and maintenance of substance use. Therapists aim to: (1) teach youth communication and problem-solving skills; and (2) change negative family interaction patterns. Liddle and colleagues found MDFT led to more rapid reduction in drug use than group-based cognitive behavioral therapy (CBT) among a diverse sample of ethnic minority youth. Additionally, recent treatment outcome studies indicated that for youth with more severe drug use and greater psychiatric comorbidity, MDFT produced better treatment outcomes when compared to individually focused CBT and enhanced services as usual. Liddle and colleagues found that MDFT was more effective than a peer-group intervention in reducing substance use, substance use problems,

delinquency, and internalized distress among young adolescents (average age = 13.73 years)

A number of programs have been developed for youth belonging to a specific ethnic group. We will present two examples here. The Shadow Project, conducted by Boyd-Ball, is a pilot study involving 60 AI families with youth enrolling in substance abuse inpatient treatment. Participants were asked to participate in one of the two treatment modalities: treatment as usual and a brief family-enhanced intervention. In order to adapt the family-based intervention for AI families, culturally relevant assessment and intervention were used. For example, two legends were used to assess the families' skill level in relationship building, problem solving, and communication as a family unit. Preliminary findings were promising; Indian stories were connected to prosocial behavior among youth and the percentage of days abstinent from drug use.

Ma and colleagues have conducted a study to identify cultural variables that enhance the efficacy of smoking cessation curricula for Chinese American youth ranging between 14 and 19 years old. Male youth smokers ($N = 17$) were recruited from community-based Asian American organizations in the Northeast region of the US. Cultural themes (e.g. collective orientation of the Asian culture) were identified and addressed in curricula. Participants joined one of the two treatment groups: a standard smoking cessation curriculum (SC) and a culturally modified program (ACT) for Asian adolescents. Findings indicate a 23.1% quit rate for the SC program and an 18.2% quit rate for the ACT program three months following treatment. For those who continued to smoke, there was a larger decrease in cigarette use among ACT participants than the Standard (SC) group. The ACT protocol has been evaluated in other clinical trials based on a larger sample size of participants.

RESEARCH ON YOUTH IN OTHER COUNTRIES

As indicated earlier, rates for alcohol use in different countries are available for people over 15 years and older in reports produced by the WHO. Although these reports do not focus on youth per se, it provides analyses on alcohol use trends from 1961 to 2006 and a brief review on alcohol policy for each country. Patterns of drinking, drinking-related mortality, and health consequences were also available for some countries. In Europe, the European School Survey Project on Alcohol and other Drugs (ESPAD) provides a comprehensive overview of trends in tobacco, alcohol and substance use among students (aged 15–16 years) between 1995 and 2007. In the most recent report, Hibell and colleagues found that over the 12-year interval, there was a decrease in smoking in a majority of the countries. While trends for alcohol use largely remained the same in the past 12 months and the past 30 days, there was a continuous increase of heavy episodic drinking. Additionally, all countries showed no increase for marijuana use in the past 30 days. With regard to illicit drugs, there was an increase between 1995 and 2003 but the figures in 2007 indicated a decline. In sum, Hibell and colleagues pointed out that the national cultural context for students in different countries most certainly varied, suggesting opportunities to examine the role of cultural variables in substance use in these countries. Indeed, a literature review in the Psychinfo indicates that there is a growing interest in examining cultural variables for youth outside of US. Research was found in countries such as Canada, Lebanon, Chili, Ireland, Finland, Norway, Germany, and Hungary. For instance, Martin and colleagues discussed the process of modifying Strengthening Families Program, a US family-based program preventing substance abuse and behavioral problems, for Germany youth. No studies were found for youth in African countries, as WHO pointed out that data on alcohol consumption among youth from low-income countries is generally limited.

CONCLUSION

Findings in the above review suggest that contact with the dominant culture (i.e. the US culture) is a risk factor for substance use and misuse for some ethnic minority youth whose native countries have lower alcohol consumption per capital compared to the US. It is clear that the relationship between culture and substance use is complicated in part due to the methodologies employed in assessing the cultural variables. This issue has been well documented. Given that acculturation is a risk factor for many ethnic minority youth in the US, it is imperative to identify the timing of delivering prevention programs. For those who are first generation immigrants, the ideal timing may be shortly after individuals gain some fluency in English and begin to assimilate into the dominant culture. For those who are of later generations (and English fluency is not a factor), the timing of delivery should be similar to that for youth in the dominant culture. However, in designing the prevention program, special consideration should be given to the overall acculturation level of the family and parent–child acculturative gap. It is likely that ethnic minority youth would be at high risk when experiencing a combination of risk factors (e.g. family conflict as a result of acculturative gap) as well as conventional risk factors for substance use (e.g. low

socioeconomic status, male, family history of substance abuse).

Another factor that needs to be considered is the diversity within a given ethnic group. Thus, more within-ethnic studies should be conducted to clarify the relationship between cultural variables and substance use patterns among ethnic minority youth. There has been an increased awareness of subgroup differences within an ethnic minority group. For example, as discussed earlier, recognizing that Asian American is not a homogeneous group due to the rich language and cultural diversity existing in this group, much of the recent literature has been dedicated to understanding how substance use patterns as well as predictors of use may differ in Asian subgroups. A report conducted by the US DHHS has pointed out that this movement will in turn address the concern of treating an ethnic group as homogeneous and thus potentially limiting resources for subgroups that are at high risk for developing substance use disorders.

Castro and Hernández-Alarcón suggested that the examination of moderators as well as mediators has been an increasingly important focus in this line of research. This approach is imperative, given that it allows us to understand the specific conditions and the social and biological processes under which such cultural traits may operate as risk or protective factors. Such information provides insight on for whom we should design intervention and what the active ingredients in an intervention should be. For example, based on Epstein and colleagues' research, school-based prevention and intervention should target bilingual Hispanic youth and their peers. Based on evidence in Asian youth literature, poor parent–child communication must be considered and addressed when treating substance abuse disorders among Asian youth. The initial evidence for culturally relevant interventions is encouraging. Several scholars, such as Lau, Castro, and Hwang, have provided guidelines for adapting a specific intervention or for a specific population are available. This line of work will in turn increase the effectiveness of evidence-based treatment when serving ethnic minority youth with substance use issues.

Substance Use and Mental Health Issues on the College Campus

Jason R. Kilmer, Irene M. Geisner

Center for the Study of Health and Risk Behaviors, University of Washington, Seattle, WA, USA

OUTLINE

OVERVIEW OF SUBSTANCE USE TRENDS IN THE UNITED STATES

Alcohol consumption by college students continues to be both highly prevalent and problematic. Research has shown up to 90% of college students in the US drink alcohol, with 25–50% considered "heavy" or "binge" drinkers (four drinks per occasion for women and five drinks per occasion for men). Recent research by the Monitoring the Future team at the University of Michigan indicates that almost four out of five US college students (79.4%) report that they drink alcohol at least once per year, with 65.8% reporting use in the past month. Of those that make the choice to drink, over half report that they have gotten "drunk," (61.5% in the past year, and 42.4% in the past month). The college years are also associated with increased risk for alcohol use disorders; problems typically first appear in the mid-teens, peak in young adulthood, and then gradually decline, with up to 70% of those meeting criteria for dependence doing so before age 25. In 2007, 18.6 million people over the age of 12 endorsed symptoms related to past-year alcohol abuse or dependence, representing 7.5% of the US population. Full-time college students report much higher rates, with 12.5% meeting criteria for alcohol abuse and 8.1% meeting criteria for alcohol dependence.

Alcohol use does not occur in a vacuum, and other substances are being used. Over one-third (36.0%) of US college students report that they have used an illicit drug in the past year, and marijuana is, by far, the most commonly used illicit substance. In fact, the 32.8% of students who report past-year marijuana use exceeds the 29.9% who report past-year tobacco cigarette use. When marijuana is excluded, 16.9% of US college students report past-year use of an illicit substance. Seven drug categories were associated with over 5.0% of college students indicating past-year use, including: Vicodin (8.4%), Adderall (7.9%), Narcotics other than heroin (7.6%), Amphetamines (7.5%), Oxycontin (7.3%), Salvia (5.8%), and Tranquilizers (5.4%). In addition to the use of any one of these substances on its own, it is possible that students could combine substances (for use at the same time), which opens up the possibility of dangerous drug interactions.

Excessive drinking by students is associated with consequences including damaged property, poor class attendance, hangovers, legal problems, and injuries. Researchers estimate over 1700 alcohol-related

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00061-9

unintentional injury deaths annually among US college students, with an additional 599,000 injured because of drinking and 696,000 hit or assaulted by another drinking college student. The American College Health Association (ACHA) indicates that as a consequence of drinking in the past year, 2.6% of students have gotten in trouble with the police, 1.8% physically injured another person, and 10.7% physically injured themselves. Almost one-fourth (22.3%) of students reported that as a consequence of their drinking in the past year they did something they later regretted, and 19.0% reported that they forgot where they were or what they did. An estimated 474 000 students annually have unprotected sex due to alcohol use and 97 000 report being victims of sexual assault or date rape. Alcohol's impact on cognitive functioning can significantly affect ability to give and obtain consent for sex; as a consequence of drinking within the past 12 months, 1.5% of US students endorse having had sex with someone without giving their consent, and 0.3% of students state that they had sex with someone without getting their consent. Clearly, these consequences have great costs both to the individual (in suffering, pain, losses, etc.) and to society (loss of productivity, property damage, violence, etc.). Out of 12 possible challenges or difficulties from which they could select, almost half of US college students (44.2%) indicated that academics represented the issue that had been most "traumatic or very difficult to handle" in the past year. Survey data also indicate academic impairment is a primary consequence of alcohol use, with 22% of over 40 000 students responding to the Core Alcohol and Drug Survey reporting poor test performance, 28% missing a class, 12% with legal problems, 8% causing damage to others' property, and 30% involved in fights or arguments. However, students might not acknowledge or recognize the impact of alcohol use on academics. Out of 31 possible past-year issues or behaviors that could impact academic performance, only 3.9% of college students acknowledged the impact of alcohol use (ranking it 17th of 31 behind homesickness and in front of a chronic health problem or serious illness), and only 1.6% reported that drug use impacted their academic performance (resulting in a rank of 24 out of 31, behind an injury, including a fracture, sprain, strain, or cut, and in front of pregnancy).

OVERVIEW OF MENTAL HEALTH TRENDS IN THE UNITED STATES

The college years are a particularly stressful time for many young adults while cognitive, emotional, and intellectual development continues at a great pace. The developmental tasks confronting college students include achieving emotional independence from family, choosing and preparing for a career, preparing for relationship commitment and family life, developing an ethical system as well as numerous features related to the transition from adolescence to adulthood, referred to by Arnett as "emerging adulthood." These features include exploration of one's identity, instability (including moving, changing jobs, starting and ending relationships, and shifting educational status), being self-focused (as Arnett notes, not in a pejorative way) by making decisions independently, feeling "in between" as one approaches "full" adulthood, and entertaining numerous possibilities for the future. These tasks require students to develop new social roles and modify old ones, which can result in chronic stress and lead to distress. Specifically, college students' stressors in school and achievement domains, interpersonal relationships, finances, sexual relations, and deviant behaviors can pose significant challenges to overcome. Phenomena such as feeling homesick and moving away from an established network of friends can take their toll on new college students and impact psychological adjustment.

Data from the National Epidemiologic Study on Alcohol and Related Conditions (NESARC) highlights the prevalence of mental health issues in college settings in the United States. Data collected from individuals ranging from 19 to 25 years of age who had attended college in the past 12 months were used ($n = 2188$), and 45.8% had any psychiatric diagnosis in the past 12 months. In fact, 20.4% of students met criteria for past-year alcohol use disorders (12.5% alcohol dependence, 7.9% alcohol abuse), followed by 17.7% with any personality disorder (though they noted this was assessed on a lifetime basis), 11.9% with any anxiety disorder, and 10.6% with any mood disorder. Interestingly, findings and percentages for college student diagnosis were not significantly different than for nonstudents of the same age, suggesting that despite additional opportunities and access to education, students remain at risk. Within mood disorders, 7.0% met criteria for major depressive disorder, 3.2% met criteria for bipolar disorder, and 0.8% met criteria for dysthymia; within anxiety disorders, rates were 8.1% for specific phobia, 3.2% for social anxiety disorder, 2.0% for panic disorder, and 1.6% for generalized anxiety disorder. Personality disorders (again, assessed on a lifetime basis) included obsessive–compulsive (8.2%), paranoid (4.9%), antisocial (4.7%), histrionic (3.5%), schizoid (3.3%), avoidant (2.3%), and dependent (0.5%). Data from the ACHA indicate that over two percent of college students received past-year treatment with medication, psychotherapy, both, or some other treatment for five issues: depression (7.6%), anxiety (7.3%), panic attacks (3.1%), attention-deficit hyperactivity disorder (2.6%), and insomnia

(2.3%). Past-year treatment for eating disorders (not assessed in the study by Blanco and colleagues) was at 0.6% for both anorexia and bulimia.

A review of mental health issues endorsed by students highlights the challenges students encounter during the year. A survey from Fall 2009 examining past-year consequences found 80% of students felt exhausted (not from physical activity), 60% felt very sad, 56% felt very lonely, 46% felt things were hopeless, 30% felt so depressed it was difficult to function, and 6% seriously considered suicide. Hopelessness and depressed mood are increasingly reported at university counseling centers, with 45% of those seeking counseling for any reason being diagnosed with depression. Even depressive symptoms (without a major depressive disorder diagnosis) have been shown to relate to reductions in GPA of up to 0.25 compared to nondepressed students, and up to 90% of students presenting to US counseling centers experience academic difficulties due to their mood. In addition, depressed mood relates to lower self-esteem, peer difficulties, poor psychosocial functioning, less energy, higher levels of externalizing and internalizing problems, and may lead to a major depressive episode.

Stress and anxiety also pose challenges. A majority of students (85%) report they have felt overwhelmed by all they had to do at least once in the past year; in fact, over half (52%) have felt overwhelmed at least once in the past 2 weeks. Another 47% felt overwhelming anxiety at least once in the past year. Also related to emotional difficulties, approximately 37% of college students felt overwhelming anger at least once in the past year. Stress has been suggested as a possible cause of depression, as well as a factor leading to relapse into another depression episode. In college students, stress has been related to more headaches, sleep problems and minor illness (colds), hopelessness, and suicidal ideation. Since more stressful life events have been related to poor psychological adjustment, it is not surprising that college students experience more mental health problems than older adults. Even within the college years, freshmen are more depressed than are seniors. Popular media refers to today's college students as the "therapy generation." The common concerns of leaving home, making friends, finding a relationship, doing well in school, and finding a career path are complicated by more divorced families, more lifestyle choices, alienating effects of technology, too much information, and a poor economy. In addition, sleep deprivation and substance use are common college experiences that can act as stressors related to depressed mood in those vulnerable. In fact, the amount of alcohol consumed was a predictor of less nighttime sleep, later sleep schedules, more sleep on weekends compared to weekdays, and greater delays between bedtimes on weekdays and weekends. Daytime sleepiness appears to mediate alcohol's impact on academic difficulties. Collectively, these issues can impact adjustment, development, perseverance, relationships, and success in the college setting.

OVERVIEW OF THE OVERLAP OF MENTAL HEALTH ISSUES AND SUBSTANCE USE

Depression, anxiety, and substance use often co-occur. This overlap is particularly problematic because substance use can increase the likelihood of high-risk behaviors including suicide attempts. The ACHA survey suggests 3.8% of US students have seriously considered suicide in the past year. Additionally, 1.2% of students seriously considered suicide in the past 12 months as a consequence of drinking. For years, researchers and clinicians have observed a relationship between problematic drinking and depressed mood. Research indicates the risk of having major depression is about three times higher for those with an alcohol use disorder (9.6%) than without (3.3%). Similarly, depressed mood has been associated with increased risk of problematic alcohol use and related problems. The odds of meeting criteria for an alcohol use disorder in the context of depression, compared to those without, are roughly four times greater. Data from the mid-1990s indicated for those with major depression, 21% also had an alcohol use disorder (approximately three times greater than the 7% who were not depressed). More recently, results from the National Survey on Drug Use and Health (NSDUH) demonstrated that 17% of adults 18 and older with a past-year major depressive episode also met criteria for past-year alcohol dependence or abuse, compared to 7% of those without.

Numerous studies have found a relationship between greater alcohol use and/or related problems and depression or depressed mood in both community and college samples. Researchers have found a 2.4 odds ratio for college students with alcohol dependence to have a mood or anxiety disorder, and even non-binge drinkers had a 50% increase in risk of mood or anxiety disorder compared to abstainers. Finally, hopelessness, depression, and high-risk drinking have all been identified as risk factors for completed suicide. Similarly, college students with depressed mood have been shown to be more likely than nondepressed peers to use alcohol and other drugs and have more related consequences. Approximately 82% of students with "poor mental health/depression" report drinking alcohol, half report heavy episodic or binge drinking, and these students report increased likelihood of drinking to get drunk compared to those without depression.

There is a debate about how these co-occurring disorders originate (i.e., which comes first, the chicken or the egg?). One hypothesis is that students experience mental health issues and turn to alcohol in order to manage negative affect (i.e., self-medicate). For example, the tension reduction hypothesis suggests that alcohol reduces stress and other negative affect and is consumed for these tension-reducing effects. Consistent with the self-medication hypothesis, higher negative affect is related to increased coping motives for drinking, and drinking to cope has been shown to be related to greater alcohol use and directly related to alcohol problems even when use is held constant. Furthermore, coping motives appear to moderate the relation between stress and drinking in community and college samples. For example, a 3-week study of moods, situations, and drinking in a college sample found weekday drinking, especially at home, appeared motivated by tension-reduction, and was associated with negative experiences and moods. Thus, negative experiences earlier in the day predicted evening alcohol consumption at home and this was strongest in those endorsing stronger coping motives. Recent studies using frequent monitoring designs have supported and helped refine various aspects of the self-medication and tension-reduction models. Specifically, these studies have shown that the comorbidity of alcohol misuse and depressed mood, as well as drinking for primarily coping reasons, is related to increased risk of negative consequences, decreased likelihood of maturing out of alcohol use problems in the future, and more likelihood of developing chronic alcohol problems postcollege.

Conversely, others have proposed that college student drinking is primarily motivated by social reasons, but due to the deleterious effects of heavy drinking and related negative consequences the drinking leads to depressed mood. For example, excessive alcohol use can exacerbate mood symptoms due to sleep disruption, can impact cognitive functioning, which influences individuals' ability to appropriately process negative events, and can interfere with important role obligations like school/academics, etc., which in turn creates stress and impacts students' mood. It is likely that these relationships are actually bidirectional. For example, some researchers found sadness and hostility predicted subsequent drinking behavior, and drinking was associated with relief from sadness and hostility. However, drinking was also related to increased sadness and hostility dependent upon timeframe and social context, illustrating the complex nature of these relationships. It remains an empirical question that has been largely unaddressed in the field whether treating alcohol first, depression first, or both at the same time is most efficacious, with individual differences likely contributing to the determination. Unfortunately, students experiencing these difficulties are often not identified, and when they are, they often receive no services. Thus, an additional challenge involves connecting people who could benefit from clinical services with appropriate care, earlier, to prevent development of a more significant problem in the future.

SCREENING/OUTREACH EFFORTS

Given the well-documented issues and associated risks for college students, there is still much need for development, testing, and broad scale implementation of screening and outreach (i.e., prevention) efforts. For example, slightly under one-half (49%) of college students in the US report receiving any information about depression or anxiety from their college or university, and slightly over one-half (54%) report receiving information about stress reduction. Those with comorbid depressed mood and problematic alcohol use may face barriers to getting help. In a national community sample, 65% of individuals with a substance use disorder and one or more mental health symptom received no treatment. These results are consistent with research demonstrating college students needing services for alcohol or depression often do not seek or receive such services. For example, though 20% of college students in the 2002 NSDUH met criteria for an alcohol use disorder, only 3.9% of students with an alcohol use disorder had received alcohol services in the past year. Further, only 2.4% of full-time college students with an alcohol use disorder perceived a need for treatment.

Utilization of services for depression also fails to match prevalence of those with a need for treatment. Most people with depression receive no treatment, and the Surgeon General has advocated promoting access to treatment as a more significant need than developing better treatments. On US college campuses, out of 103 suicides reported by counseling center directors, only 19% were current or former counseling center clients. Similarly, up to 72% of US college students who screened positive for major depression felt they needed help, but only 36% received services of any kind. Factors related to not accessing help included students being unaware of or unfamiliar with service options, questioning the helpfulness of treatment, and being uncertain about insurance coverage. Additionally, there was less use of services by students who identified as growing up in a "poor family" and by students who identified as Asian or Pacific Islander. Six reasons for not utilizing services were directly identified by at least 20% of the students with positive depression screens who did not receive services, including the belief that stress is normal in a college setting, not perceiving a need for services, believing things would get better in time without

intervention, not having time to get services, thinking no one could understand their problems, and worrying about what others would think. Routine screening in health care settings is one strategy for identifying students who could be having difficulty with mental health or substance use issues. Only 32.5% of health centers on college campuses routinely screen for alcohol problems, and, of those that assess, only 17% use standardized measures. One possible screening measure that has been used in a college setting to facilitate referral to brief interventions is the Alcohol Use Disorders Identification Test (AUDIT). The AUDIT is a 10-item, self-report measure that assesses alcohol use and related consequences. In a sample of college students, a cutoff of 8 results in sensitivity of 82% and specificity of 78% in comparison to diagnostic interview. Scores between 8 and 15 typically warrant a brief intervention using simple advice and patient education materials, and scores between 16 and 20 could also include continued monitoring. A recent study used the AUDIT to screen students when they arrived for their appointment in the health center or the counseling center (even if alcohol use had nothing to do with the presenting issue). Using this strategy, researchers identified 175 students who screened as engaging in "at risk" alcohol use and who attended a Brief Alcohol Screening and Intervention for College Students (BASICS) motivational feedback session. Students who received the intervention demonstrated reduced alcohol consumption, correction in misperceived norms, and increased use of protective behavioral strategies. Even briefer interventions have been tested in college health settings, in which all interventions were delivered by primary care providers. Students at five universities were screened using a health screening survey, and referred students for a brief intervention if they exceeded cutoffs for past 28-day quantity (more than 50 drinks for men, more than 40 drinks for women) or past 28-day heavy drinking episodes involving consumption of five or more drinks (eight or more episodes for men, six or more episodes for women). The 15-min intervention (which used motivational interviewing in its delivery and utilized a manual consisting of 24 intervention strategies) was followed by a follow-up phone call or email in 2 weeks, an in-person 15-minute reinforcement session in 1 month, and a follow-up phone call or email 1 month after the reinforcement session. Results indicated significant reductions in alcohol use and related consequences, and the authors suggested widespread implementation of screening and brief intervention efforts on campuses, including implementation in health settings.

Screening for depression is also important, and research on the properties of the Patient Health Questionnaire-9 (PHQ-9) for major depression has indicated that a PHQ-9 score greater than or equal to 10 has a sensitivity of 88% (i.e., 88% of people with major depression are correctly identified as being at risk by exceeding the cutoff score on the screening measure) and a specificity of 88% (i.e., 88% of people without major depression are correctly identified as being below the cutoff score on the screening measure). Most recently, a cutoff of 10 and endorsement of having a "very" or "extremely difficult" time functioning in academic, social, or occupational realms has been utilized with college students. In the National College Depression Partnership, screening using the PHQ-9 in primary care settings across eight colleges and universities resulted in more than 800 students with clinical depression being identified, enrolled into a tracking registry, and followed to assess outcomes. Within 12 weeks, over half of the students reported improved functioning, which represents greater intervention response than is typically seen in studies with community samples.

In addition to screening, other steps can be taken to reduce barriers to accessing services. Researchers suggest that colleges and universities could consider educational and awareness campaigns regarding mental health services, given that underutilization of services was associated with not being aware of available services or the potential utility of these services, and not knowing what would be covered (or not covered) by insurance. Additionally, with students suggesting that they were unsure if counseling was indicated (due to the perception that stress and struggling are "normal"), other beliefs and targets could also be indicated. It is important to consider that these campaigns can only be successful if counseling centers are prepared to support and handle increased demand.

COUNSELING CENTER IMPRESSIONS

College counseling centers in the United States have done much to keep up with the changing times and needs of their students. Counseling center staff members are aware of the increased demand and greater severity in psychological problems among students presenting for counseling. In the National Survey of Counseling Center Directors sponsored by the American College Counseling Association (ACCA) and published by the International Association of Counseling Services (IACS), over 93% of 302 directors indicated they have seen evidence supporting the widely reported trend that in recent years there has been an increase in students arriving at counseling with serious psychological problems. Directors were asked to compare their perceptions of presenting issues now to 5 years ago, and indicated increases in severe psychological problems (89.4% perceived an increase), medication issues (75.9%), crisis issues requiring an immediate response

(70.6%), learning disabilities (57.7%), self-injury (55.7%), illicit drug use other than alcohol (46.5%), and alcohol problems (45%). When asked to identify administrative issues or concerns that occupy the time of counseling center directors, the four most frequently endorsed concerns were administrative issues related to students with severe psychological problems (75.5%), balancing the varying demands for counselors' services (71.5%), keeping administration at the institution informed while protecting student confidentiality (69.2%), and the growing demand for services without an appropriate increase in resources (66.2%).

These numbers were corroborated through the annual survey of the Association for University and College Counseling Center Directors (AUCCCD), which invites directors from universities outside the United States to participate (though, of the 385 who participated, 97.4% were from the Unites States). Similar to the findings of the IACS survey, 94% of respondents indicated that the number of students with significant psychological problems is a growing concern on their campus. In fact, 71% of directors felt that the numbers of students with severe psychological problems increased on their campus in the past year alone. However, over two-thirds (67.3%) of centers either lost positions or stayed the same size despite these perceived increases in severity.

Research across counseling centers does not, however, suggest an actual change in severity of psychopathology over time. Rather, it is possible that individual schools have seen a change that is not reflected globally. Alternatively, the National Center on Addiction and Substance Abuse (CASA) at Columbia University (2003) suggests that a range of factors could be contributing to the perceived increase, including an actual increase in mental health problems, greater similarity in the college setting to the general population with more inclusive enrollment, greater availability of medication allowing students to attend college who previously would not have done so, lesser stigma allowing for more students to seek help, students discontinuing or interrupting care with a provider, students discontinuing a medication upon starting college, students using substances while taking prescription medications, increased pressure/competitiveness and sleep deprivation contributing to depression, and fewer students taking time off to become stabilized during high levels of stress or mental health problems.

IMPLICATIONS FOR PREVENTION AND INTERVENTION

When a student with both substance use and mental health issues gets involved in counseling, much of what takes place in the counseling session will likely be impacted by the clinical orientation of the provider. This, too, will impact case conceptualization, and will contribute to whether the provider will approach initial treatment of the mental health issue, the substance use issue, or both (i.e., as co-occurring issues). Certainly the clinician will have to take care when considering diagnoses (e.g., many Diagnostic and Statistical Manual of Mental Disorders, 4th edition text revision (DSM-IV-TR) disorders warn that symptoms cannot be better accounted for by use of a substance). Further, the clinician will need to consider the ways in which use of a substance could contribute to, exacerbate, or even cause a mental health issue of relevance to the student. With almost one-fourth of students reporting that they did something they later regretted as a consequence of drinking, it is likely that depression or anxiety could follow something that occurred while intoxicated (again, a matter of the "which comes first?" debate); without adequate coping strategies, a student could turn to substances to cope with these feelings. Considering the context of these issues will likely be important to a positive clinical outcome.

Designing effective prevention and treatment programs for college students has been a top concern of educators, administrators, researchers, and clinicians alike. Because the risks of using alcohol are high, and students perceive excessive drinking to be normative, more traditional treatments (e.g., 12-step programs, medical model programs) are often not relevant or acceptable for this population. In the past several decades, brief treatments have been designed, tested, and successfully implemented on college campuses.

Efficacious prevention efforts for reducing alcohol use or related consequences exist, and many involve interventions delivered to high-risk individuals. These efforts include cognitive-behavioral skills-based approaches, normative feedback interventions, motivational enhancement strategies, and interventions to challenge alcohol expectancies. One approach with a great deal of empirical support involves delivery of Personalized Normative Feedback (PNF). PNF is individually delivered information designed to correct normative misperceptions and contains feedback regarding: (1) personal drinking behavior, (2) one's perceptions of other's drinking behavior (perceived descriptive norm), and (3) other's actual drinking behavior (actual descriptive norm). Presentation of such information has been found to reduce misperceptions of drinking norms among heavy drinkers and to subsequently reduce drinking for periods ranging from 6 months to 2 years, both as a stand-alone intervention and as a component of larger interventions. Recent findings have shown that computerized and web-based PNF alone, without other intervention components or in-person interventions, have effects on drinking of

a comparable magnitude to more intensive interventions. A range of commercial products provide online, web-based alcohol education, including personalized feedback, and vary in the degree to which they have been rigorously evaluated; certainly, as additional research is conducted, these will provide one possibility for reaching college students.

A variety of treatments for depression have been evaluated, including psychological and pharmacological therapies as well as combinations of therapy and medication. Cognitive therapy, cognitive behavioral therapy (CBT), and medications have all been shown to reduce depressed mood and depression. Strategies such as targeting intrusive thoughts and explanatory styles have been successfully incorporated into treatments. In addition, approaches focusing on mindfulness meditation, religion and prayer, social support, and exercise, have all produced improvements with depressed clients. In general, research has suggested treatment is associated with better outcomes than no treatment. Data are less consistent regarding the advantages of any one treatment over another with meta-analytic studies failing to systematically differentiate therapies.

Providing a stepped care approach, moving from a more education/prevention model for those at lower levels of risk, to a brief treatment for those moderately at risk, and so forth has been used with other mental disorders (e.g. generalized anxiety disorder, substance use, eating disorders). This has recently begun to be viewed as an effective and efficient model for delivering targeted intervention for people along the continuum of depression.

Evidence for effectiveness of brief treatments for depression and depressed mood is available. Alternative implementation strategies have also been shown to reliably improve depressive disorders. Telephone administered therapy, computer administered treatment, bibliotherapy, music therapy, and writing brief narratives are less expensive and intensive, yet effective treatments, especially for those at lower risk on the continuum. However, many of these approaches have not been evaluated with college students, and given the high prevalence rates, costly consequences, and the barriers to treatment for this population, new, and even briefer interventions with easier access need to be designed and evaluated.

Recently, randomized controlled trials have supported the efficacy of web-based targeted/indicated prevention as well as "self-help" interventions with minimal or no clinician contact for depression. These therapies are based on CBT and deliver modules often conducted in person (e.g., core beliefs, automatic thoughts) and/or provide some educational content to raise awareness and encourage utilization of other treatment options. Results show moderate to large improvement in symptoms. Other reported benefits include greater satisfaction with the treatment, ability to customize feedback based on personal or tailored information, removal of common barriers, and economic feasibility. Despite these recent advances in computer- or internet-based depression treatment, studies to date are limited by small sample sizes and short follow-ups, thus more research on these approaches is needed. While some computerized and web-based programs have now been developed and tested for a variety of mental health issues including depression and alcohol use, we are not aware of any published clinical trials of web-based interventions addressing both alcohol use and depressed mood (i.e., a comorbid population) in college students. Certainly, education and prevention to raise awareness and reduce barriers to access, screening to promote early identification and/or detection of those needing services, referral to efficacious interventions and treatment, and research into ways to address the overlap of substance use and mental health issues should be part of an overall strategic plan to improve mental health and reduce comorbidity in college campuses.

CHAPTER

62

Costs and Consequences (Morbidity and Mortality) Associated with Adolescent and College Drinking and Related Problems

Ralph W. Hingson, Aaron M White

National Institute on Alcohol Abuse and Alcoholism, Bethesda, MD, USA

OUTLINE

This chapter examines (1) trends from 1998 to 2005 in the magnitude of morbidity and mortality associated with college drinking among 18- to 24-year-old students (earlier reports examined data from 1998 through 2001) and (2) interventions established through scientific research to reduce alcohol misuse among college students.

HEAVY EPISODIC DRINKING AND DRIVING UNDER THE INFLUENCE OF ALCOHOL

National surveys conducted by the Substance Abuse and Mental Health Services Administration (SAMHSA) indicate that from 1999 to 2005 the percent of 18- to 24-year-old college students who drank five or more drinks on an occasion in the previous 30 days increased from 41.7 to 45.2%, a significant 8% proportional increase. Among 18- to 24-year-olds not in college, the percent increased from 36.5 to 40.2, a significant proportional 10% increase.

A greater percentage of 18- to 24-year-old college students compared with noncollege respondents drank five or more drinks on an occasion. However, because only one-third of 18- to 24-year-olds are in college, the number not in college who consumed five or more drinks on an occasion in 2005 exceeded the number of college students who did so (7 884 398 versus 4 351 887). From 1999 to 2005, among 18- to 24-year-olds, the

Published by ELSEVIER Inc.

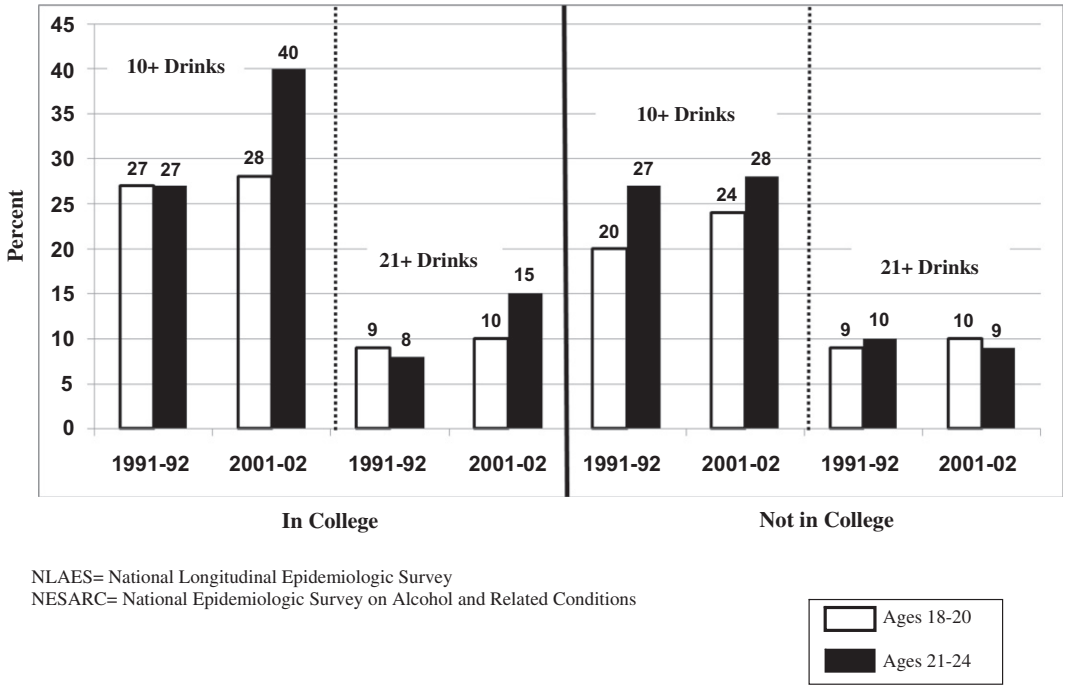

FIGURE 62.1 Consumption of 10+ drinks or 21+ drinks on drinking occasions in the past year by 18–20 and 21–24-year-olds in college versus not in college, 1991–92 (NLAES) and 2001–02 (NESARC).

proportion of college students who drove under the influence of alcohol increased significantly from 26.1 to 29.2%. Among those in the same age group who are not in college, the proportion also increased significantly from 19.8 to 22.8%.

Of note, the increases from 1999 to 2005 in binge drinking and driving under the influence of alcohol occurred among respondents aged 21–24, not those aged 18–20. In each year examined, a greater percentage of 21- to 24-year-olds than 18- to 20-year-olds engaged in these behaviors. Among both 21- to 24-year-olds and 18- to 20-year olds, college students were more likely than same age respondents not enrolled in college to report these behaviors.

Some have argued that the legal drinking age of 21 in the United States drives underage drinking underground into areas lacking adult supervision. Under such circumstances, they maintain persons under age 21 that are more likely to drink very large amounts of alcohol on drinking occasions.

Data collected in two national surveys conducted by the National Institute on Alcohol Abuse and Alcoholism (NIAAA), the 1991–1992 National Longitudinal Epidemiologic Survey (NLAES) ($N = 42\,862$), and the 2001–2002 National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) ($N = 43\,093$) offer an opportunity to explore this issue. Both surveys included a question exploring the maximum number of drinks respondents consumed on any drinking day in the previous year as well as questions about respondent age and whether they were college students. Figure 62.1 indicates the percentages of 18- to 20-year-olds and 21- to 24-year-olds who consumed 10 or more or 21 or more drinks on their heaviest drinking days. Twenty-one or more drinks is the equivalent of one-fifth of spirits, a very large and dangerous amount to consume on one occasion. Three findings emerge. First, the highest percentages consuming alcohol at these levels are in college relative to their same age counterparts. Second, a higher percentage of persons ages 21–24 than 18–20 consume these high amounts of alcohol. Third, increases in the percentages consuming these high amounts of alcohol are specifically found in the 21- to 24-year-old age group who are college students.

TOTAL ALCOHOL-RELATED UNINTENTIONAL INJURY DEATHS

Among 18- to 24-year-old college students, deaths from all alcohol-related unintentional injuries, including traffic and other unintentional injuries, increased from 1442 in 1998 to 1825 in 2005, corresponding to increases in rates of death from 18.5 to 19.0%, a 3% increase per 100 000 college students that approached, but did not reach, statistical significance, relative risk 1.03 (95% CI 0.96–1.1). Among all 18- to 24-year-olds, alcohol-related

unintentional injury deaths increased from 4809 in 1998 to 5534 in 2005. Most of the injury deaths resulted from traffic crashes involving alcohol (1357 among college students ages 18–24 and 4114 among all individuals in that age group) in 2005.

Poisoning deaths in the United States increased over 60% among persons of all ages between 1999 and 2004, with the steepest increases involving prescription drug misuse overdoses, particularly opioids. According to the Centers for Disease Control and Prevention (CDC), poisonings claimed the lives of 2290 18- to 25-year-olds in 2005, with 609 involving alcohol, up nearly threefold since 1998. Because the percentages of those who use illicit drugs are similar amongst 18- to 24-year-olds in college and not in college, college students probably account for approximately one-third of the poisoning deaths in that age group.

The role of alcohol in these poisoning death increases warrants close scrutiny. Heavy drinking may impair judgment and contribute to ingestion of larger quantities of drugs, and alcohol may potentiate the adverse effects of drugs.

The National Survey on Drug Use and Health collects data on drug use among college students and others ages 18–25. Similar proportions of college students and others the same age report drug use. Past 30-day use of any illicit drug or prescription drugs used illicitly tended to be slightly higher among persons ages 18–20 than those 21–25 (20% versus 14%). By 2005, those percentages increased to 21.1 and 18.8%, respectively.

Marijuana was by far the most commonly used illicit drug. It was consumed by 18% of college students 18–20 in 1999 and 2005. Among college students ages 21–25, its use rose slightly from 14% in 1999 to 16% in 2005. Use of drugs other than marijuana was reported by 7% of 18- to 20-year-old college students in 1999 and 8% in 2005. Corresponding percentages for college students 21–25 for these years were 5% and 8%.

Not surprisingly, college students and others ages 18–24 who reported binge drinking in the past month were two to three times more likely to report illicit drug and prescription drug misuse than those who did not binge drink.

NIAAA reports have also documented that heavy-drinking college students not only place their own health at risk, they jeopardize the well-being of others. As many as 46% of the 4553 people killed in 2005 in crashes involving 18- to 24-year-old drinking drivers were people other than the drinking drivers. Further, a national survey in 2001 indicated that over 690 000 college students that year Nationwide were hit or assaulted by a drinking college student, and 97 000 students were the victim of a date rape or assault perpetrated by a drinking college student.

INTERVENTIONS TO REDUCE COLLEGE DRINKING

The increase in the past 7 years in alcohol-related traffic and other unintentional injury deaths among 18- to 24-year-olds, both in college and not in college, underscores the need for colleges and their surrounding communities to expand and strengthen interventions demonstrated to reduce excessive drinking among college students and those in the same age group who do not attend college. Numerous individually oriented counseling approaches, environmental interventions, and comprehensive community interventions can reduce drinking and related problems among college students and the college-aged population.

INDIVIDUAL-LEVEL INTERVENTIONS

A meta-analysis of 62 randomized controlled studies of individual-level interventions to reduce college student drinking conducted between 1985 and 2007 with 13 750 participants and 98 intervention conditions reported at short-term follow-up (4–13 weeks post-intervention), and at intermediate follow-up (14–26 weeks post-intervention) intervention, participants reduced the quantity of alcohol consumed and frequency of heavy drinking. At long-term follow-up (27–195 weeks post-intervention), frequency of drinking days and alcohol-related problems were reduced.

Intervention characteristics influenced problem outcomes. Interventions delivered to individuals rather than groups and interventions that used motivational interviewing provided feedback on expectancies or motives, normative comparison, and included decisional balance exercises (e.g. exercises that engage subjects in exploring the pros and cons of particular decisions) were more successful at reducing alcohol-related problems than a range of comparison conditions. In contrast, interventions that used skills training or expectancy challenge components were less successful in reducing alcohol-related problems. They also reported that the magnitude of the effect on drinking diminished over time. In contrast, reduction in alcohol-related problems took longer to emerge but continued in long-term follow-up.

A different review of individually oriented interventions in studies published between 1984 and 2006 found no support for the effectiveness of approaches that only provide information about the health risks linked to alcohol misuse. However, brief motivational interventions (BMIs) received strong support. This approach was found to be effective in reducing drinking problems in 18 of 22 studies that examined that approach,

prompting the conclusion that research continues to strongly support BMIs with personalized feedback delivered individually in groups or as stand-alone feedback with no in-person contact.

Of note, seven studies of mandated populations were reviewed. Mandated populations consist of students instructed to undergo BMIs because they violated alcohol policies. Five of seven studies found that brief motivational feedback interventions were associated with reduced alcohol use or negative consequences. Research conducted in the 2 years since publication of this review supports the effectiveness of BMIs for reducing alcohol consumption as well as the use of other drugs, including computer-based interventions.

An experimental study of college students attending a student health service clinic, found that students screened for heavy episodic drinking who received a two-session brief motivational counseling intervention had significant reductions in typical blood alcohol concentration (BAC), peak BAC, and several other drinking outcome measures at 3 and 6 months follow-up. This is important because most college students at that university went to the student health service at least annually. These findings were recently replicated at five different university health services. These studies are important because routine screening in that setting could have population-wide effects.

NORMATIVE RE-EDUCATION INTERVENTIONS

Research suggests that college students often overestimate the amount of alcohol consumed by fellow students. Misperceptions of normative drinking behavior lead some students to consume more alcohol in an effort to reflect what they perceive to be normal group behavior. A growing body of literature has explored whether informing students of the true norms for alcohol consumption on their campus leads some students to curtail their drinking. This general approach is known as normative re-education or social norms marketing.

A Cochrane review identified 22 randomized trials with 7275 participants and assessed the impact of social norms interventions on college students. It studied the effects of web/computer feedback, individual face-to-face feedback, group face-to-face feedback, mailed feedback, and social marketing campaigns. The web/computer feedback programs achieved significant reductions up to 16 months after the interventions in alcohol problems, peak BACs, frequency of drinking quantity of drinking, and binge drinking. Individual face-to-face feedback produced declines in frequency of drinking at the 6-month follow-up and alcohol-related problems at 4–6 month and 17-month follow-ups. Group face-to-face effects on quantity of drinking and binge drinking lasted only 3 months, and mailed feedback produced no effects. Results from two social marketing studies were inconsistent. Of note, in a recent review summarized earlier in this chapter, four of eight studies examining individual normative feedback found reductions in drinking.

PARENT INITIATIVES

Pre-College Initiatives

An experimental study evaluated two different parent-focused interventions offered to sixth grade students and their parents in 33 rural Midwestern schools. Subjects were randomly assigned to three experimental conditions: the Iowa Strengthening Families Program (ISFP), the preparing for the drug free years (PDFY), and control groups. ISFP sought to improve parent–child relations, strengthening family communication skills, and increase child chopping skills through implementation of a 7-session, 13-h intervention at school with some sessions focused on parents-only and others on children-only. PDFY programs (since relabeled Guiding Good Choices) is a family competency training program offered in five weekly 2-h sessions designed to enhance parent–child interaction and reduce children's risk for early substance initiation. When those sixth graders were reinterviewed during their senior year of high school, compared to students in the control group, those exposed to the ISFP were one-third less likely to report drinking to intoxication. Smaller differences in the same direction were observed among PDFY students.

A recent follow-up study surveyed these subjects at age 21. Compared to controls, the ISFP students reported significantly fewer episodes of drunkenness, frequency of alcohol problems, and cigarette and illicit drug use. Differences between the PDFY and control group students were not significant. Hierarchical latent growth curve models indicated that much of the ISFP intervention's effects resulted from delays in alcohol use initiation during early adolescence. While the study did not report effects specifically among college students, it indicates family interventions targeting sixth graders can delay alcohol use initiation and reduce drunkenness and alcohol problems among college-age youth.

College Initiatives

An experimental design tested the effects of sending parents a 45-page handbook for talking with college

students about alcohol. Parents in the comparison group received a brochure detailing university alcohol policies and consequences of alcohol policy violations.

Of 347 parents in the intervention group, 72% evaluated the handbook and 83% said they had read most or all of it. Students who did not drink prior to college whose parents reviewed the handbook were less likely to start drinking, and those already drinking were less likely to show growth in drinking over the freshman year. This latter finding resulted from effects on female, but not male, students. Other experimental studies found that this parental intervention, in combination with a brief motivational intervention, produced lower levels of alcohol consumption and high-risk drinking among college students compared with a control group. These new findings are important because they indicate parental influence can extend into college-aged youth.

ENVIRONMENTAL INTERVENTIONS: LEGAL DRINKING AGE OF 21

College University Alcohol Policies

In 1998, the Massachusetts Board of Higher Education adopted more restrictive alcohol policies for all schools under its authority, including the following:

- Restricting alcohol to specific, supervised locations
- Required advanced registration of all social events involving alcohol
- Restricting legal possession of alcohol to separate residence halls for students ages 21+
- Mandatory provision of alcohol education and prevention programs
- Established procedures for enforcement of all federal, state, local, and campus regulations
- Requirement for colleges to work with local towns to enforce alcohol laws
- New sanctions for student alcohol violations up to and including expulsion
- Parental notification of alcohol policy violations

In 1999 and 2001, over 1000 randomly selected students at 11 schools each year were surveyed, as were 11 deans or college vice presidents concerning student drinking practices, 14 alcohol policies, and the level of enforcement. Past 30-day drinking declined from 73 to 63% among students under age 21 and from 81 to 74% among campus residents. Heavy episodic past 30-day drinking declined from 56 to 46% among underage drinkers and 37 to 25% among those living on campus. No changes on either measure were recorded for legal age students and those living off campus. No changes were observed in the proportions of students driving under the influence of alcohol or riding with drinking drivers. Declines in college drinking measures over time were greatest in schools where deans cited high alcohol policy enforcement at baseline, and during both surveys. No attempt was made to separate analytically the effects of specific alcohol policies.

Minimum Legal Drinking Age of 21

In 1984, when 17 states had a legal drinking age of 21, the US Congress passed legislation that would withhold highway construction funding for states that did not make it illegal to sell alcohol to people younger than age 21. By 1988, all states adopted the law.

However, there are some important exceptions. In 24 states, individuals under 21 can possess alcohol with parental or guardian consent and/or presence. In 31 states, parents can legally furnish alcohol to their children who are under 21. Only 31 states and the District of Columbia explicitly prohibit consumption by a person under 21. In 47 states, people under 21 can serve alcohol.

In August 2008, a group of 130 college presidents called for a debate about whether the drinking age should be lowered to age 18. Some suggested, after receiving education about safe drinking levels, that 18-year-olds should be given drinking licenses that would be rescinded if their drinking posed dangers to themselves or others. Given this widely publicized challenge to the legal drinking age of 21, it is worth reviewing evidence on the topic. Figure 62.2 examines trends in the frequency of binge drinking from 1982 to 2007 (five or more drinks on an occasion) from Monitoring the Future, a yearly survey assessment of the attitudes, behaviors, and values of nearly 50 000 8th, 10th, and 12th graders. According to the survey data, binge drinking among high-school seniors dropped from 40% to just over 25%. Among individuals 1 to 4 years past high school, the declines were less, from 40% to just under 35%. Little change was seen among full-time college students. Figure 62.3 examines trends in alcohol-related traffic fatalities among individuals aged 18–20 targeted by the drinking age changes and those aged 21–24 not targeted. Both groups experienced proportional declines, but the declines were greater in the 18- to 20-year age group than in the 21- to 24-year age group (60% versus 44%).

A review of 49 studies of the legal drinking age changes revealed that in the 1970s and 1980s, when many states lowered the drinking age, alcohol-related traffic crashes among people younger than 21 increased 10%. In contrast, when states increased the legal drinking age to 21, alcohol-related crashes among people younger than 21 decreased 16%. A separate review examined 48 studies of the effects of drinking-age changes on drinking and 57 studies on traffic

crashes. The study concluded that increases in the legal age of alcohol purchase and consumption have been the most successful interventions to date in reducing drinking and alcohol-related crashes among people under 21.

One recent analysis found significant declines in traffic fatalities among individuals under 21 in states that changed the minimum legal drinking age to 21 prior to the 1984 Federal mandate to raise the drinking age to 21. However, in states that raised the drinking age after

the Federal legislation, the minimum legal drinking age increases were not associated with significant declines in traffic deaths. The analyses controlled for whether states had a seatbelt law, the legal blood alcohol limit, beer taxes, and vehicle miles traveled. Of note, this study did not explore whether the traffic deaths were alcohol related. After adjusting for changes in the population for that age during the time period 1982 to 2007, alcohol-related traffic fatalities among people aged 16–20 declined 62%, whereas those that did not involve alcohol increased 22% (see Fig. 62.4).

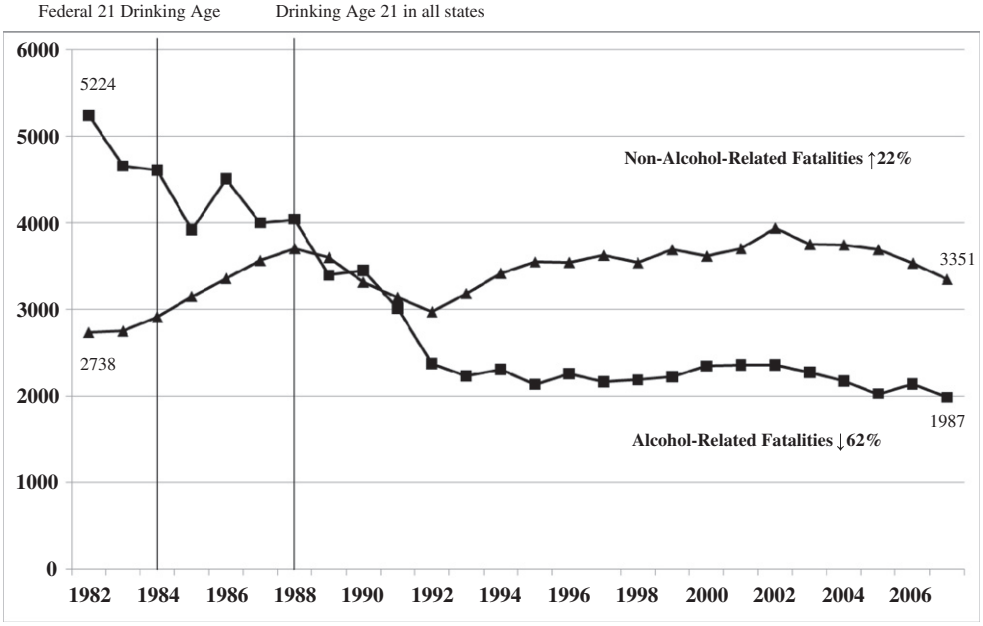
A different study examined trends in the ratio of drinking to nondrinking drivers in fatal crashes in each state annually from 1982 to 2004. This analysis controlled for zero-tolerance laws, graduated license night restrictions, and use/lose laws that target drivers under 21 and could influence their involvement in alcohol-related crashes. It also controlled for 0.10 and 0.08% BAC, per se, legal limits, mandatory seatbelt laws, per capita beer consumption, unemployment rates, vehicle miles traveled, frequency of sobriety checkpoints, number of licensed drivers, and the ratio of drinking to nondrinking drivers aged 26 or older in fatal crashes.

The findings are quite informative. Adoption of the minimum legal drinking age of 21 was associated with a 16% decline in the ratio of drinking to nondrinking drivers in fatal crashes involving those under 21, even after controlling for all the other factors listed above. Of note, other laws targeting drivers under 21 independently predicted lower involvement of drinking drivers in fatal crashes. Use/lose laws and zero-tolerance laws were each associated with 5% declines. Further, laws aimed at adult drivers also independently contributed to declines in the ratio of drinking to nondrinking drivers in fatal crashes: 0.08% BAC laws were independently associated with an 8% decline, 0.10 BAC percent laws a 7% decline, administrative license revocation a 5% decline, and seatbelt laws a 3% decline. Thus, the preponderance of evidence suggests that raising the drinking age to 21 reduced alcohol involvement in fatal crashes involving drivers under 21 and that other laws aimed at drivers of all ages can also reduce alcohol-related fatal crashes involving drivers under the age of 21.

Of note, a recent analysis of over 33 000 adult respondents in two national surveys 10 years apart compared respondents who grew up in states where they legally were allowed to drink prior to age 21 with respondents who grew up in states where the legal drinking age was 21. The analysis, which controlled for numerous potential confounding variables, found that those allowed legally to drink prior to age 21 were more likely as adults to meet both alcohol and drug use disorder criteria.

Zero-Tolerance Laws

Zero-tolerance laws, which make it illegal in every state for those under the age of 21 to drive after any drinking, also have contributed to declines in alcohol-related traffic deaths among people younger than 21.



Source: U.S. Fatality Analysis Reporting System, 2009

Unfortunately, despite their demonstrated benefits, legal drinking age and zero-tolerance laws generally have not been vigorously enforced. Young drivers are substantially underrepresented in the driving-while-intoxicated (DWI) arrest population relative to their contribution to the alcohol-related crash problem. Stepped-up enforcement of alcohol purchase laws aimed at sellers and buyers can also help reduce alcohol misuse and related problems.

Price of Alcohol

The majority of published studies have reported an inverse relation between the tax on or price of alcohol and alcohol misuse and related negative health outcomes. A National Academy of Sciences review recommended that Congress and State legislatures raise excise taxes to reduce underage alcohol consumption and to raise additional revenues to reduce underage drinking problems. Further, research is needed about the effects of price increases on (1) college students relative to others in the same age and (2) college-age people relative to older people.

Three recent extensive literature reviews examined the relation of alcohol price and tax with consumption and related harms. One analysis of 1003 separate estimates from 112 studies reported very strong evidence that price affects drinking of all types of beverages and across the population of drinkers, from lightest to heavy drinkers.

A separate review of 78 alcohol tax studies meeting the Centers for Disease Control and Prevention's Community Guide inclusion criteria also found consistent evidence across different countries, time periods, study designs, analytic approaches, and outcomes that higher alcohol prices and taxes are associated with reductions in both excessive alcohol consumption and related subsequent harms.

An international review found that when income, the price of other goods, and other factors were analytically controlled for, a rise in alcohol prices was linked to less alcohol consumption and less alcohol-related harm, and vice versa. The authors concluded that increased alcohol prices delay the time when young people start to drink, slow their progression toward drinking large amounts, and on balance reduces their heavy alcohol consumption. Although very high prices for alcohol might stimulate illegal production, in the United States alcohol prices have not kept pace with inflation over the past 60 years.

Alcohol Outlet Density

Higher alcohol outlet density has been associated with increased alcohol-related problems in both cross-sectional and prospective studies, and reducing outlet density may, in turn, reduce drinking-related problems. Prospective research is needed to specifically test whether reducing outlet density will reduce consumption, related problems, and specific effects on college students. One recent study found that higher alcohol outlet density near colleges was related to higher campus rape offense rates.

Comprehensive Community Interventions

Several community-based initiatives have successfully reduced drinking- and/or alcohol-related problems among young people. These programs typically coordinate efforts from the following:

- City officials from multiple departments of city government, school, health, police, and alcohol beverage control, etc.
- Concerned private citizens and their organizations and students, parents, and merchants who sell alcohol.
- Often multiple intervention strategies are incorporated into the programs, including school-based programs involving students, peer leaders, and parents; media advocacy; community organizing and mobilization; environmental policy change to reduce alcohol availability to youth; and heightened enforcement of laws regulating sales and distribution of alcohol and laws to reduce alcohol-related traffic injuries and deaths.

Six comprehensive community programs have achieved reductions in alcohol problems among college-aged youth:

- Communities Mobilizing for Change Program – This program attempted to reduce the flow of alcohol to youth from illegal sales by retail establishments and from the provision of alcohol to youth by adults in the community
- Community Trials Program – Communities formed coalitions aimed at reducing illegal sales of alcohol to youth, implementing responsible beverage service and decreasing drunk driving offenses by increasing awareness of consequences.
- Saving Lives Program – This program tried to reduce drunk driving and related consequences through media campaigns, police training, high-school peer-led education, college prevention programs, increased alcohol outlet surveillance, and other measures.
- Fighting Back Program – This program tried to reduce availability of alcohol through environmental policies and expanded substance abuse screening, counseling, and treatment.
- Sacramento Neighborhood Alcohol Prevention Project – This program included community mobilization, a public awareness campaign, responsible beverage service training, legal drinking

age enforcement, and intoxicated patron law enforcement.
- Reduce Underage Drinking through State Coalitions – This initiative used a community coalition model at the state level in 10 states to mobilize citizens, increase media coverage, and implement policy changes such as alcohol price and tax changes and greater restrictions on commercial and social access to alcohol.

Six studies have now explored elements of the comprehensive community-organizing model as a method for reducing drinking or alcohol-related harms specifically among college students. One study adapted some of the community trials interventions to a college setting. At an experimental university, there was a marked increase in DUI enforcement coupled with a media campaign. The prevention campaign featured DUI checkpoints, media coverage, and a student-designed social marketing campaign designed to increase student perception of risk of arrest for DUI. DUI checkpoints were operated jointly by campus and local city police. Telephone surveys of randomly selected students revealed significant declines in self-reported DUI from pre- to posttest.

The Matter of Degree college–community partnership implemented environmentally based interventions to reduce drinking and related problem behaviors among college students. Interventions included keg registration, mandatory responsible beverage service, campus–community police collaboration on increased wild-party enforcement, substance-free residence halls, and a variety of media efforts. Significant reductions were achieved in binge and frequent binge drinking, frequent intoxication, driving after drinking, alcohol-related injury, and a variety of other alcohol-related problems.

A study of a comprehensive community program focused on underage drinking and driving among 16- to 24-year-olds in Huntington, West Virginia, home of Marshall University (enrollment 18 000 students). Morgantown, West Virginia, home to West Virginia University, with 40 000 students, was selected for comparison. During late winter 2006 and spring 2007, local, university, and state enforcement agencies increased enforcement of drunken and driving laws, including zero-tolerance laws, through low-manpower sobriety checkpoints, saturation patrols, and stepped-up DUI directed patrols. The State Alcohol Beverage Control Administration, with assistance from local and state law enforcement agencies, increased enforcement of the minimum legal drinking age laws. This included enforcement of laws aimed at servers/sellers and underage people, including use of fake identifications. A multimedia campaign that included paid and earned print and broadcast media publicized these efforts.

Roadside surveys of nighttime drivers conducted alcohol breath tests during the fall of 2006, spring of 2007, and fall of 2007. Compliance check survey of underage alcohol purchase attempts produced declines in successful buy attempts, from 43 to 18% in the intervention city. Little change occurred in the comparison city. Reductions in BACs at the roadside surveys in the intervention city showed marked declines in the proportions of drivers aged 16–20, 21–24, and 25 or older at 0.02, 0.05, and 0.08%, respectively. Little change was found in the comparison city.

An examination of a college–community partnership at Western Washington University and another at Washington State University. Police patrols focused on off-campus student parties, and compliance check surveys were used to restrict sales of alcohol to minors. Public forums brought community residents, students, and police together for dialogues about disruptive parties and other neighborhood issues. The colleges also offered alcohol-free late-night activities. Significant restrictions in the prevalence of heavy drinking (five or more consecutive drinks) were observed at the two intervention colleges relative to a comparison college.

An evaluation of the Common Ground Program, a University of Rhode Island/community partnership featuring increased DWI and minimum legal drinking age enforcement, a media campaign, and a safe-rides program. Although the program resulted in increased student awareness of alcohol control measures and a greater perceived likelihood of apprehension for underage drinking, as well as a reduction in police-reported alcohol-related incidents, no changes were observed or reported regarding alcohol use or alcohol-impaired driving by college students.

The largest college/community interventions study to date explored a college/community risk management approach to reduce college student drinking to intoxication and intoxication-related harm and compared seven California public university system colleges/universities to seven comparison colleges/universities in the same state system. The intervention included a social host Safe Party campaign, compliance checks, DUI checkpoints, party patrols, and passage of a social host response cost ordinance. Each college/university focused on at most two settings, focused on the beginning of the school year, underwent a highly specific planning and implementation process that focused more on implementation of intervention rather than motivating colleges. Student surveys during 2 years prior to the intervention were compared with repeat cross-sectional surveys collected twice annually after the intervention. The intervention achieved significantly lower levels of drinking to intoxication at off-campus parties, bars, restaurants, and across all settings studied. They estimated their intervention, on average at each intervention college/university,

produced 1500 fewer students drinking to intoxication and 10 000 fewer incidents of drinking to intoxication. Further analyses revealed no displacement of alcohol problems to other college/community settings. Of note, colleges varied in the extent and intensity with which the interventions were implemented. However, the reported results included even those schools with minimal intervention efforts even though their program effects were negligible.

Taken together, these studies underscore the potential for comprehensive community and college collaborative interventions to specifically reduce alcohol misuse and problems among the difficult-to-reach college student population. Key questions about this approach that warrant future investigation include the following:

- Will a combination of (a) environmental interventions to reduce alcohol availability and enforce alcohol policies, such as minimum legal drinking ages, drinking-and-driving laws, and (b) efforts to expand screening and brief interventions or other individually oriented counseling approaches achieve greater problem reductions than either alone?
- Are programs that target people of all ages more effective in reducing college student alcohol problems than those that focus only on college students?
- Will programs that reduce alcohol misuse among college students and college-aged individuals produce carry-over benefits into adult life?
- Will programs that delay the onset of alcohol use among individuals before they reach their college years reduce drinking and related problems among people in college?
- How can comprehensive campus–community collaborations be sustained over time?
- Which college–community interventions are most effective in reducing alcohol misuse and related problems with the least cost?

CONCLUSIONS

It is ironic that binge drinking and driving under the influence of alcohol continued to rise, and unintentional injuries attributable to alcohol did not decline during a period of time when there was a considerable expansion of the scientific literature and knowledge base regarding how to reduce drinking and related harms among college students. An important research question is how to translate our new knowledge into reductions in alcohol misuse and related problems in the future.

A unique national survey of deans and vice presidents at 351 four-year colleges in the United States in 2008, explored their awareness of a major NIAAA report in 2002 on college student alcohol use and related problems and recommended interventions to reduce student alcohol use. They found nearly 80% of college deans and vice presidents were aware of the report and its recommendations and 77% of their colleges had implemented at least one of the research-supported strategies recommended in the report.

However, the types of NIAAA-recommendations most likely to be implemented were interventions designed to identify individual students with drinking practices that pose risk to health and then offer some form of individual counseling. Two of every three colleges (67%) provided intervention programs for college students who are problem drinkers or at high risk for experiencing drinking-related problems. Most colleges (76%) offered at least one empirically supported program: 66% offered norms clarification, 57% cognitive behavioral skills training, 62% brief motivational interviewing, and 38% expectancy challenge programs. Reviews of these types of interventions since the NIAAA report have reinforced their beneficial value as more new studies have tested and supported their efficacy. Indeed, a promising new finding since the NIAAA report is that these types of interventions can be effective not only with students who voluntarily seek them out but also with students who are mandated to receive them because of alcohol infractions or other disciplinary action.

An important concern, however, is that only a small fraction of college students who might benefit from these programs actually are exposed to them. Based on the NESARC, NIAAA estimated that nearly one in five (19%) college students met alcohol use disorder criteria (dependence or abuse) during the year preceding the 2001–2002 survey, but only 5% of them received any treatment or counseling for their problem. Further, national surveys indicate most adolescent and young adult patients are not asked by their physicians about their drinking and offered advice during medical care encounters about what drinking patterns pose risk to their health.

As noted earlier in this chapter, recent studies have reported efficacy of screening and brief motivational counseling interventions for alcohol in university health services. If student health services were to adopt alcohol screening and brief counseling interventions for at-risk drinkers as a routine part of each university health service visit, that would greatly enhance the potential of these interventions with demonstrated effectiveness to reach a broader segment of the college community and ultimately achieve population-level benefits.

In addition, it is noteworthy that colleges were much less likely to employ environmental policy and comprehensive college/community interventions that have been shown to be effective in reducing youth alcohol problems. Only one in three reported compliance checks to prevent underage drinking were done in their

community, usually (60%) without university involvement. Most administrators had not discussed, planned, or implemented efforts to restrict the numbers of nearby alcohol outlets (79%), increase the price of alcohol (86%), or institute mandatory beverage service training (73%).

Evidence concerning the effectiveness of environmental alcohol policies has expanded considerably since the release of the NIAAA report. As documented in this chapter, a large and growing body of literature supports the beneficial effects of establishing a minimum legal drinking age of 21 in reducing underage drinking and alcohol-related crashes. Further, the majority of published studies have reported an inverse relation between the price of alcohol and alcohol misuse and related negative health outcomes. Higher alcohol outlet density has been associated with increased alcohol-related problems in both cross-sectional and prospective studies, and reducing outlet density may, in turn, reduce drinking-related problems. Prospective research is needed to specifically test whether reducing outlet density will reduce consumption, related problems, and specific effects on college students.

Finally, as also documented in this chapter, several community-based initiatives have successfully reduced drinking and/or alcohol-related problems among young people. These programs typically coordinate efforts of:

- City officials from multiple departments of city government, school, health, police, and alcohol beverage control, etc.
- Concerned private citizens and their organizations and students, parents, and merchants who sell alcohol.

Often multiple intervention strategies are incorporated into the programs, including school-based programs involving students, peer leaders, and parents; media advocacy; community organizing and mobilization; environmental policy change to reduce alcohol availability to youth; and heightened enforcement of laws regulating sales and distribution of alcohol and laws to reduce alcohol-related traffic injuries and deaths. Six of these comprehensive community programs have achieved reductions in alcohol problems among college-aged youth.

In addition, six studies completed since the initial NIAAA report have now explored elements of the comprehensive community organizing model as a method for reducing drinking or alcohol-related harm, specifically among college students. Most achieved reductions in college student drinking or related harms.

The growing evidence on effectiveness of alcohol policy and comprehensive community interventions should prompt more colleges to work together with their surrounding communities. Clearly, colleges by themselves cannot optimally reduce the alcohol problems among college students or other persons the same age not in college, and binge drinking and driving under the influence of alcohol has also increased among this group. For every 18- to 24-year-old college student, there are two persons their age not in college. Entire community norms and policies need to be changed. If colleges adopt stricter alcohol policies and enforcement but surrounding communities do not, the college student alcohol problems will simply be pushed off campus into surrounding communities. Conversely, if communities tighten their policies and enforcement and colleges do not, it will only push the problems back onto college campuses. Also, many of the problems experienced as a result of excessive student alcohol consumption can affect people other than the college drinkers themselves.

Further, many college students develop problematic drinking habits before they enter college. Analyses of the National College Alcohol Survey indicate the younger college students were when they first drank to intoxication, the greater the likelihood that they experience alcohol dependence, rode with drinking drivers, drove after drinking, were injured under the influence of alcohol, and had unplanned and unprotected sex after drinking. The recently published analyses of elementary and middle school interventions that produced reductions in drinking and related problems that carried over to young adult years suggests these approaches might help further reduce in college drinking and related problems. This warrants research attention.

Consequently, colleges and surrounding communities need to work together to implement multi-faceted programs at various levels. They need to expand the reach of individually oriented counseling programs to include university health services and web-based outreach, test and refine promising new approaches to involve parents, and test and further implement policies that can further reduce college age and underage alcohol misuse.

Collectively, they need to involve multiple departments of city government as well as concerned private citizens and organizations and multiple sectors of the college community, presidents, deans, other administrators, campus security, residence counselors, health service providers, alumni, faculty, and students if they want to most effectively reduce harmful drinking and the myriad of health and social problems linked to harmful drinking.

CHAPTER

63

Drinking Patterns, Alcohol Consumption, and Aggressive Behavior

Brian M. Quigley, Kenneth E. Leonard

Research Institute on Addictions, Buffalo, NY, USA

OUTLINE

ALCOHOL AND AGGRESSION

The co-occurrence of alcohol use and physically aggressive behavior has been observed throughout recorded history and across numerous cultural contexts. In the 1400s, Netzahualcoyotl of Texcoco described alcohol as a cause of violence among family members. In the mid-1700s, William Hogarth issued two prints, one of which, Gin Lane, depicted the pernicious effects of gin, including two men attacking each other in front of a distillery. Throughout the 1800s, alcohol was described in morality tales of the temperance movement as well as in specific court cases as leading men and women to violence. In one of case, a man in Middletown, Connecticut, was hung for beating his wife to death after 2 days during which both he and his wife had been drinking, arguing, and fighting with each other. Despite these destructive effects of alcohol, there has also been a recognition that most instances of alcohol use are accompanied by positive effects. The challenge for research has been to understand whether alcohol leads to aggressive behavior, and if so, for whom and under what circumstances. The co-occurrence of alcohol use and physically aggressive behavior has been examined in numerous domains including crime statistics, survey research of general and domestic violence, and experimental studies.

DEFINITIONS AND DISTINCTIONS

In this chapter, "aggression" is defined as any behavior with the intent to cause harm to another person. This term often includes behaviors with the intent to cause psychological harm, such as psychological, verbal, or emotional aggression, but in general, the term "aggression" refers to the intent to cause physical harm. The term "violence" usually refers to more severe acts of physical aggression that have the potential for injury or death, as well as acts that have been judged as "criminal."

Several distinctions regarding alcohol also need to be made. The intoxicating effects of alcoholic drinks should be considered acute effects and distinguished from

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00063-2

chronic effects, which refer to effects that occur only after the individual has used the substance for some time. Chronic effects associated with long-term alcohol use include, but are not limited to, physical damage, such as liver cirrhosis and changes in executive cognitive functioning, and social damage, such as disrupted friendships and marriages. Similarly, when discussing the association between alcohol use and aggression, we need to distinguish substance user from substance use. Although alcohol use may show certain relationships with aggression, possibly due to the acute effects of alcohol, an individual who is a substance user may be more likely to engage in aggressive behavior for various other reasons, some of which may have little to do with the alcohol itself. An individual who is a heavy drinker may differ in a variety of important ways from an individual who is not. These may include individual differences in impulsiveness and cognitive functioning as well as differences in the typical social and physical environment in which drinkers or heavy drinkers find themselves.

ALCOHOL USERS AND VIOLENCE

Studies of violent criminals have often found that they are very likely to be heavy drinkers, to have experienced alcohol problems, or to have an alcohol disorder. Based on data from the National Survey of Jail and Prison Inmates, 50% of homicide offenders were classified as "heavier" drinkers (2–5 drinks per day) or "much heavier" drinkers (more than 5 drinks per day). The use of offender populations (i.e. individuals arrested and convicted for the commission of a violent crime) has the strength of ease and efficiency. It is very convenient inasmuch as the individuals have been already been identified and located. In addition, the violent behavior of interest has been documented by evidence and by the judicial process, and it is not reliant on the individual admitting responsibility. Studies of incarcerated offenders have provided fairly clear results regarding the prevalence of alcohol and substance use/abuse among violent and nonviolent offenders. In general, studies of incarcerated criminals have found that the typical drinking patterns of violent and property offenders were very similar, although this is not true for the use of other drugs.

Although offender populations provide a useful and convenient sample from which to collect data, these populations also have limitations. Offender populations reflect a minority of individuals who have behaved violently. Many crimes of violence go unreported or unsolved. In comparing police reports to victims' reports, it has been found that only 4% of the violent incidents reported by victims come to the attention of the police. Consequently, the characteristics of violent offenders may reflect both the causes of violence as well as the factors that expedite arrest and conviction. For example, the common observation that about 50% of homicide offenders were drinking at the time of the homicide may reflect the inability of intoxicated offenders to avoid detection. Second, the selection of nonviolent individuals from incarcerated populations can be difficult. Although one can rely on the crime of conviction to identify the violent offenders (i.e. homicide offenders, assault offenders), conviction of a nonviolent crime does not ensure that the sample is not violent. The nonviolent conviction may be the result of a plea bargain for a violent offense, or it may reflect the most serious charge that the district attorney could substantiate. Also, many individuals engage in both violent and nonviolent crimes. Thus, many of the individuals convicted of a nonviolent crime have committed violent crimes in the past. Despite a variety of methodological problems with much of this research, it is clear that violent criminals are very likely to use alcohol excessively. The critical issue to recall is that data indicating substance users and/or abusers are likely to engage in violence do not necessarily suggest that the substance use or even substance abuse caused the violence.

Despite the difficulty and cost, studying the occurrence of alcohol and violence in the general population is an important approach to identifying a sample of violent individuals. For example, The Epidemiology Catchment Area (ECA) project studied the prevalence of psychiatric disorders in the general population as well as information regarding involvement in violent episodes. Evidence from analysis of these data demonstrated that 15.3% of individuals with alcohol problems had been involved in violent incidents. Only 2% of the individuals without alcohol abuse problems were involved in violent incidents. Another general population survey, the Household Survey of Drug and Alcohol Abuse found similar results. Among those with no alcohol use in the previous year, only 2.7% were involved in violence. When the respondents drank at least monthly, 14.6% had experienced violence in the previous year. Meta-analyses of more than 100 case–control and cross-sectional studies in the general population have reported significant associations between drinking patterns and criminal violence and between drinking patterns and intimate partner violence.

Studies of general populations have also been conducted in several other countries. The association has been found in large general population studies in Great Britain, Canada, Australia, and the United States. Multicountry studies conducted by the World Health Organization found associations in population surveys conducted in Central and South America (Brazil, Columbia, Venezuela, Costa Rica, and El Salvador),

Asia (India and Indonesia), Europe (Spain), and Africa (South Africa). Other multinational studies and smaller studies have expanded the countries in which the relationship has been observed to China, Cambodia, Columbia, Dominican Republic, Haiti, Nicaragua, Peru, Bangladesh, Uganda, Ethiopia, Egypt, Nigeria, and Iran. Thus, the relationship between heavy drinking and violence has been observed in many diverse cultures.

Research has also been conducted among more select samples. Studies have observed the relationship between drinking and violence among alcoholics, battered women, and men arrested for partner violence. Studies in health clinics and emergency rooms, which tend to identify victims of violence, have also consistently found that heavy drinking was associated with the occurrence or severity of violence. Recent research in emergency rooms in Argentina, Australia, Canada, Mexico, Spain, and the United States found that individuals injured in a violent event showed heavier drinking patterns than those injured in an accident.

Although much of the research has used cross-sectional designs, a small number of studies have examined the relationship between alcohol and violence using longitudinal designs. These longitudinal studies have mainly focused on aggressive behaviors in the context of intimate partners. Several studies have examined the relationship over periods of 1 to 2 years. These studies have almost consistently found that men's drinking was longitudinally predictive of men's aggressive behavior toward their spouse, either as a main effect or in certain subgroups of men (e.g. hostile). However, none of these longitudinal studies have found that women's drinking was related to their own aggressive behavior nor to their husband's aggressive behavior. In addition, a number of treatment studies have found that alcoholics who maintain sobriety after treatment engage in less partner violence in the year after treatment compared with alcoholics who relapse. Studies that have examined alcohol and partner aggression over longer periods of time have been less consistent, as have the few longitudinal studies of alcohol and general (not partner) aggression.

In addition to the general finding of an association between drinking patterns and violence, several additional findings are important to note. First, across the cross-sectional and longitudinal studies, a wide variety of measures of drinking patterns have been used, including average daily use, frequency of heavy drinking, alcohol problems, and alcohol use disorders. Some research has found that measures of current alcohol problems are related to current violence but measures of lifetime problems are not. Moreover, research suggests that indicators of heavy episodic drinking are most consistently associated with aggression but measures of the typical frequency of drinking are often not associated with aggression. Second, although the relationship between drinking patterns and aggression has been observed among men and women, the results are less consistent with respect to women. Most of the research on women's aggression has focused on intimate partner violence. Studies in general population samples have often failed to find an association between drinking patterns and women's violence toward a partner, or have found that a significant univariate relationship is no longer significant after controlling for the male partner's drinking pattern. In contrast, an association between women's drinking pattern and aggression toward her partner often emerges in studies of clinical samples, perhaps suggesting that some of the characteristics of women in clinical samples may potentiate the association between drinking patterns and violence.

ALCOHOL USE AND AGGRESSIVE EVENTS

The earliest and most well-known approach to understanding the relationship between alcohol and aggression was to examine criminal events. Since the 1950s, crime statistics have consistently shown a co-occurrence of alcohol use and criminal behavior. It has been estimated that approximately 60% of violent crimes involve alcohol use, with estimates ranging from 24 to 82% of perpetrators in assaults having consumed alcohol prior to committing the crime. According to data from the National Survey of Jail and Prison Inmates, 36% of the offenders had consumed only alcohol prior to committing a homicide and an additional 13% had consumed alcohol in combination with some other drug. As only 7% of the offenders had consumed drugs but no alcohol prior to the homicide, these data show that alcohol use commonly precedes the occurrence of violent actions, but the use of other substances is less common. However, the use of alcohol prior to the crime of conviction was more common for violent offenses than property offenses.

Although these statistics seem impressive, there are a number of caveats regarding their interpretation. Although we can estimate the frequency of alcohol use in episodes of violence, we do not know the frequency of alcohol use in nonviolent interactions. Finding that 50% of assaults were accompanied by alcohol consumption by the offender would not be of interest if 50% of the time that two individuals got together, one or the other had been drinking. Even though we do not have information concerning the presence of drinking in nonviolent get-togethers, it seems unlikely that it would approach 50%. However, it is also clear that not

everyone is equally likely to become involved in an assault. We know that violence is more common among young adults than among older adults, and among men than among women. There are also individual difference factors that place some individuals at higher risk for assault than others, such as antisocial personality characteristics. Perhaps 50% of the time that antisocial young men get together, one or the other has been drinking. If this were the case, the fact that 50% of assaults occur under the influence of alcohol would not be impressive. The point of this discussion is that simple rates of involvement are interesting, but do not provide meaningful information concerning associations of substance use and violence. Studying the involvement of alcohol use in aggressive events requires research designs that can assess the presence of alcohol in events differing in aggression, such as no aggression versus aggression, or moderate aggression versus severe aggression. Alternatively, designs that can examine the occurrence of aggression in events varying in alcohol use can also provide information about the association. In either of these approaches, it is of critical importance to control for individual characteristics that might be associated with the type of event under investigation.

One approach has been to compare aggressive events involving some individuals with control events, such as verbal conflict, involving other individuals. Because people who have never experienced an aggressive event are likely to differ from those who have, individual differences need to be controlled for statistically. Although the earliest research using such a "between-subjects" approach did not find a relationship between alcohol and assaults, more recent research has. In one recent study, observers of police–citizen encounters found that alcohol consumption was more common in instances of spousal assault and other violent crimes than in instances of nonviolent police–citizen encounters. In a study of intimate partner aggression among newlywed couples, alcohol consumption by the husband was more common among episodes of moderate and severe aggression than among episodes of verbal conflict. Alcohol use has also been found to be more common in more severe episodes of violence in contrast to less severe episodes, even when these contrasts involved homicide versus nonlethal violence.

A second approach to examining alcohol and aggression in events has been to compare aggressive events and less aggressive events reported by the same person, the "within-subject" approach. This could be accomplished by comparing alcohol use before an event among people who reported both a verbal and physical aggressive event. One might examine all the individuals who report both a physical violence and a verbal aggression event, and compare the alcohol consumption preceding these two events. In studies of young married couples, drinking by the husband has been found to be more common in a violent event than in an argument. In one study, youthful offenders reported on an assault that they committed that resulted in an injury and the last time that they were with the same people at the same time and on the same day of the week. The assaultive event and the control event were very similar in terms of the context of the event, but the offenders reported drinking more prior to the assaultive event than prior to the control event. In a similar vein, in a study of conflict events occurring in bars, alcohol consumption did not predict the occurrence of aggression, but it was associated with aggression severity and physical harm, and this relationship was present after controlling for personality and situational factors. In addition, in treatment samples, the level of alcohol consumption has been found to be higher prior to violent events in contrast to verbal aggression events.

In recent years, rather than collecting data on two discrete episodes differing in the level of violence (or level of alcohol consumption), researchers have begun to collect detailed data regarding drinking, conflict, and aggression every day over the course of 2–3 months. In some studies, this has been collected retrospectively using the Time Line Followback procedure, an interview designed to collect data on drinking as well as other events on a daily basis over an extended period of time. Other studies have used similar interviews focusing on the preceding week. The most sophisticated approach has involved daily reports regarding drinking and the occurrence of aggression in the preceding 24 h. All of these approaches allow for the use of highly sophisticated multilevel models to examine the relationship between alcohol and violent events. This approach allows the researcher to examine whether drinking on one day was associated with the occurrence of aggression the same or the following day. This approach has found associations at the daily level and the occurrence of aggression in a number of diverse samples. One study conducted weekly interviews of mentally ill individuals at high risk for violence and found that alcohol use was predictive of violence the same day and the next day, but that violence was not predictive of subsequent alcohol use. Among college students reporting on drinking and a variety of different behaviors, the students estimated blood alcohol concentration (BAC) on a specific day was associated with the occurrence of aggression and vandalism on the same day. In a recent study, drinking on one day was linked to aggression against members of a sexual minority group, controlling for drinking patterns and other risk factors for aggression. In short, across a variety of event-based methodologies, heavier alcohol use on a given day is clearly associated with aggressive behavior on that specific day, and sometimes is predictive of aggression on the subsequent day.

EXPERIMENTAL STUDIES

Some of the best evidence for the causal effect of alcohol on aggressive behavior comes from laboratory studies. In such studies, participants may ostensibly be allowed to administer an aversive stimulus to an individual who is believed to be another subject but is, in actuality, an experimental assistant or confederate. The aversive stimulus may be physical (such as noise or electric shock), verbal (such as an evaluation), or symbolic (as in a response that reduces the money that can be earned in a task). These behaviors are viewed as an analog for real-world aggressive behavior and although they are an underestimate of the actual behavior of interest, they are generally accepted as reasonably valid measures of aggressive responding. Laboratory studies are important because they allow for the precise examination of acute alcohol effects on aggressive behavior. The pharmacological effects of substances are often dose related, and tied to the amount of the substance in the brain, which is indexed by their breath or blood alcohol concentration. In the natural environment, individuals differ with respect to the amount of alcohol they drink, the alcohol content of the beverage, the duration and speed of their drinking, and the activities that they engage in while drinking. Each of these can have an impact on the person's actual BAC. In the laboratory, these factors can be controlled and a more precise BAC can be achieved by participants. Laboratory studies allow for control over extraneous variables and provide the ability to rule out alternative explanations for findings allowing the conclusion that one variable has caused the changes observed in another variable. In the case of alcohol, through the inclusion of a placebo condition, the use of laboratory studies permits the assessment of any effects that occur simply on the basis of the individual's expectations concerning the drug. Experimental paradigms allow for the inclusion of situational variables that allows us to specify the conditions under which alcohol does and does not result in increased aggression. These factors, coupled with the ability to evaluate individual difference factors involved in the relationship, allow for the testing of theoretical explanations of the relationship.

The most common procedure used in the laboratory when dealing with alcohol and aggression has been the Taylor reaction time procedure (TAP). In this procedure, participants play a reaction time game with another participant (usually a confederate of the experimenter). For each trial, the subject sets a level of shock that they wish to deliver to the other person. The loser of the reaction time trial (i.e. the slower reactor) then gets shocked. The game is rigged so that the participant receives some shocks (usually in an escalating manner) and is allowed to deliver shocks on others on other trials. The first trial is sometimes considered a measure of proactive or instrumental aggression and subsequent trials a measure of reactive aggression.

Meta-analyses of the laboratory literature have concluded that, in general, the administration of alcohol does lead to increased levels of aggression. Higher levels of alcohol intoxication (BAC = 0.08 to 0.10) have been found to lead to more aggressive responding in the TAP than low levels of intoxication (with effect sizes as estimated by Cohen's d ranging from 0.47 to 0.61). In one review of 30 laboratory studies investigating the effects of alcohol on aggressive responding, there was significantly more aggression when comparing alcohol administration conditions with no alcohol control conditions as well as to placebo conditions, suggesting that alcohol has a psychopharmacological effect beyond any effect of believing that one has consumed alcohol. Several studies have found that high doses of alcohol result in higher levels of aggression than low doses of alcohol. In addition, the relationship between alcohol dose, at least at the levels given in the laboratory, was found to be linear in a study in which various alcohol doses were given to participants (0.0 g kg^{-1}, 0.125 g kg^{-1}, 0.25 g kg^{-1}, 0.50 g kg^{-1}, 0.75 g kg^{-1}, and 1.00 g kg^{-1}).

These meta-analyses of laboratory studies have also typically failed to find that placebo conditions increase aggression over no alcohol control conditions. Although placebo effects in alcohol and aggression research are rare, recent evidence suggests that alcohol-related cues can instigate aggressive responding even in the absence of alcohol consumption. In two recent studies, when individuals were exposed to alcohol-related cues, even subliminally, they tended to respond faster to aggressive words and to be more aggressive toward a person who had insulted them. This effect was also largest among those holding the expectancy that alcohol makes them aggressive. These findings, in contrast to the negative placebo findings, suggest that alcohol expectancies may have effects on aggression although other factors may ameliorate the effects when actually consuming alcohol. It is one of the current contradictions in the data that will require additional research to untangle.

In the TAP procedure, it is possible to examine the effect of alcohol on aggression in relation to the provocations of the other person (confederate) in the experiment. This may be accomplished through the verbal behavior of the participant or through feedback to the participant that the other person is increasing the level of aversive stimuli to be administered to the participant. Studies using verbal behavior suggest that alcohol does not increase aggressive behavior relative to no alcohol controls when there are verbal behaviors that reduce the aggressive threat of the other person, such as a declaration by the other person that he intends to select only low shock levels. Similarly, alcohol does not seem to result in

increased aggression in the presence of other situational cues that press for nonaggressive behavior, such as a nonaggressive norm or pressure from another person in the room to behave nonaggressively, even in the face of increased attack from the other person. In contrast, alcohol does lead to increased aggression in the presence of aggressive instigations. For example, participants who have received alcohol increase their aggression against a nonaggressive opponent if an observer pressures them to do so, but sober participants do not. Similarly, intoxicated participants increase their use of an extreme level of shock more than sober participants in response to an attempt by their opponent to administer that extreme shock to them. However, when the provocative cues are at their highest level, the difference between alcohol and control conditions is often attenuated. For example, after overhearing their opponent indicate an intention to use only the highest shock settings, intoxicated and sober participants are equally aggressive. Similarly, in many studies, the opponent gradually increases the level of shocks selected for the participant. As this provocation increases, the difference between the alcohol condition and the control condition decreases.

Laboratory research has also investigated the individual differences that may moderate the effect of alcohol on aggressive behavior. Among the individuals, the differences that have been found to moderate the effects of alcohol on aggressive responding are empathy, irritability, dispositional aggressiveness, trait anger, self-control, and cognitive executive functioning. In general, it appears that alcohol has stronger effects among individuals with higher levels of traits that facilitate aggression and among individuals with lower levels of inhibitory characteristics. For example, alcohol facilitates aggression among those who are high in anger and low in empathy. It should be recognized that most of this research focuses on one specific moderator at a time, and virtually none of the research has examined individual differences and situational characteristics in the same study. In addition, although research very rarely finds placebo effects (which are meant to control for expectancies regarding alcohol), individual differences in expectancies regarding alcohol's effects on aggression have sometimes been found to be related to aggressive responding. In one study using the TAP, individual differences in alcohol expectancies regarding alcohol interacted with alcohol consumption such that those with high expectancy that alcohol makes them aggressive, who consumed alcohol and who were provoked, were more likely to respond with the most extreme reactions. Recent research has indicated that the belief that alcohol makes one aggressive does lead to greater aggressive responding when given alcohol in the laboratory, although this effect seems to disappear when controlling for trait aggressiveness.

EXPLANATIONS FOR THE RELATIONSHIP BETWEEN ALCOHOL AND AGGRESSION

Noncausal Explanations

One set of explanations for the alcohol/aggression relationship suggest that the use of alcohol does not precipitate violence, rather the use of alcohol and the commission of violent acts are precipitated by a common set of circumstances. The relationship between alcohol use and violent behavior only exists because some third variable is the actual cause of both behaviors. According to the general deviance syndrome, individuals who are likely to engage in violent behavior also demonstrate predispositions to engage in other deviant behavior. These subcultures are most likely to exist among lower socioeconomic classes, especially among men, and are distinguished by a concern for a masculine identity and engaging in exciting or dangerous activities. This explanation can be seen in the findings on violence in bars indicating that certain types of aggressive people combined with certain types of permissive bars are the recipe for violence. College-age males view the bar environment as a place of sexual competition and rivalry as well as a place to display one's masculinity. It has been found that those with a history of substance dependence are more aggressive in laboratory measures of aggression than those who have no history of substance dependence. In addition, early onset of aggressive behavior in boys has been found to be predictive of later violence, criminal behavior, and alcohol use. In addition individuals with certain personality characteristics may be more likely to engage in aggression and use alcohol, for example those high on sensation seeking or impulsivity, or low on self-control or other aspects of executive cognitive functioning.

Alcohol may also be related to aggression because of the context of typical alcohol consumption. One of the most frequent locations in which individuals report experiencing violence is in or around bars. In one recent survey, over 40% of males and females who reported that they had experienced physical violence in the past year reported that the most severe incident had occurred in or around a bar. In a separate survey of young adults in the Albany, NY, area, young males who engaged in more nightlife activities were more likely to be targets of violence and to have experienced non-family-related violence. Nightlife activities are often permeated by a culture of masculinity. Drinking itself is used to promote one's masculinity with "real men" being able to hold their liquor and being able to have one up on others in the pub. An analysis of drinking occasions in Sydney, Australia, demonstrated that physical aggression while drinking was motivated by personal pleasure

and by a desire to present or create a masculine identity. In addition, much violence is also motivated by the carnival atmosphere at some drinking establishments. It both provides a show for the clientele and a pleasurable diversion for those who wish to engage in the behavior. Thus, the clientele, the bar environment, and the effects of alcohol all play roles in generating bar violence. When comparing bars in which violence was common with bars in which violence was infrequent, there were several differences related to both the clientele and to the bars themselves. Clientele at violent bars were more likely to report alcohol problems and more likely to score higher on individual differences in anger. Bars at which violence was more common were noisier, warmer, employed bouncers, disregarded illegal activity, and generally provided a more permissive atmosphere. The differences in clientele were also predictive of the bar characteristics, suggesting that certain types of people choose certain types of bars, which leads to violence in some places but not in others.

Those committing crimes may use alcohol and drugs in order to help them prepare themselves for the act. Ritual behaviors engaged in by street gangs, such as the induction of a new member or the expulsion of old members, often involved the use of alcohol and drugs as well as the commission of violent or criminal acts. Alcohol and drugs are used by Chicano gang members in Los Angeles to relax before engaging in acts of violence. To prepare themselves for conflict with other gangs, the members drank alcohol and smoked phencyclidine-laced cigarettes. Associating alcohol and drug use with going into a dangerous situation is not restricted to street gangs. Male college students generally associate heavy alcohol consumption with masculinity. According to some research, up to two-thirds view alcohol as a fuel for strength and aggression and believe that alcohol induces courage or invincibility in men.

It is clear that alcohol and drugs may be indirectly associated with the occurrence of aggression. However, the alcohol/aggression relationship cannot be totally explained by these types of mechanisms. They do not explain the laboratory research in which these variables are controlled and yet alcohol administration leads to higher levels of aggression. In order to more fully explain the relationship between alcohol and aggression, we must examine other mechanisms.

Expectancy Explanations

In general, alcohol expectancy explanations for the relationship between alcohol and aggression take three forms. The first is the deviance disavowal hypothesis. According to this perspective, periods of intoxication may be socially defined as a "time out" from usual social rules in which one can engage in behavior not normally sanctioned. The preponderance of the evidence suggests that alcohol use, at times, may lead one to be seen as less blameworthy, but overall it does not support the use of alcohol as an excuse for aggression. More often, alcohol use has the opposite effect and it increases attributions of blame to the drinking perpetrator. When evaluating the deviance disavowal hypothesis, it is important to recognize that attributions regarding blame are not simple and that one is not simply engaging in attributions for the behavior enacted while intoxicated, but for the act of intoxication itself. Although alcohol may have played a causal role in a person enacting the negative behavior, the person may be seen to be blameworthy for becoming intoxicated and ultimately to blame for the behavior while intoxicated. Consequently, it does not seem that individuals generally use intoxication as an excuse for engaging in antinormative behavior such as aggression.

The second expectancy explanation for the relationship between alcohol and aggression suggests that alcohol expectancies provide a guide or script as to how to behave when drinking. The belief that alcohol makes one aggressive has been found, somewhat inconsistently, to be correlated with measures of aggressive behavior. Individual differences in this expectancy have been found to be related to trait measures of aggression and to self-reports of aggressive behavior. They have also been predictive of reports of intimate partner violence. In laboratory studies, individual differences in alcohol expectancies have inconsistently been found to lead to more aggressive responding and alcohol placebos, which are meant to manipulate alcohol expectancies, rarely have an effect on aggressive responding (as cited above).

Currently, a newer interpretation of the alcohol expectancy concept has provided a third explanation based on a more cognitive model of expectancies combined with the General Aggression Model. Alcohol expectancies, rather than just being considered beliefs or attitudes, can also be conceptualized as a cognitive associative network in memory involving both explicit and implicit cognition and affect. Explicit measures such as self-report measures may underestimate the construct and, in addition, are susceptible to social desirability biases. In this model, the activation of certain expectancies subsequently activates other concepts, memories and scripts. Alcohol concepts are closely associated with aggression in some people but not in others. The expectancies activated in any given situation are dependent on cues in the environment as well as on the person's cultural background and learning history. For those with a close association between alcohol and aggression, an alcohol cue may be all that is needed to give rise to aggressive thoughts and scripts. The aggressive cue would likely also serve to orient the person toward the aggressive aspects of the situation, and once a cognitive

associative network related to aggression has been activated, it influences the processing of subsequent stimuli. Current research showing that subliminal alcohol-related cues give rise to the activation of aggressive thoughts and behaviors in individuals holding the expectancy that alcohol causes aggression fits with this model.

Pharmacological Explanations

Because alcohol can have many effects including making one relaxed, happy, or sleepy, there is no reason to assume it will automatically make one aggressive. As a consequence, the pharmacological explanations for alcohol's relationship with aggression have to do with how alcohol influences cognitive processes. The pharmacological explanations for alcohol's effects on aggression emphasize alcohol's influence on what cues are attended to in the environment. For example, when a mirror is placed in front of intoxicated individuals, they attend to self-relevant cues more than if the mirror had not been there. The question of why some cues are attended to and others are not has been discussed by numerous theories including alcohol myopia, anxiolytic effects of alcohol, and the social information processing theory.

The alcohol myopia theory posits that alcohol interferes with the processing of attentional information, causing one to attend to the most salient aspect of the situation. When both instigating and inhibiting responses are equally likely, intoxication causes an individual to attend to instigating cues more so than to inhibitory cues, a situation known as "inhibition conflict." In a meta-analysis of several different types of social behaviors including aggression, risk-taking, self-disclosure, and sexual interest, it was demonstrated that alcohol's effects on all of these social behaviors only occurred when situations of inhibition conflict existed. However, none of the studies explicitly examines manipulated inhibition conflict. The authors used a post hoc categorization of the studies to identify situations of inhibition conflict. Some primary research supportive of the myopia hypothesis has been reported. Additional research has shown that alcohol myopia effects predict numerous types of behavior including prosocial behavior, positive self-evaluations, as well as decisions about drinking and driving and condom use. More current studies using the TAP to explicitly study intoxicated aggression have shown that when intoxicated participants are distracted by another cognitive task, the relationship between intoxication and aggression is reduced, suggesting that when attention is diverted from aggression-facilitating cues, intoxicated individuals are less likely to respond aggressively.

However, alcohol myopia is not the only theory as to why alcohol makes one attend to facilitative cues and disregard inhibitory cues. The anxiolysis–disinhibition model proposes that in situations in which aggression has the potential to occur, anxiety is also present. This anxiety can be due to fear of retaliation for engaging in aggressive actions or fear of censure for aggressive actions. The anxiety arising from the situation may inhibit responses to it. Hence, in situations in which aggression is likely and alcohol is also present, those who have been drinking alcohol feel less anxiety than those who have not been drinking, and are therefore more likely to engage in aggressive behavior. A meta-analysis examining the myopia hypothesis versus the anxiolytic hypothesis found evidence supporting both mechanisms. In terms of alcohol myopia, a significant effect of alcohol on aggressive behavior was found in situations of high inhibition conflict (as rated by the researchers). A small but significant effect was also found in situations of low inhibition conflict. However, the effect of alcohol was stronger for high versus low inhibition conflict suggesting a significantly stronger effect under situations of high inhibition conflict. In addition, the influence of inhibition conflict depended on the dose of alcohol. When low dosages were used, a significant effect of alcohol on aggression was found in both low and high inhibition conditions. However, when high doses of alcohol were used, the effect of alcohol was present only under high conflict inhibition conditions. The low inhibition condition did not produce a significant effect. In support of the anxiolysis–disinhibition model, the difference between intoxicated and sober individuals in aggressive behavior increased as the amount of anxiety present in the studies increased. Although these results suggest that inhibition conflict and anxiolysis–disinhibition do play roles in the effect of alcohol on aggressive behavior, it is unclear if they are mutually exclusive hypotheses or really part of the same mechanism.

One other model has been used to explain the effects of alcohol on aggressive behavior. The social information processing perspective argues that aggressive actions are a product of several separate cognitive skills, including the encoding and interpretation of cues existing in the interpersonal situation, response generation, outcome evaluation, response selection, and response enactment. In one study, participants who consumed or did not consume alcohol were presented with a video tape showing one individual rudely changing the television channel on another person. Different versions of the video showed the individual behaving aggressively or in a more neutral manner. Participants were then asked to rate the individuals on several dimensions and then decide what would happen next. Results showed that alcohol did not have an effect on participants' perceptions of the situation. Intoxicated individuals did not view the offending individuals' action as any more intentional or aggressive than sober participants.

However, there was a difference between intoxicated and sober subjects in terms of decision making. Those who had consumed alcohol made less adaptive (i.e. more aggressive) response options and were more likely to endorse the use of aggressive options then were subjects who received a placebo.

The evidence that alcohol does have pharmacological effects on aggressive behavior is substantial. It is clear that alcohol influences the cognitive decision-making ability of individuals; however, the mechanism for that effect is still not well understood. Alcohol myopia, anxiolysis–disinhibition, and social information models all have some support in the literature. It is not yet clear which is the best explanation. It is possible all three may actually be aspects of a single mechanism. As mentioned earlier, alcohol myopia and anxiolysis–disinhibition are similar in the mechanisms they propose and in many hypotheses. The social information model is not necessarily at odds with either the myopia or the anxiolysis–disinhibition models. In addition, the current evidence for some people who hold expectancies about alcohol, the presence of alcohol-related cues in the absence of intoxication giving rise to aggression suggests that a more cognitive perspective integrating all these models may be the most complete explanation for the acute effects of alcohol on aggressive behavior.

Glossary

Aggression any behavior performed with the intent to harm another person.
Alcohol myopia the state of tunnel vision or the limiting of attention caused by intoxication.
Anxiolysis-disinhibition model the process by which inhibitions are reduced because intoxication reduces the anxiety associated with said inhibitions.
Anxiolytic a substance that pharmacologically reduces anxiety.
BAC blood alcohol concentration.
Deviance disavowal the concept that alcohol consumption provides a time out from normal social rules and allows one to avoid blame or punishment for antinormative behaviors.

CHAPTER

64

Alcohol and Sexual Violence

Kelly C. Davis, Debra Kaysen, Amanda K. Gilmore, Trevor J. Schraufnagel
University of Washington, Seattle, WA, USA

OUTLINE

OVERVIEW

Sexual violence involves sexual contact that occurs without a person's consent. Anyone – men and women, boys and girls of all ages and backgrounds – can become a victim of a sexual violence, which may be perpetrated by partners, family members, friends, acquaintances, or strangers. This chapter focuses on the role of alcohol in situations involving sexual violence. We detail the definitions of various forms of sexual violence, provide prevalence rates of sexual violence and its co-occurrence with alcohol consumption, review the types of research conducted regarding alcohol and sexual violence, describe the alcohol-related pathways to both perpetration and victimization, and discuss efforts to prevent alcohol-involved sexual violence.

Definitions

A variety of terms have been used to describe nonconsensual sexual behavior, including sexual assault, sexual violence, sexual aggression, sexual abuse, sexual coercion, attempted rape, and completed rape. The terms *sexual violence* and *sexual assault* refer to any type of sexual contact that is not freely consented to by one of the persons involved. Thus, both of these terms have a fairly broad definition that includes a wide scope of behaviors ranging from nonconsensual sexual kissing or touching to nonconsensual oral, anal, or vaginal sex, and these general terms are used interchangeably throughout this chapter. The term *rape* refers specifically to a completed nonconsensual sex act in which the perpetrator penetrates the victim's vagina, anus, or

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00064-4

mouth with a penis, hand, finger, or other object. *Child sexual abuse* incorporates any nonconsensual sexual contact of a minor or where there is sexual contact between a minor and someone older than them, regardless of whether consent was obtained.

Consent involves actual words or actions indicating freely given agreement to engage in sexual activity. If one's "agreement" is in any way pressured, coerced, or forced, the individual did not truly consent to the sexual activity. Additionally, one's ability to give consent may be compromised by a number of factors including drug or alcohol intoxication (voluntary or forced), age (being a minor), or physical or mental disability. For example, a person who has passed out due to alcohol intoxication is not capable of consenting to sexual activity; thus, any sexual activity that occurs with an individual who is unconscious due to alcohol intoxication is considered sexual assault. Although clear in this example, many instances of sexual violence involve lesser amounts of alcohol intoxication which can lead to uncertainty about the provision of consent. Unlike drunk driving, there is no established blood alcohol content (BAC) for assessing one's capability of providing sexual consent. Thus, distinguishing intoxicated sex from rape creates challenges within forensic, clinical, and research domains. Importantly though, the presence of alcohol in sexually violent situations should in no way be used to justify, excuse, or minimize the occurrence of sexual assault or its effects.

PREVALENCE OF SEXUAL VIOLENCE

Sexual violence is present across the globe in all social, economic, ethnic, racial, religious, and age groups. According to the 2006 National Violence against Women Survey (NVAWS), over 300 000 women and almost 93 000 men are raped in the United States each year, and one of every six women and one in 33 men in the United States has been raped at some time in her or his life. Studies estimate that up to 80% of women experience sexual assault, including unwanted verbal or physical coercion. More than half of female sexual assault victims experienced their first sexual assault while under the age of 18.

While both women and men can be perpetrators and victims of sexual assault, by far the most typical sexual assault scenario involves a female victim and a male perpetrator. For example, of the sexual assault victims in the 2006 National Crime Victimization Survey (NCVS), 89.3% were female compared with 10.7% male. Because of this consistent pattern of victimization, the preponderance of research on sexual aggression has examined male-on-female sexual assault. As such, the current understanding of other patterns of assault (i.e. female-on-male or same-sex sexual assaults) remains extremely limited, and future research into such incidents (alcohol-involved or otherwise) is needed. However, for this chapter we primarily reference sexual assaults involving a male perpetrator and a female victim as this is the modal – and most studied – form of sexual violence.

Research indicates that most sexual assaults are committed by someone known to the victim. The NCVS found that approximately 62% of the sexual assaults reported in 2006 were perpetrated by someone known to the victim, while 38% were perpetrated by strangers. Rapes committed by strangers occurred in only 16.7% of the female victim cases reported in the NVAWS.

Prevalence of Alcohol-Involved Sexual Violence

One contributing factor to sexual assault risk is alcohol. Event-level survey research has consistently found that a majority (55–74%) of acquaintance sexual assault incidents involves alcohol use by male perpetrators, female victims, or both. In toxicology analyses of blood and urine samples from female sexual assault victims who reported their crime to the police, 43% of the samples had ethanol present, and 12% had ethanol and at least one other drug. Sexual assaults that involve alcohol consumption can differ in important ways from those that occur when both the victim and the offender are sober. For example, completed rapes are more likely when both victim and offender have been drinking than when both are sober. Moreover, there may be differences between assaults where the victim could not consent because of her level of intoxication versus those where she was given alcohol intentionally to facilitate sexual assault.

RESEARCH ON ALCOHOL AND SEXUAL VIOLENCE

Research regarding the relationship between alcohol and sexual violence has employed a variety of methods for examining the characteristics of alcohol-involved sexual assault, as well as the distal and proximal factors that may predict alcohol-involved perpetration and victimization. Survey studies investigating global correlations and situational covariation consistently report a positive association between alcohol use and sexual violence. While these nonexperimental findings point to the possibility of a relationship between alcohol use and sexual violence, these data are primarily cross-sectional and correlational, thereby precluding the ability to establish a causal stream of events.

Experimental investigations of alcohol's influence on sexual violence corroborate the relationship between

alcohol consumption and sexual violence. Moreover, controlled laboratory conditions allow for establishing a causal connection between these variables. Using either written, audio, or video-based hypothetical sexual encounters, laboratory studies have consistently found that after alcohol is administered to participants, intoxicated men report greater sexually aggressive intentions toward a hypothetical female partner than their sober counterparts, while intoxicated women are less perceptive of sexual assault risk cues. The experimental method affords several advantages over other methods, including the ability to test causal relationships and theoretical mechanisms of causation, tight control of important variables (e.g. alcohol dose, expectancy set, BAC, and limb of the blood alcohol curve), and isolation of in-the-moment moderating and mediating variables.

Focus groups and individual interviews have also been utilized to gather qualitative information regarding the relationship between alcohol and sexual violence. When interviewed, sexually aggressive men often cite alcohol consumption as a causal factor in the occurrence of rape. Approximately two-thirds of the perpetrators in one study viewed high levels of alcohol intoxication as a causal factor in the assaults. Studies of female focus groups indicate that women believe that alcohol intoxication decreases their ability to perceive sexual assault risk accurately and to engage in effective protective strategies. Much like surveys, these methods do not enable investigators to determine if the relationship between alcohol consumption and sexual violence is a causal one. However, these methods do allow researchers to capture a rich portrait of real-world sexual violence events.

CHARACTERISTICS OF ALCOHOL-INVOLVED ASSAULTS

Research suggests that episodes of sexual aggression involving alcohol often possess different characteristics than sexual violence perpetrated in the absence of alcohol. Episodes of alcohol-involved sexual aggression may differ in terms of the relationship between the victim and perpetrator as well as the characteristics of the aggression itself (e.g. setting, perpetrator use of force, etc.). The post-assault experiences of the victim may also be related to whether alcohol was involved or not.

Victim and Perpetrator Relationship

Compared to sexual assaults without alcohol involvement, alcohol-involved sexual assaults are less likely to be perpetrated by a person well known to the victim, although not all studies support this assertion. In one study, female victims that were impaired or incapacitated during the assault were more likely to report that the perpetrator was an acquaintance and less likely to report that the perpetrator was a romantic partner. Other studies indicate that victim–perpetrator relationship may vary according to whether only the perpetrator was drinking, only the victim was drinking, or both were drinking. Thus, while alcohol does seem to be related to the degree of familiarity between perpetrator and victim, the available data suggest that additional insight may be gleaned by examining precisely who was consuming alcohol and what volume was consumed.

Setting

Unsurprisingly, sexual violence that co-occurs with alcohol use is likely to occur in social settings or in venues that serve alcohol such as bars and nightclubs. One study found that alcohol was involved in only 6% of sexual assaults that occurred in a victim's home, whereas alcohol was involved 29% of the time if the assault occurred at a party or at another person's home. Women in these settings may be at increased risk of sexual violence due to their own drinking or the perpetrator's drinking, greater exposure to an increased number of male perpetrators, and/or men in these situations may be more likely to misconstrue women's sexual intent.

Level of Force

Whether or not alcohol was consumed prior to a sexual assault appears to be associated with the amount of force used by a perpetrator, but the nature of this relationship is affected by factors such as who is drinking and how much alcohol has been consumed. Current research generally suggests that perpetrator drinking is associated with increased use of force and greater victim injury. However, often both the perpetrator and victim have been drinking, and research suggests that victim alcohol use may temper perpetrator use of force. Indeed, several studies indicate that sexual assaults in which only the perpetrator was drinking were more violent, resulted in more injury, and inspired more fear in the victim than episodes in which both parties had consumed alcohol. In sum, while research suggests that alcohol consumption and the use of force during sexual assaults are not independent of one another, the relationship is not simple and may be influenced by how much alcohol was consumed and by whom was it consumed.

Assault Disclosure and Response to Victimization

Research suggests that victims of alcohol-related sexual violence blame themselves more for the assault

and receive less favorable social responses to assault disclosure than do victims of assault in which alcohol was not involved. Both of these factors may decrease the likelihood that the assault is disclosed or may affect to whom the assault is disclosed. However, published research findings are mixed. One study reported that when compared to non-impaired victims, victims that were impaired or intoxicated prior to their assault reported more self-blame but did not receive more frequent negative responses from others. However, impaired and intoxicated victims were more likely to disclose to informal sources of support (e.g. friends and family members) but not to formal sources of support such as the police or treatment providers. Another study found that self-blame was increased if the victim had consumed alcohol beforehand and that self-blame was the lowest if the perpetrator only had been drinking. Further, perpetrator-only drinking was also associated with more frequent disclosure and more positive and helpful social responses compared to assaults in which both parties were drinking and compared to non-alcohol-involved assaults (although greater assault severity may also have contributed to these findings).

ALCOHOL-RELATED PATHWAYS TO PERPETRATION AND VICTIMIZATION

Investigations of alcohol-involved sexual assault have relied upon two frames for conceptualizing how alcohol might foster sexual assault perpetration and victimization. The "distal" frame focuses on explaining factors associated with the likelihood that someone would be in a drinking situation where there is the potential of perpetrating, or being victimized by, sexual assault. Survey research has effectively identified important alcohol-related factors in this frame, including drinking habits and alcohol expectancies. The "proximal" frame focuses on explaining – once the person is in the situation – how alcohol can lead to a sexually violent outcome. Factors assessed in the proximal frame include acute alcohol intoxication and in-the-moment processes and reactions that may facilitate sexual assault. Experimental research has established that intoxication-related cognitive impairment, reduced behavioral inhibition, and sexual arousal may function as important factors predictive of sexual assault perpetration, while reduced risk perception and physical incapacitation may facilitate alcohol-related sexual victimization.

Distal Factors

Sexual Assault Perpetration and Alcohol Use

Research indicates that men who perpetrate sexual aggression report higher levels of alcohol use than the general population. For example, college men who reported sexual assault perpetration are more likely than men who did not report perpetration to meet the diagnostic criteria for alcohol abuse or dependence. Additionally, incarcerated sexual offenders are more likely to report alcohol problems than are incarcerated nonsexual offenders. Sexual assault severity has also been related to alcohol consumption such that the more an individual tends to drink, the more severe his sexual assault perpetration. It is critical to note, however, that analysis of these associations at the global level does not address possible third variables, such as sensation seeking or psychopathology, which may underlie the relationship between alcohol use and sexual assault perpetration.

Sexual Victimization and Alcohol Use

Greater alcohol consumption, more negative consequences associated with drinking, higher endorsement of problem drinking, and higher rates of diagnoses of alcohol use disorders have all been associated with sexual victimization. In general, higher alcohol use and problems have been demonstrated in treatment seeking, college student, and community samples. The association between sexual victimization and higher alcohol use and problems has been documented for heterosexual, lesbian, and bisexual women, as well as with gay men.

The majority of the research conducted to date on victimization and drinking outcomes has been conducted cross-sectionally comparing sexual victimized to non-victimized women or comparing women based on the level of severity of the sexual assault. Causal relationships between drinking and sexual assault have not yet been disentangled, in part because of the relatively low number of prospective studies. Several longitudinal studies have found a relationship between sexual assault and risk of problematic drinking later in time, although findings are mixed. Adolescents with histories of child sexual abuse have been found to be at higher risk for substance use outcomes including more problematic drinking. However, longitudinal studies conducted with adult victims of sexual assault have had more mixed findings, with some studies finding sexual assault predicts future high-risk drinking and other studies failing to find this relationship.

More consistently, alcohol use has been found to increase risk of later victimization. In general, women who drink more are at increased risk for sexual victimization. Increased substance use has been found to mediate the relationship between child sexual abuse and college revictimization. Binge drinking (defined as consuming either four standard drinks (for women) or five standard drinks (for men) in 2 h or less) and heavier drinking both appear to increase risk of later

victimization. Moreover, novice drinkers who experience a heavy drinking episode appear to be at especially high risk for sexual victimization.

Drinking to Cope with Prior Victimization

As noted above, women with a sexual assault history (including women with a history of child sexual abuse or adult sexual assault) drink more than women with no sexual assault history. This difference in drinking habits appears to put these women at higher risk for sexual revictimization. For example, alcohol consumption mediates the relationship between sexual assault and revictimization such that sexual assault history increases risk for heavy alcohol consumption, which reciprocally increases risk for additional sexual assault. Increased alcohol consumption after a sexual assault or after child sexual abuse may be due to drinking as a means of coping with distress from the assault. Women with a history of child sexual abuse or adult sexual assault are more likely to endorse that they use alcohol to cope than women with no sexual assault history. Coping motives, or endorsing the use of alcohol to regulate negative emotions, were also found to mediate the relationship between child maltreatment and negative consequences of drinking in both male and female college students and in a separate study were found to mediate the relationship between child sexual abuse and alcohol problems in adult women. It was also found in this study that sexual revictimization was predicted by the number of maladaptive coping strategies used, including the use of drugs or alcohol to cope. However, little research has been devoted to examining the relationship between drinking motives and sexual assault history; therefore, it is difficult to make generalizations.

Alcohol Expectancies

An alcohol expectancy is defined as one's belief about how people (or oneself) will behave while under the influence of alcohol. Alcohol expectancy theory contends that alcohol consumption may influence behavior through individuals' expectations about alcohol's emotional, physiological, and behavioral effects, which are often influenced by overarching cultural beliefs regarding alcohol-related outcomes. Alcohol expectancy theory posits that alcohol consumption can result in an increased likelihood of sexual assault outcomes due to commonly held beliefs in our society that alcohol increases sexual arousal, sexual behavior, sexual enhancement, and sexual aggression. Thus, sexual behaviors, including those that are coercive or aggressive, are viewed as more normative when performed under the influence of alcohol and may in turn occur more frequently while intoxicated.

Regarding sexual assault victimization, alcohol expectancy theory stipulates that positive alcohol expectancies may lead to increased drinking, which may be predictive of a higher risk of experiencing sexual assault. Research has documented global differences in alcohol expectancies based on sexual assault history such that women with a sexual assault history endorse more positive beliefs about what alcohol will do as compared to women with no sexual assault history. Studies examining the relation between alcohol expectancies and sexual assault have used various measures to investigate alcohol expectancies and frequently vary in how they define "sexual assault" (e.g. using different assault severity ratings or comparing women based on the presence or absence of substance use prior to the assault). However, despite these differences, there have been consistent findings that women with a sexual assault history report greater expectations that alcohol improves relaxation, enhances sexuality, and increases sexual disinhibition compared to women without a sexual assault history.

Experimental balanced placebo designs have enabled investigators to disentangle alcohol expectancy effects from physiological effects by independently manipulating alcohol content and alcohol expectancy set (the belief that one has or has not consumed alcohol) through the use of placebos, in which a study participant is told that she is consuming an alcoholic beverage when, in fact, the beverage is nonalcoholic. One study found that women who expected to receive, but did not receive, alcohol and believed that alcohol enhances sexual behavior generated less effective resistance responses to an audio-taped portrayal of a sexual assault relative to control participants, while another study documented that women who expected alcohol rated a "risky" man more positively than controls but not as much as intoxicated women did. However, a third study found no effect of expectancy set on women's sexual assault risk appraisals. It appears that beliefs about alcohol's effects may be an important element in women's resistance; however, their role in predicting risk appraisals is less clear.

In terms of sexual assault perpetration, sexually aggressive men, especially those involved in alcohol-related assaults, report a greater belief in alcohol's enhancement of men and women's sexuality as compared to men without a history of sexual assault. Further, stronger alcohol expectancies regarding sex drive distinguish alcohol-involved perpetrators from both non-alcohol-involved perpetrators and non-perpetrators. Thus, beliefs that alcohol enhances sexual responding can increase men's sexual arousal and their perceptions of women's sexual arousal and may, through a form of self-fulfilling prophecy, result in increased sexual aggression likelihood.

This idea is supported by several alcohol administration studies that have assessed individually held alcohol

expectancies regarding sexual aggression before the administration of alcohol to determine whether the strength with which individuals hold such beliefs influences their responses. In one such study, men with stronger sex-related alcohol expectancies reported a greater likelihood of sexual aggression as mediated by greater sexual and affective responding to an eroticized rape depiction. Similarly, men with stronger beliefs about women's sexual vulnerability when drinking reported greater sexual arousal to an eroticized rape depiction, which in turn predicted greater estimates of their sexual aggression likelihood.

Although many experimental balanced placebo studies have found significant effects for expectancy set (i.e. placebo conditions) on dependent sexual aggression measures such as the amount of time to make a decision to stop unwanted sexual advances (i.e. decision latency), these effects are smaller than those for actual alcohol consumption. One study found that alcohol expectancy set had indirect effects on men's estimations of their sexual aggression likelihood. However, a similar number of studies have not found expectancy set effects for sexual aggression-related dependent measures. Thus, results regarding the influence of expectancy set manipulations on sexual aggression dependent measures are both inconsistent and relatively modest.

Alcohol expectancy theory contrasts with "deviance-disavowal," a theoretical conceptualization of alcohol's effects which suggests that alcohol consumption may contribute to deviant or anti-normative behavior by granting intoxicated individuals a respite from social norms, thus providing an excuse for formerly inexcusable behavior. The appeal of deviance-disavowal explanations for sexual aggression seems to be largely intuitive and not empirical, with one recent study finding that men who were intoxicated at the time of perpetration actually rated their offense as more serious and accepted more blame than did sober perpetrators – in direct contrast to what would be predicted within a deviance-disavowal framework.

Proximal Factors

Cognitive Impairment

According to alcohol myopia models, alcohol intoxication pharmacologically reduces cognitive processing ability, resulting in a narrowed attentional focus. The underlying notion is that as intoxication level increases a person becomes less able to process information in the environment. This cognitive impairment results in restricted focus on the most salient situational cues. Because sexual assault usually occurs after a man and a woman have been socializing, cues associated with having a good time or possibly developing a relationship may be more prominent than sexual assault cues. For men, this may mean that alcohol intoxication decreases their ability to process less salient verbal or physical resistance cues. For women, this may mean that alcohol intoxication decreases their ability to process sexual assault risk cues.

In reference to sexual assault risk appraisals, both experimental and survey research have found that alcohol intoxication decreases sexual assault risk perception; however, not all studies find support for this relationship. Most experimental and retrospective surveys of sexual assault victims have found that alcohol consumption decreases the ability to perceive risk cues, and one study showed that risk perception mediated the effect of alcohol on resistance. However, a qualitative analysis showed that intoxicated and sober women did not differ in their risk recognition. Therefore, the relationship between alcohol intoxication and sexual assault risk perception is not yet clearly understood.

Regarding perceptions of the victim's actual sexual interest and willingness, research indicates that alcohol increases men's likelihood of misperceiving their partner's true desires. Experimental investigations have shown that intoxicated participants tend to perceive ambiguous cues as indicative of sexual interest, more so than their nondrinking counterparts. A survey of 814 undergraduate men supported these findings: Men with higher overall alcohol consumption also reported a higher frequency of misinterpreting women's sexual intentions. Moreover, intoxicated men perceived female acquaintance rape victims as more sexually aroused and enjoying themselves more during the assault than sober men. One study found that when presented with a dating situation in which unwillingness cues were strong and clear, alcohol consumption did not influence men's ratings of acceptability of forced sex. However, when sexual interest cues were salient but unwillingness cues were not, men who consumed a moderate dose of alcohol (BAC 0.065%) rated forced sex as more acceptable than did controls. These findings support an alcohol myopia explanation in that intoxicated men had a greater focus on female sexual arousal rather than on less salient unwillingness cues.

Perpetrator Behavioral Disinhibition

Another pharmacologically based theory of alcohol's effects on aggression suggests that alcohol may directly (versus myopia theory's indirect-effect prediction) allow for aggression by increasing behavioral disinhibition. That is, alcohol intoxication may impair one's typical restraint of socially unacceptable or otherwise problematic impulses or behaviors – a supposition with recent support in the cognitive neuroscience literature. Two studies have compared a myopia model to a behavioral disinhibition model in the realm of alcohol and sexual assault; however, the first supported a myopia

perspective and the second supported disinhibition. Given the equivocal findings and that both of these studies have been criticized for their methodological limitations, further research is needed to evaluate the nature of alcohol's pharmacological effects on sexually aggressive behavior.

Perpetrator Sexual Arousal

Because both male perpetrators and female victims indicate that sexual assaults which occur in dating situations are typically preceded by consensual sexual activities, perpetrator sexual arousal may play a key role in predicting sexual assault likelihood, particularly among acquaintances. In support of this idea, one experiment manipulated men's level of sexual arousal and found that men in the high arousal condition reported a greater likelihood of engaging in acquaintance sexual aggression in a hypothetical situation than did men in the non-arousal condition. Notably, alcohol intoxication, or the expectancy thereof, can facilitate men's sexual arousal and thereby increase the likelihood of sexual aggression perpetration. In support of this, a laboratory study reported that when reading an eroticized rape depiction, intoxicated men reported greater sexual arousal than did sober men, which in turn increased their sexual aggression intentions.

Victim Resistance, Passivity, and Incapacitation

Survey studies have documented that women who were intoxicated at the time of a sexual assault generally report that they resisted the assault less assertively than did women who were sober at the time of the assault. Similarly, acute alcohol intoxication studies have found that, compared to sober women, intoxicated women report less resistance of hypothetical unwanted sexual advances. For example, several studies have found that intoxicated women were more likely to respond passively or politely compared to sober women. Other studies have found that women's sexual assault risk perception or other appraisals of the situation partially mediated the relationship between alcohol and resistance intentions. Thus, because assertive resistance can often thwart a sexual assault, intoxicated women may be more likely to experience a completed rape than sober women in that they are more likely to engage in generally ineffective forms of resistance. Moreover, heavily intoxicated women who are passed out or otherwise physically or mentally incapacitated are obviously unable to engage in sexual assault resistance of any type.

Synergy of Distal and Proximal Factors

Research suggests that sexual assault history and alcohol intoxication may synergistically increase the likelihood of sexual assault. In women, a history of childhood or adult sexual assault has been associated with adult revictimization. This may occur because previously victimized women do not perceive sexual threat cues or may not effectively resist new assaults. Childhood sexual abuse has been related to increased immobility and passivity in adolescent/adult sexual assaults, while prior adolescent/adult sexual assault has also been associated with heightened non-forceful resistance and lowered assertive resistance.

To the extent that alcohol intoxication impairs women's ability to assess risk accurately and resist effectively, it may interact synergistically with women's pre-existing tendencies regarding risk perception and resistance (which may themselves be associated with prior victimization). For example, in a study using latent profile analysis of women's actual experiences with sexual assault, women with the highest level of alcohol consumption during the assault and high levels of prior victimization felt more powerless, recognized that alcohol made them vulnerable and impeded their resistance, and engaged in low levels of resistance. Women who had consumed alcohol but were low in prior victimization reported that alcohol made them vulnerable, that alcohol was a barrier to their self-defense, and resisted through diplomatic tactics. These profiles show how alcohol intoxication and victimization history can both individually and concomitantly relate to specific types of risk appraisals and resistance responses.

For men, distorted cognitions, particularly in relation to the appraisal of women's sexual interest and willingness, have been theorized to act as key precursors to sexual aggression in that they allow sexually aggressive men to ignore a woman's refusal cues that would typically inhibit the continuation of sexual pursuit. Research has corroborated this notion that sexually aggressive men's cognitive appraisals differ from those of nonsexually aggressive men.

The cognitive impairment that results from alcohol intoxication may further exacerbate these cognitive distortions. That is, men with a proclivity toward sexual aggression may be most likely to commit assault when intoxicated. A laboratory experiment found that intoxicated sexually coercive men took significantly longer than sober sexually coercive men to determine when a man should stop unwanted sexual advances. Moreover, sexually aggressive men often cite alcohol's effects on their perceptions as a causal factor in the occurrence of rape. In interviews with self-disclosed date rapists, almost one-half commented that alcohol intoxication increased perceptions of their partner's sexual willingness. Alcohol expectancies may further moderate these proximal effects of intoxication.

SEQUELAE OF ALCOHOL-RELATED VICTIMIZATION

There is a large body of literature detailing negative long-term effects associated with sexual victimization, including increased rates of major depression (isolated or recurrent episodes of severely depressed mood lasting for at least two weeks), posttraumatic stress disorder (PTSD), suicidal behavior, substance use disorders, and risk of revictimization. However, only recently have researchers begun to examine whether there are differences in psychological effects between alcohol-involved versus non-alcohol-involved assaults.

Elevated risk of PTSD has been associated with both child sexual abuse and adult sexual victimization. PTSD involves a constellation of symptoms that develop after exposure to a life-threatening traumatic event and may include persistent re-experiencing of the traumatic event, avoidance of trauma-related stimuli, emotional numbing, and increased physiological arousal and reactivity. Completed rape is associated with one of the highest rates of PTSD across traumatic events. Studies conducted to date examining the relationship between alcohol-involved assault and PTSD yield contradictory results. Some studies have found lower rates of PTSD associated with alcohol use, whereas other studies have found no differences in PTSD rates between alcohol-involved assaults and other assaults. However, in these studies, PTSD has often been assessed retrospectively, making it impossible to examine alcohol's role in the development of PTSD symptoms. Based on the few prospective and longitudinal studies, alcohol may alter the trajectory of development of PTSD over time. Alcohol-involved assaults have been associated with lower initial PTSD symptom severity. This could be explained by alcohol's pharmacological effects on stress and on memory. Acute alcohol administration can dampen stress responses. Alcohol also has been shown to reduce acquisition of fear memories. For example, in a PTSD analog study, higher doses of alcohol were associated with fewer intrusive memories of a stressful film a week later than what was reported by participants who had not consumed alcohol or who had consumed low doses. These differences also may be due to the assault characteristics mentioned above that may differ between non-alcohol-involved assaults including degree of force during the assault, relationship with the perpetrator, and the extent to which the victim thought they would be injured or killed during the assault. Similarly, some studies have found no differences in rates of depression between alcohol-involved and non-alcohol-involved assaults, whereas other studies have found lower rates of depression in the alcohol-involved assaults. As this body of literature is still very small, it is too early to be able to determine the role of alcohol at the time of the assault on the long-term risk of depression. It is important to note that alcohol-involved assaults are still associated with PTSD and depression, even in those studies that have found higher rates of those disorders associated with forcible rapes.

There do appear to be more consistent differences between alcohol-involved and non-alcohol-involved assaults in substance use outcomes. Women who have experienced alcohol-involved assaults are at higher risk for later problems with alcohol use including higher consumption, higher rates of binge drinking, and higher rates of substance abuse. However, the majority of these studies have only looked at cross-sectional relationships. As alcohol use itself increases the risk of experiencing alcohol-related sexual assault, it may be that these findings predominantly reflect risk factors for alcohol-related assaults rather than reflecting consequences of experiencing an assault per se.

PREVENTION OF ALCOHOL-RELATED ASSAULTS

To date, the vast majority of rape prevention programs have been directed at women, as women are predominantly the victims of sexual victimization. Despite a large number of rape prevention programs, there is little research suggesting that these programs are effective in reducing sexual assaults. In general, these programs focus on changing attitudes, such as decreasing myths about rape, increasing women's self-efficacy, or increasing women's ability to use self-defense. They often include education about rape definitions and prevalence, relate information about sexually coercive behavior, discuss high-risk situations and how to increase safety while dating, and provide resources for victims. There is a lack of well-controlled randomized clinical trials to evaluate these programs, despite how widely they are implemented. The studies that have been conducted evaluating rape prevention programs for victims have generally failed to demonstrate changes in the rates of victimization or in those behaviors that are thought to increase risk of being assaulted. Interestingly, one of the few prevention programs to show an effect in decreasing victimization did not find that the prevention program worked for women who used alcohol, despite their overall elevated risk for victimization. Despite the link between alcohol use and increased risk of victimization, few prevention programs address alcohol use as a means of reducing risk of victimization, nor have studies examining prevention of high-risk drinking in college students

addressed whether these general prevention programs may work to reduce risk of victimization. Early findings from one study suggest that reducing binge drinking prior to entry into college may be a means by which to reduce victimization, especially during the most high-risk period for sexual assault. Although interventions regarding alcohol use are unlikely to address all types of sexual victimization, it is promising as a means to address alcohol-related sexual assaults.

While the preponderance of sexual assault prevention work is conducted with females and aims to reduce vulnerability to violence, research has also examined the effect of programs designed to enlist male participation in assault prevention. These studies largely show that the attitudes, knowledge, and empathy (which have been linked to violence perpetration) of men can be modified via various programs. Surprisingly, only one study has reported findings regarding alcohol-related aggressive behaviors and attitudes following an intervention. The program examined in this study (The Men's Program) included an increased emphasis on alcohol based on qualitative data from an earlier project. By bolstering men's self-concept as helpers having the potential to intervene, The Men's Program resulted in men reporting greater concern over sex while intoxicated as well as the role alcohol may play in comprising a woman's ability to consent to sexual activity. Moreover, these qualitative data also evidenced behavioral changes. For instance, participants noted intervening to prevent their friends from engaging in alcohol-related sexual activity. Men also reported abstaining from sexual activity if either they or a prospective partner were intoxicated.

SUMMARY

Sexual violence is a major public health risk. Because the majority of sexual assault incidents involve alcohol consumption by either the perpetrator, the victim, or both the perpetrator and victim, scientists have labored to understand the ways in which alcohol-related factors may influence the occurrence, phenomenology, severity, and sequelae of sexual assault. These empirical investigations have yielded important information about the alcohol-related pathways toward sexual violence. First, distal factors such as typical drinking habits and alcohol expectancies may increase the likelihood of a particular individual being in a drinking situation that involves an elevated risk of sexual violence. Second, proximal factors like alcohol-induced cognitive and physical impairment may influence one's actions before or during the event in ways that increase the potential for sexual violence. Phenomenological differences such as the prior relationship between victim and perpetrator and the degree of force used during an assaultive incident also tend to differ based on whether alcohol was involved. Additionally, the sequelae of alcohol-involved sexual assaults, such as PTSD symptom development and substance use outcomes, may differ in important ways from assaults that do not involve alcohol. As research continues to identify and parse the psychological and physiological mechanisms through which alcohol influences both the occurrence and consequences of sexual violence, programs addressing the prevention of perpetration and reduction of victimization will necessarily require continued modification and rigorous evaluation. Finally, although the results of extant research clearly indicate that alcohol is a risk factor for both sexual assault victimization and perpetration, alcohol consumption should neither diminish perpetrator accountability nor increase victim culpability. As with other crimes, while alcohol may facilitate sexual violence, it does not excuse it.

OUTLINE

Research has demonstrated that a vast majority of individuals in the United States report using alcohol in the last month. Moreover, roughly 75% of the alcohol consumed in the United States is in the form of heavy-episodic drinking (often referred to as binge drinking), which is typically defined as having at least four or five drinks on a single occasion during a specified time period for females and males, respectively. The proportion of current drinkers that engage in heavy-episodic drinking is highest among 18- to 20-year-olds, with roughly 90% of all alcohol consumed in the form of heavy-episodic drinking. In addition to young adults, research indicates that adolescents (ages 12–18) engage in alcohol use. In 2005, about 10.8 million persons ages 12–18 (28.2% of this age group) reported drinking alcohol in the past month and nearly 7.2 million (18.8%) were classified as heavy-episodic drinkers. Individuals, and adolescents and young adults in particular, experience a range of alcohol-related negative outcomes such as poor class and/or work attendance, damaging property, hangovers, trouble with authorities, injuries, unprotected sex, sexual assault, and death. Thus, research demonstrates that high-risk drinking is problematic in the United States, particularly among adolescents and young adults.

AT-RISK POPULATIONS

Adolescents and Young Adults

The Centers for Disease Control and Prevention (CDC) estimates that more than one million people are living with human immunodeficiency virus (HIV) in the United States. Of particular concern, it is also estimated that one in five (21%) of those people living with HIV is unaware of their infection. In addition to HIV, sexually transmitted infections (STIs) remain a major public health challenge

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00065-6

in the United States. It is estimated that there are approximately 19 million new STIs each year. Almost half of these new STIs are among young people 15–24 years of age. The number of HIV and acquired immune deficiency syndrome (AIDS) cases that occurred among this same age group accounted for approximately 14% of all HIV/AIDS cases in 2006. Thus, similar to high-risk alcohol use, research demonstrates that STIs and HIV are a public health concern in the United States, particularly among adolescents and young adults. These findings also highlight the importance of examining any hindrances to condom use, such as alcohol consumption, as condom use is a reliable method of STI and HIV prevention for individuals who choose to engage in penetrative sex (i.e. vaginal or anal sex).

Sexual Minority Populations

In addition to adolescents and young adults, men who have sex with men (MSM) are also a group at risk for heavy alcohol use and STIs/HIV. According to the latest surveillance data from the CDC, MSM account for an estimated 61% of all new HIV infections in the United States in 2009, despite representing approximately 2% of the adult male population. A recent study by the CDC demonstrated that 19% of gay and bisexual men in 21 cities were infected with HIV, with nearly half of those infected unaware of their serostatus. For this reason, attention to the association between substance use – including alcohol – and sexual risk-taking among sexual minorities has primarily been on HIV risk behaviors among MSM, with relatively few studies examining the role of alcohol in STIs other than HIV or on sexual minority women or transgender populations.

It is important to recognize that our understanding of the associations between alcohol use/misuse and STI/HIV acquisition among sexual minority populations is hampered by a number of factors. Fully explicating alcohol use patterns among sexual minority persons and their associations with STI acquisition is complicated by limitations in sampling and assessment. Perhaps most problematic may be that it is not possible to determine the sampling frame for sexual minorities, and therefore obtaining a truly nationally representative sample of lesbian, gay, bisexual, transgender, queer, or questioning (LGBTQ) is not feasible (although we recognize that the term "transgender" reflects gender orientation, for brevity we refer to the spectrum of LGBTQ individuals as "sexual minorities" throughout this chapter). Even when questions about sexual orientation or same-sex behavior are included in national surveys, respondents may underreport on these items for fear of being "outed." Problems in sampling these hidden populations are reflected in the overrepresentation of white and highly educated respondents in studies of LGBTQ individuals. With respect to assessment, it is widely recognized that sexual orientation is multidimensional and includes identity (e.g. gay, lesbian, bisexual, or heterosexual), behavior (i.e. same- or other-sex sexual contact regardless of identity), and attraction (the degree of sexual affection toward same and/or opposite sex persons). Researchers have not established standard terms and definitions for assessing these dimensions of sexual orientation, and oftentimes these and other terms to capture sexual orientation are used interchangeably. Difficulties in establishing common definitions for sexual orientation mirror the lack of standardized measures in the assessment of alcohol consumption and time frame.

Alcohol use and alcohol-related problems among LGBTQ persons cannot be attributed to sexual minority status by itself, but rather emerge from a complex array of historical and social factors that stigmatize and marginalize these communities. Foremost, it must be emphasized that, in spite of stigmatizing experiences faced by LGBTQ individuals, most persons who identify as a sexual minority or engage in same-sex sexual behavior do not drink heavily or experience alcohol-related problems. Estimates of heavy drinking among gay men range from 14 to 19%, compared to 8 to 11% among heterosexual men. Similarly, studies comparing alcohol use patterns between lesbian and heterosexual women show more frequent alcohol use and higher rates of drinking to intoxication among lesbian women. However, other studies using probability samples of MSM show similar rates of heavy or frequent drinking to the general population.

ASSESSMENT OF ALCOHOL'S ROLE IN SEXUAL RISK TAKING AND STIs

Alcohol use before and during sex is common (i.e. one-fourth to a half of people reported doing so during the most recent sexual encounter). Research by Patrick and Maggs found that in a 14-day period, 40% of college students who engaged in sexual behavior reported drinking before or during at least one sexual encounter. Although alcohol has a pharmacological effect of impairing sexual performance, a strong cultural and popular belief that drinking increases the likelihood and/or pleasure of sexual experiences persists. At the same time, research has shown that individuals tend to overestimate how much alcohol they can consume without experiencing negative consequences, including unwanted sex. In other words, it seems that there is a prevailing cultural belief that alcohol facilitates sex without increasing risk for negative sexual consequences. In fact, college students reported experiencing

more positive consequences (e.g. enhancing sexual arousal) of sex if they had sex after drinking. However, this may result from self-fulfilling prophesies regarding the role of alcohol in sexual behavior rather than a true effect of alcohol consumption itself. In addition, the *negative* consequences (e.g. STI contraction, pregnancy) are not immediately evident and therefore cannot be reported accurately in short-term self-report surveys.

The particular intersection of alcohol use with sexual behaviors is not yet clearly understood. Although we know that individuals who drink more alcohol also tend to engage in more sexual behavior, the causal direction is not clear. In terms of describing potential causal mechanisms, there are three possibilities. First, there may be a causal effect from alcohol to sex because of the disinhibitory effects of drinking. For example, alcohol myopia theory suggests that the disinhibitory effects of alcohol allow immediate goals and impulses to influence behavior more strongly than long-term goals. In that case, sexual arousal may be the most salient impulse and lead to sexual behavior, and perhaps riskier sexual behavior, when individuals are intoxicated. Second, there may be a causal effect from sex to alcohol. That is, people may drink alcohol based on the expectation that it will make sex more likely. When individuals hold expectancies that alcohol will facilitate sexual behavior or feelings (e.g. sexual drive, sexual affect), they may be more likely to drink for these effects. Third, the association between alcohol and sex may be a spurious relationship, or the result of a common third variable, such as sensation seeking or spending more time in a setting that provides opportunity to engage in both behaviors (such as bars). The notion that alcohol consumption results in sexual risk taking (e.g. sex without a condom) is still being researched. In addition to these explanations, alcohol consumption might increase the biologic susceptibility to an STI, if exposed, which may occur through adverse effects on the immune system or other direct biologic changes.

The strength of the association between alcohol with sexual risk taking and risk for STIs appear to vary by whether alcohol and sexual behavior are measured globally (i.e. alcohol consumption in an extended time frame), at the situation level (e.g. alcohol use in the context of sexual activity), or at the event level (i.e. alcohol consumption at a specific sexual encounter). For these reasons, clearly identifying the relationship between alcohol use and sexual risk taking is a challenge.

Global-Level Research

A commonly used method to study the relationship between alcohol and sexual risk taking is global-level research. In most global-level research studies, participants report information about the quantity and frequency of their alcohol use over some extended period of time (e.g. past 3 months). Additionally, participants provide information about the number of times they engaged in specific sexual risk and protective behaviors during the same extended time period. These two pieces of information for alcohol and sexual behavior are then correlated to determine the strength of relationship between alcohol use and sexual risk-taking variables. Overall, a vast majority of global-level studies show that participants who use alcohol, and particularly those who use alcohol heavily, are more likely to report sexual risk-taking behaviors. For example, a national survey of college students found that heavy-episodic drinkers were nearly three times as likely to report having multiple sexual partners in the last month than were non-heavy-episodic drinkers. The same relationship also appears to hold for adolescents, ages 12–17, such that reporting engaging in heavy-episodic drinking has been linked with risky sexual behavior.

Another line of global association research looking more specifically at the relationship between alcohol use and STIs has found that problem drinking is associated with treatment for STIs and history of past infections. In particular, previous research indicates that young adults who report substance abuse are at greater risk for STIs. Based on a 2005 national survey of young adults ages 18–25, 3.9% who used both alcohol and illicit drugs and 3.1% who were heavy drinkers had an STI in the past year compared to 1.3% of those who did not use alcohol or illicit drugs. A meta-analysis found alcohol use increased the likelihood of incident HIV infection such that heavy-episodic drinkers had more than double the risk for acquiring HIV.

Arguably, when examining the relationship between alcohol use and STI/HIV, the most consistent finding is that heavy alcohol use is associated with HIV infection and unprotected anal intercourse (UAI), the sexual behavior most likely to transmit HIV and other STIs. Although the association between drug use and UAI has been clearly demonstrated, the degree to which alcohol use in low or moderate amounts is associated with increased risk taking or infection is less clear.

As noted earlier, studies of the association between alcohol consumption and sexual risk behavior or STI acquisition that focus on non-MSM sexual minority groups are relatively sparse. In one of the few studies of alcohol use and STI rates among lesbian women, Lindley and her colleagues found that women who self-identified as bisexual (9.1%) were more likely to report an STI in the past year than women who were unsure of their sexual orientation (6.3%), heterosexual (5.8%) or lesbian (2.3%). Slightly more women who identified as heterosexual (55.8%) or bisexual (55.5%) reported engaging in heavy-episodic drinking the last

time they "partied" than women who were unsure of their sexual orientation (49.8%) or were lesbian (48.3%). Although high rates of HIV (12–28% depending on method of assessing HIV status) have been found among male-to-female transgender groups, little is known about the contribution of alcohol use to sexual risk behavior and STI acquisition among this population. There is a demonstrable need for greater attention on the contribution of alcohol use to sexual risk behavior and STI acquisition among non-MSM sexual minorities.

These findings highlight the potential role that alcohol use plays in regard to STI/HIV risk for several high-risk populations. The results of these different lines of global association studies support the notion that alcohol and risky sexual behavior are linked. However, these types of global association studies do not provide information about the mechanisms that might link alcohol consumption and sexual risk beavior.

Event-Level Research

To address the limitations of global-level research, event-level methodologies have been developed to more adequately study the causal link between alcohol use and sexual behavior. Event-level studies can capture the dynamics and context of one or more particular sexual episodes rather than assessing general alcohol and sexual risk behavior patterns across a given time period. The primary advantage of event-level research is that detailed information is gathered regarding specific sexual events during which alcohol was consumed. This detailed information often includes, but is not limited to, whether a condom was used, amount of alcohol consumed at each event, as well as other factors (e.g. relationship status) that may exert influence on the relationship between alcohol use and sexual risk-behavior.

Event-level studies generally show that alcohol intoxication is associated with greater sexual risktaking depending on the outcome being evaluated. Overall, event-level studies yield inconsistent results when examining alcohol and condom use, with some studies finding that alcohol use leads to increased likelihood of using condoms, whereas others have found null or inverse results. A meta-analysis of event-level studies concluded that alcohol use is not necessarily associated with condom nonuse. Rather, other factors, such as the context, relationship between the participant and the sexual partner, and experience of the sexual partners are more influential. Morrison and colleagues found that of participants who reported sexual activity with and without prior drinking, 37% used condoms similarly whether drinking or not, 29% used condoms less frequently when drinking, and 34% used condoms more frequently when drinking. These idiosyncratic differences underscore the likely importance of mediating and moderating factors, such as alcohol expectancies, sensation seeking, relationship status, and gender, on the alcohol–condom use relationship.

Research has shown that the association between alcohol use and sexual protection behaviors is moderated by the nature of the relationship between sexual partners. Whether the partners have just met, are acquaintances, are occasional partners, or are in a committed relationship influences the decisions to have sex and to use a condom. A series of studies have examined the differential impact of relationship status, with a majority finding that more drinking before sex is more likely with casual partners, although more condom use is also more likely with casual partners.

In addition to partner relationship status, gender may be an important moderator of the event-level relationship between alcohol consumption and condom use, with men more likely to report condom use than women. This may be in part because different standards and social norms apply to men and women regarding condom use. Research indicates that men report less embarrassment when purchasing condoms, and women may receive (or at least perceive) negative evaluations for providing or carrying condoms. Moreover, because men ultimately have the decision of whether or not to wear a condom, women are at a disadvantage for successfully negotiating condom use. In event-level studies, findings are inconsistent regarding the role of gender as a moderator of the alcohol and condom use relationship. Some studies indicate a stronger relationship among women, others among men, and some report no gender differences.

Event-level studies on MSM populations show that MSM who have more than four alcoholic drinks prior to or during sexual activity are more likely to engage in risky sexual activity than those who consume fewer drinks. In contrast, event-level studies in which only the presence of alcohol before sexual activity was assessed have typically found little or no association with UAI. In sum, heavy alcohol use, but not consumption in lower amounts, may contribute to sexual risk taking and possible STI transmission among MSM.

INFLUENCES ON ALCOHOL AND SEXUAL RISK TAKING

Individual-Level Influences

A key to preventing alcohol use and related negative consequences in any population is gaining a better understanding of why individuals initiate and continue to engage in those behaviors. Individual-level influences include a range of genetic and biological factors, sociodemgraphic (e.g. age, gender, race, and ethnicity), and

alcohol use expectancies factors. Alcohol outcome expectancies vary across persons as a function of their learning histories and drinking experiences. Alcohol outcome expectancies also vary within person across time; as one has different experiences with or makes changes to their drinking over time, her or his alcohol outcome expectances may change.

Social Influences

Several commonly acknowledged social influences on the association between alcohol use and sexual behavior include the role of peers, family environment, modeling, and perceived social norms. These influences are thought to begin early in life and change across the life course. During adolescence, the role of peers becomes increasingly important as teenagers spend more time together, develop more intimate relationships, and begin experimenting in romantic relationships. In addition, the time between adolescence and young adulthood (sometimes referred to as emerging adulthood taking place between 18 and 25 years of age) is characterized as a period of exploration. Substance use peaks in the early twenties, and the majority of young adults (62% of males and 70% of females) are sexually active before age 18.

Influences Specific to Sexual Minority Populations

Although results vary across studies, research on patterns of alcohol consumption and problematic alcohol use suggests that rates of both alcohol use frequency and alcohol-related problems among LGBTQ communities may be higher than their heterosexual counterparts as a function of multiple interfacing influences. Although studies of alcohol use patterns in the general population overall show that alcohol consumption decreases with age, studies of lesbian and gay men show smaller declines in alcohol use and alcohol-related problems as they age. Gay men and lesbian women who hold expectancies that alcohol will reduce tension are more likely to drink alcohol, become intoxicated more frequently, and report alcohol-related problems than those who do not. However, by themselves, individual-level factors account for only a small proportion of the variance in alcohol use patterns and must be considered along with other factors.

Specific to the LGBTQ experience, "coming out" (i.e. disclosing one's LGBTQ identity) to family and peers as a member of a stigmatized group may be psychologically distressing, particularly when members of one's social network hold negative views toward sexual minorities. Although the association between psychological distress and increased alcohol use and problems remains tenuous, a study by McKirnan and Peterson found that nearly one quarter (22%) of gay men reported using alcohol at least half of the time to cope with personal stress. Because bars and drinking establishments traditionally have been one of the few places where LGBTQ individuals could socialize, peer norms around alcohol acceptance and use were widely adopted within these communities. Partner factors affecting alcohol use and consumption include relationship satisfaction and distress. The absence of institutional and family support for nonheterosexual partnerships may be associated with relationship disruption within LGBTQ partnerships, which has been shown to be associated with drinking-related problems. Although the association between intimate partner violence and alcohol consumption in LGBTQ communities is still unclear, some studies suggest that alcohol and other substance use often precedes violent events.

Social roles and expectations for lesbian women and gay men are significantly different than for heterosexual women and men. Most notably, fewer LGBTQ-identified persons have children than their heterosexual counterparts and until recently being legally married was not an option for most sexual minorities; both having children and being in a legally recognized marriage appear to be protective factors against alcohol-related problems. Particularly for lesbian women, having employment outside the home and employment in male dominated occupations are associated with more alcohol consumption. Both gay men and lesbian women who experience workplace discrimination and harassment are more likely to experience psychological distress and use alcohol as a coping strategy. Well-documented environmental influences on alcohol use patterns of LGBTQ communities include targeted marketing and advertisements toward these groups and unequal access to quality or LGBTQ-supportive health care. Although attitudes toward homosexuality have become more positive within recent years, studies show that there continue to be some health care providers who would deny health care to LGBTQ individuals based on their sexual minority status and/or hold strong negative opinions about nonheterosexual persons. Even subtle forms of disapproval may be associated with LGBTQ persons struggling with alcohol-related problems to avoid seeking appropriate treatment from a health professional.

PREVENTION AND INTERVENTION

Adolescents and Young Adults

Group, individual, computer- and web-delivered interventions have been found to be efficacious in reducing drinking among several populations. The

most successful brief interventions for adolescent, young adult, and college student alcohol use involve personalized feedback, which incorporates information about one's own drinking patterns in comparison to those of their peers, accurate norms of others' drinking, risk factors for dependence, and negative consequences related to use. Among alcohol programs, these motivational enhancement approaches have reported some of the largest effect sizes. Group, individual, computer-, and web-delivered interventions have also been found to be efficacious in reducing risky sexual behavior. In noncollege samples, the majority of efficacious interventions for risky sexual behavior are delivered in groups and/or in multiple sessions. Despite encouraging results, group and multi-session interventions are more expensive and difficult to implement than web-based interventions. In addition, group and multi-session interventions have limited reach, which supports the need for additional research using efficacious web-based interventions targeting high risk sexual behavior.

Fewer programs have incorporated intervention materials for both alcohol use and sexual behavior simultaneously, although this is an active area of research. Ingersoll and colleagues evaluated an in-person personalized feedback intervention to reduce alcohol-related pregnancy risks among college women, which consisted of personalized feedback for drinking and contraception. At 1 month, women who received the intervention were less likely to engage in heavy drinking, more likely to use effective contraception, and at lower risk for alcohol-related pregnancy. Risk reduction was associated with reductions in the number of drinks per drinking day. Kalichman and colleagues evaluated the efficacy of a single-session group HIV-alcohol risk-reduction intervention among men and women in South Africa. At the 3-month follow-up, findings indicated intervention effects were moderated by alcohol use, such that lighter drinkers demonstrated greater gains from the intervention in comparison to heavier drinkers. Even for effective interventions for risky sexual behavior, intoxication may decrease intervention efficacy. Thus, alcohol interventions shown to reduce drinking may hold particular promise in reducing sexual risk taking.

Sexual Minority Populations

LGBTQ-specific alcohol prevention and intervention services are relatively few despite the recognition that persons in these communities may face additional barriers to reducing or abstaining from alcohol, such as coming out, managing their sexual orientation and gender identity, family and societal stigma and discrimination, coping with health issues that disproportionately affect these communities (e.g. HIV/AIDS), and other comorbid disorders. An approach to assessing alcohol use and alcohol-related problems is to incorporate questions of sexual minority status and behavior into routine medical and psychological screening. Unique considerations when assessing the role of alcohol among LGBTQ patients and clients include their personal experiences during the coming out process, their level of acceptance and comfort with their sexual minority status, social support networks, their relationship to their family of origin, relationship history, past and current sexual behavior, previous treatment experiences, and level of participation in the bar scene.

Alcohol-related treatment models for LGBTQ communities parallel to those of traditional treatment models, with emphases on the disease model of addiction and LGBTQ-specific education and therapy programs. Providing safe spaces to explore the possible association between alcohol use and sexual minority status appears crucial to addressing the needs of LGBTQ clients, which may require the establishment of exclusively LGBTQ treatment programs. In addition, improving the quality of care in programs designed to meet the needs of sexual minorities should include developing LGBTQ-specific outreach programs, sexual minority staff trainings to educate addiction specialists about the unique needs of these communities, and allowances for including partners and families in the treatment process. In addition to these recommendations, it is clear that a greater understanding of the role and impact of alcohol treatment programs tailored for sexual minorities is needed and should be addressed as a future research priority. For example, Velasquez and colleagues found that a tailored individual counseling and peer group intervention focusing on both alcohol use and risky sexual behavior reduced drinking and frequency of alcohol-related risky sexual among MSM.

SUMMARY

The current literature demonstrates the complexity of examining the association between alcohol, sexual risk taking, and HIV/STIs. Numerous variables such as personality traits and characteristics of the sexual partner and context relate to alcohol use and sexual behavior. There is a need for additional event-level research to determine whether alcohol consumption precedes risky sexual behavior and the acquisition of STIs. In addition, event-level research can continue to shed light on which situational variables moderate the alcohol and condom use relationship. Regardless of whether alcohol consumption is a causal risk factor for sexual risk taking and STIs or if alcohol consumption is indirectly related to sexual risk taking and STIs, the literature suggests that individuals who consume

heavier levels of alcohol are at higher risk. Thus, efforts toward developing efficacious interventions aimed to reduce alcohol may be helpful in reducing this risk. Additional randomized controlled trials are needed to definitively demonstrate the causal link between alcohol consumption, sexual risk taking, and HIV/STIs.

OUTLINE

DEFINING ALCOHOL USE DISORDERS

Alcohol use has a long tradition in human society, having been used in religious and cultural ceremonies for millennia. Apart from caffeine, alcohol is the most widely used drug in the Western world and is typically associated with celebration, relaxation, and socializing. However, while the majority of people consume alcohol at levels that pose minimal risk to themselves or others, alcohol use can lead to adverse social, personal, and health outcomes, both as a result of acute intoxication and in the long term as a result of chronic use. According to the *Diagnostic and statistical manual of mental disorders 4th edition* (DSM-IV), two patterns of alcohol use are of particular concern: alcohol abuse and alcohol dependence.

Alcohol abuse refers to a recurrent pattern of alcohol use that results in significant impairment in at least one domain of a person's life (e.g. failure to meet commitments at work, relationship problems, legal problems, or financial problems). In addition, a person who abuses alcohol may use alcohol in dangerous situations that place either themselves or others at risk (e.g. driving while intoxicated).

Alcohol dependence refers to a markedly maladaptive pattern of alcohol use. A person who is dependent on alcohol may have difficulty controlling their drinking, feel urges to drink, and continue to consume alcohol despite experiencing adverse consequences (e.g. relationship breakup, losing a job, poor health). In addition, tolerance and withdrawal are defining features of alcohol dependence. Tolerance refers to needing to drink more

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00066-8

alcohol to reach the desired effect. Withdrawal refers to symptoms that appear within several hours to up to 3 days after ceasing to drink. Alcohol withdrawal occurs in several stages. The first signs of withdrawal (including sweating, anxiety, insomnia) may appear within 24 h of ceasing to consume alcohol. Hallucinations and seizures may be present between 1 and 3 days after drinking, while delirium tremens may appear in the later stages of withdrawal. However, it is important to note that the symptoms experienced, their severity, and timing of onset may vary according to the severity of alcohol dependence.

Researchers, clinicians, and policy makers are increasingly expressing concern about binge drinking, particularly among young people. Binge drinking is associated with elevated levels of violence, hospital admissions for alcohol poisoning, traffic accidents, memory loss, and unsafe sexual practices. Unfortunately, there is little consensus on how to define binge drinking. Some define binge drinking as drinking with the primary intention to get drunk, or continual drinking over hours or days. Others attempt to quantify binge drinking as the consumption of five or more drinks within a single drinking session.

In an effort to minimize the health risks associated with alcohol consumption, government agencies have developed guidelines to help educate the public about what constitutes risky drinking. In Australia, the National Health and Medical Research Council recommends that men and women consume no more than two standard drinks each day and encourages several alcohol-free days each week, in order to prevent long-term harm. To prevent acute health risks and injury, it is recommended that men and women consume no more than four standard drinks on a single occasion. In the United Kingdom, the National Health Service advises men to drink fewer than 3–4 units and women to drink fewer than 2–3 units on any given day. In the United States, the National Institute on Alcohol Abuse and Alcoholism recommends up to two drinks per day for men and one drink per day for women and older people. Similar guidelines have been developed throughout the European Union. However, the definition of a standard drink differs across countries. In Australia, a standard drink contains 10 g of ethanol. In the United Kingdom, a single unit of alcohol is approximately 8 g of ethanol, while in the United States, one drink is 14 g of alcohol. Thus, knowledge of the volume of a standard drink as well as the national guidelines is required in order to minimize risky drinking.

PREVALENCE OF ALCOHOL USE DISORDERS

Although rates of alcohol use vary around the world, the World Health Organization estimates that, worldwide, approximately 76.3 million people can be diagnosed with alcohol use disorders. Alcohol abuse is more common than alcohol dependence, and both are more common among males; approximately 5% of the global population may be diagnosed with alcohol dependence at any one time. However, in some countries adolescent girls are drinking at higher rates than their male counterparts, suggesting this gender gap may close in future years.

In most Western countries, alcohol use commonly begins in adolescence. In Australia, 20% of young people aged 14–19 years consume alcohol at least once a week. Rates of abstinence fall sharply between the age brackets 12–15 years and 16–17 years, suggesting the majority of young people begin drinking regularly at about 15 years of age. As early onset of drinking is associated with greater risk of alcohol use disorders later in life, there is a growing concern about the high level of drinking in this age group.

HARMS ASSOCIATED WITH ALCOHOL USE

Alcohol use is responsible for over 2.3 million deaths worldwide, with alcohol-related injuries accounting for one-third of the global burden of disease. Intoxication and alcohol use disorders result in considerable harm as a result of accidents and injuries and have particularly negative consequences in terms of physical and psychological health, as well as social and financial costs.

Accident and Injury

Alcohol plays a major role in road accidents, falls, violence toward others, and self-inflicted violence. In many parts of the world, alcohol is the primary factor implicated in unintended and unwanted sexual intercourse, vandalism, property damage, and accidental death. Accidents and injuries may result from alcohol's effects on coordination, reaction time, and visual focus. However, people who are intoxicated are also more likely to be impulsive, place themselves in high-risk situations, be less averse to taking risks, and have poor judgment and decision making. Together, these physical and cognitive effects of alcohol place intoxicated individuals at significantly increased risk of harm. Importantly, harm resulting from intoxication is rarely limited to the intoxicated individual. The effects on the victims (e.g. other motorists in a car accident, victims of property damage) increase the overall burden of alcohol-related accidents and injuries.

Alcohol use plays a significant role in completed suicide, suicide attempts, and self-harm behavior.

Alcohol abuse among young people who inflict self-harm increases their risk of suicide. The link between alcohol use and self-harm is not clear; however, it has been proposed that alcohol use exacerbates negative affect and minimizes inhibition, which together increase the risk of both fatal and nonfatal self-harm.

Health Effects

Alcohol affects every organ in the body. Chronic alcohol use can have wide-ranging health effects. Alcohol has been linked to a variety of cancers including esophageal cancer, liver cancer, and cancers of the pharynx, larynx, and mouth. There is growing evidence that alcohol use increases the risk of breast cancer in women. As the liver is primarily responsible for the metabolism of alcohol, liver disease, including liver cirrhosis, is a common outcome of alcohol use disorders.

Poor nutrition is common among individuals dependent on alcohol, as essential nutrients usually gained from food are replaced with nutrient-poor, but calorie-rich, alcohol. One nutrient that is often deficient in people with alcohol use disorders is thiamine. Thiamine deficiency may be responsible for many adverse effects including fatigue, mental confusion, and lack of appetite. Poor nutrition may also be partially implicated in alcoholic myopathy. Alcoholic myopathy involves the breakdown of skeletal muscle tissues, leading to tissue loss and pain among people dependent on alcohol.

Alcohol use also has a significant effect on cardiovascular functioning. Hypertension, cardiac arrhythmia, and cardiomyopathy are all associated with increased alcohol consumption. Heavy drinking also increases the risk of hemorrhagic strokes for both men and women.

Drinking alcohol while pregnant places the fetus at significant risk of a number of alcohol-related cognitive and neurological impairments. Fetal alcohol spectrum disorders range from relatively mild cognitive impairment to fetal alcohol syndrome and are 100% preventable. The exact prevalence of fetal alcohol syndrome is difficult to ascertain but is thought to occur in approximately 1% of live births.

Psychological Effects

Alcohol use disorders have been associated with many mental health disorders, and comorbidity is generally considered to be the expectation rather than the exception in those dependent on alcohol. The direction of these relationships is often difficult to ascertain, as mental health issues are known to precede alcohol use, while alcohol use disorders can also result in mental health problems. Arguably the strongest evidence for alcohol use preceding a mental disorder exists for depression. Significant comorbidity between depression and alcohol use disorders exists; however, recent studies suggest that depressive symptoms are alleviated with abstinence, suggesting that at least for some people, alcohol use disorders may increase the risk of depression. There is mixed support regarding a relationship between anxiety disorders and alcohol use disorders. Social anxiety appears to precede alcohol use disorders, with some individuals consuming alcohol for its anxiolytic properties. Withdrawal from alcohol causes anxiety; however, this appears to be a relatively short-term effect.

In addition to causing health problems, lack of thiamine is an underlying cause of Wernicke–Korsakoff syndrome. In Western countries, alcohol use disorders are the primary cause of Wernicke–Korsakoff syndrome, which is characterized by severe memory problems, including both retrograde and anterograde amnesia and confabulation. Wernicke–Korsakoff syndrome is relatively rare, affecting between 1 and 2% of the population.

Consumption of alcohol also disrupts sleep patterns. While intoxication can reduce sleep onset, it can disrupt sleep during the later part of the night. With chronic use of alcohol, the sedative effects appear to diminish, while disruption to the later sleep phases increases. Increased wakefulness and restlessness is related to daytime sleepiness. Withdrawal from alcohol also disrupts sleep patterns, most notably through a rebound of rapid eye movement (REM) sleep. These disruptions to sleep have long-lasting effects, even among individuals who remain abstinent from alcohol after treatment.

Financial Costs

The economic impact of alcohol use disorders is substantial, with the burden on society estimated between 0.45 and 5.44% of gross domestic product. Throughout the European Union, health care costs exceed €22 billion each year. Similarly crime costs (€33 billion), lost productivity (€23 billion), and costs associated with alcohol-related traffic accidents (€10 billion) confer significant economic burden on society. The social costs are also significant and have been estimated to be €270 billion in the European Union, US$185 billion in the United States, and CAN$14.6 billion in Canada.

THEORIES OF ALCOHOL USE DISORDERS

Numerous theories have been proposed to explain the initiation and maintenance of alcohol use as well as the development of alcohol use disorders.

Pharmacology of Alcohol Use

The pharmacology of alcohol use relates to the way in which alcohol acts on the body and the way in which the body responds. The essential premise of a pharmacological view of alcohol use disorders is that people use alcohol because it is inherently reinforcing. Although most people dislike the taste of alcohol initially, social and pharmacological reinforcement encourage continued use of alcohol. From a pharmacological viewpoint, most drugs of abuse, either directly or indirectly, act on dopamine receptors in the pleasure center of the brain. In the case of alcohol, this results in activation of the ventral tegmental area, which produces a release of dopamine in the nucleus accumbens. The release of dopamine in the nucleus accumbens leads to feelings of euphoria and pleasure. Although not as potent as other drugs of abuse, alcohol has an indirect effect on both dopamine and opiate systems. Increased firing of dopamine neurons in the ventral tegmental area is associated with alcohol-induced euphoria. The role of the opiate system is less clear; however, it seems that alcohol use may facilitate the release of natural endorphins, and opioid receptor blockers such as naltrexone reduce the craving for alcohol. However, the primary effect of alcohol is to increase the inhibitory action of γ-aminobutyric acid (GABA), resulting in anxiolytic and sedative effects.

The Role of Genetics in Alcohol Use Disorders

Genetic theories argue that some people are biologically predisposed to alcohol use disorders. The focus is on identifying specific genes, or patterns of genes, that may explain alcohol dependence. The search for a specific gene related to alcohol dependence comes from genetic association studies. Recent studies, in both animals and humans, suggest that the presence of specific dopamine receptors is related to alcohol use disorders.

Genetic Association Studies

Genetic association studies attempt to find a link between a single gene (or group of genes) and a disorder. Researchers attempt to find relationships between individual traits, at least one of which is known to be genetic.

The most consistent genetic association results concern enzymes involved in the metabolism of alcohol. The metabolism of alcohol occurs in several stages. Alcohol is absorbed from the stomach and metabolized by the liver. Here, the enzyme alcohol dehydrogenase (ADH) converts alcohol to acetaldehyde. Acetaldehyde is then converted to acetic acid by the enzyme, aldehyde dehydrogenase (ALDH). Finally, acetic acid is then converted to carbon dioxide and water.

Since the 1970s, researchers have suspected that social drinkers and those dependent on alcohol metabolize alcohol differently and that those who are dependent on alcohol have a genetic fault in the metabolic process. It has been observed that some ethnic groups tend to exhibit an increased flushing response to alcohol. These groups possess an inactive form of the ALDH2 gene (ALDH2*2). Thus, alcohol is metabolized more slowly, resulting in a buildup of ethanol. Those with the inactive form of ALDH2 are thought to be more resistant to dependence due to the aversive flushing reaction that results from the accumulation of acetaldehyde.

Studies have shown a higher frequency of the ALDH2*2 gene in control groups relative to alcohol-dependent samples and that those with the ALDH2*2 gene drink less. These studies have primarily focused on Asian populations, who have a higher frequency of the ALDH2*2 gene. However, it is difficult to separate race effects. ALDH2*2 is not found in Caucasian populations, so this cannot solely explain resistance to alcohol dependence.

Dopamine Receptors

Recently, researchers have investigated genetic differences in dopamine receptors, particularly D2 and D4 receptors. As noted previously, most drugs of abuse, including alcohol, have a direct or indirect effect on dopamine. Thus, differences in dopamine receptors may partially explain susceptibility to alcohol use disorders. The A1 allele of the D2 receptor gene has consistently been associated with alcohol use. This allele is associated with a decrease in postsynaptic dopamine receptors, reducing postsynaptic binding of dopamine. It is theorized that people with this deficiency use or abuse alcohol to compensate and inflate dopamine activation. D2 receptor dysfunction is also associated with a bias toward placing excessive salience on alcohol-related stimuli. As such, alcohol-related cues elicit craving and alcohol-seeking behavior. Similarly DRD2 is associated with a lower self-efficacy for refusing alcohol.

D4 receptors have also been related to alcohol use, but the effects are not as strong or consistent as those noted for D2. Early research suggested that the DRD4 variable numbers of tandem repeat (DRD4 VNTR) polymorphism was associated with urges and craving for alcohol. While some studies have shown a relationship between DRD4 receptor variation and alcohol dependence, other studies have failed to find a relationship. It may be that the effect of DRD4 receptor variation is not a direct one but works in conjunction with other genetic influences, such as those associated with the metabolism of alcohol.

Gene–Environment Interactions

Although the work mentioned above is progressing the search for a genetic factor underlying alcohol use disorders, the role of environmental factors is also important. Family, twin, and adoption studies highlight the complex interplay between genes and environment in the development of alcohol use disorders.

Family Studies

Numerous studies have been conducted to examine the rate of alcohol dependence in children of those who are alcohol dependent. In these studies, the risk of alcohol use disorders in children is three to four times higher if a first-degree relative is dependent on alcohol. These finding are more consistent for males than females. However, alcohol dependence is more prevalent in males, and many studies include only male samples. In addition, although a familial link might suggest a genetic component, family studies cannot rule out other contributing factors such as a shared environment and learned behavior. Thus, familial links are thought to be a combination of genetic and environmental effects.

Twin Studies

Twin studies aim to address the concern that familial links in alcohol dependence may be the effect of a shared environment. If alcohol dependence has a genetic component, then it is more likely that monozygotic (MZ, identical) twins will both develop alcohol use disorders than dizygotic (DZ, fraternal) twins. Overall, twin studies do reveal that the concordance of alcohol dependence is higher in MZ twins than DZ twins, suggesting a role for genetics in alcohol dependence. On average, these studies suggest that between 40 and 60% of variance in drinking can be explained by genetic influences. However, there are several limitations to twin studies that must be considered in assessing the findings, including the assumption that the environment of each twin pair is the same.

In summary, twin studies support the role of both genetic and environmental influences on alcohol dependence.

Adoption Studies

Adoption studies aim to address the criticism that family and twin studies often cannot rule out environmental factors. In adoption studies, children of alcohol-dependent parents who were adopted by nondependent couples are examined. While the children share part of their genetic makeup with a parent who is dependent on alcohol, their environment is not influenced by substance use. These studies have generally found a higher rate of alcohol dependence among children of dependent parents. These rates are again higher for male offspring; however, some support also exists for female offspring.

Behavioral Theories

According to behaviorist theories, alcohol use is viewed as a learned behavior, governed by a set of rules. There are two primary approaches within the behaviorist paradigm: operant conditioning and classical conditioning.

Operant Conditioning

According to operant principles, behavior is learned by associating the consequences of behavior. In other words, if something good happens as a result of engaging in a behavior (reinforcement), we are likely to engage in that behavior again. However, if something bad happens (punishment), we are less likely to engage in that behavior again. Two kinds of reinforcement may increase the likelihood of a behavioral response. Positive reinforcement involves delivering a positive consequence. For example, an individual may gain peer respect by drinking heavily at a party. Negative reinforcement involves the removal of an unpleasant stimulus. For example, the anxiolytic effects of alcohol are a strong negative reinforcer. Both positive and negative reinforcement increase the likelihood of the behavior occurring again.

Operant conditioning has been shown to effectively explain the initiation of substance use. Approval from peers, pharmacological reinforcement, and reduction in aversive moods (e.g. stress) encourage use, and continued use, of alcohol. Further, few people who experiment with alcohol experience punishment as a result of alcohol use (e.g. they are not arrested, do not lose a job, do not suffer negative physical reactions). This combination of reinforcement and a lack of punishment explain why people begin to use alcohol and why they continue to experiment with alcohol. However, one artifact of alcohol use is that these initial effects diminish with repeated use. While alcohol initially results in relaxation, it is likely to increase anxiety over time. As such, an individual can feel the need to drink more to reduce their increased anxiety. Thus, a cycle develops in which a person needs to drink more and more to deal with the anxiety that is actually caused by alcohol.

Classical Conditioning

The classical conditioning, or Pavlovian, approach suggests that people learn behavior by associating previously unrelated events or stimuli. Craving can be a conditioned response to any cue that has been repeatedly paired with alcohol use. In the presence of these

conditioned cues, individuals begin to expect administration of the drug. In the case of alcohol, the body increases the production of the enzymes required to metabolize alcohol; thus alcohol is metabolized more quickly. Consequently an individual needs to consume more alcohol to achieve the desired effect. In other words, tolerance to alcohol can be the result of classical conditioning. If the drug is not administered in the presence of conditioned cues, the body begins to react to the absence of the drug, resulting in withdrawal.

Cognitive Theories

Cognitive theorists argue that behavior cannot be sufficiently explained by stimulus–response relationships proposed by behaviorism. Specifically, our thoughts are believed to mediate the relationship between stimulus and response. Negative or dysfunctional thoughts are the key elements that predict behaviors such as alcohol use. According to Beck's model, either internal (e.g. feeling stressed) or external (e.g. a fight with a friend) events activate the core beliefs that a person holds (e.g. I am unlovable) or beliefs about the effects of a drug (e.g. alcohol helps me relax). These beliefs in turn activate automatic thoughts. Automatic thoughts are fleeting thoughts that everyone has but of which we are often unaware (e.g. a drink will help me relax). These automatic thoughts lead to cravings or urges to use alcohol. This urge to drink leads the individual to construct permissive beliefs (e.g. just one drink won't hurt). Once permission is granted, the person can focus on obtaining alcohol, which then leads to continued use or relapse. This use or relapse can itself become an activating stimulus or lead to modification of other activating stimuli (e.g. change internal mood or external environment).

Social Cognitive Theory

Social cognitive theory (SCT) serves to integrate behavioral and cognitive explanations for human behavior. Central to SCT is the notion that humans do not passively respond to past or current environmental influences but possess the ability to foresee the consequences of our actions. The cognitive outcome expectancies we form allow us to appraise potential consequences of engaging in any given behavior, and thus determine which behaviors we will engage in. Actions we expect will result in positive outcomes are readily adopted, while those that we believe will result in negative outcomes are avoided. This forethought allows us to predict events, set goals, and play an active role in achieving such goals. According to Bandura, self-efficacy is the key factor underlying the human agency central to SCT. Intention to act and a desired outcome are not sufficient to enact behavior; rather individuals must possess self-regulatory mechanisms that allow them to exert control over their behavior. Specifically, regardless of what other factors may affect behavior, unless someone believes they have the ability to perform a behavior or change their circumstances, they will not attempt to do so.

When examining the role of self-efficacy in drinking, researchers have most often studied the role of an individual's belief in their ability to resist drinking (refusal self-efficacy). Refusal self-efficacy is an important predictor of drinking and intention to drink alcohol in children and adolescents. Longitudinal designs have been used to predict teenagers' alcohol and drug use from cognitive and social variables, including refusal self-efficacy. Regardless of whether the participants had experience with alcohol use, refusal self-efficacy was predictive of alcohol use 9 months later. Research by Hasking and Oei has confirmed that in addition to demonstrated salience in clinical and adolescent samples, drinking refusal self-efficacy can discriminate problem and nonproblem drinkers and high- and low-risk drinkers in community samples.

Expectancy Theory

Grounded in SCT, expectancy theory explores the role of anticipated consequences of drinking in the initiation and maintenance of alcohol consumption. Theoretically, individuals who expect positive consequences (positive expectancies) to arise from drinking should consume more, while those who expect negative consequences (negative expectancies) should drink less. The relationship between positive expectancies and drinking behavior has consistently been found in a variety of samples, including adolescents, university students, social drinkers, and dependent drinkers. Jones and McMahon have found negative expectancies to differentiate lone and group drinkers, discriminate satisfaction with current drinking patterns in social drinkers, and predict abstinence and relapse in problem drinkers. Expectations of aggression, risk, affect change, and impaired control have all been related to drinking behavior in social and dependent drinkers.

The Role of Coping in SCT

In the absence of more adaptive coping strategies, a reliance on alcohol to cope predicts drinking behavior. Drinking to cope has been found to be a primary coping strategy predicting alcohol consumption in university students, while a longitudinal study found that drinking to cope was predictive of long-term alcohol consumption and drinking problems in a community sample. Drinking to cope with negative affect has also been

shown to predict DSM-IV alcohol use disorders in a sample of people who did not meet criteria for alcohol abuse at the commencement of the study. More generally, maladaptive or avoidant coping strategies have been related to increased alcohol consumption.

Marlatt and Gordon proposed that after a period of abstinence, being in a high-risk situation without an effective coping strategy results in an individual having a low self-efficacy for their ability to cope with the high-risk situation. Given that an individual has positive outcome expectancies concerning alcohol, this lack of self-efficacy heightens the chance that the individual will engage in drinking. This initial lapse leads to the abstinence violation effect, where individuals question their ability to abstain from alcohol. This process is likely to result in a full relapse to drinking. Hence, Marlatt and Gordon explained how outcome expectancies, self-efficacy, and coping interact to predict relapse of alcohol use disorders.

Hasking and Oei propose that just as coping, outcome expectancies, and self-efficacy are thought to work in concert to determine relapse behavior, they also work in conjunction to govern the decision to drink and the volume of alcohol consumed once this decision has been made. Individual processes such as beliefs about the outcome of drinking, beliefs in the ability to refuse a drink, and coping strategies can explain much of the individual variation in drinking patterns. More importantly, these three constructs have the potential to explain both social and dependent drinking behavior, although the relationships between these variables differ according to drinking patterns.

Intergenerational Transfer

The observation that alcohol use disorders tend to run in families and that cognitions such as outcome expectancies and self-efficacy are the salient predictors of drinking has led Campbell and Oei to propose a cognitive model explaining intergenerational transfer of alcohol use behavior. Campbell and Oei propose that parental behavior (i.e. drinking) influences the formation of the beliefs that their offspring hold about alcohol, which in turn predict alcohol use in the offspring. In addition, the beliefs a parent holds about drinking also influence the cognitions of the child. By observing the drinking behavior of a parent, the child forms expectancies regarding the effects of alcohol consumption. These beliefs, as outlined above, are directly related to the frequency and quantity of alcohol consumption. As such, parents and their offspring share common cognitions regarding alcohol use, and ultimately share similar drinking patterns. This model draws together the findings garnered from family studies as well as those from SCT and provides an explanation for why alcohol use disorders tend to be more common among offspring of parents with alcohol use disorders.

TREATMENTS FOR ALCOHOL USE DISORDERS

The above discussion clearly shows that both genetics and environments are involved in the development, maintenance, and recovery of alcohol use disorders. Alcohol use disorders, in particular alcohol dependence, are complex, chronic, and relapsing disorders. Thus, many treatment approaches ranging from Alcoholics Anonymous(AA) and psychosocial psychotherapy to pharmacotherapy have been developed and implemented. This section discusses the major treatment approaches to alcohol use disorders, in particular alcohol dependence.

Pharmacological Treatment

Many pharmacological agents for the treatment of alcohol abuse and dependence have been identified and tried. They range from baclofen, a GABA-B receptor agonist, to anticonvulsants and mood-stabilizing agents, to disulfiram, acamprosate, and naltrexone. While the list is long, only four such drugs are approved by the Food and Drug Administration (FDA) of the United States of America and many other countries for clinical use in the treatment of alcohol abuse and dependence. These four drugs are acamprosate, disulfiram, oral naltrexone, and ingestible and extended-release naltrexone. The efficacy of these drugs is presented here. Prescription data in the United States indicate that about 1–13% of people suffering from alcohol use disorders received approved pharmacotherapy treatment.

Acamprosate received approval for clinical use by the FDA in 2004. Since then, there have been many randomized controlled trials (RCT) published. A recent review noted that the results of a meta-analysis of 20 RCTs in the United States showed that alcohol-dependent patients receiving 1–3 g of acamprosate had stopped drinking at 6 months follow-up significantly more often than patients who received placebo. However, approximately 36% of patients receiving acamprosate achieved continuous abstinence compared with 24% who received placebo. Thus, the majority (64%) of the patients who had received acamprosate did not stop drinking at all. Other clinical trials completed in Europe show no significant differences in the abstinence rate between patients receiving 2 g (56%) to 3 g (60%) of acamprosate and placebo (54%). A recent systematic review of 24 RCTs found that acamprosate significantly

reduced the risk of drinking compared with placebo, although the effects were modest.

Similarly, patients who received 250 mg of disulfiram drank less frequently than patients who received placebo. There were no significant differences between the disulfiram and placebo groups on the measures of abstinence or time of first drink after treatment. One major point worth noting is that there was a very high noncompliance rate in patients with disulfiram. The rate of nonadherence can be as high as 80%. Another study showed that the nonadherence rate can be improved with the addition of supportive family members in supervision of medication intake. When used in conjunction with family support, disulfiram has been noted to be as efficacious as other pharmacotherapies, at least in the short term.

Oral naltrexone has been used clinically for more than a decade. A clinical dose of 100 mg per day of oral naltrexone could reduce the risk of heavy drinking and also increase the number of days abstinent compared with placebo. However, the effect is modest and not long lasting. In addition, there are numerous side effects of oral naltrexone, including vomiting, diarrhea, and somnolence. Injectable extended-release naltrexone was approved for clinical use to increase the bioavailability of naltrexone and enhance the efficacy of the drug. The literature shows that intramuscular injection of 380 mg of naltrexone had no effect on the number of heavy drinking days but had a modest effect on time to first drink compared with placebo (5 days vs 3 days for the placebo). An advantage of injectable over oral naltrexone is that patients with injectable naltrexone reported minimal side effects. Data from the naltrexone RCTs are somewhat inconsistent, with several large studies finding no significant improvement. However, the majority of studies do report positive treatment outcomes, especially when naltrexone is combined with cognitive behavioral therapy (CBT). A systematic review of 27 RCTs concluded that naltrexone may reduce the risk of drinking in the short term, but evidence was weaker for medium-term and long-term outcomes.

The literature demonstrates that the efficacy of these drugs is generally positive, although the effects are modest. Although disulfiram, acamprosate, and naltrexone are the only FDA-approved drugs for the treatment of alcohol use disorders, other drugs have shown efficacy in treating alcohol use disorders. One of the more promising drugs to emerge is topiramate, an anticonvulsant. A critical review of 26 studies reporting on the use of topiramate to treat a range of substance use problems (12 studies related to alcohol dependence) concluded that topiramate shows efficacy in reducing heavy drinking days, relative to placebo and oral naltrexone. However, only a few RCTs have been conducted, and therefore the research into the efficacy of topiramate continues.

Psychosocial Psychotherapy Treatments

Over the years, a large number of individual psychotherapeutic approaches, ranging from aversive therapy and counseling to CBT, have been used for the treatment of alcohol use disorders. While most individual psychotherapy approaches can claim to have some positive impact on the outcome measures in patients with alcohol use disorders, good solid RCTs confirming positive and sustained long-term treatment outcomes are hard to find. In a large-scale and well-designed multisite RCT, PROJECT MATCH directly compared the efficacy of AA, motivational enhancement therapy (MET), and CBT for the treatment of alcohol-dependent patients. The findings showed that the three therapies had equally significant and sustained improvements in drinking outcomes and that matching specific characteristics of patients to a particular treatment did not improve the drinking outcome.

Similarly many group psychotherapies are commonly used. These can range from self-help delivered by nonprofessionally trained therapists such as AA groups, to manually driven well-structured group CBT, and couples therapy delivered by highly trained professional therapists. Again, group psychotherapeutic approaches, in particular AA, show a high degree of efficacy in drinking outcome, but there is no clear evidence to show that group therapies achieve better drinking outcomes than individual therapies.

Integration of Psychotherapy with Pharmacotherapy

While there is modest evidence to show that pharmacotherapy and psychotherapy alone can have positive outcomes, the literature suggests that combining pharmacology and psychotherapy treatments can produce better treatment outcomes than either pharmacotherapy or psychotherapy alone. The evidence is clearer in showing that the addition of psychotherapy to pharmacotherapy can increase the compliance rate of medication usage and thus can have a positive effect on the treatment outcomes. A recently published RCT demonstrated the efficacy of medical management, with the use of naltrexone and/or behavioral intervention, with the best clinical results observed for the combination of medical management and naltrexone with or without the addition of behavioral intervention. The efficacy of medical management with pharmacotherapy opens the way to general practitioners assisting in the treatment of alcohol dependence.

CONCLUSIONS

There is a consensus that alcohol use disorders are complex, chronic, and relapsing disorders with psychosocial, environmental, and genetic factors contributing to the complexity. However, there is still no consensus on a unifying theory to guide treatment approaches that can provide a sustained and long-term treatment outcome. At present there are too many theories but very little empirical evidence to confirm the validity of such theories. Similarly, there are many treatment approaches, but there is a lack of evidence to show a superior treatment approach that can deliver consistent and sustained treatment outcomes. Thus, improvement and refinement in both theories and treatment are needed. The complex interactions of the psychosocial, environmental, and genetic factors involved in the development and maintenance of alcohol use disorders need further specification, and empirical evidence confirming the validity of theories must be provided. Further empirical evidence for the integration of pharmacotherapy and psychotherapy is needed. It is clear that over the years there has been significant progress in our understanding and treatment of alcohol use disorders. It is also clear that further progress can be made in the future.

Heroin Addiction

Andriy V. Samokhvalov[*,**], *Jürgen Rehm*[*,**,$,†]

[*]Centre for Addiction and Mental Health (CAMH), Toronto, ON, Canada [**]University of Toronto, ON, Canada [$]Institut für Klinische Psychologie und Psychotherapie, TU Dresden, Germany [†]Dalla Lana School of Public Health, Toronto, ON, Canada

OUTLINE

PREVALENCE OF HEROIN ADDICTION

Heroin addiction is a major health problem worldwide. According to the data of European Monitoring Centre for Drugs and Drug Addiction 657 t of heroin were produced globally with only 75 t (13%) seized worldwide. Two major forms of heroin historically were manufactured and are offered worldwide nowadays – base form or brown heroin, produced almost exclusively in Afghanistan, and its salt or white heroin, manufactured in Southeast Asia. Heroin purity varies from country to country and correlates significantly with its price and origin, with mean purity of brown heroin in EU being between 15 and 30% and purity of white heroin between 30 and 50%. In USA and Canada heroin purity has significantly increased in the past decade ranging between 40 and 90% in cases of especially expensive shipments.

The most recent and comprehensive systematic review of the data on the prevalence of use and dependence of illicit drugs worldwide was published in 2011 as part of the Comparative Risk Assessment within the Global Burden of Disease Study, and found evidence of opioid use or dependence for 192 out of 229 countries and territories, comprising more than 99% of the world population aged 15–64 years. Past year/point prevalence estimates of opioid dependence ranged from smallest values of around 0.1 per 1000 population in several countries such as Cyprus (0.11), Czech Republic (0.14), India (0.10), and Finland (0.12) to extremely high

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00067-X

values of Iran (8.8) with majority of estimates fluctuating between 0.26 and 1.00 (most European countries). It must be noted that these estimates include, but are not limited to heroin dependence, as many data are based on legal or treatment data.

It has been shown that opioid use has significant impact on social and vocational functioning of the users in high-income countries – patients who cited opioids as their primary drugs when entering treatment have higher rates of unemployment, lower levels of educational attainment and higher levels of psychiatric disorders than those who cited other primary drugs. Almost all opioid users reported initiation of use before the age of 30 and approximately half of them before the age of 20. Estimated time lag between first use of opioids and first contact with drug treatment is approximately 10 years.

PHARMACOLOGICAL AND CLINICAL ASPECTS OF HEROIN ADDICTION

Heroin (morphine diacetate, 3,6-diacetylmorphine) is a semisynthetic opioid produced by acetylation of morphine, natural alkaloid of opium poppies *(Papaver somniferum*). First, it was synthesized by English chemist C.R. Alder Wright in 1874 in London though at that time the substance did not receive any attention. It was independently resynthesized 23 years later by the chemist working for Bayer pharmaceutical company (Aktiengesellschaft Farbenfabriken then), Felix Hoffmann, while trying to synthesize codeine (3-methylmorphine). During the experiment morphine was acetylated that resulted in accidental production of morphine diacetate, which was approximately twice as potent as morphine itself.

Since morphine addiction was a major health care concern at that time and little was known about addictive properties of morphine diacetate, Bayer started its mass production marketing it as nonaddictive and potent morphine substitute under the trade name "Heroin" due to its perceived "heroic" effects on its users. For a little bit more than decade heroin was an over-the-counter medication. Some attempts were made to use it as a treatment for morphine addiction until it was discovered that it is being rapidly deacetylated to monoacetylmorphine and morphine.

After discovery of addictive properties of Heroin its manufacturing and administration was heavily regulated and banned in almost every Western country. Nevertheless, due to simplicity of morphine acetylation it has been efficiently manufactured in illegal laboratories all over the world. It must be noted that heroin is still legally used medically in selected countries.

Pharmacokinetics

Heroin is a prodrug – it is readily deacetylated in human body to 3- and 6-monacetylmorphine and then – to morphine with pharmacokinetic parameters varying to a great extent depending on the route of administration of the drug. The most common route of administration of heroin is intravenous injection that allows for 100% bioavailability of the drug and extremely rapid onset of its action. Due to the presence of acetyl groups diacetylmorphine is more fat soluble than morphine and penetrates blood–brain barrier faster and then is deacetylated to morphine thus ensuring the fastest delivery of morphine to the brain. If administered orally, diacetylmorphine has significantly lower bioavailability and undergoes first-pass metabolism – deacetylation to morphine in the liver. Morphine then, being less fat-soluble substance, penetrates blood–brain barrier slower than heroin would thus resulting in slower delivery of morphine to the brain than in case of intravenous injection. Heroin can also be smoked, insufflated, and in rare cases, used in the form of vaginal or rectal suppositoria.

Pharmacodynamics

Diacetylmorphine and one of its metabolites 3-acetylmorphine have no significant pharmacological effects that are attributable mainly to its fully deacetylated metabolite morphine and to certain extent – to 6-monoacetylmorphine. Both substances have high affinity to and are full agonists of opioid receptors. There are three major kinds of opioid receptors (μ, δ, κ). All three of them are responsible for analgesia, whereas each individual type has several other effects as described below:

μ-opioid receptors were the first receptors identified due to their ability to respond to morphine (μ stands for morphine). In addition to analgesia when activated these receptors cause euphoria – effect sought by heroin recreational users. Also they are responsible for constriction of pupils or miosis, which is one of the hallmarks of opioid intoxication. Two other major effects of μ-opioid receptors activation are constipation (very common in heroin addicts) and respiratory depression (major health risk).

κ-opioid receptors were named after a chemical named ketocyclazocine that binds to them. They also contribute to analgesia, miosis, and sedation, but at the same time they antagonize μ-opioid receptors in respect of mood changes – they cause dysphoria. Though morphine and 6-acetylmorphine bind to both kinds of receptors, effects mediated by μ-opioid receptors predominate resulting in overall euphoric reaction to the drug.

δ-opioid receptors were first identified in murine vas deferens tissues (δ stands for vas deferens). Though they

contribute to analgesia and have certain effects on mood, their role in heroin addiction is minor.

Overall, major effects of heroin are attributable to its active metabolites, morphine, and 6-monoacetylmorphine, and its addictive properties are mediated mostly via μ-opioid receptor agonism.

Heroin Intoxication

Heroin users experience similar symptoms of intoxication every time heroin is being injected, ingested or snorted with some variations depending on the route of administration and heroin experience. The most prominent signs and subjectively perceived symptoms of heroin intoxication are euphoria, relaxation and slight derealization – real stimuli lose their acuity and become numb. These symptoms are most prominent in heroin-naïve users, whereas experienced users tend to need higher doses of heroin in order to achieve the same level of euphoria with repetitive uses as tolerance to heroin builds up very quickly, especially in respect for desirable effects. Historically heroin was used for its analgesic properties, but nowadays it is prescribed for pain control only in selected countries and mostly as a palliative treatment. It doesn't seem likely that someone would start using street heroin for pain management because of its high street value, health risks associated with injection, social and legal risks, tolerance to analgesic effects of heroin and availability of other, cheaper, safer, and legally acceptable options

In addition to the main effects – euphoria and analgesia – heroin use elicits several other symptoms that create a very typical picture of heroin intoxication. They include dryness of mouth and miosis, or pupillary constriction, often described as "pinpoint" pupils of heroin addicts; inhibition of respiratory center leads to lower respiratory rate; decreased gastrointestinal tract motility leads to chronic constipation.

It must be noted that the picture of heroin use varies depending on the route of administration. Intravenous injection is preferred by many users due to pharmacokinetics of intravenous heroin administration described above – rapid onset of action and prominent peak of euphoria in the first moments that together to histamine-mediated vasodilation is described by heroin addicts as heroin flushes. When ingested heroin's effects are not that acute and there is no wave or flush of euphoria. Also due to lower oral bioavailability higher doses are needed in order to achieve similar effect that makes oral heroin use more expensive. Altogether these features of oral heroin use make it less likely to be administered this way. At the same time insufflation, smoking, and rectal suppositoria allow heroin to circumvent its first-pass metabolism in liver and thus are close in perceived effects to intravenous use. Nevertheless, intravenous heroin injection still remains the major route of its administration and is a cause of major adverse effects associated with heroin use.

Individual-Level Harm and Socioeconomic Burden Associated with Heroin Use

Primary set of adverse effects is related to heroin use itself and includes development of withdrawal symptoms after short periods of not using the drug, creation of tolerance and associated risks of overdose and death as well as a number of direct effects of heroin as an opioid agonist as described above in heroin intoxication section.

Besides direct effects of heroin use, it is also associated with a number of risks related to intravenous injections i.e. risk of acquisition of HIV, hepatitis C or any other blood-borne infections. Injections are also associated with a high risk of infection with host's own skin flora such as *Staphylococcus aureus* that is a cause of infectious endocarditis – a hallmark of injection drug use. Another microorganism, *Streptococcus pyogenes*, often causes formation of purulent lesions, abscesses. Chronic injections of heroin lead to deterioration and gradual sclerosis of superficial veins normally used for injections and experienced heroin addicts often have to use veins of lower limbs or groin in order to continue injections. It also complicates the access to the veins for health care professionals, which is extremely important in emergency room settings.

Another common adversity is associated with pharmacologically neutral substances such as talc that are being used for cutting heroin powder. These substances may and often lead to chronic inflammation of blood vessels, vasculitis, that in turn significantly changes the physiological properties of blood vessels and propagates development of atherosclerosis, thrombi formation and thromboembolism, narrowing of the blood vessels section and their increased resistance, etc. Talc and other substances are known for being a cause for pulmonary emboli in heroin use.

The third category of heroin-attributable harm is related to the sequelae of its manufacturing, trafficking, and distribution as well as to the socioeconomic burden related to the costs of treatment, legal proceedings, years of life lost and workforce losses due to disability. All these costs translate into hundreds of billions of dollars spent worldwide on medical services, lawsuits, police enforcement, military operations, disability, welfare payments, etc.

Tolerance to Heroin

Tolerance to various effects of heroin develops with different paces for each effect, i.e. the fastest increase of tolerance is observed with respect to euphoria and

other psychoactive effects. This leads to necessity of constant dose increases, which quickly reach extremely high levels and pleasurable effects of heroin disappear. Heroin analgesic effects require gradual dose increase, but it takes months or years to render heroin absolutely inefficient as analgesic at high doses. Similar pattern of tolerance increase is observed with respiratory center inhibition whereas some, primarily autonomic effects (miosis, constipation) of heroin remain almost unchanged over many years. Such discrepancy in tolerance development inevitably leads to a dangerous clinical scenario when high tolerance to psychoactive effects of heroin leads to extremely high doses of the drug being injected and at the same time tolerance of respiratory centers is not as high and risk of respiratory depression is extremely high.

Heroin Overdose

Overdose is a very common condition among heroin users due to several reasons. One of the major causes of overdose is unevenness of development of tolerance to various effects of heroin described above. Another reason is concomitant use of several substances potentiating psychoactive effects of heroin as well as respiratory depression associated with its use. The most common substances are alcohol, benzodiazepines and barbiturates, antihistamines and sleeping pills (e.g. zopiclone). The third reason is sudden dose increase that can be caused by changing route of administration or process of preparation, switching to a new supplier who provides the user with high purity heroin or banal mistake.

Clinically heroin overdose is characterized with extreme sedation and drowsiness – patients are often described as being "nodding off" as if falling asleep. Pinpoint pupils are classical presentation of heroin overdose as well as any other opioid or opiate. Another set of symptoms is related to respiratory center inhibition – shallow breathing with low respiratory rate (usually below 12) and cyanosis often accompanied with bradycardia.

Overdose Management

Management of heroin overdose is based on identification of the clinical problem and reversal of heroin effects. The first task is to associate sedation with heroin use – presence of a relative, a friend or simply witness of drug use as well as paraphernalia for injection or drug per se can be of great service for quick decision making. Clinical picture of sedation, respiratory depression in association with pinpoint pupils is very patognomic for opioid overdose. Needle marks might be indicative of heroin injection, but there is little clinical importance in identification of particular opioid for overdose management. Possibility of concomitant use of other drugs should be considered and blood toxicology screen should be ordered. Effects of heroin are reversed by intravenous injection of naloxone – potent short-acting opioid receptor antagonist that has higher affinity to opioid receptors than heroin and displaces it from its binding sites. In majority of cases several doses of naloxone are required in order to rouse the patient as well as its repetitive administration in order to achieve stable result due to a very short half-life of naloxone.

Administration of an oral long-acting opioid antagonist such as naltrexone did not become too common due to difficulties with administration of oral medication to semi- or unconscious patient and longer lag time till the onset of action due to absorption. Also, long-acting opioid antagonists put patient in prolonged and subjectively insufferable withdrawal and are feared among drug users.

Heroin Withdrawal

Withdrawal symptoms are generally the opposite of the symptoms of intoxication and are mainly attributable to hyperreactivity to sympathetic nervous system. Normally withdrawal begins several hours after the last dose of heroin, peaks in 2–3 days and resolves mainly within 5–6 days with some symptoms lasting for up to 10 days. Addicts experience extreme anxiety, restlessness, insomnia, fatigue, and strong cravings for heroin. Analgesic effects of previous administration of heroin result in lowered pain threshold and those in withdrawal experience severe muscular and joint pain. Multiple other symptoms are typical for heroin withdrawal – hypersecretions from multiple glands and hypermotility of gastrointestinal tract resulting in sweating, lacrimation, rhinorrhea, diarrhea, and vomiting. Characteristic features are also dilated pupils, chills, piloerection, tachycardia, and hypertension. It must be noted that though heroin withdrawal is subjectively hard to withstand it doesn't lead to any serious medical complications except for cases with somatic comorbidities.

Withdrawal Management/Detoxification

There are several treatment options for heroin withdrawal management often called detoxification or detox. The simplest approach is based on the management of most prominent symptoms of withdrawal preferably in controlled environment – sedatives are used to cope with anxiety, restlessness, and insomnia, often short

course of benzodiazepines is used for this purpose. In order to relieve pain nonsteroidal anti-inflammatory medications are prescribed, nausea and vomiting usually respond well to antiemetics. Diarrhea can be managed with loperamide – opioid that cannot be absorbed from gastrointestinal tract and thus acting locally. Physiotherapy and supportive care are provided.

There are also methods of heroin withdrawal management based on specific medications such as clonidine, methadone, and buprenorphine.

Clonidine Detoxification

Clonidine is an α_2-adrenergic receptor agonist. α_2-adrenergic receptors are located on presynaptic membrane and act as a biofeedback mechanism – each time catecholamines such as epinephrine, norepinephrine or dopamine are released in a synapse they also activate α_2-adrenergic receptors that in turn inhibit further neuromediator release. Thus, clonidine reduces adrenergic tone by stimulating α_2-adrenergic receptors and inhibiting release of norepinephrine, which is the major pathological basis for development of heroin withdrawal.

Usually patients are administered 0.1 mg of clonidine orally with a blood pressure being checked 1 h after that. Since one of the effects of clonidine is hypotension, clonidine is not administered to those whose blood pressure drops below 90/60 after initial dose. If the blood pressure is still above the threshold, clonidine is prescribed in doses of 0.1–0.2 mg orally 3–4 times per day. Duration of treatment is normally limited to several days with potential extension to 8–10 days in total. If doses higher than 0.2 mg four times a day are needed or significant blood pressure drops are observed inpatient treatment is indicated.

Methadone Detoxification

Methadone is a full agonist of opioid receptors with a half-life significantly longer than one of heroin (see Table 67.1: Comparison of opioid agonists). Slow onset of action and longevity of methadone effects almost completely deprive this opioid of addictive properties, though it still has some street value. Due to high potency of the drug extreme precautions are taken when it is prescribed for either detoxification or maintenance. In many countries special license is needed in order to prescribe methadone.

The rationale of methadone detoxification is based on replacement of short-acting highly addictive heroin with the substance of significantly lower abuse potential and less intense withdrawal symptoms due to longer period of elimination allowing for subsequent quick tapering off of it. Due to multiple health risks associated with methadone inpatient detoxification is preferred when methadone is being used. When performed in controlled environment, recommended initial methadone dose is 5–15 mg administered every 6 h for the first 2–3 days. Prior to each administration opioid withdrawal scale is used in order to estimate the severity of withdrawal and necessity of additional dose of methadone. After relatively stable state has been achieved, methadone dose is reduced by 1/3 of previous day's dose and then – tapered off by 5–10 mg day^{-1} unless the patient is to be transferred to methadone maintenance program (see Methadone maintenance).

Outpatient detoxification with methadone is more risky and thus more complicated. Initial doses of methadone are 15–30 mg day^{-1} with subsequent titration – increments of 10–15 mg every 3–5 days. When optimal dose is achieved patients are being tapered off methadone at the rate of 5 mg day^{-1} every 3–14 days. Since there is no direct control over patient's substance use dose titration and tapering should be guided by regular urine toxicology screening. Supportive symptomatic treatment can also be provided.

Buprenorphine Detoxification

Buprenorphine is a newer medication that has been approved for clinical practice in most Western countries with different restrictions. Buprenorphine is also an opioid receptor agonist with a half-life even longer than one of methadone that allows its administration every other day. Unlike methadone it is a partial agonist that contributes to a safer pharmacological profile of buprenorphine with significantly lower risks of sedation and respiratory depression. On the other hand partial agonism of buprenorphine complicates initiation of treatment – when prescribed to someone who still has opioids in their system, it reverses effects of opioids and precipitates withdrawal. In order to prevent precipitated withdrawal buprenorphine should be administered only to those who haven't been using opioids for 24–48 h. In practice this means that these people should be in moderate withdrawal prior to administration of buprenorphine, which in turn will alleviate withdrawal symptoms.

Similarly to methadone buprenorphine detoxification can be performed in either in- or outpatient settings with preference still made to more controlled environment. In inpatient unit buprenorphine is administered to patients who reached moderate withdrawal and quickly titrated to the doses of 16–24 mg day^{-1}. When patients stop experiencing withdrawal symptoms dose of buprenorphine is being quickly tapered off at the rate of 1–4 mg day^{-1} every 1–2 days depending on their condition. In outpatient setting both titration and taper are more spaced in time: initial dose can be up to 8 mg day^{-1} and increased by 2–4 mg day^{-1} every other day until it reaches optimal level. Tapering is usually performed at the rate of 1–4 mg day^{-1} removed every

TABLE 67.1 Comparison of Heroin, Morphine, Methadone, and Buprenorphine

	Heroin	Morphine	Methadone	Buprenorphine
Trade names	Heroin NB: Manufacturing of heroin was mainly discontinued	Kadian Oramorph Avinza Roxanol Kapanol MS Contin	Methadol Dolophine Amidone Heptadon Symoron Physeptone Amydone Phy Methadose	Subutex Suboxone (with naloxone at 4:1) Temgesic Buprenex Norspan Butrans

Development of withdrawal	Fast	Fast	Slow	Slow
Addictive potential	High	High	Low	Low

several days. Supportive symptomatic treatment can also be provided.

Maintenance/Substitution Treatment

Rationale and methods of maintenance treatment overlap in many aspects with methadone or buprenorphine detoxification though it pursues a different goal – harm reduction versus abstinence in case of opioid-assisted detoxification. Though the same substances are generally used – methadone or buprenorphine – the schedule of titration has a different timeframe; in fact, maintenance treatment may last for infinite time period as long as it prevents harm

associated with illegal activities related to drug-seeking and using behaviors and their sequelae. Also the use of prescribed oral opioid in better controlled environment is intended to prevent risks associated with drug injections and overdose. Opioid maintenance treatment combined with psychosocial interventions was found to be the most effective treatment option for opioid users. In comparison to detoxification methadone or high-dosage buprenorphine treatments show significantly better outcomes in terms of drug use, criminal activities, risk behaviors, HIV transmission, overdoses, and overall mortality as well as better rates of retention in treatment. It is estimated that methadone is used in approximately 75% of maintenance treatment cases and buprenorphine in 20–25% of cases.

Methadone Maintenance

Methadone has been used for opioid maintenance treatment for decades and is well-recognized treatment option in many countries. At the same in some countries (e.g. post-Soviet Union countries) it has never been accepted and is still labeled as narcotic and prohibited.

Due to high potency of methadone and associated risks its use is heavily regulated in most authorities. Unlike short detoxification, maintenance treatment is less aggressive and doesn't require inpatient settings. Normally initial doses are between 15 and 30 mg of methadone administered daily. This dose is not sufficient in most of the cases and is increased slowly at the rate of 5–15 mg added every 3 or more days until it reaches optimal dose. In majority of cases doses of 80–120 mg of methadone are sufficient for maintenance. At the same time small portion of patients who metabolize methadone quickly might require significantly higher doses. Usually during the first weeks or even months of methadone maintenance doses are daily dispensed and taken under supervision of pharmacist. Later when patient's condition is more or less stable and regular urine toxicology do not show any opioids or sedative substances other than prescribed patients are allowed to have take-home doses or "carries" with the maximum of 6 per week so that at least one dose of methadone is observed every week.

In many cases dose of methadone can be partially or completely tapered over the period of months and maintenance therapy resembles extended detoxification. It is considered to be less stressful than detoxification due to longer period of taper and less intense or in some cases no cravings and withdrawal symptoms.

Special attention is paid to potential drug interactions – patients should be educated regarding the side effects of methadone and higher risks of QT-interval prolongation, sedation, and respiratory depression in case of the use of benzodiazepines, alcohol, and other substances with known sedative effects (antihistamines, zopiclone) or those that cause prolongation of QT-interval (some antiarrhythmics, tricyclic antidepressants, etc.).

Buprenorphine Maintenance

Buprenoprhine is considered to have significantly safer pharmacological profile than methadone. It is also relatively new medication and its use is not as rightly regulated as methadone. Due to partial agonism buprenorphine has ceiling effect, i.e. it cannot cause full activation of opioid receptors and hence – dangerous side effects are observed very rarely and in most of the cases are associated with concomitant use of other substances, most often – alcohol and benzodiazepines.

Due to safer profile initiation of treatment and titration of buprenorphine are very fast even in outpatient settings – usually initial dose ranges from 4 to 8 mg day^{-1} with subsequent increases by 2–4 mg every 1–2 days until it reaches optimal level. Normally doses between 12 and 24 mg are enough to control withdrawal symptoms, though in some cases buprenorphine prescribed in doses of up to 32 mg day^{-1} and in some heavy opioid users full control of withdrawal cannot be achieved due to ceiling effect of buprenorphine. Tapering is performed on as needed and as tolerated basis depending on the ultimate goal of treatment – whether it is harm reduction or abstinence. Carries can be provided sooner than in case of methadone, but the same prerequisites should be met – stable control of withdrawal symptoms and no use of illicit substances and drugs with sedative effects as per toxicology screens. Most of the fatalities while on buprenorphine maintenance are associated with the use of alcohol or benzodiazepines. Patient should also be educated about buprenorphine properties and its interactions with other drugs and illicit substances.

Heroin Maintenance

Recently, a program of heroin maintenance for opioid dependence was launched in several European and North American countries that included approximately 2000 opioid users in total. It must be noted that most of the study subjects did not benefit from conventional treatment options. Despite high addictive potential of heroin preliminary results of this project demonstrate significant harm reduction in those involved in heroin-assisted treatment. Moreover, some publications reported better results in patients treated with injectable heroin in comparison to oral methadone. Despite high scientific quality of these findings, heroin-assisted treatment of opioid dependence still seems very limited due to short action of heroin, which in turn dictates frequent dosing; strong psychoactive effects that are the basis of addiction per se; high street value of heroin increasing

the diversion potential of prescribed heroin; use of injectable heroin creates additional risk of development of abscesses and use of other drugs as well as the chances of transmission of blood-borne infections. Another aspect of injectable heroin use is a high risk of overdose and respiratory arrest that makes inpatient treatment settings almost imperative for this kind of opioid dependence treatment. Also, use of heroin as a maintenance treatment masks the use of street heroin, morphine, and codeine in laboratory tests and renders urine sampling virtually ineffective. All these drawbacks of heroin maintenance set significant limits to the use of this modality of opioid dependence treatment and have been proposed for application in specific cohorts of patients, namely, those who were not responsive to other treatment options.

Heroin Detection

Detection of heroin is crucial for medical and legal purposes. In medical settings detection of heroin and its metabolites is diagnostically necessary for confirmation of heroin overdose and heroin dependence. Also regular toxicology screens are required for effective opioid maintenance treatment.

Since heroin is being readily metabolized to monoacetylmorphine and then to morphine testing for diacetylmorphine has not been proven feasible. Instead current laboratory testing methods are aimed to detect heroin metabolites in various bodily fluids that include blood, urine, sweat, saliva, and hair samples testing. While sweat, saliva, and hair samples testing techniques are available, major and most reliable tests for heroin are still based on identification of heroin in blood and urine samples. Blood samples are more reliable and are used during legal procedures and in medical settings when blood samples are taken for multiple purposes or when urine sampling is not possible or complicated e.g. unconscious patient in emergency room. At the same time urine sampling for heroin and other opioids detection is widely used by addictions clinics for confirmation of opioid dependence and for monitoring of treatment progress due to their noninvasive nature and cost-effectiveness. There are two basic methods used for detection of heroin metabolites in urine samples – express qualitative tests based on immunological reactions and more complicated quantitative methods such as gas chromatography–mass spectrometry (GCMS).

Immunological methods are widely used in the form of immunoassays or testing kits for a number of substances. They are cheap, fast, and reliable enough to be used in most of the settings including point-of-care testing of urine samples when samples are processed while the patient is still in the clinic. Since no advanced laboratory equipment is necessary for such testing it becomes more and more popular in smaller clinics. It must also be noted that no detection limit is possible for immunoassays that renders them very sensitive and sometimes leads to false positive results.

GCMS is more complicated and requires expensive laboratory equipment in order to be performed. It renders this technique with several specific properties that in turn define the settings of its usage. First, GCMS is more expensive and can be performed in large laboratory, so no point-of-care testing is possible (some hospital laboratories perform these tests, but even in these settings samples are normally sent to laboratory and it takes at least several hours to retrieve results). Second, due to quantitative nature of testing detection limits are normally set and chances of obtaining false positive results are significantly lower. Third, GCMS produces quantitative results that might be indicative of the dose of the drug used and/or time since exposure.

Normally, individual dose of heroin can be detected 1–2 days after simple use and urine samples remain positive within up to 4–5 days of last use in case of chronic and/or heavy use. It must also be noted that several substances can produce false positive results. These substances can be medical such as codeine, which is available in some over-the-counter or prescribed preparations and is being metabolized into morphine, or even some domestic products such as poppy seeds widely used in baking.

In many cases both immunoassays and GCMS are used simultaneously in order to produce the most reliable results as well as testing for multiple substances is performed. Testing for a spectrum of illicit and medical substances is necessary for several reasons – in case of emergency room testing cumulative effects of several drugs are always considered. Opioid treatment, whether it is detoxification or maintenance treatment, requires confirmation of treatment adherence as determined by presence of methadone or buprenorphine in urine samples and absence of illicit substances. Special attention is paid to substances that can cause sedation such as benzodiazepines, alcohol, barbiturates, antihistamines, antipsychotics, tricyclic antidepressants, etc.

One of the major drawbacks of urine sampling is a risk of urine samples being tampered or switched by patients in order to evade legal consequences or continue use of medical facilities without being penalized (i.e. more structured and restrictive settings of provided maintenance treatment services, loss of driver's license or parental rights) for continued use of heroin despite treatment agreement and goals. Since both methadone and buprenorphine have street value another goal of urine samples tampering might be to continue receiving prescribed opioid for subsequent selling it on black market while using only portion of it for own needs or not using it at all. The most effective

way of prevention of such activities is incorporated in essentials of any maintenance schedule – as at least one dose a week must be taken under supervision of pharmacist users who only use part of methadone or buprenorphine prescribed them on daily basis tend to become extremely sedated when taking full dose and thus are easily identified.

The most common way of urine samples' tampering is providing urine samples of another methadone or buprenorphine user who doesn't use illicit drugs. It can be prevented by several safety checks. The most common of them is supervised urine collection, sometimes performed randomly. Another way to check if urine sample belongs to the patient is to check its temperature – in most of the cases tampered urine samples have temperature significantly lower than freshly urinated ones. Since urine toxicology testing often includes multiple substances, presence of medications not prescribed to the patient is an excellent indicator of urine being taken from another person.

Some users are also trying to dilute their samples with tap water in order to prevent identification of illicit drugs in urine by GCMS. This tampering technique is controlled for by including urine creatinine levels in laboratory reports that when extremely low are indicative of urine dilution. Also, urine dilution does not prevent detection of many substances by immunoassays that are extremely sensitive. Some clinics also use special markers or coloring agents added to the water in their washrooms that render sample dilution virtually impossible.

POLICY

Since the very discovery of addictive properties of heroin, it became a subject for multiple polices aimed to regulate its use and restrict the spread and scope of heroin addiction both in separate countries and worldwide.

Legal Prohibition

Heroin production, distribution, and prescription became illegal in many countries decades ago. It is hard to say how prevalent would be heroin use and dependence without this prohibition, though it is clear that on the one hand it would be significantly more prevalent, but on the other hand it is still unacceptably high. Empirical research has pointed out, that further increases in enforcement and incarceration in many countries would yield very little or no added benefit.

Worldwide Incentives to Reduce Production of Heroin

Several wealthy countries, must notably the USA, have invested billions of dollars in efforts to reduce cultivation of *Papaver somniferum* in poor countries. Unfortunately this did not lead to any significant changes of heroin production in a long run. Inquiry in the US-sponsored programs of agricultural development in Afghanistan showed not only that these programs failed to reduce drug production, but moreover that heroin production has increased the most in those areas receiving such aid. The evidence on mass defoliation campaigns is also pessimistic – sustained and intense campaigns of crop spraying in Colombia and Mexico had little effect on drug production in these countries.

Harm Reduction

Several incentives were proposed in order to reduce heroin-associated harm. Majority of them aimed to reduce the harm associated with injections – needle exchange, providing drug addicts with free needles, needle disposal, etc. These incentives resulted in significant decrease of HIV and hepatitis C infections rate in selected communities, but at the same time left a wide range of medical, social, and legal problems associated with heroin use unsolved.

Treatment for Heroin Dependence

As it was shown above several treatment options were proposed and widely used for management of heroin dependence that include both abstinence-based approach (detoxification) and maintenance treatment options. These strategies imply either complete elimination of heroin use or substitution of heroin, highly addictive short-acting illegal substance that requires higher and higher doses to be injected, – with long-acting oral prescription opioid that is less addictive and tolerance to which doesn't build up as quickly as to methadone or buprenorphine. Both medications have significant advantages in comparison to heroin – they are cheaper or free to the patients in most countries, oral administration eliminates the risks associated with intravenous drug use, they have longer half-life so there is no blood concentration "roller-coaster" and hence these medications give no or very little positive reinforcement and at the same time provide patients with steady levels of opioid effectively preventing development of withdrawal and eliminating the necessity of drug-seeking activities.

School, Family, and Community Prevention Programmes

Multiple attempts were made to prevent the use of heroin, especially its injection, based on educational campaigns targeting certain communities or social

groups, especially children. Prevention programmes that are delivered to younger people before they initiate drug use and targeting a wide spectrum of mental and behavioral problems as well as drug use have emerged over the last 20 years and seem to be the most promising of this kind of intervention. In contrast, purely didactic prevention programmes delivered through mass media, in the community or in the classroom have no evidence of effectiveness. Overall, the impact of individual-level prevention is limited.

SUMMARY

Heroin addiction is a major health problem globally. Though during past two decades it was partially substituted by misuse of prescription opioids in high-income countries, especially in North America, and multiple harm reduction programs were initiated in many countries worldwide, size and burden of heroin addiction remains unacceptably high. Heroin and heroin addiction have been well studied on multiple levels starting with chemical analysis of the substance, its pharmacological properties and effects on human organism to the impacts of heroin use on economy, health services usage and society in general. Methods of heroin intoxication, overdose, withdrawal, and dependence treatment are well established in many Western countries as well as in a number of developing countries. Various forms of policies and programs were introduced with some degree of success in reducing the harm associated with heroin.

At the same time millions of people worldwide begin and continue using heroin, become addicted to it and are involved in various illegal activities related to heroin addiction, significant portion of patients involved in heroin addiction treatment programs either relapse or do not benefit from these programs at all. All these factors point to the necessity to further elaborate effective anti-heroin policies as well as to improve heroin addiction treatment to better meet the needs of heroin addicts.

Glossary

Buprenorphine partial agonist of opioid receptors used for maintenance treatment of heroin addiction.

Clonidine α_2-receptor agonist used for alleviation of heroin withdrawal.

First-pass metabolism metabolism of the drug that happens only in case of its oral administration when the drug is being drained to liver and being partially metabolized by liver prior to reaching systemic circulation. Some drugs, e.g. buprenorphine, have extensive first-pass metabolism that renders them virtually ineffective when prescribed orally.

GCMS gas chromatography–mass spectrometry

Maintenance therapy synonym of substitution therapy.

Methadone full agonist of opioid receptors used for maintenance treatment of heroin addiction.

Naloxone short-acting opioid receptor antagonist used for reversal of excessive activation of opioid receptors in heroin overdose, primarily sedation and respiratory depression,

Opiates natural alkaloids of opium or its semisynthetic derivatives (also called semisynthetic opioids). This category includes morphine, codeine, thebaine, and papaverine.

Opioids synthetic opioid receptor agonists. In many cases this term is used more broadly for semisynthetic opioid receptor agonists or interchangeably with "opiates."

Substitution therapy therapeutic replacement of illegal substance with less harmful prescribed medication, e.g. substitution of heroin with buprenorphine or methadone.

Withdrawal management, or detoxification complex of therapeutic measures aimed at treatment of withdrawal syndrome and ultimately achieving abstinence.

Cocaine Addiction

Robert Malcolm, Kelly S. Barth, Lynn M. Veatch

Medical University of South Carolina, Charleston, SC, USA

OUTLINE

INTRODUCTION

The coca plant, *Erythroxylum coca*, and related species have grown naturally in the northern mountains of South America for thousands of years. The chewing of coca leaves with alkaline substances such as lime powder is an ancient practice of pre-Incan peoples. The improvement in fatigue, reduction of hunger, augmentation of cognition, and enhancement of mood were compelling assets of the plant for indigenous peoples. Processing the leaves into cocaine hydrochloride or alkaline cocaine (crack) and distributing it in modern society highlighted the compelling liabilities of the drug. Stimuli salience, reward, learning, memory, cognitive focus, and emotion are altered by repeated cocaine use. Using to get high is replaced by intense craving and compulsive drug seeking/using, defying legal, social, and medical adverse consequences. At the core of this progression is the intense euphoric and hedonic joy produced initially by cocaine, quickly followed by drug hunger. Repeated seeking and use are based on cocaine's ability to influence and subvert fundamental brain reward systems by redirecting dopaminergic and glutaminergic circuitry. The journey from first exposure to cocaine addiction is a complex one involving individual vulnerabilities as well as cultural, economic, legal, and demographic modifiers.

BOTANY

Cocaine is a complex pharmacologic agent. It has the combined properties of a systemic stimulant, a local anesthetic, and a powerful vasoconstrictor. Cocaine is derived from the leaves of the coca plant, which is indigenous to western mountainous South America. It is farmed at higher altitudes of the Andes and is part of the family Erythroxylaceae. The best-known plant in this genus is *E. coca*, but multiple species and subspecies exist throughout the Andes Mountains. Indigenous peoples of Peru, Colombia, Ecuador, Venezuela, Bolivia, and northwestern Argentina have cultivated, sold, and consumed the plant since prehistoric times. The plant resembles a tall bush, growing to a height of 2–3 m. The leaves are green, thin, and tapered at both ends. In South America, the seeds are generally sown from

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00068-1

December to January in small shaded plots of ground, and then later transplanted to a sunnier location to complete the growing cycle. Plants may be harvested for many years, but only the new growth leaves are harvested. Harvest seasons are normally three times a year: March, June, and November. Leaves are spread in thin layers and dried in the sun, then packed in sacks for transport. The leaves must be kept dry to preserve the quality of the cocaine. Depending on the species and the location grown, the leaf contains about 0.3–1.5% cocaine. Coca plant cultivation has been tried in Java, Taiwan, Africa, India, Ceylon, and Australia.

HISTORY OF COCA AND COCAINE

Traces of coca have been found in Andean mummies dating back to 3000 BC, and other investigators have asserted that traces of coca can be found back as far as 8000 BC. Many archaeological sites reveal widespread coca cultivation and use by the sixth century AD. Coca leaves were routinely buried with the dead. Excavations of pottery and statues illustrate cheeks bulging with the chew of coca leaf/balls as well as paraphernalia, such as spatulas for adding alkali to coca chew, often made from gold or silver. After the Spanish conquistadores came to South America and broke the Inca Empire, coca leaves became a literal cash crop, being the currency exchanged for goods and services. Coca leaf chewing with lime became common among laboring classes of Incas and other indigenous peoples. The Catholic Church in South America banned coca leaf chewing in the early 1500s, but the decision was reversed when the indigenous peoples, enslaved to work in the mines and other hard laboring tasks, were found to work more and ate less when chewing coca leaves. Philip II of Spain issued a proclamation allowing for coca leaf use among indigenous peoples and began to tax the coca leaf. Medical writings of the physician Nicolas Bautista Monardes, published in 1574, detailed the pharmacologic and behavioral actions of coca leaves. Monardes was the first to describe the mixture of a white alkaline powder made from seashell ash with coca leaves rolled into a ball and chewed in this fashion to enhance absorption of the cocaine alkaloid. Discovery of the anesthetic effects of cocaine was attributed to the Jesuit priest Benarbé Cobo in 1653, when he described chewing coca leaves to stop his toothache.

Despite these early writings being circulated in Europe, the chewing of coca leaves with alkali powder never spread to Europe like the smoking of tobacco. Whereas dried tobacco leaf is relatively stable over ocean voyages, coca leaves are not, and their pharmacologic effects were probably greatly degraded by the time they reached Europe. Undoubtedly, the route of administration of nicotine, primarily by smoking, also contributed to its spread and nicotine addiction. The innovation of smoking cocaine took about 400 years.

In 1582, a European account detailed the morbidity and mortality among indigenous peoples using coca leaves on a regular basis. Although some of the mortality was likely due to comorbid infectious diseases, poor diet, and harsh working conditions, this is an early record of the negative consequences of coca leaf use.

In 1859, Albert Niemann isolated the major active alkaloid in coca leaves and named it cocaine. He noted its local anesthetic properties. Sigmund Freud published an influential review paper on cocaine in 1884, *Uber Coca*. Freud at first supported the pharmacologic value of cocaine, using it to treat opioid dependence. Later, after several adverse reactions, including a patient's psychosis, he abandoned its clinical use. Freud had discussions with his friend Karl Koller, an ophthalmologist, about the anesthetic properties of cocaine. Koller is given credit for developing the local anesthetic properties of cocaine by operating on a patient with glaucoma and publishing the outcome. Use of injectable cocaine quickly spread to dental and otolaryngologic applications, and cocaine is still used today for local and regional nerve block anesthesia. From the 1860s to 1900, cocaine was used in medicinal tonics and recreational beverages. In Europe, Vin Mariana, an elixir made from red wine, coca leaves, and possibly refined cocaine, was popular, but frequently led to abuse and addiction. In the United States, John Pemberton created Coca-Cola, which contained coca products until 1903. In 1906, the Pure Food and Drug Act ordered the removal of opioids and coca products from over-the-counter medications in the United States.

EPIDEMIOLOGY OF COCAINE USE

Coca leaf ingredients and the alkaloid of cocaine itself were frequently used in patent medicine products and popular drinks from the 1880s until the early 1900s. This was the first cocaine epidemic. Exposure to cocaine and coca leaf products was extensive until the Pure Food and Drug Act of 1903 and the Harrison Narcotic Act of 1914. Cocaine use remained at a low level until the 1960s, when nasally used cocaine hydrochloride became popular among upper income classes. Organized drug cartels, seeing a market for the drug, began importing large quantities of cocaine hydrochloride from South America, and the use of nasally insufflated cocaine peaked in the mid-1980s. Reports of cooking cocaine with alkaline substances (i.e. baking soda) began appearing in the early 1970s, and by the mid- to late 1980s, smoking of rock, more commonly known as crack

cocaine, became widespread. Cocaine base (crack) is easy to transport, is highly potent, and may be smoked to give effect on the brain in a few seconds. The cost of crack was lower than nasally insufflated cocaine hydrochloride and could therefore be sold to lower socioeconomic groups. Laws passed during this time were more severe against crack users compared with laws against nasal use of cocaine hydrochloride. Only recently are laws becoming more equable. For reasons that are not clear, all forms of cocaine use have declined over the last decade. Prevention programs, public media campaigns, and law enforcement all prefer to take credit for these trends. By 2005, fewer high school students had tried cocaine than in the previous decade. About 34 million individuals had used cocaine at some point in their life, almost six million individuals had used cocaine in the past year, and 1.5 million individuals used some form of cocaine on a regular basis, largely crack cocaine.

Use among males is usually two or three to one compared with females. The rate of unemployed individuals using cocaine is double that of employed individuals. Cocaine use by males generally begins in the late teen years to the early 20s; in females it begins about 5 years later. Cocaine use in females is said to have a telescoping effect in that use begins later but more devastating psychosocial effects from cocaine occur sooner. The Drug Abuse Warning Network reported about 78 emergency department visits out of 1000 were related to cocaine use. For comparison, about 7 per 100 000 were said to be methamphetamine related. These figures are probably low estimates in that individuals who develop chest pain involving cardiovascular or pulmonary symptoms, or for that matter adverse psychological symptoms, will often go to an emergency room and will not admit that cocaine is involved unless a urine drug screen is done. An epidemiological curiosity is that generally cocaine use is higher east of the Mississippi, and methamphetamine use is higher west of the Mississippi. Chicago, Philadelphia, Baltimore, and Miami are known as cocaine cities. Methamphetamine cities include San Francisco, Seattle, Los Angeles, and Phoenix. Possibly, these patterns of cocaine and methamphetamine use are related to organized crime distribution issues.

PHARMACOLOGY OF COCAINE

Cocaine is an ester of benzoic acid and methylecgonine. Ecgonine is an amino acid base. Both topical application and local injection of cocaine solution blocks the generation and conduction of nerve impulses. The site of action is the cell membrane where cocaine prevents conduction by reducing membrane permeability to sodium. This blockade of sodium channels increases the threshold for electrical excitability, which reduces the probability of nerve impulse transmission. In addition, cocaine inhibits the reuptake of norepinephrine conferring vasoconstrictive effects as well. The significance is that other local anesthetics do not have this property of vasoconstriction and generally must be given with a separate vasoconstrictive agent. Cocaine is used primarily as a topical anesthetic in dental, ear, nose, and throat procedures. The combined vasoconstrictive and local anesthetic properties make cocaine an ideal agent providing anesthesia and shrinking swollen mucosa.

Cocaine metabolism is primarily hydrolysis of ester groups. Esterases are found in blood, and benzoylecgnine (the major metabolite of cocaine found in urine) is detectable up to 2–5 days after binge use. Cocaine itself can only be measured in the serum from minutes to 2–3 h after use. Rarely, heavy users may have cocaine metabolites for up to 10 days after use. A minor pathway of cocaine metabolism is through a CYP3A4 mechanism with degradation to norcocaine.

The absorption of cocaine varies greatly with its route of administration. Oral cocaine (or coca leaves) is absorbed into the central nervous system in 30 min to 1 h. Nasal cocaine is absorbed in 2–3 min. Smoked cocaine and intravenous cocaine reach the brain in 10–30 s. With smoked cocaine, craving and new drug seeking may occur as quickly as 5–10 min. Positron emission tomography studies of cocaine abusers using cocaine labeled with carbon 11 demonstrated that the time course of the subjective euphoria of cocaine paralleled the uptake of the drug in the corpus striatum (nucleus accumbens and related structures).

Clinical Pathology and Course of Cocaine Use

Cocaine intoxication is described as a high or rush feeling, and other effects include heightened euphoria, rapid pulse, increased blood pressure (more systolic than diastolic), and increased motor behavior and talking. Greater alertness, greater anger, increased anxiety, greater gregariousness, increased vigilance, poor judgment, and labile mood also occur. In heavier users, stereotyped repetitive behaviors (i.e. rubbing one's nose, rubbing one's forehead) or more complex changes of behavior occur. Repetitive cocaine users will often say that their first high was the best, and no high approaches the first one, hence the phrase, "chasing the [first] high." A large amount of cocaine leading to overdose, on any one acute use, can be associated with medical complications, which can include death from cardiac arrhythmias, seizures, hyperthermia, dehydration, and localized vasoconstriction leading to myocardial infarction or stroke. Some paranoia is common with repeated

cocaine use. In some users, this may increase to a paranoid psychosis lasting for days or weeks.

Recurrent users of cocaine have withdrawal symptoms, but they are not as well defined as can be seen with alcohol, sedative-hypnotic, or opioid dependence. Following the end of a cocaine binge, which may last for hours to days, individuals have dysphoric mood, decreased motor activity, social withdrawal, exhaustion, bradycardia, and lowered blood pressure. Symptoms may persist for a few days after cessation. Complaints of dysphoric mood, lack of pleasure (anhedonia) from biological and social rewards may persist for weeks to months to years. Drug craving, increased appetite, or unpleasant dreams may occur in the same interval. Some cocaine users report immediate spontaneous craving and drug seeking after use. Others deny any conscious craving but also quickly begin seeking and use. Another segment of users report no use unless stressed (an argument, work demands, financial or legal troubles) or very specific cues occur (cash, a dealer, another user, a drink of alcohol, a street, or a building). The list of stressors and cue triggers can appear infinite to family and therapists.

Physical examination findings in cocaine users are not that common or diagnostic. Acute users will have tachycardia, increased blood pressure, and motor agitation. Heavy intranasal users will occasionally have an eroded nasal septum and/or frequent nosebleeds. Injection users have the usual signs of frequent needle use on arms, legs, or neck, and concurrent infections with hepatitis B or C and human immunodeficiency virus occur. Crack smokers will occasionally have burns on the hands and lips. Urine drug screens have some benefit in detecting cocaine use, but again they are limited by the rapid metabolism and excretion of benzoylecognine and the requirement to test individuals three or more times weekly. Episodic bingers may go for years with occasional use, without detection by employers, probation and parole agencies, and the military.

The clinical course of cocaine addiction is extremely variable. Inexperienced younger users are more likely to be victims of the complications of overdose and to develop medical, psychiatric, and legal difficulties. Older chronic users, who have survived the entanglements, may present for treatment in relatively good health after more than two decades of use. It is common for that latter group to be underemployed, estranged from families and significant others, and to have significant comorbidities with alcohol and marijuana. The course of cocaine use from initial use to chronic use is extremely variable. The authors know of individuals who, on the very first use of intravenous cocaine, suffered cerebral hemorrhage and died. Other patients come to mind who used cocaine on one single occasion, probably suffered a fatal arrhythmia, and died shortly thereafter. Other individuals have moved gradually from snorting cocaine hydrochloride with a rather stable pattern of recreational social use, predominantly at weekends over a number of years, to intravenous use or, in more recent years, smoking crack cocaine with devastating social and medical consequences. One individual who comes to mind lived in a wealthy resort area, owned several regional businesses, had a house on the beach and one in the mountains, and several horses boarded in stables. After switching from many years of nasal cocaine use to smoking crack cocaine, he lost both of his houses and his riding stables in less than a year. Spending money on cocaine for himself and others, poor business decisions, and the alienation of key people in his social network led to his rapid socioeconomic decline.

Cardiovascular complications are common with acute cocaine use. Chest pain and tachycardia are frequent reasons why individuals go to emergency departments. Myocardial infarctions are relatively uncommon but can occur in people with preexisting heart disease who are often cigarette smokers; myocardial infarction may also occur in individuals with normal coronary arteries. Patients developing acute ventricular arrhythmias from cocaine probably do not live to make it to emergency rooms. Cocaine use has been associated with dissection and rupture of the abdominal aorta. Frequently in cigarette smokers, peripheral vascular disease has been associated with chronic cocaine use. Sometimes this is preceded by accidental injection of cocaine into an artery.

Smoking crack cocaine can cause acute constriction of the bronchi and may lead to wheezing and attacks indistinguishable from asthma. Increased blood pressure in the pulmonary arteries has been reported in intravenous cocaine users. Nasal users of cocaine have been reported to have nasal septal erosions, ulcers, and perforations. Oronasal fistulas have been reported, and perforations of the hard palate have also been seen. Worsening of kidney function has been noted occasionally in chronic cocaine users, especially in individuals with high blood pressure who are crack smokers.

Cocaine can produce numerous neurological and muscular complications. All types of strokes have been seen with cocaine use. Ischemic stroke leading to clot formation has been reported. Intracerebral bleeds have been reported, and subarachnoid hemorrhages occur in some cocaine users. A transient ischemic attack or a stroke in an otherwise young healthy individual without risk factors should suggest cocaine or other stimulants as part of the differential diagnoses. Heat stroke and other forms of hyperthermic injuries can occur in cocaine users. This is usually in the context of high environmental temperatures, hyperactivity, lack of fluid intake, and possibly impaired heat loss from lack of sweating.

In vulnerable individuals, cocaine use can lead to a variety of psychiatric syndromes including generalized anxiety, panic attacks, and psychosis. Agitation and paranoia are frequent in cocaine users and may persist for hours to days after binge use.

In summary, the clinical course of cocaine dependence varies greatly depending on individuals' vulnerabilities, socioeconomic factors, co-occurrence of psychiatric and medical comorbidities, as well as issues of polysubstance use.

Antecedents of Cocaine Dependence

There are social, psychological, and biological factors operating simultaneously to affect the initiation, perpetuation, and course of cocaine dependence. Some of the social factors that lead to the initial use of cocaine have been hinted at in the section on epidemiology. Humans are social animals, and it is usually in the context of a social setting, peer pressure, modeling of other individuals' behaviors, desire for greater acceptance, and exploratory and experimental behaviors that cocaine use is initiated. Cocaine use usually occurs in the setting of some other previous drug experience such as alcohol, marijuana, or prescription medicine use. For clinicians, etiologies of cocaine abuse and dependence are only valuable insofar as they may point to meaningful treatment interventions that lead to effective treatment outcomes for individuals with addiction to cocaine. The complexities of genetics, public policy, local social norms, geopolitical events, and economic conditions play a role in the cause and perpetuation of cocaine addiction. These subjects and the neurobiological foundations of cocaine dependence are examined in detail in other chapters in this volume.

Koob and Kalivas refer to the social drug use as regulated relapse and a more serious second phase of almost automatic drug use as compulsive relapse. For a clinician, the first might be defined as regulated drug seeking and use and the second as compulsive drug seeking and use; relapse is reserved for an extended period of abstinence with or without treatment that is followed by drug use again.

There are some important distinctions about the release of dopamine in the nucleus accumbens by cocaine compared with dopamine release by physiologic rewards such as food, water, or sex. In animal research, release of dopamine with cocaine achieves a greater amplitude and duration of dopamine release than biological rewards. Tolerance rapidly develops to the release of dopamine by food, sex, or water reinforcers. Although tolerance develops to cocaine-promoted release of dopamine, this generally can be overcome by a higher dose of the drug, enabling the same enhanced level of dopamine release. Satiation to biologically motivated reinforcers such as food, sex, or water generally occurs quickly, although some human pathological conditions, such as binge-eating disorder and bulimia, are exceptions in which these conditions mimic drug addiction. Each time cocaine is used, expanded learning occurs, strengthening the associations between the environment and the drug. This leads to a myriad of cues that will later trigger the addicted individual to begin drug seeking. Thus, repeated use of addictive drugs increases the probability of a cued connection between drug and multiple life events, whereas biologically relevant reinforcers may have fewer cue triggers.

A number of factors are likely to promote drug use over more adaptive behaviors such as the control of sexual behaviors, food and water acquisition, and even complex social behaviors. One is the switch from declarative conscious decision-making behaviors leading to reward to habit-generated behaviors triggered by cues. Another is the repeated increase in dopamine above physiologic levels induced by drug use.

TREATMENT

The treatment of cocaine dependence remains challenging and as yet incomplete compared with the treatment of other addictive disorders. For several addictive disorders, particularly alcohol dependence, a wide array of psychosocial treatments have undergone rigorous scientific study and are known to improve the health of the individual as well as treating the addictive processes. Several US Food and Drug Administration (FDA) medications are available that aid in promoting abstinence, decreasing the likelihood of withdrawal states, and lowering relapse rates. No effective medications have been approved by the US FDA for the treatment of cocaine dependence, although some medicines show promise in early trials, and these are briefly reviewed at the end of this section. There is good empiric evidence for several psychosocial treatments. A recent meta-analysis of 34 well-controlled treatment trials contains much useful information. A total of 9 of the studies were for cocaine dependence, 5 for cannabis dependence, 13 for polysubstance abusers, and the remaining 7 were for opiate dependence. Psychosocial treatments evaluated in these studies included contingency management, relapse prevention, general cognitive behavior therapy, and combinations of cognitive behavior therapy and contingency management. Across this meta-analysis, the average age of the study participants was 34.9 years, 62.2% were male, 61.0% were Caucasian, 67.7% were unmarried, and 42.5% were employed part-time or full-time leaving the majority unemployed. About half of the sample met criteria for

comorbid alcohol dependence. A little over 40% of the study subjects received replacement medication in conjunction with psychosocial treatment. Across all substance use groups, cocaine had the highest mean dropout rate of about 42%. Of the psychosocial treatments, contingency management treatments had the lowest dropout rates at just fewer than 30% followed by general cognitive behavior therapy and combined psychosocial treatments. Efficacy for cocaine-dependent subjects yielded mixed outcomes. Acute abstinence rates were about 32% for cocaine users compared with 13% of subjects in the control treatment conditions. Treatment involving relapse prevention has the largest rate of abstinence at 39%. A higher number of treatment weeks was related to a positive outcome, but the number of treatment sessions per week did not affect treatment outcome or treatment retention. Medication maintenance for opioid agonist therapy did reduce the dropout rate. Limitations of meta-analysis studies include the specific demographics of the sample subjects, the lack of information regarding treatment or treatment as usual, and no information regarding specific comorbid medical and psychiatric conditions.

Self-help support groups abound for the treatment of alcoholism. Large communities have numerous meetings occurring at multiple times every day. Even small rural communities usually have Alcoholics Anonymous meetings on a regular basis throughout the week. Although Narcotics Anonymous and Cocaine Anonymous meetings may be available in large urban areas, they are often not available in medium-sized cities or in small rural communities. Self-help groups have generally not been as intensively studied for the treatment of cocaine dependence as they have been for the treatment of alcohol dependence. Another challenge is that small community-based programs, often run at the level of a county or parish, have limited resources for hiring and training staff, and particularly for using more innovative evidence-based treatment practices, such as contingency management, for their psychosocial treatments.

One of the innovative approaches over the last 20 years has been the development of the Clinical Trials Network (CTN) by the National Institutes of Drug Abuse (NIDA). This is an affiliation of university treatment centers (nodes), which serve as resources to develop affiliation with county, state, and community substance abuse treatment clinics. The CTN nodes serve as a source of funding, innovative training, and clinical trials, some of which can be conducted in community settings. This promotes the innovative transfer of information and skills to smaller treatment centers, establishes scientific methodology for studying program outcomes, and provides clients and CTN-affiliated centers with the latest in effective and/or experimental psychosocial and pharmacological treatments.

Consumer Issues

Clients seeking treatment for cocaine dependence should be encouraged to not only obtain word-of-mouth information regarding the treatment center's reputation, but also avail themselves of resources on the Web about treatment centers using home computers or, when not available, through community centers or public libraries. A treatment center that is part of the CTN, either a university node or a community participation center, is a good sign that the highest level of evidence-based innovative treatments will be used. Another thing to look for is treatment centers that offer multiple services for clients and their families. This is discussed in more detail later. Programs that offer thorough assessments in multiple aspects of the person's medical, social, psychological history are also important. Programs that are individually tailored to a person and their stage of addiction are equally important. An excellent source of information for clients, family members, and professionals is the US Department of Health and Human Services Treatment Improvement Protocol Series published by the Substance Abuse and Mental Health Services Administration Center for Substance Abuse Treatment. Tip 33 (Treatment for Stimulant Use Disorders) is particularly valuable. The Tip Series may be ordered by contacting the National Clearinghouse for Alcohol and Drug Information or through the following Internet site: http://www.kap.samhsa.gov. There is a growing trend for treatment centers to publish their outcome results. Looking at this information, when it is available, is often a helpful guide for clients and their families.

Initial Assessment

Comprehensive treatment of the cocaine-dependent individual begins with a thorough assessment in biological, social, and psychological areas. Many domains of a person's life can be damaged by cocaine, become dysfunctional, or disappear entirely. An initial assessment generally conducted by a multidisciplinary team consisting of physicians, psychologists, social workers, therapists, and nursing personnel are valuable in establishing which parts of a person's life may have been damaged by the ever-growing sphere of influence that cocaine has on a person's life. There is evidence to show that when these services are all available (one-stop shopping), the treatment outcomes are better. However, in some communities, these assessments may need to be gathered piecemeal, and cost may realistically be a barrier to obtaining all of these assessment services in a short period of time. It is generally assumed that a client has the cognitive capacity to participate in any given type of psychosocial treatment, but this may,

at times, be a false assumption. Poor nutrition, concomitant use of other drugs and alcohol, other medical illnesses, head injuries, and educational deficiencies are potential causes of cognitive impairment that may diminish the client's capacity to profit from psychosocial treatments. In most treatment programs, individuals are started in the program, and the therapist detects cognitive problems as they are seen. Then a person may be referred for evaluation of specific cognitive deficits if such skilled personnel are available. If they are not available, switching a client to a form of treatment that can be managed at the patient's current capacity is often necessary. Assessing marital and family problems is also an important part of the process. Vocational problems with unemployment and underemployment also have to be assessed and a practical determination made as to what resources can be brought to bear considering the level of resources that each client may or may not possess. The next section deals with individual forms of treatment. These are somewhat arbitrarily separated for discussion, but in fact, in many treatment centers, these different treatment modalities are intermingled.

Psychosocial Treatment Modalities

The treatment modalities of relapse prevention, community reinforcement, and contingency management have all been studied in double-blind controlled trials and their effectiveness is well established. Some of the other treatment modalities discussed below have not been as well studied, but small research studies and/or clinical consensus support their effectiveness. Many of these therapies have been standardized. Training manuals for therapists and workbooks for clients are available commercially and often through governmental sources such as the Substance Abuse and Mental Health Services Administration and NIDA. This has resulted in greater fidelity of therapies, improved therapist skills, and better client outcomes.

Because return to use/relapse is a ubiquitous feature of all addictions, cognitive behavioral techniques should be applied to develop skills to heighten relapse prevention. Most relapse prevention treatments in use today incorporate elements such as general coping/problem solving, managing slips (light exposure to cocaine) to avoid a major relapse binge, coping with craving, rehearsal of substance refusal and strengthening assertive skills, stress management without drugs and managing seemingly irrelevant decisions and events that frequently led to past relapses. Randomized clinical trials pairing relapse prevention to other psychosocial therapies have not always demonstrated end-of-treatment superiority for relapse prevention techniques. However, the efficacy of relapse prevention strategies appears to strengthen over time. In one study conducted by Carol and colleagues, relapse prevention about as effective as case management procedures at the end of treatment; but at 1 year after treatment, patient outcomes using relapse prevention were superior to case management procedures. Frequently, relapse prevention techniques are now coupled to treatment modalities.

Community reinforcement techniques are often coupled with vouchers so both are discussed together. Community reinforcement is a highly individualized set of treatments designed to promote improvement in several key areas that have been shown to be important for recovery from cocaine dependence. Clients with spouses or significant others are offered marital/couples therapy to repair relationships and build stronger bonds. Unemployed or underemployed clients are given vocational assistance to improve this domain. Usually the group setting of clients' treatment aids in building new social network and recreational behaviors in ways that avoid exposure to cocaine-using friends. To support this latter goal, clients are often encouraged to attend self-help groups such as Cocaine Anonymous and Narcotics Anonymous when such programs are available. Various types of cognitive behavior training build skill proficiency in substance refusal, improve social skills, and provide structure in the person's life and mood control without the use of drugs. When alcohol dependence is a complication of the cocaine dependence, Alcoholics Anonymous self-help groups and medication management such as disulfiram, naltrexone, or acamprosate may be recommended, depending on the health or special needs of individual clients. Voucher-based incentive programs may facilitate abstinence from cocaine and other substances, improve client retention and treatment, and are frequently used as motivational enhancements. Urine drug screen (UDS) monitoring is often conducted two to three times a week and negative UDS results are linked to receiving vouchers. The sophistication of a voucher system can include banking of vouchers with negative urine results and reducing the bank for positive urine results. However, research has noted that a carrot and stick approach with too many aversive consequences leads to higher client dropouts.

Self-Help and 12-Step Groups

Techniques of Alcoholics Anonymous have been scientifically studied in research funded by the National Institutes Alcoholism and Alcohol Abuse. The techniques compare favorably with the cognitive behavioral therapies discussed above, particularly in individual treatment. Large comparison trials enrolling cocaine-dependent clients in therapies such as Narcotics Anonymous or Cocaine Anonymous have not been conducted.

For most clients with cocaine dependence, self-help groups appear to provide an additional source of support with socialization augmenting the formal treatment program. It is important that therapists and other health care providers prepare their clients for self-help groups. When possible, having a client escorted to the first few meetings by an established stable member is a good introduction. Clients need to be reminded that self-help groups may provide contradictory and sometimes even counterproductive information that is in contrast to their standard therapies. This can be particularly problematic for patients with a dual diagnosis and special needs who are on pharmacotherapies for psychiatric disorders. One client with bipolar disorder said, "I was told that being drug free, meant not taking my lithium, too." Re-hospitalization and personal and family suffering can be the result. Therapeutic processing of early self-help group experience is extremely valuable.

Inpatient Treatment

Inpatient treatment programs for cocaine dependence were developed from the 28-day treatment models for alcohol, sometimes called the Minnesota model. Such programs were common in the 1970s and 1980s but have lost favor with private insurance carriers. Treatment in these residential hospital facilities was highly structured and included multiple activities such as 12-step self-help meetings, group psychotherapy, relaxation and coping training classes, educational classes, and individual therapy. Treatment was often supportive and confrontational, combining techniques of motivational training, cognitive behavior therapy, and relapse prevention, but rarely contingency management.

Residential Treatment

Residential treatment programs are usually defined as programs that are 90 days or longer in duration. Such programs are generally reserved for people who fail the intensive outpatient treatments, 28-day treatment programs, or sometimes for individuals whose environment is so destructive to the treatment process that only the distant long-term treatment setting seems plausible. Some residential treatment centers are affiliated with drug courts and receive most of their referrals from the criminal justice system. It is common in these programs for clients to be expected to work at least part-time, and to participate in therapeutic community groups, group psychotherapy, and 12-step self-help meetings. These programs have limited access to medical and psychiatric services on-site. Senior staff members are often clinical psychologists, social workers, or counselors. Much of the therapeutic work structure and guidance are provided by clients who have been enrolled in the program for relatively long periods of time. Residential programs often provide transitions to halfway houses similar to those for patients with other disorders. However, halfway houses for cocaine recovery are often only available in larger communities. Sometimes these are self-regulated group homes where one resident is in charge of rents and ensures the conduct within the community. Clients are expected to work, maintain the rules of the halfway house, stay clean from all drugs, and follow their outpatient treatment.

Treatment as Usual

The term treatment as usual is no more than a cliché that is often used in studies evaluating the efficacy of cognitive behavior therapy, that is, motivational effectiveness training, contingency management, or relapse prevention. Treatment-as-usual programs represent a spectrum of intensity of care and therapist experience and education levels. In larger urban areas, many state programs have the benefit of local state and federal funding plus some fees paid by clients. Intensive outpatient programs are likely to be the norm, sometimes associated with small inpatient detox units that are usually reserved for the treatment of withdrawal from alcohol or sedative hypnotics. Medical and psychiatric services are extremely limited. The exception is methadone maintenance programs, where nursing staff and some physician coverage is provided. In dual-diagnosis programs, psychiatrists and psychologists play significant roles. Rural treatment programs that are underfunded may offer limited individual outpatient counseling services and urine drug screen testing, but empirically-based treatment approaches as described above are often lacking. Twelve-step groups for cocaine-dependent patients may be nonexistent in these areas and travel to self-help groups, group therapy, and other services may represent a significant barrier for clients.

In summary, psychosocial treatments are effective but have significant limitations when viewed from a public health perspective. Even with the best of therapies, only somewhere between a third and a half of individuals attain abstinence from cocaine dependence with any one treatment. Psychosocial treatments are time intensive, expensive, and not available in many parts of the country.

Medication Treatment of Cocaine Dependence

The topic of medication development for the treatment of cocaine dependence is described in detail elsewhere in this volume. In this section, we briefly summarize three biological and pharmacologic areas

that show promise as proof-of-concept therapies augmenting psychosocial treatments for cocaine dependence.

Disulfiram has been used to treat alcohol dependence since the late 1940s. It blocks dopamine beta-hydroxylase in synapses and increases extracellular dopamine levels. Several small double-blind controlled trials in cocaine-dependent subjects have demonstrated efficacy superior to placebo. Nevertheless, questions regarding the safety of disulfiram remain and larger trials evaluating effectiveness and safety have not been conducted. Similar drugs that have more focused pharmacologic activity may be effective and safer.

N-Acetylcysteine is a commonly occurring amino acid used to treat acetaminophen overdose and as a mucolytic agent to treat pulmonary complications of cystic fibrosis and chronic obstructive pulmonary disease. Recent preclinical studies indicate that it is a prodrug converted into cysteine in glial and nerve cells. Extracellular cysteine exchanges one to one with intracellular glutamate to raise extracellular glutaminergic tone and can block cocaine-induced reinstatement and cue-induced reinstatement in animal models. Two small clinical trials, one in nicotine dependence and one in cocaine dependence, indicate promise for this type of therapy. *N*-Acetylcysteine itself is not ideal. It has a relatively short half-life requiring multiple oral administrations during the day, limiting practical compliance. Absorption and bioavailability are poor and more favorable agents are needed to alter glutaminergic tone.

Vaccines that link cocaine to molecules that, when injected into humans, form antigen–antibody complexes that cannot cross the blood–brain barrier is another area in which proof of concept has been established. In human laboratory studies, antibody production is adequate to markedly reduce the subjective experience of smoked cocaine. Not all subjects make adequate antibody levels, the vaccine must be injected frequently, and, with high amounts of cocaine use, the effects of the vaccine can be overridden. It is likely that these technical problems will be overcome.

SUMMARY

Cocaine addiction is a complex phenomenon involving individual vulnerabilities as well as cultural, economic, legal, and demographic modifiers. The clinical course of cocaine dependence varies greatly depending on individuals' vulnerabilities, socioeconomic factors, co-occurrence of psychiatric and medical comorbidities, as well as issues of polysubstance use. In addition, there are social, psychological, and biological factors operating simultaneously to affect the initiation, perpetuation, and course of cocaine dependence.

The treatment of cocaine dependence remains a challenge and is as yet incomplete compared with the treatment of other addictive disorders. Treatments relevant to both clinicians and the lay audience include pharmacologic and psychosocial treatment modalities, initial assessment and inpatient/residential treatment of the individual, and consumer issues including self-help and 12-step groups. Although pharmacologic treatments are limited, disulfiram, *N*-acetylcysteine, and cocaine-binding vaccines are showing promise as potential medications. Psychosocial treatments are currently the most effective but have significant limitations when viewed from a public health perspective. Even with the best of therapies, only somewhere between a third and a half of individuals attain abstinence from cocaine dependence with any one treatment. Psychosocial treatments are time intensive, expensive, and not available in many parts of the country.

Glossary

Benzoylecgonine the major metabolite of cocaine. Benzoylecgonine is the most common metabolite measured in urine drug screens to detect cocaine use.

Erythroxin coca one of several species of cocaine plants grown in the Andes mountains. Cocaine is contained in the leaves.

***N*-Acetylcysteine (NAC)** an amino acid that is used in clinical medicine to treat acetaminophen overdose and several pulmonary diseases such as cystic fibrosis and emphysema. Some preliminary research indicates that NAC may be of value in treating cocaine and nicotine addictions.

Nucleus accumbens a bilateral collection of neurons forming nuclei that are found within the midbrain. The accumbens plays a major role in reward, learning, addiction, and other compelling behaviors. Although small, the accumbens nuclei have complex functions, morphology, and multiple inputs and outputs.

OUTLINE

INTRODUCTION

Marijuana (also referred to as cannabis) is a drug derived from the flowers, stems, leaves, and seeds of the hemp plant (*Cannabis sativa*). The need for public health awareness and evidence-based clinical care for marijuana use and its disorders remains a major health care priority in the United States and beyond. Rates of marijuana use, abuse, and dependence in the United States represent a significant public health concern considering that several well-documented negative consequences have been associated with daily or weekly drug use (e.g. increased risk of severe medical disease, increased risk-taking behavior, and clinically significant life impairment).

The main aim of the present chapter is to provide an overview of marijuana use and its disorders. The chapter is organized into seven sections. First, we describe the prevalence of marijuana use and its disorders. Second, we clarify the nature of marijuana use in terms of its pharmacokinetics and acute intoxication features. In the third section, we describe the classification of marijuana use and its disorders using the current diagnostic nomenclature. Fourth, we describe the motivational bases for use of the drug. In the fifth section, we provide a synopsis of some problems associated with marijuana use and its disorders, including health problems, social problems, and psychological disturbances. Sixth, we provide a summary of the scientific work focused on marijuana, the reasons for its use, and users' relative success in quitting. In the final section, we describe some practically oriented clinical issues for primary care medical practitioners to consider in terms of the recognition and treatment of marijuana use and its disorders.

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00069-3

PREVALENCE

Marijuana has been the most widely used illicit substance in the United States for 30 consecutive years, with approximately 25 million Americans (8.6% of the population) having used marijuana in the past year, and approximately 15.2 million (6.1% of the population) having used marijuana in the past month. An estimated 10% of individuals who have ever used marijuana will become daily users. Lifetime marijuana dependence is estimated at 4% of the general population, a rate that is the highest of any illicit drug. Rates of conditional dependence, defined as the risk for developing dependence among those who have ever used the drug, indicate that marijuana is associated with a high rate of dependence potential. For example, the relative risk of marijuana dependence, given use of the drug in the past year, is estimated to be 7% among adults, which is only slightly lower than that for cocaine (12%) and greater than that observed for alcohol (5%). Furthermore, greater levels of use are related to an increased risk for dependence. Studies suggest that the rate of dependence is 20–30% among persons using marijuana on a regular (weekly) basis. Moreover, marijuana use problems have increased, with 35% of adult marijuana users in the United States currently meeting criteria for marijuana abuse or dependence, compared with 30% 10 years earlier, representing an increase of approximately 730 000 individuals.

Treatment and community studies have examined prevalence rates of marijuana use among samples suffering from a variety of medical and psychological problems. Among those seeking treatment for psychosis, approximately 23% currently use marijuana, with about half of that group currently misusing the drug. It has been reported that approximately 16% of people with spinal cord injury use marijuana. Other work has found that marijuana use accounts for as much as 25% of the primary drug problems of individuals seeking residential drug treatment. These studies suggest that marijuana use may be overrepresented among certain vulnerable populations.

PHARMACOKINETICS AND INTOXICATION FEATURES

Pharmacokinetics

Marijuana can be consumed via smoking (e.g. hand-rolled cigarettes, water pipes, nonwater pipes) or ingestion (e.g. mixed into foods, used in the process of brewing tea). The active agents in marijuana are cannabinoids (unique to the marijuana plant). There are at least 60 different cannabinoids in marijuana, although the pharmacokinetics of the vast majority of these compounds is largely unknown. Of these, the most well-known, and arguably the most important cannabinoid is tetrahydrocannabinol, which is believed to be the most potent psychoactive agent in the cannabinoid plant. The tetrahydrocannabinol content of plants from a range of sources and strains varies dramatically. With a focus on improved plant breeding and improved growing techniques, the tetrahydrocannabinol content of marijuana has increased dramatically. As one illustrative example, tetrahydrocannabinol content from a typical marijuana cigarette (joint) in the 1960s was 10 mg, whereas estimates suggest that it is currently around 1 g (or 150–200 mg). Given that the effects of marijuana are dose dependent (i.e. greater amount or potency yields greater effect), the significantly increased potency of marijuana is a major public health concern and is important in understanding the current and historical prevalence rates of use, abuse, and dependence.

Since the discovery of a cannabinoid receptor within the brain in the late 1980s, researchers have been able to explicate the process by which tetrahydrocannabinol acts on the brain. Currently, there is evidence of three potential cannabinoid receptors, only one of which is located within the brain (the cannabinoid-1 receptor). When tetrahydrocannabinol is inhaled into the body via marijuana smoking, it passes from the lungs into the bloodstream. Once in the blood, tetrahydrocannabinol attaches to cannabinoid receptors, such as the cannabinoid-1 receptor, adding to or reducing the naturally occurring endogenous ligands for these receptors (e.g. anandamide). The cannabinoid-1 receptor, in particular, has been found to mediate both neurochemical and behavioral properties of these cannabinoids including tolerance. It also is noteworthy that tetrahydrocannabinol and other cannabinoids move rapidly into fat and other body tissues but are slowly released from these tissues back into the bloodstream. Eventually, cannabinoids are cleared from the body via urine and fecal matter.

Acute Intoxication Features

In general, marijuana consumption produces a mild, relatively short period of intoxication (being high). Specifically, marijuana can produce a range of acute psychosensory experiences including perceptual distortions (e.g. hallucinogenic properties), relaxation, anxiety, acute paranoia, inhibition, and so on. Periods of intoxication depend on use patterns and potency, but tend to last for at least a few hours. Marijuana intoxication also impairs cognitive and psychomotor performance with complex, demanding tasks. There is a dose-dependent relation between marijuana use and psychomotor and

cognitive impairment, with higher doses being associated with more impairment for more demanding tasks. Although cognitive impairment for hours after using marijuana is a well-replicated phenomenon in laboratory studies, there has been consistent debate about the permanent cognitive effects of using marijuana. Some recent work suggests that individuals who have used marijuana over long periods of time demonstrate impaired performance on a variety of neuropsychological tests (e.g. attention, memory, and processing complex information) even when not acutely intoxicated. These negative cognitive effects appear to be present months and even years after successful cessation.

CLASSIFICATION

The current diagnostic criteria for problematic patterns of marijuana use, according to the *Diagnostic and statistical manual of mental disorders, 4th edition* (DSM-IV-TR), include abuse and dependence (see Table 69.1 for the diagnostic criteria for marijuana abuse and dependence). Marijuana abuse is a pattern of marijuana use that includes significant and unpleasant consequences associated with frequent use within a 12-month period. Some of the consequences associated with marijuana abuse include multiple legal problems, repeated use in physically hazardous situations, and recurrent social and interpersonal problems as a result of use. What differentiates substance abuse from dependence is that abuse only includes harmful consequences of frequent use, whereas dependence indicates compulsive use, tolerance, or withdrawal. As with diagnosis of other substance use disorders, marijuana abuse cannot be diagnosed if marijuana dependence criteria are met, highlighting the putative, more severe nature of marijuana dependence.

There are relatively few empirical data pertaining to the validity of distinguishing among marijuana use, abuse, and dependence. Moreover, for a long period of time, scholars did not uniformly endorse or support a marijuana dependence syndrome. Current research has partially laid these earlier questions to rest in that heavy users of the drug tend to report problems controlling their use, despite noted negative consequences, and experience withdrawal and other adverse symptoms when discontinuing use. In fact, estimates suggest that approximately one out of every ten individuals who use the drug become dependent on it at some point in time.

To date, researchers have used standardized interviews to index marijuana diagnoses in a manner identical to those for other types of substances (e.g. alcohol, tobacco). In contrast to the relatively recent emerging perspective that classification of marijuana along the nosological lines of use, abuse, and dependence is the optimal and most accurate approach, it has been more common historically to denote marijuana use variability by asking respondents to indicate their level of use (e.g. frequency) over a specified period of time. Collectively, then, deciding on whether nosological classification and/or a use-oriented assessment protocol (i.e. volume and frequency) is indicated may depend on the specific clinical need or research question being posed and the theoretical basis for it.

MOTIVATIONAL BASES

Researchers and clinicians have increasingly found merit in applying motivational models to understand and clinically intervene with marijuana use and its disorders. At the most basic level, such an approach recognizes that there are a number of distinct motives for using marijuana that can vary both between and within individuals. Motivational models predict that distinct motives may theoretically be related to particular types of problems. For example, specific motives may play unique roles in various aspects of use (e.g. addictive use, withdrawal symptoms, craving) or problems related to use (e.g. psychological disturbances, risk-taking behavior). Thus, enhancing efforts to explicate marijuana use motives empirically will presumably facilitate our understanding of the nature of marijuana use and its disorders as well as linkages between marijuana use and its clinically important correlates.

The Marijuana Motives Measure was developed to assess marijuana use motives. This measure has demonstrated a multidimensional measurement model across extant work – specifically, a five-factor solution denoting Enhancement, Conformity, Expansion, Coping, and Social motives for marijuana use, each with satisfactory levels of internal consistency. Existing motivation-oriented work on marijuana is important in terms of informing the understanding of how and why marijuana use may be related to certain patterns of substance use and psychological problems. Greater levels of Coping, Enhancement, Social, and Expansion motives for marijuana use have each been found to be concurrently, significantly associated with frequency of marijuana use in the past 30 days. Likewise, more severe forms of marijuana use (e.g. dependence) are associated with greater motivation to use marijuana for multiple reasons. These associations between motives for use and frequency of use do not appear to be attributable to alternative factors such as the amount of time being a marijuana user or other types of concurrent substance use. However, the exact directional relation between marijuana motives and patterns of marijuana use remains underexplored. Still, it is noteworthy that specific motives may be relevant to the understanding of psychological vulnerability.

TABLE 69.1 Diagnostic and Statistical Manual of Mental Disorders, 4th Edition, Text Revision Criteria for Marijuana Abuse and Dependence

Abuse criteria

A. Maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by one (or more) of the following, occurring within a 12-month period:

- **I.** Recurrent use resulting in failure to fulfill major role obligations at work, school, or home
- **II.** Recurrent use in which it is physically hazardous
- **III.** Recurrent marijuana-related legal problems
- **IV.** Continued use despite persistent or recurrent social or interpersonal problems caused by or exacerbated by the effects of marijuana

B. The symptoms have never met criteria for marijuana dependence

Dependence criteria

A. Maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following, occurring at any time in the same 12-month period:

- **I.** Tolerance, as defined by either of the following:
  - **(a)** A need for markedly increased amounts of the substance to achieve intoxication or desired effect
  - **(b)** Markedly diminished effect with continued use of the same amount of the substance
- **II.** Withdrawal, as defined by either of the following:
  - **(a)** Characteristic withdrawal syndrome associated with marijuana
  - **(b)** The same (or closely related) substance is taken to relieve or avoid withdrawal symptoms (Note: In the current version of DSM-IV-TR, marijuana withdrawal is not a diagnostic criterion)
- **III.** Marijuana is taken in greater amounts or over a longer period of time than was intended
- **IV.** There is a persistent desire or effort to cut down or control marijuana use
- **V.** A great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects
- **VI.** Important social, occupational, or recreational activities are given up or reduced because of marijuana use
- **VII.** The substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by marijuana

For example, coping motives for marijuana use, but not other motives, have been significantly predictive of negative affect, anxious arousal, posttraumatic stress symptoms, and anhedonic depressive symptoms. These types of findings may have important theoretical implications for a better understanding of previous research linking marijuana use to affect-based psychological vulnerability.

NEGATIVE CORRELATES

Marijuana has historically been viewed by some as a less severe or soft drug. In contrast, scientific study has provided empirical evidence that marijuana use and its disorders are associated with a number of clinically significant problems. Indeed, there are several empirically documented negative consequences of frequent or problematic marijuana use (typically defined as weekly or daily use). These negative effects are evident in physical, social, interpersonal, and, more recently, psychological realms. In this section, we describe examples of work pertaining to possible negative correlates of marijuana use.

Health-Related Problems

Perhaps the foremost negative effect linked to various types of marijuana use is its impact on physiological processes, particularly the cardiovascular and pulmonary systems. For example, frequent marijuana use is associated with increased risk of severe respiratory illnesses, especially chronic bronchitis. Other work has shown that compared with individuals who do not use marijuana or tobacco, or with tobacco smokers who have no history of marijuana use, the lung function of those who use marijuana regularly is significantly poorer. A series of important large-scale prospective studies also has documented the negative effects of marijuana over time on pulmonary functioning. Though

the results across investigations are not fully consistent, they converge on the observation that greater duration of marijuana use is related to increased bronchitis symptoms (e.g. coughing, wheezing).

There also is a link between marijuana use and cancer. Most investigations suggest that there is an increased risk of lung cancer among more frequent and longer-term users of the drug. Controlled studies of these cancer-related negative effects of marijuana use, however, are largely underrepresented in the literature. In addition to the increased risk for lung cancer, it is noteworthy that some research suggests that marijuana use may be related to impaired immune system functioning, but these investigations, again, have not been consistently replicated. Upon close inspection of these studies, it becomes clear that some of the inconsistencies may be related to problems in the measurement of marijuana use and individual differences in use. A similar set of issues is evident for links between marijuana use and impaired reproductive effects. Nonhuman research suggests that heavier marijuana use is related to impaired reproduction capacity, but controlled evidence in humans is currently lacking.

It should be noted that although the vast majority of research has focused on elucidating putative negative health consequences or correlates of marijuana use, there has been scientific and clinical interest on possible health benefits of the drug. Namely, it has been suggested that marijuana improves certain disease symptoms (e.g. decrease in perceived pain, decrease in eye pressure, decrease in involuntary movement) and stimulates appetite. Although this body of work is complicated, the strongest evidence of possible health benefits for marijuana use appears to be focused on increasing appetite, decreasing nausea and vomiting, preventing systemic weight loss, and possibly improving pain tolerance. Notably, a recent meta-analysis including 18 controlled trials that compared cannabis treatment to placebo concluded that cannabis treatment is moderately effective for treating chronic pain. However, this analysis also indicated that there are a number of potentially harmful effects associated with cannabis treatment (e.g. impaired cognitive and motor function, mood disturbances). These findings therefore suggest that this treatment may be potentially more risky than beneficial for patients with chronic pain in the long term.

Social Problems

In addition to a number of negative physical consequences, adverse social consequences related to frequent marijuana use have been reported. For example, marijuana use is a contributing factor to impaired educational attainment, reduced workplace productivity, and impaired judgment within hours after marijuana use (e.g. among airline pilots). In all of these studies, a consistent pattern emerges: the greater the amount of use (measured in frequency of use or severity of use), the greater the impairment. The specific mechanism(s) underlying these use-related effects are as yet theoretically and empirically unspecified.

Marijuana use also has been shown to be related to other social problems. For example, quantity of marijuana use and acute intoxication have been related to general risk-taking behavior and impaired judgment. For instance, marijuana use has been linked to fatal traffic accidents and general driving impairment, even after statistically controlling for the variance accounted for by alcohol use. Also evident of risk-taking behavior, marijuana use has been found to be associated with risky sexual behavior among young adult women. Other work suggests that frequent or more severe marijuana use may lead to using more severe forms of other drugs (e.g. gateway theories). One overarching limitation to work linking certain types of marijuana use to social and interpersonal functioning, and even future use of other substances, is that there is a dearth of prospective evaluations.

Psychological Problems

A variety of psychological problems seem to be associated with marijuana use and its disorders, with psychotic spectrum disorders being more prominent. Indeed, case reports have documented that marijuana use can precede the onset of psychotic spectrum disorders such as schizophrenia at higher rates than what would be expected by chance of psychosis among regular marijuana users. Although the directional nature of the marijuana and psychotic spectrum problem association has been the subject of debate, one position has been that the use of marijuana may actually increase the risk of psychotic spectrum disorders. Consistent with this marijuana to psychotic symptoms/disorders perspective, the acute effects of marijuana use have been found to contribute to psychotic episodes and exacerbations of such symptoms among previously afflicted persons (e.g. the recurrence of psychotic symptoms). Other work has found that intravenous tetrahydrocannabinol administered to patients with schizophrenia treated with antipsychotics and nonpsychiatric controls exacerbated positive schizophrenic symptoms in the patient sample and induced positive symptoms in controls. Neuroimaging studies have found similarities between neural networks impaired by marijuana use and those known to be implicated in the cause of schizophrenia. Finally, two meta-analytic reviews of the existing empirical literature both concluded that the use of marijuana increased the risk of schizophrenia and psychotic symptoms and disorders. Although a model

proposing that marijuana may lead to psychotic spectrum disorders provides only one possible way in which these factors may be related, it documents the importance of understanding marijuana in the context of severe mental illness.

Another area of research has focused on addressing the relationship between marijuana and depressive symptoms or problems. Clinically, regular (e.g. on a daily or weekly basis) marijuana users often report a lack of motivation for completing day-to-day activities (e.g. going to school). The literature on depression and marijuana has sometimes identified statistically significant relations between marijuana use and depressive symptoms and disorders. However, the strength of the associations between marijuana and depression may be relatively weak after controlling for common variables such as gender. As one illustrative example, it has been found that marijuana use in early adolescence does not significantly predict later depressive symptoms after controlling for distress and interpersonal functioning in earlier adolescence. These findings, when considered in the context of the psychotic spectrum research noted earlier, highlight that marijuana should not be considered to have the same types of linkages with all forms of mental illness.

Another stream of more recent work has begun to address the relations between marijuana use and anxiety symptoms and disorders. This work was initially stimulated by the observation that marijuana use may acutely promote heightened levels of anxiety symptoms and elicit panic attacks under certain conditions or among certain individuals. For example, approximately 40% of weekly marijuana users reported at least one panic attack related to such use. These prevalence rates are noteworthy in light of lifetime rates of panic attacks among the general population of approximately 5–8%. The interaction between marijuana use and anxiety sensitivity (fear of anxiety and related internal sensations) is related to increased levels of anxiety symptoms among marijuana users who also use tobacco. Thus, certain individual differences such as anxiety sensitivity may be important to consider in understanding the links between marijuana use and anxiety states and disorders.

It also has been found that a lifetime history of marijuana dependence, but not use or abuse, is related to an increased risk of panic attacks after covarying the effects of polysubstance use, alcohol abuse, and demographic variables. Likewise, other research also has found that adolescent-onset marijuana use and dependence are significantly, prospectively associated with increased odds for the development of panic attacks and panic disorder. However, marijuana use or dependence is not incrementally associated with the development of panic after controlling for daily cigarette smoking. These recent findings underscore the importance of considering the role of cigarette smoking in the context of marijuana use in regard to understanding panic vulnerability.

Another emerging area of study has focused on marijuana and posttraumatic stress disorder (PTSD). Extant, albeit limited, empirical work has documented that (1) PTSD symptoms are associated with greater frequency of marijuana use; (2) greater (subclinical) PTSD symptom severity among persons exposed to trauma is significantly related to increased coping-oriented marijuana use (e.g. "To forget my worries"); and (3) hyperarousal symptoms, generally, and sleep problems, specifically, among those with PTSD may be key mechanisms underlying coping-oriented marijuana use.

Recent research indicates that coping motives may facilitate the relation between various anxiety constructs and marijuana use and disorders. Specifically, coping motives for marijuana use mediate the relation between anxious arousal symptoms and frequency of current marijuana use, as well as the relation between anxiety sensitivity and marijuana dependence. This research indicates that people may use marijuana as a means of coping with anxious arousal symptoms and anxiety sensitivity.

MOTIVATION TO QUIT, REASONS FOR QUITTING, AND SUCCESS IN QUITTING

It is important to point out that marijuana has many cardinal features of addiction similar to hard drugs. For many individuals who use marijuana, tolerance to the drug develops and, presumably, contributes to more frequent or heavier use patterns or dosing with more potent (more pure tetrahydrocannabinol) forms of the drug. For example, nonhuman research and, more recently, a smaller human empirical database suggest that marijuana discontinuation among regular users produces an internally consistent withdrawal pattern. Disrupted sleep, nightmares, nausea, anxiety, tension, irritability, sweating, and chills are common withdrawal symptoms. Many of these symptoms appear early after drug discontinuation, and some may last for weeks beyond the quit day (e.g. disrupted sleep). This withdrawal profile can appear relatively quickly during the course of use (e.g. relatively early in the marijuana using career) and may have clinical importance in terms of predicting relapse, although current data are not yet sufficiently developed to yield conclusions in this regard. With the recognition that marijuana use and its disorders are common addictive behaviors and can be related to life impairment and a variety of related negative consequences, it is natural to question how motivated users are to quit, what their reasons are for

quitting, and what their relative degree of success is in doing so.

Motivation to Quit

Two bodies of empirical evidence indicate that a large number of individuals who use marijuana on a regular basis (e.g. monthly) and who meet a range of diagnostic criteria (from use to dependence) are motivated to quit. The first literature has evaluated treatment-seeking behavior. Here, the Drug Abuse Reporting Program and other reports first documented that a clinically significant number of individuals were seeking therapeutic services for problematic marijuana use. Other large-scale surveys independently replicated such findings. For example, 35% of adults admitted to the US public treatment system in 1998 were admitted for treatment of marijuana problems. This rate is higher than those found for cocaine (32%), opioids (18%), stimulants (9%), and other psychoactive substances (12%). In addition, other reports involving national databases have found that the demand for treatment of marijuana use and its disorders doubled between 1992 and 1998. Even college students, who are often perceived as lacking interest in treatment, report interest in marijuana treatment. For example, studies have found that nearly one-fourth of students with more than one marijuana-related problem expressed interest in marijuana treatment, and nearly 60% of adolescent marijuana users indicated that they would participate in a marijuana treatment program targeting adolescents. It also is important to note that marijuana treatment outcome studies have documented that a large number of treatment-seeking marijuana users are not current polysubstance abusers. For example, 80% of a large, marijuana-dependent sample did not report abuse of other substances in the past 90 days and 40% reported never abusing an illicit drug other than marijuana. These data indicate that marijuana represents a significant clinical and public health problem in its own right and commonly prompts treatment-seeking behavior even in the absence of other drug use.

The second body of evidence related to motivation to quit suggests that, despite the notable rates of documented treatment-seeking behavior, most persons using, abusing, or dependent on marijuana actually attempt to quit on their own. Self-quit behavior is operationally defined as attempts to quit without professional assistance (i.e. enrolling in a formal treatment program that uses pharmacological, psychosocial, or combined therapeutic approaches). Numerous studies have reported that by young adulthood, many individuals have made multiple marijuana quit attempts on their own. It also is noteworthy that rates of self-quit attempts from marijuana are generally similar to those observed for other substances (e.g. tobacco). For example, studies of weekly marijuana users have indicated that by age 30, individuals have reported a range of three to seven quit attempts on their own. Although some of these unsuccessful quitters may seek professional treatment when they continue to fail in their quit efforts, it is not presently clear what percentage will ultimately do so and under what circumstances.

Reasons for Quitting

Current marijuana users, ranging from monthly users to those dependent on the drug, report multiple concurrent reasons for quitting. Among adults, worry about physical and psychological effects of marijuana use is the factor for wanting to quit most often cited. For example, 60% of non–treatment-seeking adult weekly marijuana users reported worry about health problems (both real and perceived) as a motivating factor for quitting, and 63% desired to quit in order to gain more self-control over their lives. Similarly, other research has found that anxiety or depressive symptoms are the most commonly reported negative effects of marijuana use and the primary reason for quitting among weekly marijuana users. Others have reported similar findings among both nontreatment seekers and treatment seekers. Such findings do not seem to vary as a function of the type of marijuana use problem. Overall, these data suggest that marijuana users typically express multiple reasons for quitting, with the most common reasons pertaining to excessive negative emotional symptoms (and impaired levels of personal self-control associated with regular marijuana use).

Success in Quitting

Individuals attempting to quit marijuana experience marked difficulty whether they make a quit attempt on their own or seek professional treatment. Numerous survey studies, for example, have documented that current, regular marijuana users (both those who are and are not dependent on the drug) who try to quit on their own report difficulty in remaining abstinent, as indexed by numerous unsuccessful quit attempts.

Although self-quit attempts (without professional assistance) tend to be the most frequently used quit strategy, it is striking that even among those who do seek professional treatment, relapse to use is a common experience. Indeed, a critical review of the treatment outcome literature for marijuana dependence concluded that patients do not show a positive response to treatment, suggesting that it is difficult to treat marijuana dependence. For example, 63% of adults receiving two

of the best available intervention strategies – motivational individualized intervention or cognitive behavioral therapy – relapsed to regular use within 4 months. At 16 months, relapse rates rose to 71 and 72% for the motivational individualized intervention and cognitive behavioral therapy, respectively. Other studies have reported similar results, and more recent clinical trials have extended such work by noting that in addition to full relapse, lapses are very common and clinically significant. For example, among marijuana-dependent adult outpatients receiving treatment, 71% lapsed (defined as any marijuana use) within 6 months, 46% within 3 months, and 24% within 1 month. In addition, 71% of lapsers ultimately experienced a full relapse (defined as four or more days of use per week).

It also should be noted that there have been historically few pharmacotherapy options available for marijuana use disorders. In fact, currently there are no medications approved by the United States Food and Drug Administration for marijuana use disorders, although a number of agents are currently being investigated.

Although marijuana relapse is now a well-documented, prevalent clinical problem, there has been relatively little scientific work focused on predictors of success or failure in attempts to quit using marijuana. The work that has been completed has been broadly guided by social learning, stress and coping, and behavioral economic theories of substance use and relapse. These studies have thus far provided a number of initial and important observations: (1) early lapses are predictive of later relapses among adult and adolescent individuals abusing or dependent on marijuana, regardless of whether they receive formal treatment or not; (2) personal stressors (e.g. family conflict) are related to relapse among individuals who abuse or are dependent on marijuana and are receiving outpatient treatment; (3) other substance use and substance use by peers are predictive of relapse to marijuana use among adolescent outpatients who are abusing or dependent on marijuana; and (4) the level of self-efficacy (i.e. beliefs regarding one's ability to refrain from use) for abstaining from marijuana use among adults who are abusing or dependent on marijuana and are seeking treatment is predictive of later relapse.

CLINICAL ISSUES

Given that marijuana use and its disorders are common and can be associated with a relatively wide variety of negative problems, clinicians, such as primary care physicians who interact with patients in nonspecialty clinical settings, ought to be knowledgeable about the basic issues in clinical care for this drug problem. To facilitate this process, we now turn to a discussion of some core clinical competencies by highlighting basic assessment and treatment strategies. This discussion is broadly relevant to clinical practitioners working in medical, dental, and psychological sectors of the health care industry.

Basic Competencies

The most basic level of competency of clinical relevance focuses on simply being aware of the scientifically developed knowledge on the prevalence and impact of marijuana and its disorders. Clinicians should initially strive to attain an overall awareness of marijuana use and behavior as it relates to their patient population(s). By obtaining such knowledge, the clinician is better equipped to offer patients accurate information about problems related to marijuana use. More specific goal-oriented targets can include, but are not limited to, being able, efficiently and capably, to: (1) describe the prevalence of marijuana use and its disorders; (2) describe regional marijuana use patterns; (3) describe the negative physical and psychological consequences of marijuana use and dependence; (4) describe the importance and role of marijuana treatment, particularly those methods based on evidence-based resources; (5) maintain a general awareness of emerging research related to the treatment of marijuana use and its disorders; (6) understand the criteria used for defining marijuana use, abuse, and dependence; and (7) communicate an interest and willingness to consult with other resources when marijuana knowledge may be limited.

A second basic competency skill domain pertains to developing basic assessment and counseling skills for dealing effectively with marijuana use and its disorders. This domain of competence builds naturally from the foregoing description of general knowledge and awareness. This area of work necessarily begins with developing a level of clinical comfort with marijuana use topics and being capable of engaging a patient in a discussion focused on this topic. From the counseling perspective, a variety of core skills are necessary, including, but not limited to: (1) having the capacity to be an active listener and demonstrate an empathetic stance regarding clinical care involving marijuana-related issues; (2) being able to communicate the strengths and challenges of evidence-based care treatment approaches for marijuana use and its disorders in a nonthreatening manner; and (3) being able to understand basic models of behavior change that pertain to marijuana use and meaningfully communicate levels of motivational stage and readiness to clients.

From an assessment perspective, basic competencies are needed to understand how to evaluate marijuana

use behavior and history adequately. Without this level of proficiency, it will be challenging to document readiness to quit or success in doing so. The overarching goal is to learn to comprehensively document and obtain accurate information that can be used in a clinically meaningful manner. The assessment process can be usefully divided into two global phases: intake (or initial assessment) and ongoing assessment. For the intake assessment, key variables to assess include the extent and nature of marijuana use from a lifetime and current perspective; documenting current interest and motivation in quitting; using evidence-based technologies for documenting marijuana use, abuse, and dependence; identifying (with the client) barriers to quitting currently; identifying strengths in the client or the environment (e.g. social support) for quitting; documenting the nature of past quit history and relative degree of success in such attempts; and personal as well as cultural variables that may affect marijuana use and decisions regarding use. The intake assessment process should also integrate information about the client's medical and psychological history in order to understand how such factors may influence the ongoing marijuana use or attempts to quit.

Ongoing assessments require an understanding of each client and the specific variables that need to be regularly tracked to accurately and objectively document (and understand) the motivation to quit marijuana use behavior. Marijuana use behavior, ongoing life stressors, and current motivation to quit are possibly important targets. This information can be used to track and understand ongoing efforts to quit, and to help clients formulate a plan for making a quit attempt that is individualized to their specific needs and life circumstances.

Aside from the individual level of commitment to professional development, it is a reality that most medical care occurs within a context that intersects with other health care professionals. Therefore, enlisting the systems involved in such clinical work in an integrated manner may be a powerful resource for dealing with marijuana use and its disorders. The need for such systems-oriented care is particularly evident given that educational efforts solely focused on the individual have not always been met with large degrees of success in the substance use field.

SUMMARY

Understanding and treating marijuana use is an important public health priority. Despite the increasing recognition that marijuana use and its disorders are not actually harmless, the scientific literature pertaining to the cause and maintenance, assessment, and treatment of marijuana use and its disorders is still in its beginnings. The next decade promises to be an important time to marshal resources to bridge major knowledge gaps and translate such developments into promising prevention and treatment approaches.

OUTLINE

WHAT IS METHAMPHETAMINE?

Methamphetamine is the chemical N-methyl-1-phenylpropan-2-amine. Common synonyms include methylamphetamine and metamfetamine (international nonproprietary name). Methamphetamine, a powerful stimulant drug, is a controlled substance under international drug control conventions due to its highly addictive nature and serious health consequences. The effects of intoxication include euphoria, wakefulness, hypervigilance, confidence, and energy. Adverse effects include dependence, psychosis, and a range of other mental and physical sequelae, which are discussed in this chapter. On the illicit drug market,

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00070-X

methamphetamine is sold under a variety of pseudonyms such as crystal, shabu, ice, tik, ya ba, base, pure, and speed.

HISTORY

Methamphetamine was first synthesized by Nagai in Japan in 1893. It was used by military combatants during World War II and Japan experienced several subsequent epidemics of use after its release onto the broader market. A similar phenomenon was observed in Europe and the United States with amphetamine, methamphetamine's less potent chemical analog. Both drugs gained popularity as pharmaceutical agents because of their decongestant properties and their capacity to suppress appetite, alleviate depression, and overcome fatigue. Throughout the subsequent decades, many accounts of abuse of pharmaceutical preparations containing these amphetamine analogs and related incidents of psychosis were published in the scientific literature. This led to the withdrawal of some pharmaceutical products from the market and their eventual international control under the 1971 United Nations Convention on Psychotropic Substances. While methamphetamine is still available as a pharmaceutical drug in some countries (e.g. under the trade name Dexosyn® in the United States), its medical application has been largely superseded by less potent and less addictive amphetamine analogs. Today, methamphetamine is more typically associated with illicit drug use.

GLOBAL TRENDS IN USE

In 2010 the United Nations Office on Drugs and Crime estimated that there were between 14 and 53 million methamphetamine consumers worldwide. Many countries do not have accurate estimates of the prevalence of methamphetamine use. Among those that do, the past year use of the drug varies between 0 and 5% of the adult population (these figures often include the use of methamphetamine and/or amphetamine). In a broad sense, methamphetamine is a major drug problem for several countries in Southeast and East Asia, North America, and the Pacific (Australia and New Zealand). There are only small pockets of methamphetamine use within Europe (the Czech Republic and Slovak Republic); amphetamine is more common in other parts of the region. Methamphetamine has recently become a concern in South Africa, and there is evidence of clandestine manufacture emerging in South Asia, Southwest Asia, and South America, but its use in these regions is not well established.

EFFECTS OF METHAMPHETAMINE

The principle effect of methamphetamine desired by its users is the euphoria, or the more general sense of well-being, that it instates. This effect is coupled with an increase in confidence, energy and enthusiasm, alertness, and an increase in mental acuity. Intoxication tempers appetite and staves off sleep. The drug also increases respiration, elevating heart rate and blood pressure; it causes pupillary dilation and decreases micturition. Studies have found that intoxication (at least mild intoxication) speeds reaction time and can improve performance of activities that require sustained vigilance, giving its users the capacity to remain engaged in even the most tedious of tasks. However, improvements in performance are offset by changes in attentional processing and shifts in goal-directed activities (e.g. users sometimes engaging in unproductive activities for long periods of time). The drug's capacity to instate bravado can also affect judgment and lead people to engage in high-risk situations. Signs of intoxication are difficult to detect at low levels, with the drug having no obvious deleterious effects on motor coordination; the only tell-tale signs of intoxication are that the person may appear more confident, talkative, and enthusiastic than normal. At high doses, intoxication may be reflected in agitation, anxiety, hyperarousal, excitability, and incessant talking. A better indicator of use is the ongoing circadian disturbances (insomnia followed by hypersomnolence), weight loss, and the labile mood that tend to accompany regular stimulant use.

DEPENDENCE ON METHAMPHETAMINE

Methamphetamine is a highly addictive drug that has a defined dependence syndrome. Dependence on methamphetamine is characterized by tolerance, affective and physical withdrawal symptoms, users taking the drug to relieve withdrawal, and rapid reinstatement of use following periods of abstinence. Tolerance to methamphetamine is reflected in the use of higher doses, more frequent use, and a shift to more efficient routes of administration (e.g. injecting). The withdrawal syndrome from methamphetamine involves an acute phase that lasts about 1 week. Dominant symptoms include fatigue, craving, irritability, depression, anxiety, circadian disturbances, poor concentration, and anhedonia. Low-level symptoms of withdrawal can persist for a further 2 weeks after this acute withdrawal phase. The management of methamphetamine withdrawal is usually symptomatic. Although a number of targeted pharmacotherapies have undergone trials, none have been found to be effective.

NEUROCHEMISTRY

Methamphetamine belongs to a family of drugs often referred to as amphetamine-type stimulants. This class of drugs shares a ring-substituted amine structure and has similar effects on monoamine transmission. Methamphetamine increases monoamine levels via several mechanisms: methamphetamine reduces the reuptake of monoamines into the presynaptic nerve terminal by binding to, and reversing, the monoamine transporters; it causes the leakage of monoamines from the synaptic vesicles inside the presynaptic nerve terminal, increasing the amount of monoamines released when the nerve fires, and it slows the metabolism of monoamines by inhibiting monoamine oxidase. The primary action of methamphetamine is on dopamine; increases in dopamine in the brain's mesolimbocortical pathway are believed to mediate the pleasurable effects of the drug.

PHARMACOKINETICS

The bioavailability of methamphetamine depends on how the drug is taken. Methamphetamine can be ingested, injected intravenously, absorbed through the nasal mucosa when snorted, or the vapors of the heated drug can be inhaled and absorbed through the lungs (i.e. smoked). Methamphetamine injection and smoking yield high bioavailability (around 90%) and the effects of the drug peak within 10–20 min after administration. Intranasal use also yields good bioavailability (79%) with peak effects within a similar time frame. The effects from oral administration are slower to occur (45 min to 1.5 h) and bioavailability is comparatively lower at 67%. The subjective effects of methamphetamine are strongest within the first hour and diminish from 4 to 6 h after using the drug. The half-life of methamphetamine in humans is around 11 h, irrespective of the route of administration. Much of the dose is excreted unchanged in urine (37–45% of the nominal dose) alongside smaller quantities of its metabolites, which include amphetamine. Elimination time varies with the pH of the urine, this being faster when urine is acidic. Methamphetamine can usually be detected in blood or urine for 2–3 days after use. Detection in saliva is less reliable.

ISOMERS

Methamphetamine occurs in dextrorotatory and levorotatory stereoisomers (i.e. D-methamphetamine and L-methamphetamine). The D and L isomers of methamphetamine are absorbed similarly in the central nervous system, but the D isomer produces a stronger and longer-lasting high, and more intense cardiovascular effects, while the L isomer has a slightly longer half-life (approximately 13–15 h vs 10 h for D-methamphetamine). The stronger potency of the D isomer lends itself to use in pharmaceutical preparations but it also has greater abuse potential. Illicitly produced methamphetamine may contain either isomer or both isomers depending on the precursor chemicals used in its production.

CHEMICAL PRODUCTION AND PRECURSORS

Methamphetamine is synthetically produced using a variety of chemical precursors and reagents. The most common precursor chemicals seen in clandestine manufacture are phenyl-2-propanone (P2P, also known as phenylacetone), ephedrine and, most recently, pseudoephedrine. These chemicals are diverted from their legitimate use (e.g. pseudoephedrine is used as a decongestant in cold and flu medications) into clandestine drug manufacture. Manufacture from P2P produces a racemic mixture of the D and the L stereoisomers of methamphetamine, but this method of manufacture has been largely replaced by production using pharmaceutical grade pseudoephedrine, which produces racemically pure D-methamphetamine. Additional chemical refining processes can be used to remove impurities and create very pure methamphetamine solution that will yield shards of crystalline methamphetamine.

PRECURSOR REGULATION AS A METHOD OF SUPPLY CONTROL

Preventing the diversion of precursor chemicals into clandestine drug manufacture has become a keystone in efforts to combat illicit methamphetamine supply. In 1988, the United Nations instigated the Convention Against Illicit Traffic in Narcotic Drugs and Psychotropic Substances, which deemed criminal the supply and trafficking of such chemicals with the intent to manufacture methamphetamine. Various countries have additionally implemented domestic regulations to prevent the diversion of precursor chemicals from their legitimate use, including restrictions on the availability of cold and flu medications containing pseudoephedrine. Some of these regulatory changes have been associated with reductions in methamphetamine-related harms, but their efficacy is, to some extent, undermined by the capacity of clandestine chemists to develop alternative methods of manufacture and to source precursor chemicals from countries where domestic controls are lax.

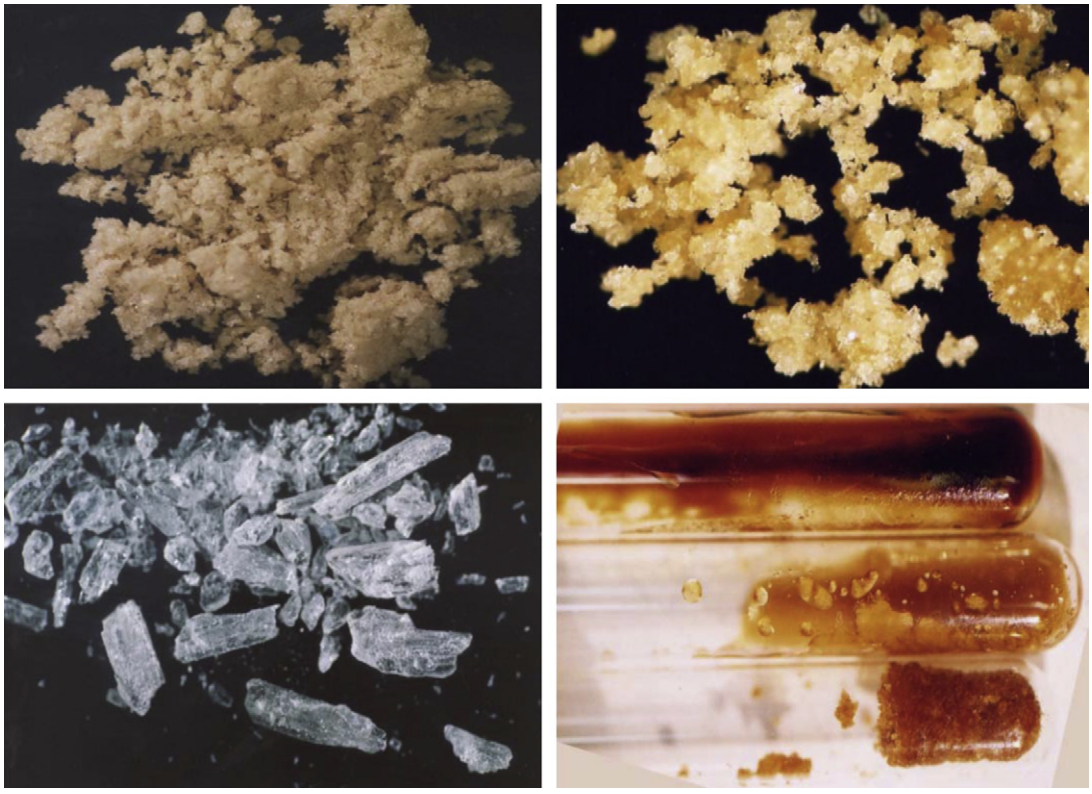

FIGURE 70.1 Methamphetamine seized in Victoria, Australia. Images provided by the Victoria Police Forensic Services Department, Chemical Drugs Intelligence Team.

ADULTERANTS

Methamphetamine that is bought and sold on the illicit drug market is typically not pure. Adulteration is necessary to control the strength of the dose being delivered; only 20–50 mg of methamphetamine is needed to induce a robust drug effect. Adulteration may also be used by drug dealers in an attempt to increase their profit margins. Contrary to popular belief, most of the adulterants used to prepare methamphetamine for sale on the illicit drug market are relatively innocuous (e.g. sucrose). Harmful constituents usually occur because of incorrect manufacturing procedures or contamination with reagents used in the manufacturing process, which can include toxic heavy metals and carcinogens.

FORMS OF METHAMPHETAMINE

Methamphetamine is an unusual drug in that it is sold on the illicit drug market in various physical forms (Fig. 70.1). Crystalline methamphetamine is probably the most widely recognized form of methamphetamine, but the drug is also sold in powder, liquid, or tablet form. In some parts of the world (especially Southeast Asia) methamphetamine is combined with ketamine, and sometimes other synthetic stimulant drugs, and sold in pills, often called ya ba (meaning crazy medicine in Thai). In Australia methamphetamine is a common ingredient in pills sold as ecstasy. This trend of marketing methamphetamine in such a variety of forms, and under different street names, has caused confusion about what drugs people are actually using and has made it difficult to monitor trends in methamphetamine use.

NATURAL HISTORY OF METHAMPHETAMINE USE

The onset of methamphetamine use typically occurs in late adolescence, after the onset of cannabis and alcohol use, with problems from these various drugs tending to coalesce in early adulthood. In line with this, most methamphetamine use is seen among young adults and consists of infrequent noninjecting use of the drug. Most people cease use as they mature into their later adulthood; however, a proportion will become dependent on the drug and may continue to use for many years.

The progression to regular use and dependence typically occurs within a few years of initiation, with

epidemiological studies suggesting that around one in five users will make this transition. Similar to the dependence on other drugs, the risk of becoming dependent on methamphetamine is influenced by a range of individual, environmental, and societal factors. More frequent drug use, and efficient routes of administration, particularly those that provide a more immediate drug effect, can also facilitate the development of dependence. While methamphetamine use overall tends to be more prevalent among males than females, males are more likely to progress to chronic dependent use.

METHAMPHETAMINE USE PATTERNS

Most methamphetamine use occurs among adolescents and young adults who use the drug in social settings (e.g. at dance venues) because it enhances confidence and increases energy. In this context, use is typically infrequent (e.g. monthly or less often) and involves noninjecting routes of administration (i.e. snorting, swallowing, or smoking the drug). Use patterns tend to become less social and more frequent with the progression to dependence. Dependent users may take the drug several times a day, and a characteristic binge and crash pattern is often observed, where users may take the drug for days on end until they eventually succumb to the effects of sleep deprivation. Occupational use is also commonly associated with methamphetamine use. The drug's ability to enhance wakefulness and improve vigilance makes it a popular drug for use among long-distance transport workers and shift workers.

METHAMPHETAMINE INJECTION

Methamphetamine available on the illicit drug market readily dissolves in water, which makes it suitable for injection. Methamphetamine use by injection tends to be associated with more problems than oral or intranasal use. Besides the risk of contracting bloodborne viruses (e.g. human immunodeficiency virus (HIV) and hepatitis B and C), and other injection-related problems (e.g. thrombosis, endocarditis), injecting users face an increased risk of dependence and related problems (e.g. financial difficulties, social problems, and poor mental health). Injecting users tend to be older, and they often have a long history of treatment attempts and involvement with the criminal justice system. It is not uncommon for methamphetamine injectors to have a history of opioid injection and heavy polydrug use. This can further exacerbate health problems among methamphetamine injectors and complicate treatment provision.

METHAMPHETAMINE SMOKING

Methamphetamine vaporizes at high temperatures, allowing the drug to be smoked. Smoked methamphetamine is absorbed in the lungs from where it directly enters the pulmonary blood supply giving a rapid drug effect that rivals injection. This efficient absorption of methamphetamine makes smoking a popular route of administration with recreational methamphetamine users and dependent users alike. Smoking can be associated with compulsive use; it conveys a greater risk of dependence than other noninjecting routes of administration (e.g. snorting or swallowing the drug) and, similarly, tends to be associated with more problems (Table 70.1).

Patterns of smoking methamphetamine are also different from those associated with other routes of administration. Crystalline methamphetamine (which is the form of methamphetamine most commonly smoked) vaporizes when heated and recrystallizes when cooled, allowing unused methamphetamine to be saved and reused later. This property of methamphetamine allows smokers to titrate their dose, inhaling small amounts of the drug at regular intervals to reinstate the high. It is also a convenient property for social users of the drug who wish to share their methamphetamine among friends. Crystalline methamphetamine is typically smoked in a purpose-made glass pipe. While crystalline methamphetamine is the form of methamphetamine most commonly smoked, other forms of the drug can also be smoked; for example, in Southeast Asia, the smoking of methamphetamine pills is common.

TABLE 70.1 Experience of a Methamphetamine Smoker

The following quote is from a 22-year-old male methamphetamine smoker who was interviewed in Sydney, Australia, in 2004. He had first tried methamphetamine when he was 15 years old and by the time he was 20 years old, he was engaging in episodic periods of heavy use. At the time of the interview he was working full-time as a manager, living in a share-house with several other people who were smoking methamphetamine, over half of his social circle was also using the drug, and he was experiencing paranoid ideation and symptoms of methamphetamine dependence

"I was on ice daily for at least two months … pretty much everyone in the house was smoking ice, dealing ice, getting high on their own supply… it's a really more-ish drug that you want to keep smoking and smoking. Even though you are feeling the effects of the ice you still feel that you've got to have that pipe and smoke it continuously… so I fell into that pattern, again, of smoking it everyday for a month. And, again, psychologically and emotionally, I had, like, not a breakdown, but I was getting there. And even though I was still going to work and everything, it was sort of like smoking ice then smoking pot to come down again, coming up again with ice, so I just became a shell of myself, and just depressed and moody and angry. I knew it was a problem… I think ice had a hold on me… and I didn't want to admit to myself that I was pretty much addicted"

METHAMPHETAMINE PSYCHOSIS

Methamphetamine can induce a transient psychotic state that is characterized by hallucinations and persecutory ideation. Less common manifestations of methamphetamine psychosis include stereotyped repetitive behavior (punding), disorganized speech, and illogical tangential thoughts. Symptoms typically last only hours and, even in severe cases, usually abate within a week of withdrawal from the drug. A minority of users experience a more prolonged symptom pattern that resembles schizophrenia, although it is often argued that this protracted form of methamphetamine psychosis would be more accurately described as a precipitation of schizophrenia in vulnerable individuals.

Methamphetamine psychosis is most often observed among heavily dependent methamphetamine users. A higher risk is associated with a younger onset of methamphetamine use, more frequent use, and a higher blood concentration of methamphetamine. The development of the more prolonged form of methamphetamine psychosis appears to have a strong familial component, whereby the presence of psychotic illness in first-degree relatives conveys a significant risk. As such, a number of candidate genes have been proposed to mediate vulnerability to (or protection against) methamphetamine's psychomimetic properties. Methamphetamine can also precipitate and exacerbate psychotic symptoms in other psychotic disorders (e.g. schizophrenia and bipolar affective disorder) and impede the effectiveness of antipsychotic medication.

Although studies consistently show elevated levels of psychosis among methamphetamine users, prevalence estimates vary widely depending on the level of methamphetamine use and the background risk for psychosis in the population being studied. Elevated levels of psychosis among methamphetamine users are not only due to the drug but also an overrepresentation of people with other psychotic disorders (e.g. schizophrenia) among methamphetamine users. Other factors associated with heavy methamphetamine use, such as sleep deprivation and a history of trauma, can further increase vulnerability to psychosis. While these background risk factors for psychosis contribute to the high prevalence of psychotic symptoms among methamphetamine users, they cannot completely account for it. Experimental studies indicate that high doses of methamphetamine can induce a psychotic reaction and this relationship has been repeatedly borne out in epidemiological studies and clinical case reports (for a description see Bell, 1973).

The symptom profile of methamphetamine psychosis is extremely similar to acute paranoid schizophrenia but the two conditions can usually be distinguished on the basis of symptom duration; methamphetamine psychosis symptoms are comparatively transient and co-occur with methamphetamine use. There is also less evidence of a residual syndrome of negative symptoms associated with methamphetamine psychosis. Knowledge about the most appropriate treatment for methamphetamine psychosis is limited, but antipsychotic drugs do alleviate the symptoms, and often sedation is sufficient because symptoms usually recede naturally with detoxification.

AGGRESSION AND VIOLENT BEHAVIOR

Historically, both methamphetamine and its less potent analog amphetamine have been associated with bizarre acts of violence and even homicide. These incidents are believed to arise from a confluence of the drug's pharmacological properties, its ability to incite paranoia, and a range of personality and contextual factors.

From a pharmacological perspective, high doses of methamphetamine and chronic exposure to methamphetamine can increase aggression. The hyperaroused state associated with intoxication can also augment aggression that is incited by a threatening situation. This relationship appears to be specific to high doses of methamphetamine, with little evidence that low doses increase aggression.

Methamphetamine-induced paranoia also plays an important role in precipitating acts of violence. Paranoid ideation can lead methamphetamine users to misinterpret events and perceive an unrealistic level of threat in their environment, accounting for the seemingly irrational and sometimes extreme nature of methamphetamine-related violence. Such situations are further exacerbated by the background risk for violent behavior among methamphetamine users, including antisocial tendencies and impulsivity, which tend to co-occur with heavy illicit drug use.

A further important consideration in understanding the relationship between methamphetamine use and violence is that illicit drug users can also get drawn into violent crimes because they are associated with a criminal underworld or because they need to fund an expensive illicit drug habit. These types of factors increase the risk of violence irrespective of the pharmacological effects of the drug.

DEPRESSION AND OTHER MENTAL HEALTH PROBLEMS

Depression, anxiety, and other mental health problems tend to be overrepresented among people who regularly use methamphetamine, as is the case with

drug users more generally. These types of mental health problems often precede drug use and may increase the risk of someone becoming dependent on methamphetamine (or other drugs). Ongoing methamphetamine use can further exacerbate some of these mental health problems, most notably psychosis (as discussed earlier), but also depression. Withdrawal from heavy methamphetamine use can induce a pseudodepressive state that lasts several days to weeks, and which is underpinned by a downregulation of monoamine activity in brain regions implicated in the regulation of mood and affect. Such methamphetamine-related mood disturbances can be sufficiently severe as to constitute a clinically meaningful entity in their own right.

NEUROTOXICITY

Chronic exposure to methamphetamine can cause a downregulation of monoamine activity and high doses can be neurotoxic. Methamphetamine neurotoxicity primarily involves the degeneration of dopamine neuron terminals, although other neurochemical systems (e.g. serotonin and noradrenaline) can also be compromised after very high levels of methamphetamine intake. Neuronal damage is largely restricted to brain regions that receive dense innervation from dopamine neurons, including the striatum and prefrontal cortex. Methamphetamine-induced neural degeneration is mediated by oxidative stress, which occurs when normal metabolic processes are unable to cope with the large efflux of dopamine following methamphetamine intake. Recent studies have implicated a range of additional neuropathological processes that may further contribute to methamphetamine-related neurotoxicity, including disruption of metabolic processes as well as gliosis and reactive astrogliosis. Together these processes result in a loss of normal neuronal function and signal transmission.

Evidence of neurotoxicity has been seen in chronic methamphetamine users, including reductions in the density of dopamine transporters, serotonin transporters, dopamine D2 receptors and vesicular monoamine transporters, and changes in metabolic activity in dopaminergic regions. These neurochemical abnormalities correlate with psychiatric symptoms and longer-duration methamphetamine use. There is evidence in humans and animals that deficits partially recover with ongoing abstinence although recovery is not always seen.

COGNITIVE DEFICITS

There are a number of studies showing poor cognitive functioning among methamphetamine users compared to non–drug-using controls. The most consistently observed deficits are in the domains of executive function and memory, with research also showing evidence of slowed information processing, poor attention, and motor problems. Cognitive deficits in methamphetamine users have been correlated with various deficiencies in the frontal and striatal regions of the brain (i.e. those brain regions affected by neurotoxicity) but these deficits are not always correlated with exposure to methamphetamine use (i.e. duration and extent of use), undermining the argument that they are due to neurotoxicity. Importantly, a host of other factors associated with illicit methamphetamine use, besides neurotoxicity, may have a detrimental impact on cognitive functioning among methamphetamine users. These include circadian disturbances and mood disturbances related to methamphetamine withdrawal, infections such as HIV and hepatitis C, head injury, and polydrug use (including brain damage from hypoxia or hyperthermia experienced during drug overdose).

HIV RISK

Methamphetamine intoxication increases libido, and some users take the drug specifically to enhance sex. Consequently, methamphetamine has been suggested as a vector for HIV transmission. The association between methamphetamine use and sexual risk behavior has been consistently observed in a range of population subgroups, including high-risk groups for HIV infection (e.g. men who have sex with men, youth in areas of high HIV prevalence). Prospective cohort studies have observed that methamphetamine use is an independent risk factor for HIV seroconversion. In addition to the relationship between sexual risk behavior and methamphetamine use, it is thought that the drug may increase susceptibility to HIV infection through immunopathological processes.

Methamphetamine use can also increase the risk of HIV and other blood-borne viruses (e.g. hepatitis B and C), through injecting drug use. Most methamphetamine use is noninjection, but injecting is sufficiently prevalent to warrant concern about its impact on HIV epidemics and blood-borne virus transmission more generally. Substantial populations of injecting methamphetamine users have been noted in Australia, New Zealand, Japan, North America, and parts of Central and Eastern Europe.

CRIME

Crime is not especially common among recreational methamphetamine users, tending to occur mainly

among heavier users of the drug. Most heavy methamphetamine users are not only funding a methamphetamine habit, but many are also heavy cannabis users, smoke tobacco, and drink alcohol and/or use other drugs socially. Couple the high cost of such regular drug use with the low income typical of chronic methamphetamine users, and it is not hard to see why many become involved in crime. Dealing drugs is by far the most common way that heavy methamphetamine users support their drug habit, although a substantial proportion also engage in theft (particularly shoplifting to obtain food and other everyday commodities) and a minority resort to more serious crimes (e.g. robbery, fraud). There appears to be a particular association between methamphetamine use and violent crime, which is likely to be related to the pharmacological effects of the drug (see section on Aggression and violent behavior). The actual prevalence of violent crimes among methamphetamine users, however, is not greatly elevated compared to that seen with other drugs (e.g. heroin), and such crimes are far less common than either selling drugs or petty theft. Crime is also most likely to be seen among younger male methamphetamine users, particularly those with a history of conduct problems and antisocial behavior — these being generic risk factors for criminal involvement which are elevated among heavy drug users.

DENTAL PROBLEMS

Excessive methamphetamine use is associated with jaw clenching, bruxism, and cracked teeth. The often cited meth mouth syndrome refers to the proliferation of dental caries and the occurrence of gingivitis in some users of the drug. Evidence suggests that this is largely caused by poor dental hygiene, resulting from a chaotic drug-using lifestyle, rather than any direct effect of methamphetamine.

CARDIOVASCULAR EFFECTS

Methamphetamine use has been associated with a range of acute and chronic effects on the cardiovascular system. Chest pain, hypertension, tachycardia, and other cardiac arrhythmias are the most commonly observed acute cardiovascular effects of methamphetamine. Other, less common, acute complications include myocardial infarction, coronary vasospasm, acute aortic dissection, and sudden cardiac death. In addition to acute forms of cardiac pathology, methamphetamine use has also been associated with chronic cardiac pathology, which, in turn, may increase the risk of an acute cardiac event.

The forms of chronic cardiovascular disease most commonly associated with methamphetamine use are coronary artery disease and cardiomyopathy. Specifically, the use of methamphetamine, chronic use in particular, is thought to contribute to the premature and accelerated development of coronary artery disease and induce dilated cardiomyopathy. Underlying coronary artery disease, cardiomyopathy, and generalized cardiomegaly (enlarged heart) have been observed among emergency department patients presenting with acute coronary symptoms following methamphetamine use, as well as among methamphetamine-related fatalities at autopsy.

The cardiovascular effects of methamphetamine are thought to be mediated primarily by the release of catecholaminergic neurotransmitters (i.e. noradrenaline and dopamine) in the peripheral nervous system, which modulates heart rate and blood pressure. High catecholamine levels are known to be cardiotoxic, causing vasoconstriction, vasospasm, tachycardia, and hypertension. While tachycardia and hypertension are associated with increased demand for oxygen to the heart muscle, vasoconstriction and vasospasm decrease the cardiac oxygen supply. The net effect of these co-occurring conditions is a deficit in the oxygen available to the heart, which can in turn cause necrosis, fibrosis, and an increase in the size of heart muscle cells (hypertrophy). Methamphetamine has also been shown to have cardiotoxic effects that are independent of the catecholamine-mediated effects described above, which are referred to as direct cardiotoxic effects, although the mechanisms underlying these effects are still unclear.

MORTALITY

Methamphetamine is less commonly associated with mortality than opioid use but deaths can result from the cardiotoxic effects of the drug, as described above, and also from an increased risk of cerebrovascular accidents. Other causes of premature death seen among methamphetamine users include suicide and accidents. A recent systematic review of mortality rates among methamphetamine (and amphetamine) users, conducted by Singleton and colleagues, found that crude mortality rates varied between 0 and 3 per 100 person years, with substantial geographic variation in mortality. It was not clear to what extent background mortality contributed to these rates, and consequently to what extent methamphetamine elevated the risk of mortality. Only one study reported a standardized mortality, which was based on the recorded mortality among a large cohort of hospitalized methamphetamine users in the Czech Republic. This study found a large elevation in deaths among methamphetamine users

compared to the expected mortality rate (standardized mortality ratio of 6.2). As pointed out by the authors, while mortality appears elevated among methamphetamine users, there is currently insufficient understanding of the factors contributing to this elevation to draw firm conclusions about the risk of mortality associated with methamphetamine.

TREATMENT AND MANAGEMENT

Few controlled trials have been conducted to evaluate the benefit of specific treatment options for methamphetamine dependence. So far none of the treatment options that have undergone trials have proved to be particularly effective, and those that have shown promise are difficult to implement on a large scale. Behavioral interventions, such as cognitive behavioral therapy and contingency management, have improved outcomes in selected trials, but a recent meta-analysis Colfax and colleagues found no conclusive evidence that behavioral interventions, overall, yield better outcomes than passive or minimal treatment interventions. Improvements were seen with high-intensity interventions, namely those that were specifically tailored to the target population and those that used adjunctive contingency management. These high-intensity interventions have not been implemented widely within community-based drug treatment services.

There is a strong demand for pharmacotherapies for methamphetamine dependence (akin to opioid pharmacotherapies). In an attempt to meet this need, a range of pharmaceuticals have been explored, both to medicate withdrawal and as potential maintenance drugs. Most of these medications have not improved outcomes enough to warrant pursuing large-scale trials or community-based implementation, and some have had adverse side effects, or carried a high risk of diversion, which has rendered them undesirable.

In the meantime, most methamphetamine users receive treatment from generic drug treatment clinics that service the needs of people with various types of drug and alcohol problems. These services include, but are not restricted to, the medical management of withdrawal symptoms, outpatient counseling services (which may include structured psychological interventions), and residential rehabilitation programs (which may incorporate various aspects of withdrawal management and counseling). These treatment-as-usual options appear to provide at least temporary relief for the majority of methamphetamine users seeking help.

A handful of generic drug treatment services have also been tailored to cater to the specific needs of methamphetamine users. In the United States, the MATRIX model of treatment was modified for stimulant use, with this program involving a structured 16-week outpatient psychosocial treatment with follow-up care. Evaluations found that the MATRIX treatment out performed treatment-as-usual for methamphetamine dependence during treatment delivery, but once people left the treatment their drug use was similar to that seen following standard care. A similar approach has been adopted in Australia with the development of outpatient stimulant treatment programs. The self-help group Narcotics Anonymous has also been adapted for methamphetamine users, this program being called Crystal Meth Anonymous, although it has not been evaluated.

One of the endeavors of providing specialized drug treatment for methamphetamine dependence, besides improving care for methamphetamine users, is to attract more methamphetamine users into treatment. Currently, treatment coverage for methamphetamine dependence is quite low. It has been estimated that less than one-third of dependent methamphetamine users have ever received treatment for their methamphetamine use. This problem is likely to reflect the lack of low-threshold interventions, such as pharmacotherapies. But it also reflects that many users feel a low need for treatment, either because they are not particularly motivated to reduce their drug use, or because they prefer to self-manage their use rather than attend a formal drug treatment program. This problem has led clinicians and researchers to embark on a creative journey of designing treatment approaches that are more likely to engage methamphetamine users in a therapeutic process. Some of these approaches are embodied within the specialized treatment options described above; others include using internet interventions and information resources to engage with methamphetamine users who are not seeking treatment, and a stepped care approach in delivering treatment, which allows the focus and intensity of the treatment intervention to be tailored to the needs of the methamphetamine user (e.g. focusing on emotional problems associated with drug use).

SUMMARY

Methamphetamine is a powerful synthetic stimulant drug that has been around for just over a century. It was initially used as a pharmaceutical agent, but its use resulted in serious adverse effects, including psychosis and dependence, leading to its control under international drug control conventions in 1971. Methamphetamine remains available as a pharmaceutical drug in some countries, but its pharmaceutical use has been largely superseded by safer amphetamine-type analogs. Today methamphetamine remains widely used as an illegal drug, with the number of current users estimated to be between 14 and 53 million worldwide. The regions

that have been most heavily affected by methamphetamine use are North America, Southeast and East Asia, Australia, and New Zealand; however, illegal manufacture and use is spreading to affect more regions, including Africa, South and Southwest Asia, and South America. While most methamphetamine use consists of infrequent recreational use among young adults, around one in five users experience dependence on the drug, resulting in chronic use and a myriad of health and social problems. Mental health is particularly compromised, with the drug having the capacity to cause a paranoid psychosis and aggressive behavior. The cardiovascular effects are also concerning, although less well recognized. Despite the risk of dependence, and the myriad of consequent health and social problems, there is a paucity of effective specialized treatment approaches to manage either dependence or the psychiatric sequelae associated with the drug's use.

OUTLINE

Hallucinogens are a diverse group of substances that cause perceptual and cognitive distortions; they can evoke mood and thought changes as well as out-of-body experiences. Traditionally derived from plants or based on plant-derived compounds, their use in medicinal and religious ceremonies goes back for centuries. Many designer drugs and two other drug classes, dissociative and deliriant drugs, are also often classified under this category. Other club drugs that overlap with hallucinogens, such as gamma-hydroxybutyrate, are not included in this chapter. This chapter provides a brief overview of the neurobiology and mechanism of action of hallucinogens, including atypical hallucinogens. The physiologic and psychological effects of hallucinogens are described, followed by discussion on the epidemiology of hallucinogen use, diagnosis of hallucinogen intoxication and abuse/dependence, comorbidity of hallucinogen use with other drug-use and psychiatric

disorders, prevention and intervention strategies to reduce hallucinogen use, and treatment of hallucinogen-related disorders.

NEUROBIOLOGY OF HALLUCINOGENS

Classification of Hallucinogen-Type Drugs

Almost all hallucinogens contain nitrogen and are classified as alkaloids. One possible way of classifying the hallucinogens is by their chemical structure and the receptors they act on. There are two main groups: (1) the indolealkylamines, which are further divided into substituted tryptamines (e.g. psilocybin (*N*,*N*-dimethyl-4-phosphoryloxytryptamine), psilocin from *Psilocybe* mushrooms, DMT (5-methoxy-dimethyltryptamine) from ayahuasca, *Psychotria viridis*) and lysergic acid derivatives (D-lysergic acid diethylamide (LSD) from the ergot fungus); and (2) phenylalkylamines, structurally related to catecholamine neurotransmitters and represented by drugs such as mescaline (3,4,5-trimethoxy-phenethylamine) and mescaline-substituted structures (2,5-dimethoxy-4-methylamphetamine (DOM) and 2,5-dimethoxy-4-bromoamphetamine (DOB)). Figure 71.1 shows the chemical structure of the hallucinogens that are considered prototypical (typical hallucinogens: LSD, psilocin/psilocybin, and mescaline).

There are also three other groups of drugs that may have hallucinogenic effects but are not always classified as hallucinogens (or typical hallucinogens): (1) designer drugs such as 3,4-methylenedioxymethamphetamine, also known as ecstasy (MDMA), 3,4-methylenedioxyamphetamine (MDA), 3,4-methylenedioxy-ethylamphetamine (MDE), and *para*-methoxymethamphetamine; (2) dissociative anesthetics (such as phencyclidine (PCP) and ketamine), which are arylcycloalkylamines, and (3) cannabinoids. Cannabinoids are presented in another chapter of this book. Figure 71.2 shows the chemical structure of the hallucinogens that are considered atypical.

Although the action of hallucinogens is not yet fully elucidated, it is known that typical hallucinogens act on serotonergic pathways.

All of these drugs are serotonergic (5-HT_2) receptor agonists or partial agonists. The 5-HT_2 receptors represent a family of receptors that are composed of three subpopulations: 5-HT_{1A}, 5-HT_{2B}, and 5-HT_{2C}. The cortical and limbic regions are the areas with the main concentration of this subtype of serotonergic receptors. The effects of each hallucinogen are not identical because there are also other serotonergic receptors involved with different affinities for each one. While phenylalkylamine hallucinogens are somewhat selective in their affinity to 5-HT_{2A} receptors, the indolalkylamines are relatively nonselective for 5-HT receptors,

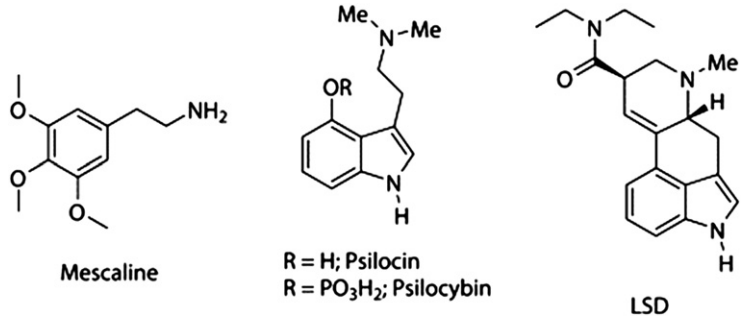

FIGURE 71.1 Chemical structures of prototypical hallucinogens: mescaline, psilocybin and psilocin, and LSD.

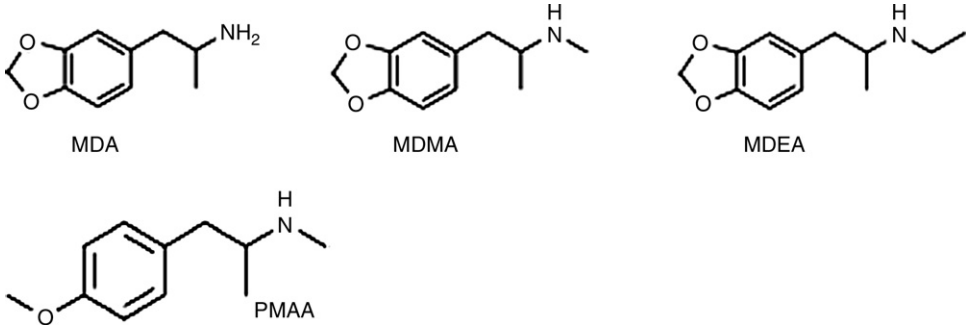

FIGURE 71.2 Chemical structure of atypical hallucinogens.

displaying moderate to high affinity for diverse 5-HT_1 and 5-HT_2 subtypes. This happens mainly because this group is very similar in chemical structure to serotonin and fits into different serotonin receptors. In addition to the psychotomimetic effects of the serotonergic pathways, it is also hypothesized that 5-HT_{2A} receptors play a major role in the discriminative stimulus actions of these agents. However, not only do the discriminative stimulus properties of the drug vary depending on the experimental conditions and context, but they may also depend on the dose of drug used.

Mechanism of Action of Atypical Hallucinogens

Designer Drugs

The synthetic drugs that have been pharmaceutically created as mind-altering drugs, such as MDA, MDMA, MDE, and many others, are not always classified as typical hallucinogens but have a common amphetamine-type mechanism of action and are sometimes classified as hallucinogenic amphetamines. Several studies in rodents and humans have shown that MDMA increases central extracellular serotonin levels. Even though MDMA initially induces increased extracellular levels of serotonin, multiple exposures and/or large doses lead to reductions in brain serotonin levels. MDMA has a low affinity for dopamine receptors, which suggests that all the psychomotor and psychological dopamine-mediated effects of MDMA are a consequence of the dopamine release induced by the drug, increasing the extracellular concentration of dopamine in the nucleus accumbens. There is sufficient evidence showing that the effect of this group of drugs on the serotonergic system is closely associated with activation of dopaminergic pathways and release of dopamine. The enhanced release of dopamine by these drugs may partially result from the reversion of dopamine transport.

Dissociative Anesthetics

Many of the effects of PCP and other arylcyclohexylamines are mediated by dopamine. PCP and ketamine are antagonists of *N*-methyl-D-aspartic acid (NMDA) (which blocks NMDA receptors on dopaminergic neurons in the tegmental ventral area) instead of having a direct effect on dopaminergic neurons. The hyperactivity that PCP induces in rodents has been proved to be related to midbrain dopamine areas. NMDA receptors are the primary mediators of glutamate-induced stimulation of midbrain dopaminergic neurons and the glutamatergic routes of substantia nigra from the prefrontal cortex is a major determinant of dopaminergic activity levels.

Because atypical hallucinogens act directly or indirectly to enhance the concentration of dopamine in the nucleus accumbens area, they may induce dependence. On the other hand, as indolalkylamines do not act in the reward area of the brain, they do not induce dependence.

PHYSIOLOGICAL EFFECTS

Hallucinogens are generally considered to be physiologically safe molecules because, although they can produce altered states of consciousness, they do so at doses that are not toxic to mammalian organ systems. Researchers believe that hallucinogens do not cause damaging effects on cardiovascular, renal, or hepatic functions due to their lack of affinity for the biological receptors and targets that mediate vital vegetative functions. Although hallucinogens may have few long-term physiologic effects, they have been shown to produce some acute effects such as dizziness, weakness, tremors, nausea, drowsiness, paresthesia, and blurred vision. LSD use has also been shown to correspond to signs of sympathetic arousal such as increased pulse and blood pressure, dilated pupils, piloerection, hyperreflexia, and slight fever. Another study examining the potential dose effects of psilocybin found that electrocardiogram and body temperature were not affected by psilocybin dosage, but plasma concentrations of thyroid-stimulating hormone, prolactin, cortisol, and adrenocorticotropic hormone did increase at the peak of the effects of high doses of psilocybin. However, the plasma levels of the hormones decreased over time, thus further supporting the low risk of long-term physiologic effects of hallucinogens.

MDMA can cause dry mouth, nausea, loss of appetite and sweating up to 1 week after ingestion. It is also well established that MDMA use can cause hyperthermic syndromes, which might lead to death.

PSYCHOLOGICAL EFFECTS

In contrast to other drugs that act on the central nervous system, where the action is usually predictable, the effects of hallucinogens are heavily dependent on the expectations of the user and the environment in which the use takes place. Furthermore, a user's response to repeated administration of the same drug and dose could also vary in that high doses do not always produce effects that are similar to the effects of low doses but at greater intensity. Typical psychiatric effects of hallucinogens observed in clinical settings include alterations in mood, tension, distorted time sense, difficulty in expressing thoughts, depersonalization, dreamlike feelings, and visual hallucinations (Hollister, 1984). LSD can also induce psychoses. In case reports of LSD

psychosis, the most common symptoms were found to be mood swings, visual hallucinations, mania, grandiosity, and religiosity, suggesting that LSD psychotics are fundamentally similar to schizophrenics in genealogy, phenomenology, and course of illness. Ayahuasca tea is a hallucinogenic beverage often used in religious and ritual settings throughout the western Amazon Basin. Barbosa and colleagues found that among subjects who consumed ayahuasca tea for the first time in a ritual experience, many experienced extraordinary visual experiences, a prominent sense of inner calm and harmony, a sense of a superior and powerful presence, elucidating thoughts, and alterations in self-body image. Similarly, in a sample of Australian adults, DMT use was reported to have been a personally meaningful or insightful experience that produced feelings of euphoria and intense visual hallucinations. Another study that pooled raw data from eight double-blind placebo-controlled experimental studies to create a sample of 100 healthy subjects who received one to four oral doses of psilocybin found that although there was a dose effect in changes in mood, perception, thought, and self-experience, most subjects described the experience as pleasurable, enriching, and nonthreatening. There has been no evidence of long-term psychological, cognitive, and behavioral deficits of hallucinogen use. In addition, in contrast to many other drugs of abuse, hallucinogens have low dependence qualities and are not generally considered to be reinforcing substances. It has been suggested that most drugs with dependence liability affect dopaminergic (DA) transmission. However, most hallucinogens lack affinity for either the DA receptors or DA uptake transporters, and as a result do not activate the brain reward pathways as observed for other drugs with high abuse and dependence potential such as opiates and cocaine.

MDMA can cause acute side effects including difficulty concentrating, anxiety, depressed mood, dissociative feelings, and insomnia. Long-term ecstasy use might lead to neurotoxic consequences. Furthermore, tablets purchased on the street often contain dangerous additives and/or other illicit drugs.

EPIDEMIOLOGY OF HALLUCINOGEN USE

United States

According to the National Survey of Drug Use and Health (NSDUH), in 2009, 14.8% of the US population aged 12 years and older had already used a hallucinogen in their lifetime (9.4% LSD, 2.5% PCP, and 5.7% MDMA), 1.8% had used hallucinogens in the past year (0.3% LSD and 1.1% MDMA), and 0.5% were past-month users (0.1% LSD and 0.3% MDMA). Past-month hallucinogen use was highest among adolescents aged 12–17 years (overall 0.9%: 0.1% LSD, 0.1% PCP, and 0.5%MDMA) and young adults aged 18–25 years (overall 1.8%: 0.3% LSD and 1.1% PCP). Only a small proportion of respondents said they had used hallucinogens as their first illegal drug (2.1%). The average age of first PCP, LSD, and MDMA use in 2009 was 16.8, 18.2, and 20.2 years, respectively. The number of new hallucinogen initiates aged 12 years and older in 2009 (1.3 million) was higher than the number of new initiates in 2003 (886 000).

In addition, other surveillance surveys have focused specifically on US adolescent behaviors and drug use. The 2009 Youth Risk Behavior Surveillance Study, which obtained data from a nationally representative sample of students in all grades, estimated that 8% of the youth interviewed had already used hallucinogens in their lifetime. Hallucinogen users were more likely to be male than female (10.2% versus 5.5%), and more likely to be White (9.0%) or Hispanic (7.9%) versus Black (3.3%). With regard to MDMA use, 6.7% of the high school students had already used MDMA in their lifetime and were more likely to be male than female (7.6% versus 5.5%), and more likely to be Hispanic (8.2%) than White (6.4%) or Black (5.1%). Another well-known school-based study, Monitoring the Future (MTF), surveys students of selected grades (8th, 10th, and 12th) and follows them up to young adulthood. MTF findings indicate that LSD is no longer the most widely used hallucinogen. Both the NSDUH and the MTF studies show declines in LSD and MDMA lifetime and past-year use among adolescents from 2002 to 2009, but increases in LSD (MTF and NSDUH) and MDMA (NSDUH only) past-month use among youth aged 12–17 years. Past-year MDMA use declined by about 50% among youth from 2002 to 2005 according to both surveys. NSDUH data indicated an increase in past-year MDMA use between 2005 and 2009 among youth, but MTF data showed no significant change in MDMA use over this same period. Both surveys found that the prevalence of LSD use has remained unchanged among young adults in recent years, but MDMA use appears to be on the increase again.

Data from the US Drug Abuse Warning Network on emergency room visits show that the number of drug-related emergency department (ED) visits involving MDMA increased significantly from 10 220 visits in 2004 to 22 816 visits in 2009, representing an 81% increase; most of these visits were made by patients aged 18–29 years. Almost 80% of these visits involved MDMA in combination with alcohol and other illegal drugs. The number of drug-related ED visits involving PCP increased from 31 342 in 2004 to 36 719 in 2009, representing a 17% increase, and those involving LSD increased from 2146 in 2004 to 4028 in 2009, representing an 88% increase.

Australia, Canada, and Europe

In Australia, using data from the 2007 National Drug Strategy Household Survey, it was estimated that 8.9% of the general population reported ever using MDMA, with 3.5% reporting past-year use; these estimates have increased over the past 12 years. On the other hand, data from the Australian School Students Alcohol and Drug Survey estimated that lifetime and past-year MDMA use among high school students remained relatively stable between 1996 and 2005 at around 4% and 3%, respectively. In Canada, with the exception of marijuana, hallucinogens were the drugs that respondents to the Canadian Addiction Survey (2004) most commonly reported using in their lifetime (11.4%). In Europe, using data from the 2007 European School Survey Project on Alcohol and Other Drugs study, it was estimated that 2–3% of all high school students aged 15–16 years in the 35 participating countries had already used hallucinogens (including LSD and MDMA) in their lifetime. The highest European rates of hallucinogen use were found to be 5% in the United Kingdom, Ireland, and the Czech Republic, and 4% in Moscow. The overall consumption levels of LSD and hallucinogenic mushrooms among European adults are generally low and have been largely stable in recent years.

Of the approximately 2.5 million (0.8 %) European adults who used MDMA in the last year, virtually all are in the 15–34 years age group.

DIAGNOSIS OF HALLUCINOGEN INTOXICATION AND HALLUCINOGEN ABUSE AND DEPENDENCE

Hallucinogen intoxication is diagnosed after recent use of one or more hallucinogens followed by marked anxiety or depression, ideas of reference, fear of losing one's mind, paranoid ideation, impaired judgment, or impaired social or occupational functioning that occurred while using the drug or immediately after using it. In addition, the individual experiences subjective intensification of perceptions, depersonalization, derealization, illusions, hallucinations, and synesthesias while using the drug or immediately after using it; and might experience clinical symptoms such as tachycardia, pupillary dilation, sweating, palpitations, blurring of vision, tremors, and incoordination.

According to *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV) criteria, hallucinogen abuse is diagnosed in an individual in the same way that abuse of other substances is diagnosed. That is, a hallucinogen user with at least one of four symptoms representing recurrent negative psychosocial consequences of use or hazardous use is diagnosed with hallucinogen abuse, as long as the individual has never met criteria for hallucinogen dependence. On the other hand, hallucinogen dependence is diagnosed when an individual meets, within a 12-month period, at least three of six criteria related to physical dependence, impaired control over substance-use behavior, and increased salience of consumption (the withdrawal criteria do not apply to hallucinogens, see DSM-IV-TR). For DSM-V, there are recommendations to combine hallucinogen abuse and dependence into a new unidimensional disorder: hallucinogen use disorder.

Few studies have focused on MDMA abuse and/or dependence. In a study conducted by Cottler and colleagues in the United States, nearly half (43%) of the adolescents who used MDMA more than four times were found to meet the diagnostic criteria for ecstasy dependence, as shown by continued use despite knowledge of physical or psychological harm, withdrawal effects, and tolerance (or diminished response); and 34% met the criteria for MDMA abuse. In a study of 200 Taiwanese adolescent MDMA users from a juvenile abstinence center, 22% of the participants met the adopted DSM criteria for ecstasy dependence, with 24% meeting the criterion for tolerance and 6.5% meeting the criterion for withdrawal. On the other hand, data from the German Early Developmental Stages of Psychopathology (EDSP) study found the prevalence of DSM-IV ecstasy use disorders to be fairly low (1.6%).

COMORBIDITY WITH OTHER DRUG USE, DRUG-USE DISORDERS, AND PSYCHIATRIC DISORDERS

Dual Diagnosis with Another Psychiatric Morbidity

The psychiatric consequences of hallucinogen use, particularly MDMA (ecstasy), remain understudied, particularly with regard to the long-term effects. Enduring outcomes, particularly in human populations, have not been fully established. Most of the literature delineating anxiety and social behavioral problems in the long term has been based on animal models. Moreover, epidemiological research studies have also mostly focused on targeted populations (rave party goers). Nonetheless, most (not all) of the available evidence based on animal models and human populations, generated using cross-sectional, longitudinal, and laboratory studies, suggests moderate to strong associations between hallucinogen use (particularly ecstasy) and psychiatric disorders.

In a cross-sectional study on a nationally representative adult population (18 years and older) from the United States (2001–2002), Keyes and her colleagues

found statistically significant strong associations between past 12-month MDMA use and axis I disorders including current anxiety disorders, panic disorders, and specific phobia; current mood disorders were only linked to former (not current) ecstasy use, potentially indicating a longer-term effect of use. This study's findings are in agreement with those from laboratory studies that have shown psychological impairment and depressive symptoms up to 2.5 years after cessation of MDMA use. The German study also corroborates the possible link to major depression and other mental health disorders, whereby MDMA users were significantly more likely to be diagnosed with a DSM-IV defined major depressive disorder after 4 years, in addition to panic attacks, phobia, and generalized anxiety disorder, compared with nonusers, and even other illegal drug users; former and current ecstasy users also exhibited higher odds of any personality disorder, specifically antisocial and paranoid personality disorders, as well as higher odds of histrionic and schizoid personality disorders (in current users only) compared with users of nonillegal drugs. Findings of a study using the 2001–2002 National Study of Alcohol and Related Conditions data conducted by Compton and his colleagues illustrated that hallucinogen use disorders (both abuse and dependence) were related to higher likelihood of adult antisocial personality disorder in both men and women (stronger in the latter). Although understudied, the possible link with suicidality is quite worrisome; one study by Kelly et al. found an increased risk for suicide attempts among males with hallucinogen use disorders.

Co-occurrence with Alcohol and Other Illegal Drug Use

Most of the literature has focused particularly on the co-occurrence of MDMA and other substances, and has shown that hallucinogen use, particularly MDMA, rarely occurs in the absence of alcohol and other illegal drugs. In a study by Keyes and her colleagues, an alarming 44% of adult past-year ecstasy users were reported to also use more than three classes of illegal drugs in addition to alcohol, not to mention their higher odds of binge drinking (62% of current users) and alcohol abuse. Epidemiological studies on young hallucinogen users, MDMA in particular, also find a strong association with cigarette, alcohol, as well as other illegal drug use (whether they were used to intensify the MDMA experience or minimize its adverse after effects). Polydrug use may be even higher among MDMA users (versus any other hallucinogen user). One recent study on youth aged 12–17 years found a higher prevalence of past-year use of alcohol, tobacco (and nicotine dependence), opioids, cocaine (and cocaine use disorders), and tranquilizers compared with all other hallucinogen users. Very few studies have examined hallucinogen use disorders (abuse, dependence, and diagnostic orphans). One study by Wu and colleagues (2009) pointed to an increased odds of marijuana and alcohol use disorders among adolescents diagnosed with hallucinogen dependence or abuse. It has been shown that alcohol–hallucinogen use is a very common alcohol–drug combination in the United States, whether in a sample of 176 adolescents or 43 000 adults. Other studies have found a threefold increase in marijuana use disorder among those with hallucinogen dependence (in addition to a fourfold increased odds of a major depressive episode). Ecstasy users were found to be at a sixfold increased odds of alcohol use disorders (compared with nonusers) and approximately a twofold increase compared with other illicit drug users. Thus, hallucinogen users in general, and MDMA users in particular, are polydrug users, often using more than one illegal substance during the same time period.

Current Issues and Future Considerations

Most studies have either examined hallucinogens in general, or MDMA in particular, and very few have examined substance use and the psychiatric correlates of other hallucinogens. Most recently, a study examining *Salvia divinorum* (a potent naturally occurring hallucinogen that is used infrequently by the general population) found that recent and former users had a greater odds of past-year depression and alcohol- or drug-use disorders, compared with past-year alcohol and drug users who did not use *S. divinorum*. Future studies on hallucinogen use need to focus, to the extent possible, on the potential effects of particular substances, exclusive of ecstasy, in order to begin to understand and delineate the potential mechanisms for intervention, be it at the prevention and/or treatment level.

The high comorbidity with other substances and mental health disorders limits our ability to tease apart the effects of MDMA from that of other substances or psychiatric diagnoses. This opens up the discussion of whether MDMA is independently related to other psychiatric disorders, irrespective of its co-occurrence with other substance use. The issue of polydrug use by ecstasy users and the difficulty in delineating independent effects have been raised by several researchers. One study found no relation between past-year and lifetime ecstasy use and any of the anxiety or depression measures once the frequency of other drug use was controlled for, and another did not establish any significant differences between ecstasy users and controls with regard to the prevalence of mental disorders.

There is a possible bidirectional nature of MDMA use with other illegal substance use. A study by Martins and

colleagues on youth aged 12–21 years using 2002–2003 NSDUH data revealed that use of marijuana, cocaine, and heroin predicted subsequent MDMA use, and earlier MDMA use was also predictive of later illegal drug-use initiation (although for marijuana, the association was stronger for the pathway from early marijuana use to later ecstasy initiation; the opposite was true for cocaine and heroin). The EDSP study from Germany also found that alcohol, nicotine, and other drugs predominantly followed MDMA use, and that very few ecstasy users had initiated use prior to the onset of these other substance-use disorders. Thus, hallucinogen use, particularly MDMA, may be a marker for earlier substance-use or mental health problems, and a predictor of subsequent drug-use and mental disorders. Now that most studies have established a correlation between hallucinogen use and other substance-use and psychiatric disorders, future studies must focus on adopting the longitudinal approach needed to address the issue of temporality and begin understanding causal effects.

This section summarizes the current knowledge on hallucinogens and their comorbid conditions, but it is important to also highlight some of the limitations inherent in all of the studies that have generated the above-mentioned conclusions and affected their validity, as acknowledged by the authors. Besides the cross-sectional nature of most surveys, and their sampling method, issues such as ensuring proper classification of users (e.g. absence of biological markers), sample size (e.g. power calculations), choice of controls (e.g. other drug use or nondrug use), and adequate observation time (e.g. long enough to miss acute effects and short enough to observe longer-term consequences of use/abstinence) are some of the methodological considerations that future studies must address. Moreover, the purity, intensity, frequency, or quantity of MDMA use is often not measured, and future national surveys must begin to measure the differential effects and perhaps a dose–response relationship that various amounts of hallucinogen use may have on the risk of substance-use and other psychiatric outcomes (or vice versa). Also, it would be interesting to distinguish between polydrug use within the same year on various different occasions and coingestion, which has severe implications on the users' well-being as well as treatment interventions.

PREVENTION/INTERVENTION

Cognitive Behavioral Skills

School-based approaches to substance abuse prevention emphasizing cognitive behavioral skills training to enhance social resistance skills and other general life skills have been found to produce both short-term and long-term effects on the prevention of hallucinogen use. Botvin and colleagues (2000) were one of the first to examine the effects of such programs on hallucinogen use using a random sample of 3597 seventh graders from rural and suburban schools in New York State further randomized into either an intervention or control group. Throughout the 15-session program, students in the intervention group were taught cognitive behavior skills for building self-esteem, resisting advertising pressure, managing anxiety, communicating effectively, developing personal relationships, and asserting rights. Furthermore, information regarding the immediate negative consequences of drug use, the decreasing social desirability of use, and the actual prevalence rates among adults and adolescents was provided. Booster sessions designed to review and reinforce the material covered during the first year of intervention were provided in eighth and ninth grades. Conversely, students in the control group received no information on cognitive behavioral skills and drug use. A subsample of 447 students from the original cohort was reinterviewed at the end of 12th grade (mean age 18.1 years), and 13% of the participants in the intervention group reported lifetime use of hallucinogens compared with 21% of the control group. Such findings suggest that prevention programs with cognitive behavioral skills training carried out during middle school produced observable and durable prevention efforts after high school with regard to hallucinogen use.

Project Towards No Drug Abuse (Project TND) is a drug abuse prevention program targeting high-risk adolescents attending continuation high schools, which are alternative schools that youths attend after they transfer out of the regular school system due to functional problems such as conduct problems and drug use. Project TND utilized a classroom-based curriculum that included sessions teaching effective listening skills, chemical dependency issues, alternative coping skills, and encouraged making no-drug-use decisions. In addition to the classroom curriculum, a community program component was added to allow students to participate in activities. To examine the long-term effects of the program, Sun and colleagues (2006) selected a subsample ($n = 725$) of the original cohort of 3813 students was recruited from 21 CHSs with complete annual follow-up up to 5 years after the program. Of the 725 participants, 32% were randomized to the control group, 33% were in the classroom curriculum only group, and 34% were in the classroom and community group. At the 1-year follow-up assessment, 30-day hard drug (hallucinogen, cocaine, stimulants, inhalants, depressants, PCP, steroids, and heroin) use was higher in the control group than both the classroom-only and classroom and community groups. Similarly, by the 5-year follow-up, the

frequency of hard drug use in the last month by those in the classroom-only intervention was less than half that in the control group; for those in the classroom and community intervention it was one-fifth that of the control group (Sun et al., 2006). Such findings demonstrate that Project TND has long-term effects on prevention of drug use in continuation high school students.

Assertive training aims to enable individuals to do what they really want to do in social situations. As a substance-use prevention strategy, assertive training rests on the assumption that many youths who would otherwise abstain from using drugs reluctantly participate in drug use because they lack the interpersonal skills necessary to separate themselves from such situations (Horan et al., 1982). Horan and colleagues conducted an assertive training program among 72 eighth graders to assess its effect on drug use. A behavioral measure of assertiveness was first taken among the 142 ninth graders enrolled in a public school, and the least assertive 36 males and 36 females were selected to participate in the program. Individuals were then randomized into assertion training treatment, placebo treatment, and no-treatment groups. The students in the assertion training group received five 45-min sessions with counselors instructing them about assertiveness and live modeling of assertive responses to a particular training stimulus involving peer pressure to use drugs through role playing. The placebo treatment involved discussions with students about assertiveness, peer pressure, and drug use; the no-treatment control students received no instructions from counselors and did not participate in any discussions. Immediately after the intervention, assertiveness was found to be significantly higher in the assertion training group than both the placebo and no-treatment groups. At the 3-year follow-up, although no significant difference was found in the mean frequency of lifetime hallucinogen use among the three groups, the assertion training group did report significantly lower frequency in lifetime hard drug use (which included hallucinogens, barbiturates, amphetamines, cocaine, and heroin) than the placebo and no-treatment groups. Horan and colleagues hypothesized that the lack of significant differences found in hallucinogen use among the treatment groups was due to the low prevalence (6.9%) of hallucinogen use in the sample. However, the lower usage of hard drugs, which included hallucinogens, in the assertion training group could indicate that assertion training could be a productive strategy for hallucinogen use prevention.

Knowledge and Expectancies

Studies have demonstrated that expectancies, particularly positive expectancies, are strongly related to substance use. In addition, knowledge about substance effects and past use of substances also shape expectancies. The In the Know preventive intervention program created by Stickle and colleagues aimed to increase knowledge about drugs and alcohol and to change the expectancies about their effects among 385 students in grades 6 to 12 from urban public schools. Students were randomized into the alcohol, tobacco, marijuana intervention group ($n = 123$), the alcohol, tobacco, marijuana control group ($n = 62$), the hallucinogen intervention group ($n = 136$), and the hallucinogen control group ($n = 64$). Only findings from the hallucinogen intervention and control groups are presented here. Students in the intervention group were shown a 15-min videotape that discussed and illustrated the effects of hallucinogens, followed by a discussion of the tape led by their health teachers. Students within the control groups were not shown the videotape and did not participate in a discussion with their health teacher. All students completed pretest and posttest survey questionnaires. The hallucinogen intervention group had significantly higher posttest scores on knowledge than the hallucinogen control group. In addition, the intervention group showed a significant increase in knowledge scores and a significant decrease in positive expectancies for hallucinogen use from pre- to posttest; the knowledge scores and expectancies for the control group did not change significantly over time. The results of the study suggest that the In the Know substance abuse prevention curriculum was effective in changing youths' knowledge and expectancies of drug use, which could in turn decrease their risks for later substance use.

Attitude and Behaviors

Due to the generally low prevalence of hallucinogen use in the general population, many prevention programs combine hallucinogens with other classes of drugs with low prevalence, such as cocaine, opiates, and inhalants, to create a hard drug outcome category. The Positive Youth Development Collaborative is one such program that incorporated its curriculum targeting substance-use attitudes and behaviors among urban minority youths into after-school programs. In this program, a total of 304 adolescents, mean age 14.5 years, 76% African Americans, and 53% males, were selected from five after-school programs, and were then randomized into either the intervention ($n = 149$) or control ($n = 155$) groups. Those in the intervention group were taught effective decision-making skills, particularly in substance use, with emphasis on identifying positive personal attributes and setting goals for healthy living. Control group participants participated in the usual activities provided by their after-school program. Seven months after enrollment, Tebes and colleagues found that those in the intervention group were significantly

more likely to view drugs as harmful at the end of the program than control participants. Although the 30-day incidence of hard drug use (hallucinogens, amphetamines, cocaine, heroin, nonprescription methadone, tranquilizers, or inhalants) in the intervention group increased over time from baseline (10.8%) to the 1-year follow-up (12.8%), the increase was significantly lower than the increase found within the control group (from 7.8% to 16.8%). Such reductions in the progression of substance use among adolescents could protect them against later increased or escalating use.

TREATMENT

Various disorders are associated with hallucinogen use and, as with most disorders, health care providers have found some success with treatment, but also experienced some frustration.

Classic Hallucinogens (LSD, Psilocybin, Mescaline)

Abuse and Dependence

Dependence on LSD, psilocybin, and mescaline is rare, perhaps partially due to a quickly developed, but short-lived, tolerance that renders chronic use ineffective. In addition, no withdrawal syndrome has been identified. However, hallucinogen users are often dependent on other substances. Thus, treatment methods common to most substances of abuse, such as 12-step programs or relapse prevention, may be useful here as well. However, there appears to be no formal research on the effectiveness of these methods in reducing use of hallucinogens.

Hallucinogen Intoxication/Psychosis

The abuse of hallucinogens, particularly LSD, psilocybin, or mescaline, may lead to experiences of panic or psychosis, colloquially referred to as a bad trip. These experiences can involve distressing sensory, somatic, and psychological effects, and have even resulted in suicides. Interpersonal support can be helpful, including gently holding a hand, arm, or shoulder, although, in extreme cases, an individual may react violently to touch. Conveying a sense of security, calm, and empathy is preferable to attempting to distract the user from the effects of the drug. It may also be useful to remind the user that the effects are temporary. Prolonged psychotic reactions have been reported but are rare.

Hallucinogen-induced panic can be treated pharmacologically with oral benzodiazepines. For example, 20 mg of diazepam is reported to end dysphoric anxiety within 30 min. Diazepam is recommended over lorazepam due its more rapid onset. The literature is more divided on the treatment of psychotic reactions. Some suggest against using antipsychotics, because the effects may be abrupt, unpleasant, intense, and result in subsequent psychological problems. Haloperidol is sometimes recommended for psychotic reactions, but some research suggests haloperidol can exacerbate symptoms. Risperidone has also been recommended, but, again, caution may be warranted. Olanzapine or ketanserin (a 5-HT_{2A} agonist not approved for use in the United States) may be a more useful antipsychotic. In cases of acute hypertension, intravenous labetalol can be used. Due to the effectiveness of these treatments, psychiatric emergency interventions in response to hallucinogen use are rarer now than in the past and, due to the potential for escalation of an adverse reaction, should be avoided if possible. In the rare cases of prolonged psychosis due to LSD usage, case studies have reported some success with first generation neuroleptics, electroconvulsive therapy (ECT), lithium, and the serotonin precursor, 5-hydroxytryptophan.

Hallucinogen Persisting Perception Disorder (HPPD)

According to DSM-IV, HPPD is characterized by persistent re-experiencing of various perceptual symptoms that were experienced during hallucinogen intoxication. The symptoms need to be persistent for a diagnosis of HPPD, as opposed to the transient experiences referred to as flashbacks. The disorder appears to be rare, given that millions of individuals have consumed hallucinogens; relatively few cases of HPPD have been reported. Accordingly, most treatment studies of HPPD are either case studies or involve very small sample sizes (e.g. 2–16 participants), which precludes rigorous designs. Treatments with some reported success include psychotherapy, behavior modification, the use of sunglasses, and at least 12 different pharmacological agents including clonazepam, benzodiazepines, clonidine, and a combination of fluoxetine and olanzapine. Worsening of HPPD has reportedly occurred due to exposure to phenothiazines, risperidone, and serotonin-selective reuptake inhibitors (SSRIs).

MDMA

Abuse and Dependence

Similar to the classic hallucinogens, MDMA is rarely taken more than once or twice a week due to quickly developing, but rapidly decaying, tolerance. In addition, users often report needing at least 1 day to recover after use. MDMA dependence has been reported, but the only longitudinal study of MDMA abusers of which we are aware found that over 90% of those classified as

dependent were no longer dependent 3 years later, suggesting that ecstasy dependence may be an invalid diagnostic classification, at least in terms of predictive validity.

However, some individuals do use MDMA frequently at very high doses, which may lead to adverse physical or cognitive complications. In addition, most MDMA users also abuse other substances and some users seek treatment for their ecstasy use. Treatment-seeking is believed to be rarer for MDMA, however, than for other substances, such as opioids. Treatment-seeking users of MDMA and other drugs can have more severe problems, in terms of mental health and other drug use, than users of other substances. MDMA users may be more likely to present for treatment due to other mental or nonecstasy substance-use disorders. Traditional substance abuse programs, such as 12-step modalities, may be useful, although there does not appear to be any formal research on treatment for MDMA, and it has been suggested that traditional treatment services may not be attractive to people with MDMA problems.

MDMA-Associated Disorders

Although the exact cause is unclear, use of MDMA is associated with at least three mental disorders: depression, anxiety, and psychosis. Cases for which clinicians can have some confidence in attributing the disorders to the use of ecstasy are rare. As a result, treatment studies are limited to animal research, case studies, and observational research. Some experimental evidence with rats suggests that fluoxetine, and perhaps other SSRIs, may be relatively ineffective in treating MDMA-induced depression. Case studies have reported some amount of success treating patients experiencing MDMA-induced depression with sertraline, mirtazapine, and ECT. Case studies of three patients suggest that MDMA-induced panic disorder with agoraphobia, an anxiety disorder, can be treated with serotonergic antidepressant drugs. Based on an observational study of 23 patients, olanzapine appears to be effective for ecstasy-induced psychotic disorder. These promising results should be cautiously followed up with more research.

Conclusion

This chapter provides a brief overview of the neurobiology of classic and atypical hallucinogens and how they act to cause perceptual and cognitive distortions. The most common physiologic and psychological effects of this group of drugs are described. The overall lifetime consumption level of hallucinogens among adults is low, at approximately 10–15% worldwide, but, in all countries, the recent use estimates among the young are at their highest. Intoxication, abuse, and dependence can occur, but hallucinogens, different from other illegal drugs, are not highly reinforcing. As with other drug groups, comorbidity with other psychiatric disorders and use of other substances within the same time period is very common. Prevention and intervention strategies to reduce hallucinogen use and treatment of hallucinogen-related disorders are similar to those used for other drugs.

Glossary

3,4-Methylenedioxymethamphetamine (MDMA, ecstasy) an atypical hallucinogen, MDMA is a designer drug that can induce euphoria, a sense of intimacy with others, and diminished anxiety.

Ayahuasca hallucinogenic infusion, usually mixed with dimethyltryptamine-containing plants, often consumed as a beverage in religious and ritual settings throughout the western Amazon Basin.

Comorbidity the presence of one or more disorders in addition to a primary disorder.

Designer drugs atypical hallucinogens that are pharmaceutically created as mind-altering drugs; they are sometimes classified as hallucinogenic amphetamines.

Dimethyltryptamine (DMT) hallucinogen that is structurally analogous to serotonin and is the primary psychoactive in ayahuasca.

Dissociative anesthetics atypical hallucinogens that either directly or indirectly enhance dopamine concentration in the nucleus accumbens region, thereby inducing dependence.

Hallucinogens diverse group of substances that cause perceptual and cognitive distortions, and can evoke mood and thought changes as well as out of body experiences.

Indolealkylamines a group of hallucinogens that is further divided into substituted tyrptamines and lysergic acid derivatives.

Hallucinogen abuse abuse is diagnosed if a user who has never met criteria for dependence and has at least one of four DSM-IV symptoms representing recurrent negative psychosocial consequences of use or hazardous use.

Hallucinogen dependence dependence is diagnosed if a user meets at least three of six DSM-IV physical dependence symptoms, impaired control over substance-use behavior, and increased salience of consumption within a 12-month period.

Hallucinogen intoxication use of hallucinogens that leads to marked psychological symptoms such as anxiety and depression, and physiologic symptoms such as palpitations and tremors.

Hallucinogen persisting perception disorder (HPPD) a rare disorder that consists of a persistent re-experiencing of various perceptual symptoms that may occur during hallucinogen intoxication.

Lysergic acid diethylamide (LSD) semisynthetic hallucinogen that can produce psychological effects such as altered thinking processes, altered sense of time, and spiritual experiences.

MDMA-associated disorders three mental disorders (i.e. depression, anxiety, and psychosis) that are associated with MDMA use.

Mescaline naturally occurring hallucinogen that can cause cross-intolerance with some other hallucinogens such as LSD and psilocybin.

Phencyclidine (PCP, angel dust) hallucinogen that can be recreationally ingested, smoked, or snorted.

Phenylalkylamine a group of hallucinogens that are structurally related to catecholamine neurotransmitters; includes drugs such as mescaline and mescaline-substituted structures.

Psilocybin hallucinogen found in mushrooms that are used both recreationally and ritually.

Psychosis bad trips that can occur after hallucinogen intoxication, which may involve distressing sensory, somatic, and psychological effects.

Serotonergic (5-HT_2) receptors family of receptors mainly concentrated in the cortical and limbic regions to which hallucinogens bind.

OUTLINE

WHAT IS ECSTASY/MDMA

Ecstasy (3,4-methylenedioxymethamphetamine (MDMA), also called Adam, E, X, XTC eccie, hug drug, or a roll/rolling) is a synthetic, psychoactive drug that is chemically similar to the stimulant methamphetamine and the hallucinogen mescaline. Ecstasy produces feelings of euphoria, increased energy, emotional warmth, and distortions in time, perception, and tactile experiences.

Ecstasy is taken orally, usually as a capsule or tablet. Tablets, which typically contain from 50 to 150 mg of the active drug MDMA, are usually imprinted with a popular icon such as a cartoon character, animal, or corporate logos (e.g. Mitsubishi, Motorola). Users sometimes refer to the drug by these imprints (e.g. a blue dolphin pill). Pills can vary in color, white being the most common. Ecstasy is typically purchased in the setting where it is used, most commonly at bars, nightclubs, or raves, although it is increasingly used in more conventional settings such as house parties. Prices range from $20 to $40 per tablet, and it is not uncommon for tablets to be adulterated with other chemicals, including aspirin, caffeine, dextromethorphan, pseudoephedrine, amphetamine, and heroin. Although MDMA tends to be the primary substance found in ecstasy pills, less than half of tablets contain MDMA only; most tablets contain either MDMA and other substances or only substances other than MDMA. Depending on a variety of factors (including the pill's content, other adulterants, and user's metabolism), the high from ecstasy typically begins within 30 min to 1 h after consumption and lasts between 4 and 6 h. Throughout this chapter, we will use the term Ecstasy

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00072-3

to refer to pills sold as ecstasy, and use the term MDMA to describe only the specific compound if relevant.

Ecstasy can produce confusion, depression, sleep problems, drug craving, and severe anxiety (for a more detailed description, see the section on Consequences of ecstasy use). These problems can occur soon after taking the drug or occasionally even days or weeks after taking the drug. In addition, severe ecstasy users perform more poorly than nonusers on certain types of cognitive or memory tasks, although some of these effects may be due to the use of other drugs in combination with ecstasy. Research in animals indicates that MDMA can be harmful to the brain. Although similar neurotoxicity has not been shown definitively in humans, animal research on MDMA's damaging properties strongly suggests that MDMA/ecstasy is not a safe drug for human consumption. This is currently an area of active research.

HISTORY OF MDMA

MDMA was developed in Germany in the early 1900s as a parent compound to be used to synthesize other pharmaceuticals. E. Merck Pharmaceuticals filed a patent for the drug in Germany in 1912, but it remained unnoticed until a large toxicological study was done under a classified contract with the US Army after World War II. During the 1970s, in the United States, some psychiatrists began using MDMA as a psychotherapeutic tool, despite the fact that the drug had never undergone formal clinical trials or received approval from the US Food and Drug Administration (FDA) for use in humans. Nevertheless, the drug gained a small following among psychiatrists in the late 1970s and early 1980s, with some even calling it 'penicillin for the soul' because it was perceived to enhance communication in patient sessions and reportedly allowed users to achieve insights about their problems. It was also during this time that MDMA first started becoming available on the street as ecstasy. In 1985, the US Drug Enforcement Administration (DEA) banned the drug, placing it on its list of Schedule I drugs, corresponding to those substances with no proven therapeutic value.

In the 1990s there was a resurgence of ecstasy use, with use proliferating in dance clubs and rave scenes. Ecstasy became known as a club drug and was one of the most commonly used drugs of this type. Ecstasy use increased among young people throughout the 1990s in the United States, peaking in 2001. In the early 2000s, there was a widespread public safety campaign to warn young people about the dangers of ecstasy as a party drug, but that effort declined as use dropped off. In 2009, there was a resurgence of ecstasy use in the United States, with reported use in mainstream settings such as bars and homes in addition to clubs and raves.

Ecstasy was initially popular among Caucasian adolescents and young adults in the nightclub scene or raves. More recently, the profile of the typical ecstasy user has changed, with the drug now affecting a broader range of ethnic groups. Ecstasy has been particularly popular among urban gay males; some report using ecstasy along with other clubs drugs (e.g. ketamine, γ-hydroxybutyrate (GHB), crystal methamphetamine) and/or other legal and illegal substances.

NEUROBIOLOGY OF ECSTASY USE

MDMA affects the brain by increasing the activity of the monoamine neurotransmitters serotonin, dopamine, and norepinephrine. Like other amphetamines, MDMA causes an increase in neurotransmitter activity in that more of these neurotransmitters are released from their storage sites in neurons. Compared with methamphetamine, MDMA causes greater serotonin release and somewhat lesser dopamine release. The serotonin system plays an important role in regulating mood, aggression, sexual activity, sleep, and sensitivity to pain. The excess release of serotonin by MDMA likely causes the mood elevating effects experienced by ecstasy users. However, by releasing large amounts of serotonin, ecstasy causes a depletion of this neurotransmitter, likely contributing to the negative behavioral and psychological after effects that users often experience for several days after taking MDMA.

EPIDEMIOLOGY/PATTERNS OF ECSTASY USE

Use

In 2008, estimates of the current (past year) prevalence of ecstasy use among young adults in the United States and abroad range from 3 to 6%, with lifetime estimates around 10%. Rates vary somewhat by data source. The National Survey on Drug Use and Health (NSDUH), conducted by the Office of Applied Studies of the Substance Abuse and Mental Health Services Administration (SAMHSA), collects information on the prevalence, patterns, and consequences of alcohol, tobacco, and illegal drug use and abuse in the general US civilian noninstitutionalized population aged 12 years and older. In 2009, NSDUH reported that 5.7% of the US population aged 12 years and over had ever used ecstasy, 1.1% had used in the past year, and 0.3% had used in the past month. Ecstasy use in the United

States is rising; lifetime use rates rose steadily in the first decade of the 2000s, from 4.3% in 2002 to 5.7% in 2009 (Fig. 72.1). Between 2008 and 2009, estimates of the number of past month ecstasy users rose 37% from 555 000 in 2008 to 760 000 in 2009. The majority of ecstasy users are young adults, with past month use rates of 0.5% among those aged 12–17 years, 1.1% among those aged 18–25 years, and 0.1% among those aged 26 years or older. Initiation of ecstasy use began rising in 1993 when there were 168 000 new users. By 2000, there were 1.9 million new users, but that number decreased to 642 000 new users in 2003, and has steadily increased since then. In 2009 there were an estimated 1.1 million new users of ecstasy, suggesting that it has once again gained popularity.

The US Monitoring the Future Survey (MTF) is a survey conducted by the University of Michigan's Institute for Social Research for the National Institute on Drug Abuse (NIDA) and assesses licit and illicit substance use among US adolescents in grades 8, 10, and 12. It reported that past year use of ecstasy peaked in 2001, declined from 2002 to 2005 and then rebounded in 2006–2008. In 2009, trend lines leveled off in all grades. In recent years, there have been declines in perceived risk of ecstasy use in all three grades, declines in disapproval of ecstasy use among grades 8 and 10, and declines in perceived availability of ecstasy in all three grades.

Surveys of club drug users indicate that ecstasy is one of the most commonly used club drugs. After cocaine, ecstasy tends to be the most commonly reported club drug used, and up to three-quarters of young people surveyed in bars, clubs, and raves report that it was the first club drug they used. Among club drug users recruited at raves, bars, and nightclubs, median days of ecstasy use among those who use the drug was 2.5 days per month in one study. Among ecstasy users, the most commonly reported contexts of ecstasy use are raves, bars, and at home with others. Some work suggests that there are patterns of ecstasy use situations, such that some ecstasy users do not use in many situations, others use in social situations when they are feeling good, and others follow a third pattern of use in varied situations, including internal and external positive and negative states.

The Drug Abuse Warning Network (DAWN) is a public health surveillance system that documents drug-related visits to emergency departments (EDs) throughout the United States. In 2007, ecstasy use was involved (either directly or indirectly) in the fifth largest number of visits to the ED in the United States (after cocaine, heroin, marijuana, and stimulants). Ecstasy-related visits to the ED increased from 10 220 in 2004 to 16 749 in 2006, and then declined to 12 748 in 2007. Of the visits in 2007, more males (7607) visited the ED than females (5141), and those aged 21–24 years accounted for the largest numbers of visit compared with all other ages (Fig. 72.2).

Addictive Potential

For some people, ecstasy can be addictive. A survey of young adult and adolescent ecstasy users found that 43% of those who reported ecstasy use met the accepted diagnostic criteria for dependence, as shown by continued use despite knowledge of physical or psychological harm, withdrawal effects, and tolerance (or diminished response with continued use of the same amount). These results are consistent with those from similar studies in other countries that suggest a high rate of dependence among ecstasy users.

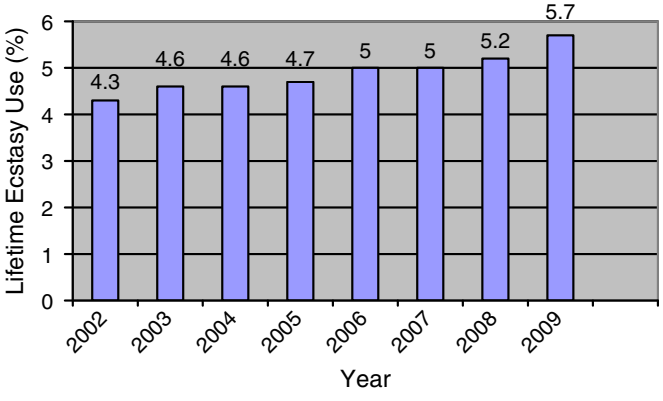

FIGURE 72.1 Lifetime ecstasy use among persons aged 12 years or older from the National Survey on Drug Use and Health: percentages, 2002–2009.

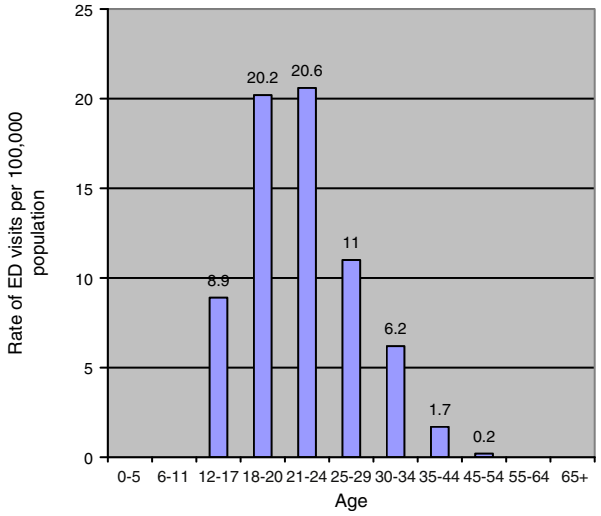

FIGURE 72.2 Rates of ED visits per 100,000 population involving ecstasy by age and gender, 2007.

Although ecstasy is currently classified as a type of hallucinogen and its withdrawal is not recognized in the *Diagnostic and Statistical Manual of Mental Disorders Fourth Edition Text Revision* (DSM-IV-TR), there is evidence for the association of withdrawal symptoms with ecstasy abstinence. Ecstasy abstinence-associated withdrawal symptoms include fatigue, loss of appetite, depressed feelings, and trouble concentrating. Findings from latent class analysis indicate that ecstasy users have a significantly higher risk of dependence than lysergic acid diethylamide (LSD) users. Of the ecstasy users who met the criteria for dependence, use despite knowledge of physical or psychological harm was the most prevalent dependence criterion (63%), while withdrawal and tolerance were also commonly reported dependence criteria. In this sample, 34% met the criteria for abuse, and hazardous use was the most commonly reported abuse symptom. Only 23% of the ecstasy-using sample did not meet the criteria for either abuse or dependence.

Research on ecstasy users compared to other hallucinogen users indicates that there are higher rates of dependence among those who use ecstasy (approximately one in five) compared to other hallucinogen users (one in six), possibly because ecstasy is more available these days and the subjective effects are less severe than some club drugs (e.g. LSD). Among ecstasy users, prevalence of hallucinogen abuse, subthreshold dependence, and dependence were 4.9, 11.9, and 3.6%, respectively. The majority with hallucinogen abuse displayed subthreshold dependence. Most with hallucinogen dependence also met the criteria for abuse. Among young adults who frequent nightclubs and other venues where ecstasy is sold, 17.4% of those who met the criteria for club drug dependence said their drug of choice was ecstasy.

Studies of ecstasy use disorders have examined which clusters of abuse and dependence symptoms best characterize ecstasy users. For example, a study examining distinctive subtypes of ecstasy users based on 24 abuse and dependence symptoms underlying standard DSM-IV-TR criteria found four latent classes representing clearly differentiated diagnostic clusters including a group of negatives, or subthreshold users endorsing few abuse and dependence symptoms (27.1%), a group of mild dependents, who had features of dependence for a select group of symptoms (34.6%), a moderately dependent group, with a similar profile of dependent symptoms as the mild dependents but also reporting some abuse symptoms (18.1%), and a severe dependent group with a distinct profile of abuse and dependence symptoms (20.1%). Studies such as those mentioned above highlight that while ecstasy is currently classified as a hallucinogen, there may be differences in the symptoms most commonly exhibited by ecstasy users compared to other hallucinogen users, and there are distinct types of ecstasy users.

ECSTASY USE AND SPECIAL POPULATIONS

Several studies have examined the sociodemographic determinants and patterns of drug use within specific population subgroups, including ethnic minorities; gay, lesbian, or bisexual males and females; juvenile detainees; injection drug users; high school or secondary school students; and college students. Since ecstasy is primarily used by young people, some work has examined its use among adolescents who are in substance abuse treatment. Lifetime rates of ecstasy are approximately 32%, and it is the second most commonly used club drug after LSD.

Although club drug use in general (including ecstasy use) has been predominantly a white, adolescent, and young adult phenomenon in the United States, club drug use among African-Americans and Hispanics is not uncommon; 45.3% of Hispanics and 56.4% of African-Americans reported a lifetime history of club drug use in one study conducted in New York City. Ecstasy was the third most commonly used club drug behind phencyclidine and LSD, with 21.7% of African-American and Hispanic youth and young adults reporting lifetime use. Of the current ecstasy users, 63.8% had used it 3 days per month or more, 31.9% used it 1–3 days per week, and 4.3% used it 4–7 days per week. Hispanics were significantly more likely than African-Americans to have used ecstasy (22.4% versus 11.7%). In a study of African-American and Hispanic heroin and cocaine users in New York City, correlates of lifetime ecstasy use included younger age, being born in the United States, and current homelessness. Compared to African-American nonintravenous drug users (non-IDUs), Hispanic non-IDUs, and white IDUs were significantly more likely to have a history of lifetime ecstasy use while African-American IDUs were significantly less likely.

Another widely studied group is men who have sex with men (MSM). There is a high rate of lifetime exposure to a variety of club drugs (including ecstasy, methamphetamine, ketamine, and GHB) in this population, with past 6-month club drug use rates in one study as high as 13.7%, and mean frequency of use of more than six times in that period. Among MSM, the use of multiple club drugs (particularly methamphetamine) over time is linked, and rates of ecstasy and other club drug use declined steadily in this population from 2002 to 2007. Among MSM club drug users, ecstasy is the most commonly used club drug, with one study showing 83% of club drug using MSM having used

ecstasy. Data are mixed about whether men identified as bisexual are more or less likely to use club drugs compared to men identified as gay. Furthermore, there is very limited data on rates of use among MSM identified as heterosexual. Among MSM, the majority of the men initiated use of club drugs with cocaine, followed by ecstasy, ketamine, methamphetamine, and GHB. Variations in patterns are related to both age and level of polydrug use of club drugs.

Various correlates of ecstasy use among MSM have been identified. Among MSM who use club drugs on a regular basis, there are high rates of a prior suicide attempt (including high rates of multiple suicide attempts), high rates of lifetime exposure to multiple types of drugs, high rates of current polydrug use (including multiple types of club drugs), and high rates of current depressive symptoms. Although high rates of condom use are reported in some types of sexual exchanges, data show multiple types of sexual risk among MSM who use club drugs regularly, including high rates of unprotected anal intercourse and concomitant other drug use among both young MSM and their sexual partners. Other correlates of ecstasy use among MSM include younger age, less education, more male sex partners, more one night stands with men, more visits to bars or clubs and sex clubs or bathhouses, likelihood of having been the victim of physical domestic violence, more gay/bisexual friends, disclosure of their sexual orientation to more friends, family members, and coworkers, and higher levels of gay community participation and affiliation. Ecstasy use has an effect on HIV status and progression of disease. Ecstasy use is associated with shorter time to seroconversion in HIV-negative MSM.

Some work has examined ecstasy use among ethnic minority MSM. For Hispanic MSM, rates of use range from 15 to 20% for recent use and are approximately 35% for lifetime use. Among Asian/Pacific Islander MSM, ecstasy is the most common drug used in conjunction with sex, and being high or buzzed on ecstasy is significantly associated with unprotected anal intercourse in this population.

PREDICTORS/CORRELATES OF ECSTASY USE

Research on sociodemographic factors associated with club drug use continues to be a main focus worldwide. Findings on sociodemographic determinants vary across studies, depending on the target populations, cultural environment, types of substances investigated, study designs, and the analytic methods used. A number of common risk factors have been identified, which can be grouped into categories.

Demographic Characteristics

According to large epidemiological studies, recent users of ecstasy tend to be young adults aged 18–21 years and residents of metropolitan areas. White young adults are more likely than others to use ecstasy, and among those who do use, whites tend to use more of the drug more often. Further, white and younger individuals are more likely to use a variety of other drugs compared to those of other ethnicities and older ecstasy users.

Males and females tend to use ecstasy at similar rates. Despite these suggestions of gender equity for rates of use, some studies have suggested that females are more likely to report negative health consequences related to the use of club drugs, specifically ecstasy. One explanation posits that this gender difference is related to the more intense subjective effects of ecstasy reported by women. Some research also suggests that females more likely than males to report recent use of multiple club drugs.

Several studies have documented differential rates of drug use by people identified as gay, lesbian, and bisexual compared with their heterosexual counterparts. In college samples, gay, lesbian, and bisexual students are more than two times as likely to have used ecstasy in the past year compared to heterosexual. In community samples, gay, lesbian, and bisexual young adults are significantly more likely to use ecstasy, cocaine, and methamphetamine over the course of their lives, as well as to be active users of club drugs, compared with their heterosexual peers. Among both male and female young adults throughout the United States, those identified as mostly hetero, bisexual, or homosexual are associated with a greater prevalence of past year ecstasy use compared to identified as completely hetero. Lesbian and bisexual women report significantly higher lifetime rates of ecstasy use compared to heterosexual women.

Other Drug Use

Use of tobacco, alcohol, and other illicit substances is associated with use of ecstasy. Using these other substances is associated with greater likelihood that youth and young adults will initiate ecstasy use. Data from the National Survey of Parents and Youth (NSPY), a longitudinal, nationally representative household survey of youth and their parents, indicates that initiation of ecstasy use is predicted by an adolescent's early initiation of smoking, drinking, or marijuana use. In particular, early initiation of either marijuana use or both smoking and drinking increases a child's risk for ecstasy use initiation. Data from the NSDUH has pointed to a gateway phenomenon whereby earlier marijuana initiation is associated with subsequent ecstasy initiation, which in turn is associated with later

cocaine and heroin initiation. While there are multiple routes in and out of substance use initiation, ecstasy initiation seems to play a role in the subsequent initiation of cocaine and heroin.

Current use of ecstasy is associated with increased likelihood of alcohol and other drug use. Ecstasy users use more types of other drugs and are more likely to be diagnosed with a substance use disorder. In a study that classified ecstasy users by the patterns of other drugs they used, it was found about 20% of ecstasy users were not likely to use other drugs, slightly more than half followed a moderate range of other substance use, and 28% were likely to follow a pattern of wide-range drug use in which they were highly likely to also use a number of other licit and illicit substances.

Using ecstasy increases the likelihood of having problems with other drugs of abuse. Relative to other drug users, those who recently use ecstasy are twice as likely to meet criteria for alcohol, marijuana, and pain reliever/opioid use disorders. They are also about twice as likely as former ecstasy users to meet criteria for marijuana, cocaine, and tranquilizer use disorders. Prescription drugs are of particular concern. In a study of the nature, extent, and consequences of prescription drug abuse among 143 ecstasy users in Miami, prescription drug abuse was reported by 87% of the sample; alprazolam (57%), oxycodone (36%), hydrocodone (32%), and diazepam (30%) were cited most often. Prescription drug abusers were more likely to report polydrug use, drug treatment histories, risky drug use behaviors, and symptoms of depression. They also reported numerous physical, psychological, and social consequences of prescription drug abuse.

Even though ecstasy users are more likely to use other drugs, they may not be more likely to use other drugs on the same days as they use ecstasy. Use of alcohol and other drugs is more likely before and during ecstasy intoxication than after. Use of ecstasy on a particular night may not be associated with any greater likelihood of using any other intoxicating drug, and use of other drugs on nights involving ecstasy use may simply reflect a natural history of drug use nights that begins with alcohol, progresses to more intoxicating drugs, and ends with little drug use.

Mental Health Problems

Mental health problems are another correlate of ecstasy use. Ecstasy users endorse more symptoms of general distress than nonusers. For example, among US high school students in the Youth Risk Behavior Survey (YRBS), disordered eating (fasting, diet product use, and vomiting or laxative use) is associated with ecstasy use. Those who use ecstasy are more likely to be diagnosed with current anxiety, specifically panic disorder, and specific phobia, and personality disorders compared with nonillicit drug users. In a study of young adult ecstasy users in Ohio, 55% had at least one lifetime disorder, with major depression (35.3%) and antisocial personality disorder (ASPD; 25.4%) the most common. The overlap between ecstasy use and ASPD is likely due, at least in part, to the common underlying personality trait of sensation seeking, which predicts ecstasy use, conduct disorder and ASPD disorder symptoms. Proportionately more women were diagnosed with depression, generalized anxiety disorder, and posttraumatic stress disorder (PTSD), while proportionately more men were diagnosed with ASPD. Proportionately more nonwhite participants had attention deficit hyperactivity disorder (ADHD). Higher levels of education were associated with proportionately less PTSD, ASPD, and ADHD. Higher frequencies of ecstasy use were associated with proportionately more ASPD and ADHD. Comparing the age of first ecstasy use with the age of onset for selected psychiatric disorders revealed that for most participants, disorders preceded use. Those who had used ecstasy more than 50 times were more likely to have experienced a lifetime disorder.

There is a neurobiological relationship between ecstasy use and depression, as MDMA can cause serotonin depletion as well as serotonergic neurodegradation, which may result in depression among users of the drug. Several studies have examined depressive symptomatology among ecstasy users. They have generally found low levels of depressive symptomatology among study participants. For example, one study found two-thirds of the sample had scores that placed them in the nondepressed/minimal depression category, while 4.7% had scores indicative of severe depression. Men were significantly less likely than women and people who used opioids were significantly more likely than nonusers to have higher levels of depressive symptomatology. Higher lifetime occasions of MDMA use were marginally related to symptoms of serious depression.

It is also possible that those who are susceptible to mental health problems are more vulnerable to using ecstasy. For example, adults who had past year psychiatric symptoms (both depressive and panic symptoms) are twice as likely to be recent-onset ecstasy users compared with those without past year psychiatric symptoms. One suggested mechanism is the desire in those who have mood disorders to regulate mood through the use of mood-altering drugs such as ecstasy (i.e. self-medicate).

Behavioral Correlates

A number of behavioral correlates of ecstasy use have been identified, including engaging in deviant behaviors and having risky sex. In a large epidemiological study, recent-onset ecstasy use was significantly more likely

to occur among adolescents and adults (18–34 years old) who engaged in deviant behaviors (i.e. attacking another person, carrying a handgun, selling drugs, stealing) during the past year compared with those who did not engage in those behaviors. Higher levels of deviancy indicated a higher likelihood of being a recent-onset ecstasy user, and associations were strongest with nonviolent deviant behaviors (e.g. selling illegal drugs and stealing). Associations between deviant behaviors and recent-onset ecstasy use were similar in strength to associations between deviant behaviors and recent-onset cocaine and marijuana use in this study, suggesting the existence of a common pathway from deviance to substance use onset.

Ecstasy use is associated with having more friends who use drugs, particularly among young women. Among college students, ecstasy users were more likely to have multiple sexual partners, spend more time socializing with friends, and spend less times studying compared to those who do not use ecstasy. However, ecstasy users are not necessarily academic underachievers, and their satisfaction with education is not necessarily any different from that of nonusers.

Ecstasy use can be associated with more sexually risky behaviors. Up to one-third of young people who currently use ecstasy have more than one sex partner in a given month, and sexual protection rates can tend to be low in this population. Some of the predictors that have been associated with the likelihood of having multiple sex partners among ecstasy users included being nonwhite, younger age at first sexual experience, using ecstasy for its touch-enhancing qualities, having higher self-esteem, handling disagreements more dysfunctionally, and not being involved in a romantic relationship.

Cognitive/Motivational Correlates

A number of studies have identified reasons why ecstasy users initiate use or maintain using once they have started. Positive attitudes toward drug use are associated with initiation of ecstasy use among adolescents. Common reasons why young people say they started using ecstasy is to experiment, while reason they maintain use tend to be to feel good or high and to have a good time with friends. Other common reasons for using are for their stimulant properties (e.g. to increase energy, to stay awake), to enhance the effect of another drug, to seek insight, or to relax and relieve tension. Less common reasons for using tend to be to get away from their problems, being hooked, to get through the day, or because of anger or frustration.

Motivational factors play a role in maintaining ecstasy use. Psychological models emphasize internal regulatory cues that motivate drug use and play a contributory role in dependence. Motivational cues tend to be strong predictors of both ecstasy use and dependence in users. For example, female ecstasy users report they are more willing to use drugs in the future compared to nonusers. Other cognitive correlates of ecstasy use are low risk perception and high perceived behavioral control of obtaining ecstasy (being able to obtain it in a short period of time).

Environmental/Familial Correlates

A number of parental or familial correlates of ecstasy use have been identified. Ecstasy users report more childhood experiences of physical abuse, emotional neglect, and physical neglect than nonusers of MDMA. Parent drug use has been identified as a significant predictor of child initiation of ecstasy use. Living with both parents and close parental monitoring are negatively associated with ecstasy use initiation, and may be protective against it. Current ecstasy users report experiencing greater difficulties with family relationships than nonusers. Peer correlates of ecstasy use include close associations with deviant peers and drug use by close friends. Current ecstasy users report greater difficulties with peer relationships than nonusers.

Economic Correlates

Some research indicates that monetary and opportunity cost, but not income, significantly predicts ecstasy use.

CONSEQUENCES OF ECSTASY USE

Positive Consequences

MDMA has become a popular drug, in part because of the positive effects that a person may experience within an hour or so after taking a single dose. Those effects include feelings of mental stimulation, emotional warmth, empathy toward others, a general sense of well-being, and decreased anxiety. In addition, users report enhanced sensory perception as a hallmark of the MDMA experience.

Among those who have used ecstasy recently (in the past year), a number of positive consequences have been reported. The most common ones are an increase in energy or stimulant effects, and improved social skills or making new friends, and experiencing everything as more fun. Less common but still reported are weight loss, euphoria, experiencing everything as more intense, bettering a current relationship, decreasing inhibitions, and relaxing or relieving stress.

Physical Consequences

Ecstasy can produce a variety of immediate and longer-term adverse health effects, including nausea, profuse sweating, chills, involuntary teeth clenching, tingling or numbness, and blurred vision (due to pupil dilation). Additional negative symptoms can include memory lapse, shortness of breath, inability to urinate, vomiting, joint stiffness, stomach pains, headaches, heart palpitations, tremors or shakes, weight loss, loss of energy, and muscle aches. Ecstasy overdose can also occur; the symptoms can include high blood pressure, faintness, panic attacks, and in severe cases, loss of consciousness and seizures.

Because of its stimulant properties and the environments in which it is often taken, ecstasy is associated with vigorous physical activity for extended periods. This can lead to one of the most significant, although rare, acute adverse effects: a marked rise in body temperature (hyperthermia) which can in turn result in kidney failure. In addition, dehydration, hypertension, and heart failure may occur. Ecstasy can also reduce the pumping efficiency of the heart, of particular concern during periods of increased physical activity, further complicating these problems. Because MDMA affects monoamine neurotransmitters that play a critical role in sleep and daytime alertness, ecstasy use interferes with sleep. Acute MDMA administration disrupts sleep and rapid eye movement (REM) sleep, specifically, without producing daytime sleepiness in the same was sleep restriction does. Compared with control subjects, recreational ecstasy users show evidence of hyperarousal and impaired REM function.

MDMA is rapidly absorbed into the human bloodstream, but once in the body, MDMA metabolites interfere with the body's ability to metabolize, or break down, the drug. As a result, additional doses of ecstasy can produce unexpectedly high blood levels, which could worsen the cardiovascular and other toxic effects. MDMA also interferes with the metabolism of other drugs, including some of the adulterants that may be found in ecstasy tablets.

Psychological Consequences

Due to the effects MDMA has on monoamines that play a role in mood regulation, ecstasy use has both acute and longer-term effects on psychological health. Some ecstasy users report experiencing visual and auditory hallucinations, depression confusion, anxiety, irritability, paranoia, and loss of sex urge at least one time after ecstasy use. However, the psychological effects of ecstasy use (e.g. depression and anxiety) are thought to be due at least in part to other substance use, which is very common among those who use ecstasy. A limited body of work has found that ecstasy and marijuana users have reported more intense feelings of depression and anxiety than those who use marijuana alone and nondrug users. A growing body of research has shown that although ecstasy users demonstrate elevated levels of psychological symptoms, these symptoms are not necessarily associated with their ecstasy consumption. Instead, other drug use (alcohol, marijuana, opioids, and inhalants) significantly account for these psychological symptoms. A number of studies have pointed specifically to marijuana use to explain elevated depression symptoms and clinical depression among ecstasy users. These studies have shown that those who use ecstasy and marijuana have higher rates of depression than those who use ecstasy use alone, and that ecstasy use, severity of use, or a diagnosis of dependence on ecstasy is not associated with depression without considering the effects of marijuana.

Lifestyle Consequences

Ecstasy use can cause a number of lifestyle consequences. In one study, 40% of recent ecstasy users reported trouble maintaining their usual daily activities, while 20% reported experiencing financial and work trouble as a result of using ecstasy. Problems with aggression were infrequent after club drug use. A small group of participants indicated that they got into verbal arguments sometimes (14%) or half the time (2%) after ecstasy use. A small percentage of individuals indicated that they ever had been involved in physical (14%) or sexual (2%) aggression after ecstasy use. Ecstasy use has been associated with low academic achievement in some epidemiological studies.

Ecstasy use also raises concerns because of its association with risky driving. Research indicates that ecstasy use impairs the perception of distance between cars, even in recently abstinent ecstasy users. Other work shows that while ecstasy use may not impair driving performance, it leads to elevated risk taking in driving situations.

Risky Sex

Ecstasy use can lead to risky sexual behaviors. Among females, findings are mixed; however, ecstasy use has been associated with having unprotected intercourse and engaging in sex acts with partners that they would not have otherwise. Among young adult ecstasy users, nearly one-third have had more than one sex partner during the preceding month, and sexual protection rates have tended to be low in some studies. Predictors of having multiple sex partners include being nonwhite, knowing someone who was HIV-positive, younger age of first sexual experience, using ecstasy

for its touch-enhancing qualities, higher self-esteem, handling disagreements more dysfunctionally, and not being involved in a romantic relationship. In contrast, heavy ecstasy users are more likely to have been tested for HIV than nonheavy users, but are also more likely to perceive no chance of contracting HIV. Although ecstasy use is associated with more HIV risk behaviors, it is not associated with greater likelihood of being diagnosed with a sexually transmitted disease.

A number of studies have examined whether ecstasy use is associated with more HIV risk behaviors among populations that are at high risk for contracting HIV. For example, among MSM, substance use before or during sex has not been associated with risk with HIV-negative partners, but has been associated with risk with partners who are HIV-positive and unknown serostatus. Further, among MSM assessed from 2001 to 2007, a greater number of HIV-positive (versus HIV-negative) men reported recent drug use, including ecstasy, across years. Among Hispanic MSM, having a higher number of sex partners, having higher social isolation scores, and having engaged in unprotected receptive anal intercourse have been associated with club drug use. Club drug users tend to have more sex partners than nonusers of club drugs and among those who do use club drugs, those who use more severely are more likely to have sex under the influence of club drugs compared to those who use less severely. Among Asian/Pacific Islander MSM, ecstasy is the most common drug used in conjunction with sex and an association has been demonstrated between unprotected anal intercourse and being high or buzzed on ecstasy, but not alcohol, marijuana, GHB, or crystal methamphetamine.

Ecstasy may also contribute to sexual side effects in men and women. For both, there may be a decreased ability to achieve orgasm if engaging in sex while on the drug, and for men, inability to maintain an erection. Efforts to achieve orgasm might include prolonged sexual encounters or rougher encounters, both of which can potentiate opportunities for a condom to break or other forms of genital irritation to occur, which increases the risk for sexually transmitted infections and HIV transmission. Although the physical ability to have sex may be diminished while high on ecstasy, sensual/sensory aspects of the drug can create a desire for touch and eroticism (e.g. kissing, fondling, genital stimulation). In one study of heterosexual female ecstasy users, this was described as sensuality as opposed to sexuality.

Neurocognitive Consequences

Numerous studies on animals have demonstrated that MDMA can damage serotonin-containing neurons; some of these studies have shown these effects to be long lasting. This suggests that such damage may occur in humans as well; however, measuring serotonin damage in humans is more difficult. Studies have shown that some heavy ecstasy users experience long-lasting confusion, depression, and selective impairment of working memory and attention processes. Such memory impairments have been associated with a decrease in serotonin metabolites or other markers of serotonin function. Functional magnetic resonance imaging studies on MDMA users have shown changes in brain activity in regions involved in cognition, emotion, and motor function. However, improved imaging technologies and more research are needed to confirm these findings and to elucidate the exact nature of the effects of MDMA on the human brain.

In 2007, a meta-analysis reviewed the literature on the association between MDMA misuse and neurocognition. MDMA use was found to be associated with neurocognitive deficits in attention/concentration, verbal and nonverbal learning and memory, psychomotor speed, and executive systems functioning. As with the psychological symptoms of ecstasy use, researchers have suggested that the neurocognitive deficits demonstrated in ecstasy users can be attributed to other substances that are commonly used in this population such as marijuana and alcohol. Some work has demonstrated that ecstasy and marijuana users are no more susceptible to these neurocognitive deficits than marijuana users alone. For example, one study has shown that ecstasy and other drug users showed comparable patterns of decision-making and impulsivity which was worse in both groups compared to control subjects who did not use ecstasy. Another study demonstrated that memory and executive functioning was similar in those who use ecstasy and those who use ecstasy and cannabis, and that both functions were poorer in these groups compared to controls. This work suggests that some cognitive impairment attributed to ecstasy is more likely due to concurrent marijuana use. However, at least one controlled study has demonstrated that ecstasy and marijuana users perform significantly worse in learning and memory compared to controls and marijuana users and that this worse performance can be attributed to differences in brain activity among ecstasy users compared to those who only use marijuana.

Effects on the Developing Fetus

Given that most ecstasy users are young and in their reproductive years, it is possible that some female users may be pregnant when they take ecstasy, either inadvertently or intentionally. Animal studies have shed light on the potential adverse effects of MDMA on the developing fetus. Behavioral studies in animals have found significant adverse effects on tests of learning and memory from exposure to MDMA during

a developmental period equivalent to the third trimester in humans. However, the effects of MDMA on animals earlier in development are unclear; therefore, more research is needed to determine what the effects of MDMA and ecstasy are on the developing human nervous system.

TREATMENT FOR ECSTASY USE

There are no specific treatments for ecstasy use and associated problems. However, harm reduction efforts have directly targeted ecstasy users by providing pill testing services at nightclubs and dance venues. For example, DanceSafe is a nonprofit organization that supplies volunteers at raves and nightclubs to provide information on ecstasy and other club drugs, including the dangers of using the drug and test pills for chemical makeup/harmful adulterants.

The most effective treatments for drug abuse and addiction in general are cognitive behavioral interventions that are designed to help modify the patient's thinking, expectancies, and behaviors related to their drug use and to increase skills in coping with life stressors. Drug abuse recovery support groups may also be effective in combination with behavioral interventions to support long-term, drug-free recovery. There are currently no pharmacological treatments for addiction to MDMA.

SUMMARY

In this chapter, we reviewed the history and patterns of MDMA/ecstasy use, along with its correlates and consequences. Although it is an illegal Schedule 1 drug, ecstasy remains popular, particularly among young adults and has been connected most strongly with the dance/rave scene (although the drug proliferates within other subcultures as well). In users, the drug produces intense feelings of euphoria, coupled with increased energy and feelings of sensuality and belonging. These factors are likely significant motivators for use in spite of its negative effects, which include acute impairment of memory and cognition, and can lead to confusion and feelings of depression and anxiety. It seems symptoms of dependence are common among users, though physical addiction is typically not associated with the drug. As a result, there are limited options available for treatment, which has perhaps furthered the growth of community-based groups providing harm reduction alternatives for users.

Glossary

Amphetamine (speed, bennies, black beauties, crosses, hearts, LA turnaround, truck drivers, and uppers) amphetamines are stimulants that often come in pill form and are sometimes prescribed by doctors for medical problems, most commonly attention deficit hyperactivity disorder (ADHD). Amphetamines can also be abused; that is, used in a way other than as prescribed (e.g. crushed and snorted) or used by someone without a prescription.

ADHD attention deficit hyperactivity disorder.

ASPD antisocial personality disorder.

Club drugs substances including ecstasy (MDMA), γ-hydroxybutyrate (GHB), ketamine, Rohypnol, methamphetamine, and lysergic acid diethylamide (LSD), commonly used in all-night dance parties such as raves. Use of these substance proliferated through the 1990s, and they remain widely used in nightclubs as well as other settings (bars, house parties).

Dopamine dopamine is a catecholamine neurotransmitter that is produced in several areas of the brain, including the substantia nigra and the ventral tegmental area. Dopamine is also a neurohormone released by the hypothalamus. Its main function as a hormone is to inhibit the release of prolactin from the anterior lobe of the pituitary. Dopamine affects brain processes that control movement, emotional response, and ability to experience pleasure and pain. Regulation of dopamine plays a crucial role in our mental and physical health. Neurons containing dopamine are clustered in the substantia nigra (midbrain). In Parkinson disease, the dopamine-transmitting neurons in this area die. As a result, the brain of people with Parkinson disease contains almost no dopamine. The drug L-DOPA can be converted in the brain to dopamine, thereby reducing these symptoms.

GHB (Xyrem, Liquid E, Liquid Ecstasy, Liquid G, Gina) γ-Hydroxybutyrate (GHB), one of the club drugs, is a central nervous system depressant that was approved by the US Food and Drug Administration (FDA) in 2002 for use in the treatment of narcolepsy. It is odorless and colorless but has a strong flavor, so it is frequently taken with alcohol or other beverages that mask the taste. It has been used to commit sexual assaults (date rape). In addition to intoxicating effects, GHB has anabolic effects (it stimulates protein synthesis) and has been used by bodybuilders to aid in fat reduction and muscle building.

Ketamine (Special K) ketamine is one of the drugs considered as club drugs. It is a dissociative esthetic, used in veterinary practice, that is usually snorted or injected by humans. It is traditionally in liquid form, and is often cooked down to a solid for nasal ingestion.

IDU intravenous drug user.

LSD lysergic acid diethylamide.

MDMA 3,4-Methylenedioxymethamphetamine.

Methamphetamine (speed, meth, chalk, tina, ice, crystal, crank, glass, fire, go fast) methamphetamine is a stimulant, originally derived from amphetamine, which comes in powder form and can be ingested orally, nasally, or injected intravenously. It is often made in large laboratories called superlabs, but is also sometimes made in small laboratories using inexpensive over-the-counter and often toxic ingredients (such as drain cleaner, battery acid, and antifreeze).

Methylenedioxymethamphetamine (MDMA, ecstasy, E, X, XTC) one of the most common club drugs, MDMA is a synthetic drug that has both stimulant and psychoactive properties. Although commonly associated with all-night dance parties (raves), its use has expanded to other settings, especially among young people. MDMA acts primarily on the serotonergic (5-HT) system, involved in many psychological states including mood and sleep.

Monoamine neurotransmitters monoamine neurotransmitters in biochemistry include organic compounds with only one amino group. The most important members in this group are the neurotransmitter group catecholamines (including dopamine, epinephrine, and norepinephrine) and the indoleamine serotonin. Monoamines seem to contribute to stable moods, and an excess or deficiency of monoamines seems to cause or result from several mood disorders.

MSM men who have sex with men.

Norepinephrine norepinephrine is a catecholamine neurotransmitter and also a stress hormone. As a stress hormone, norepinephrine affects parts of the brain, such as the amygdala, where attention and responses are controlled. Along with epinephrine, norepinephrine also underlies the fight-or-flight response, directly increasing heart rate, triggering the release of glucose from energy stores, and increasing blood flow to skeletal muscle.

NSDUH National Survey on Drug Use and Health.

PTSD posttraumatic stress disorder.

REM rapid eye movement.

Seroconversion seroconversion is the development of detectable specific antibodies to microorganisms in the blood serum as a result of infection or immunization. The word is often used in reference to testing for anti-HIV antibodies, referring to the process of becoming HIV-positive.

Serotonin serotonin is a monoamine neurotransmitter commonly found in the gastrointestinal system (gut) and the central nervous system. In the brain, serotonin neurotransmitters are involved in the regulation of mood, appetite, sleep, and muscle contraction. Serotonin also has some cognitive functions, including in memory and learning. Modulation of serotonin at synapses is thought to be a major action of several classes of pharmacological antidepressants.

CHAPTER

73

Inhalants

Li-Tzy Wu[*], *George E. Woody*[$]

[*]Duke University Medical Center, Durham, NC, USA,

[$]University of Pennsylvania and Treatment Research Institute, Philadelphia, PA, USA

OUTLINE

INTRODUCTION

In the United States, about 16% of eighth graders, 13% of tenth graders, and 10% of twelfth graders had ever used inhalants in their lifetime. In the general population, about 10% of American adults aged 18 years or older reported a history of inhalant use (13.4% of men; 6.3% of women). Inhalant use confers a high risk for significant morbidity and mortality. It is an important public health concern worldwide because household products and office supplies subject to inhalant use or misuse are omnipresent, easily accessible (from homes, offices, and a variety of stores), relatively inexpensive, conveniently packaged, and quickly produce the onset of high and toxic effects. Inhalants are particularly attractive to children, youth, and socioeconomically disadvantaged populations. This chapter summarizes current knowledge about inhalant use, including patterns of use; incidence and prevalence of use; assessment and diagnosis for inhalant use disorders according to the *Diagnostic and Statistical Manual of Mental Disorders Fourth Edition* (DSM-IV); comorbid psychiatric disorders, medical consequences, and mortality associated with inhalant use; and prevention and treatment. This review focuses on research data from major studies that include a large sample size (to ensure the generalizability of study findings) and have adequate coverage of respondents from diverse racial/ethnic groups and geographic regions.

WHAT IS INHALANT USE?

Inhalant use is the deliberate ingestion of volatile substances via (1) sniffing or snorting fumes from containers; (2) spraying aerosols directly into the nose

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00073-5

or mouth; (3) sniffing or inhaling fumes from substances sprayed or deposited inside a plastic or paper bag (i.e. bagging); (4) huffing from an inhalant-soaked rag stuffed in the mouth; or (5) inhaling from balloons filled with nitrous oxide to induce a psychoactive or mind-altering effect. Based on the profiles of pharmacological and behavioral effects, three main groups of inhalants are subject to these use patterns: (1) volatile solvents, fuels, and anesthetics; (2) nitrous oxide; and (3) volatile alkyl nitrites (e.g. amyl, butyl, and isobutyl nitrites). Some commonly used sources of inhalants include adhesives (e.g. airplane glue, rubber cement), aerosols (e.g. spray paint, hair spray, deodorant, room freshener, analgesic spray, asthma spray), cleaning agents (e.g. dry cleaning chemicals, spot remover, degreaser), solvents (e.g. nail polish remover, paint thinner, correction fluid, fuel gas, lighter, fire extinguisher), and gasoline. Any of these substances can produce a feeling of euphoria or high.

PATTERNS OF INHALANT USE

Surveys of the General Population

According to results from the National Survey on Drug Use and Health (NSDUH), a national survey of a representative sample of noninstitutionalized civilian residents aged 12 years and older in the United States (Table 73.1), the most commonly used inhalants are glue, shoe polish, toluene, gasoline, lighter fluid, spray paints, correction fluid, degreaser, nitrous oxide, and whippets for adolescents under age 18 years; nitrous oxide and whippets for young adults aged 18–25 years; and amyl nitrite (poppers or rush) for adults aged 26 years or older.

TABLE 73.1 Types of Inhalants Used Among Adolescents and Adults from the Most Commonly Used Inhalants to the Least Commonly Used Inhalants

Types of inhalants used among adolescents aged 12–17 years	Types of inhalants used among adults aged 18 years and older
Glue, shoe polish, toluene	Nitrous oxide, whippets
Gasoline, lighter fluid	Amyl nitrite, poppers, rush
Spray paints	Glue, shoe polish, toluene
Correction fluid, degreaser	Gasoline, lighter fluid
Nitrous oxide, whippets	Correction fluid, degreaser
Aerosol sprays	Paint solvents, lacquer thinner
Amyl nitrite, poppers, rush	Aerosol sprays
Paint solvents, lacquer thinner	Spray paints
Lighter gases, butane, propane	Ether, halothane, anesthetic
Ether, halothane, anesthetic	Lighter gases, butane, propane

Notes: These data are based on research findings from Wu et al. (2004) and Wu and Ringwalt (2006).

Results from the NSDUH show important age and gender differences in types of inhalants used (Table 73.2). Boys are more likely than girls to use gasoline, lighter fluid, nitrous oxide, and whippets, while girls are more likely than boys to use glue, shoe polish, toluene, spray paints, correction fluid, degreaser, and aerosol sprays. Among adults, men are more likely than women to use glue, shoe polish, toluene, gasoline, lighter fluid, paint solvents, lacquer thinner, lighter gases, butane, and propane.

Compared with adults, adolescents tend to use more types of inhalants and have a more frequent pattern of use. Approximately 50% of lifetime adolescent inhalant users in the United States have used multiple inhalants, while about 38% of lifetime adult inhalant users have a history of using multiple inhalants. In the sample of recent (past year) inhalant users, one-fifth of adolescents are weekly users of inhalants compared with about one-tenth of adults.

The National Poison Data System

Data from poison control centers provide additional information about individuals who seek help or treatment for inhalant use and the demographic characteristics of subgroups affected by use of harmful inhalants. According to data from the National Poison Data System (NPDS), the vast majority of inhalant cases are adolescents aged 12–17 years. Propellants (e.g. computer and electronics duster sprays, fluorocarbons), gasoline, and paint are the products most frequently implicated in inhalant cases reported to the NPDS. While there have been fewer changes in use of gasoline and paint products during the past few years, there has been a significant and steady increase in the use of propellants (computer and electronics duster sprays) over time. The NPDS data show that gasoline is the product most commonly used by children and adolescents under the age of 14 years, while propellants are the category of use most frequently cited by adolescents, especially older adolescents.

INCIDENCE AND PREVALENCE OF INHALANT USE

Incidence

Research findings on onset or incidence (i.e. new cases) of inhalant use can contribute important clues about the factors associated with initial use and can be

TABLE 73.2 Gender Differences in Types of Inhalants Used

Adolescents aged 12–17 years		Adults aged 18 years or older	
Glue, shoe polish, toluene	Girls > boys	Glue, shoe polish, toluene	Men > women
Spray paint	Girls > boys	Gasoline, lighter fluid	Men > women
Correction fluid, degreaser	Girls > boys	Paint solvent, lacquer thinner	Men > women
Aerosol spray	Girls > boys	Lighter gas, butane, propane	Men > women
Gasoline, lighter fluid	Boys > girls	–	–
Nitrous oxide, whippets	Boys > girls	–	–

Notes: These estimates are based on the results from Wu et al. (2004) and Wu and Ringwalt (2006).

useful for planning the timing and foci of prevention interventions. Onset of use can occur in children as young as 5–6 years of age. Research reports from the Monitoring the Future (MTF) study, a series of classroom surveys of eighth, tenth, and twelfth graders in the United States, show that inhalant use occurs early, with peak initiation rates in grades six to nine, and decreases with increasing age. However, it is important to note that school dropouts are not covered by a school-based survey like the MTF and that school dropouts in general have a high rate of illicit or nonmedical drug use, including inhalant use.

Surveys of community-based or noninstitutionalized populations that include school dropouts, such as the NSDUH, reveal that the risk of initiating inhalant use is not limited to early adolescence. Among adolescent inhalant users, the vast majority (80%) initiate inhalant use before the age of 15 years, and the remaining adolescents start inhalant use between 15 and 17 years of age. In the United States, national sample of adult inhalant users, about one-third initiate use between age 15 and 17 years, and 44% start, use in adulthood. These onset patterns are in line with age-related differences in types of inhalants used. Specifically, adolescents are more likely than adults to use readily accessible household products such as glue, shoe polish, gasoline, or spray paints, as inhalants of choice. By comparison, adults tend to initiate inhalant use within the context of a severe pattern of polysubstance use and sexual risk taking, and their inhalants of choice are likely to include nitrous oxide (whippets) and amyl nitrite (poppers or rush for sex-related activities), which are much more commonly used by illicit drug users and homosexual or bisexual individuals than by the general population.

Estimates from the 2007–2008 NSDUH show that approximately 730 000–770 000 Americans initiate inhalant use (first-time use) during a 12-month period, which represents slightly more than one-third of individuals who used inhalants in the past year. The level of perceived risk of using a psychoactive drug once or twice is generally considered an indicator for drug use (i.e. greater perceived risk by adolescents results in less psychoactive drug use). In the MTF, eighth and tenth graders are asked questions about the degree of risk they associate with using an inhalant once or twice. Unfortunately, there has been a decline in the perceived risk associated with inhalant use since 2000, and a relatively low proportion of eighth and tenth graders (less than 40% in 2008) reported that there is a "great risk" in using an inhalant once or twice. The hazards of inhalant use were communicated during the mid-1990s via an anti-inhalant advertising initiative launched by the Partnership for a Drug-Free America. The decline in perceived risk for using inhalants may be related to a generational forgetting of the hazards of inhalant use as younger cohorts were not exposed to these messages. This steady decline in perceived risk is worrisome and requires close monitoring of national trends and associated problems because inhalant use in adolescence is a robust predictor for serious substance abuse problems, including polysubstance use, heroin use, drug abuse or dependence, and injection drug use.

Prevalence

Of the nine main categories of illicit or nonmedical psychoactive drug use assessed by the MTF, inhalants are the second most widely used class of drugs among eighth and tenth graders (after marijuana) and are the third most widely used among twelfth graders (after marijuana and prescription opioids) with a lifetime rate similar to amphetamine use. In 2008, about 16% of eighth graders, 13% of tenth graders, and 10% of twelfth graders had ever used inhalants in their lifetime (Table 73.3).

School-based MTF surveys have generally found a higher prevalence of lifetime inhalant use among eighth graders than among older students, a trend that stands in contrast with lifetime prevalence rates of other categories of illicit or nonmedical drug use, which usually increase with age. This unique finding may be related to an association between early inhalant use and dropping out of school; that is, adolescents who

TABLE 73.3 Lifetime Prevalence (%) of Inhalant Use in Eighth, Tenth, and Twelfth Grades: Results from the MTF

Grade	2000	2001	2002	2003	2004	2005	2006	2007	2008
8th	17.9	17.1	15.2	15.8	17.3	17.1	16.1	15.6	15.7
10th	16.6	15.2	13.5	12.7	12.4	13.1	13.3	13.6	12.8
12th	14.2	13.0	11.7	11.2	10.9	11.4	11.1	10.5	9.9

Notes: These data are based on research findings from Johnston, L. D., O'Malley, P. M., Bachman, J. G., and Schulenberg, J. E. (2009). *Monitoring the Future national results on adolescent drug use: overview of key findings, 2008*. Bethesda, MD: National Institute on Drug Abuse.

use inhalants tend to drop out of school and are thus not included in school-based MTF surveys. Alternatively, older adolescents may be differentially more likely to under report inhalant use than use of other psychoactive drugs due to the perception that inhalants are kids' drugs. The results of inhalant use for 10th and 12th graders are considered underestimated. This is an area warranting further research.

Adolescents who are native American, native Alaskan, or of multiple races have a particularly high rate of inhalant use compared with adolescents of other racial or ethnic backgrounds; adolescents who are Asian and black have a very low rate of inhalant use. Among native American youths, inhalants are often the first psychoactive drug used. Earlier research suggests that boys are more likely than girls to use inhalants; more recent research data, however, indicate a more similar rate of inhalant use among genders. Because many adolescent girls of childbearing age are within the population of young inhalant users and there are possible adverse effects of maternal inhalant use on fetuses, the pattern and extent of inhalant use in female adolescents and youths warrant close scrutiny. Adolescent inhalant use also increases the risk for conduct problems, binge drinking, use of multiple drugs, heroin use, injection drug use, and depression.

In the general population, fewer adults than adolescents use inhalants. According to data from the NSDUH, approximately 10% of noninstitutionalized civilian adults in the United States have used inhalants in their lifetime (13.4% in men; 6.3% in women), and about 0.5% (5% of lifetime inhalant users) used inhalants in the past year. Women and blacks have a lower rate of inhalant use than men and other racial or ethnic groups. Additional characteristics associated with inhalant use include younger age (less than age 34 years), being single, receipt of mental health treatment in the past year, self-reported serious psychological distress, involvement with the criminal justice system, alcohol abuse or dependence, and past year drug use (especially polydrug use).

Nitrite Inhalant Use

Of all inhalants used, use of nitrite inhalants (amyl, butyl, and isobutyl nitrites or poppers) is associated with an elevated risk for infections and transmission of sexually transmitted diseases (e.g. human immunodeficiency virus (HIV)) because users often are polysubstance users or engage in unprotected or risky sexual behaviors. Inhaling nitrites can dilate blood vessels, increase the heart rate, and produce a sensation of heat and excitement that may last for several minutes. Since the early 1960s, nitrite inhalants have been used by individuals to enhance sexual activities or to get high. Although the rate of nitrite inhalant use is low in the general population, nitrite inhalant use is relatively common among drug abusers (especially individuals in addiction treatment) and homosexual or bisexual individuals, and its use is associated with risky sexual behaviors, illicit drug use, transmission of sexually transmitted diseases, suicide attempts, and drug-related overdose.

Nitrite inhalants are the primary inhalant used by adults, and use in adolescents is less frequent. In the MTF, approximately 1% of twelfth graders between 2007 and 2008 used nitrite inhalants in their lifetime. In the NSDUH, about 1.5% of noninstitutionalized adolescents aged 12–17 years (including school dropouts) have ever used nitrite inhalants in their lifetime. While use in the general population of adolescents is infrequent, the rate of lifetime nitrite inhalant use increases to 15% among adolescents who have an alcohol or drug dependence or who used multiple drugs in the past year. Nitrite inhalant use in adolescents can be considered a marker for serious psychiatric problems in that users not only tend to engage in delinquent activities, use multiple types of inhalants and other substances, and have alcohol/drug dependence, but also exhibit mental health problems and have received mental health treatment in the past year. Young nitrite inhalant users thus represent a subgroup of highly troubled youth in need of help. Additional characteristics associated with nitrite inhalant use in adolescents include older age (15–17 years), white race, more than one race, and residence in a nonmetropolitan area.

ASSESSMENT AND DIAGNOSIS FOR INHALANT USE DISORDERS

Assessments and diagnosis for DSM-IV inhalant abuse and dependence can be difficult since an accurate drug use history is not always possible to obtain and routine urine drug screening will not detect inhalants. Potential signs of inhalant use can be subtle and are summarized in Table 73.4.

TABLE 73.4 Potential Signs of Inhalant Use

Odors or chemical smells on the breath or clothes
Residue of the substance on clothing or skin (paint or glitter on face or hands)
Burns
Cans of gasoline or spray paint under an adolescent's bed
Rashes around nose or mouth (e.g. glue sniffer's rash)
Red or irritated eyes, throat, and nose
Trauma or injuries
Nonspecific respiratory problems (e.g. coughing, sinus discharge, dyspnea, or rale)
Headache or general weakness
Abdominal pain, nausea, or vomiting

problems), and the user does not meet the criteria for inhalant dependence in the past year (Table 73.6). DSM-IV inhalant dependence includes inhalant users who show a maladaptive pattern of inhalant use leading to clinically significant impairment or distress, as manifested by having three or more of the six dependence criteria (i.e. tolerance, taking larger amounts over a longer period of time, inability to cut down, a great deal of time spent in using or recovering from its effects, important activities given up, and continued use despite resulting medical or psychological problems) that occur during a 12-month period.

It is important to note that inhalant withdrawal symptoms (e.g. sleep disturbances, tremor, irritability, diaphoresis, nausea, and fleeting illusions) may occur within 1–2 days after cessation of use and may last for 2–5 days. However, because of a lack of research data

According to the DSM-IV (Table 73.5), inhalant intoxication is defined as the presence of clinically maladaptive behavioral or psychological changes that develop during or shortly after intentional use of or exposure to volatile inhalants (e.g. dizziness, nystagmus, lack of coordination, slurred speech, unsteady gait, lethargy, depressed reflexes, psychomotor retardation, tremor generalized muscle weakness, blurred vision or diplopia, stupor or coma, and euphoria) and that are not due to a general medical condition and are not better accounted for by another mental disorder.

Inhalant abuse as defined by the DSM-IV as a maladaptive pattern of inhalant use leading to clinically significant impairment or distress, as manifested by having one or more of the four abuse criteria (i.e. role interference, hazardous use, legal problems, and relation

TABLE 73.5 DSM-IV Criteria for Inhalant Intoxication

A	Recent intentional use or short-term high-dose exposure to volatile inhalants (excluding anesthetic gases and short-acting vasodilators)
B	Clinically maladaptive behavioral or psychological changes that developed during or shortly after use of or exposure to volatile inhalants
C	Two or more of the following signs, developing during or shortly after inhalant use or exposure: dizziness, nystagmus, incoordination, slurred speech, unsteady gait, lethargy, depressed reflexes, psychomotor retardation, tremor, generalized muscle weakness, blurred vision or diplopia, stupor or coma, euphoria
D	The symptoms are not due to a general medical condition and are not better accounted for by another mental disorder

Note: These criteria are based on the DSM-IV, Text Revision (American Psychiatric Association, 2000).

TABLE 73.6 DSM-IV Criteria for Inhalant Use Disorders

Inhalant abuse	Inhalant dependence
A. A maladaptive pattern of inhalant use leading to clinically significant impairment or distress, as manifested by one or more of the following, occurring within a 12-month period: **(1)** Recurrent inhalant use resulting in a failure to fulfill major obligations at work, school, or home **(2)** Recurrent inhalant use in situations in which it is physically hazardous **(3)** Recurrent inhalant-related legal problems **(4)** Continued inhalant use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the inhalant **B.** The symptoms have never met the criteria for inhalant dependence for this class of substance	**A.** A maladaptive pattern of inhalant use leading to clinically significant impairment or distress, as manifested by three or more of the following, occurring at any time in the same 12-month period: **(1)** Tolerance as defined by the need for markedly increased amounts of the inhalant to achieve intoxication or desired effects, or markedly diminished effects with continued use of the same amount of the inhalant **(2)** An inhalant is often taken in larger amounts or over longer periods than was intended **(3)** There is a persistent desire or unsuccessful effort to reduce or control inhalant use **(4)** A great deal of time is spent in activities necessary to obtain the inhalant, use it, or recover from its effects **(5)** Important social, occupational, or recreational activities are given up or reduced because of inhalant use **(6)** Inhalant use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by it

Note: These criteria are based on the DSM-IV, Text Revision (American Psychiatric Association, 2000).

to establish an inhalant withdrawal syndrome, the withdrawal criterion is not included for DSM-IV inhalant dependence. This may change in the future as more empirical data for an inhalant withdrawal syndrome accumulate.

PREVALENCE AND CORRELATES OF INHALANT USE DISORDERS

National surveys of the US general population show that 10.6% of adolescents aged 12–17 years who used inhalants in the past year reported a pattern of inhalant use problems consistent with the DSM-IV criteria for a current inhalant use disorder and that 7.7% of adults aged 18 years or older who used inhalant in the past year reported a pattern of inhalant use problems consistent with the DSM-IV criteria for a current inhalant use disorder.

Inhalant abuse and dependence, as well as cessation from inhalant use, have received comparatively less research attention than inhalant use. Inhalant use was not included in the Diagnostic Interview Schedule of the National Institute of Mental Health-Epidemiologic Catchment Area (NIMH ECA) study. One publication from the 1990 National Comorbidity Survey (NCS) describes the prevalence of lifetime inhalant dependence (0.3%) in the general population. More recent research data suggest that use of multiple inhalants in adolescents is common (about 50% of users) and that many have used before the age of 14 years, findings that point toward the need to identify those at risk for progressing from use to abuse or dependence. Research data from the NSDUH show that 0.2% of adolescents aged 12 years or older met the DSM-IV criteria for current inhalant abuse, and another 0.2% met the criteria for inhalant dependence in the past year. In the subsample of adolescents who used inhalants in the past year (Table 73.7), 6% met the DSM-IV criteria for current inhalant abuse and an additional 4% for inhalant dependence. Therefore, about one in ten adolescent inhalant users have an inhalant use disorder. It is also important to note that these estimates of inhalant use disorders are all based on self-reported data from survey respondents.

Different characteristics are associated with inhalant abuse and dependence in adolescents. Characteristics associated with increased odds of inhalant abuse include engaging in multiple delinquent activities, history of incarceration, and use of multiple inhalants. Characteristics associated with increased odds of inhalant dependence include early onset of first inhalant use, using inhalants weekly, history of foster care placement, receipt of mental health treatment in the past year, and the presence of other drug abuse or dependence.

Data from the NSDUH provide a unique opportunity to compare inhalant use disorders in adults against estimates in adolescents. In the national sample of adults aged 18 years or older, 0.04% met the DSM-IV criteria for current inhalant abuse (0.03%) or dependence (0.01%) in the past year. In the subsample of adults who used inhalants in the past year, 8% met the DSM-IV criteria for current inhalant abuse (7%) or dependence (1%). Although adult men have a higher rate of inhalant use than adult women, there are no gender differences in inhalant use disorders. The following groups of adult inhalant users have an elevated rate of inhalant use disorders: adults aged 35–49 years, those who did not complete high school, users of mental health treatment, and weekly inhalant users. Rates of current inhalant use disorders among adolescents and adults are summarized in Table 73.7.

Research data from the 2001–2002 National Epidemiologic Survey on Alcohol and Related Conditions (NESARC) – presently the largest study of psychiatric comorbidity among adults in the United States – provide information about lifetime inhalant use disorders among inhalant users. In the NESARC, of respondents aged 18 years or older, 2% were identified as lifetime inhalant users, and 19% of lifetime users met the DSM-IV criteria for an inhalant use disorder in their lifetime. Most adults (88%) with a lifetime inhalant use disorder met the criteria for inhalant abuse but not inhalant dependence, and 12% met the criteria for inhalant dependence irrespective of whether they had

TABLE 73.7 Prevalence of Past Year or Current DSM-IV Inhalant Use Disorders in the General Population

DSM-IV inhalant use disorders (%)	All respondents		Individuals who used inhalants in the past year	
	Aged 12–17 years	Aged 18 years or older	Aged 12–17 years	Aged 18 years or older
Abuse	0.2	0.03	6.3	6.6
Dependence	0.2	0.01	4.3	1.1
Abuse or dependence	0.4	0.04	10.6	7.7

Note: These estimates are based on results from Wu et al. (2004) and Wu and Ringwalt (2006).

ever met criteria for inhalant abuse. The vast majority (94%) of adults with a history of inhalant use had not used inhalants in the past year, and very few (1%) met the DSM-IV criteria for an inhalant use disorder in the past year.

PSYCHIATRIC COMORBIDITIES, MEDICAL CONSEQUENCES, AND MORTALITY

Substance Use and Other Psychiatric Comorbidities

Adolescent inhalant users often have comorbid DSM-IV substance use disorders and other mental health problems, and adolescents who used both inhalants and marijuana represent a severe set of drug users. Compared with adolescents who use inhalants but no marijuana, or adolescents who use illicit or nonmedical drugs other than inhalants and marijuana, adolescents who use both inhalants and marijuana have a particularly high rate of DSM-IV substance use disorders, including alcohol, marijuana, cocaine, hallucinogen, opioid, sedative, stimulant, tranquilizer, and heroin use disorders. Adolescents who use inhalants but no marijuana have rates of alcohol or drug use disorders similar to adolescents who use illicit or nonmedical drugs other than inhalants.

Adolescent inhalant users in the NSDUH are more likely than noninhalant users to have major depression and to participate in treatment for mental or psychological problems. However, empirical data concerning other DSM-IV mental disorders in the general population of adolescents are lacking. Research data from adolescents in treatment for mental or behavioral problems show that those with a history of inhalant use, abuse, or dependence are more likely than those with other problems to have other substance use disorders, major depression, suicide attempts, and a history of physical/sexual abuse and neglect. These findings suggest that adolescent psychiatric patients with a history of inhalant use should be screened carefully for the presence of serious substance abuse or mental health problems.

Similarly, psychiatric disorders among adults with a history of inhalant use also are prevalent. Research data from the 2001–2002 NESARC have documented that approximately 96% of adults with a history of inhalant use met the DSM-IV criteria for a substance use disorder in their lifetime, and that about two-thirds met the DSM-IV criteria for a substance use disorder in the past year. As shown in Table 73.8, among adults with a history of inhalant use, alcohol, marijuana, nicotine, cocaine, hallucinogen, and stimulant use disorders were all more prevalent than inhalant use disorders (19%). Less education, residence in nonmetropolitan areas, early onset of inhalant use, and a history of substance abuse treatment increased the odds of having an inhalant use disorder among adult inhalant users.

TABLE 73.8 Prevalence of Lifetime DSM-IV Psychiatric Disorders Among Adults who Reported a History of Inhalant Use in the General Population

Lifetime DSM-IV disorder	%	Lifetime DSM-IV disorder	%
Nicotine use disorder	58	Any mood disorder	48
Alcohol use disorder	87	Major depression	41
Inhalant use disorder	19	Dysthymia	18
Marijuana use disorder	68	Mania	15
Hallucinogen use disorder	31	Hypomania	8
Stimulant use disorder	28	Any anxiety disorder	36
Sedative use disorder	17	Panic disorder with agoraphobia	4
Tranquilizer use disorder	18	Panic disorder without agoraphobia	14
Opioid use disorder	20	Social phobia	12
Cocaine use disorder	35	Specific phobia	18
Heroin use disorder	5	Generalized anxiety disorder	11
		Antisocial personality	32

Note: These estimates are based on the results from Wu et al. (2008) and Wu and Howard (2007).

Other (nonaddictive) mental disorders, including mood (48%), anxiety (36%), and personality (45%) disorders, also are prevalent among adults with a history of inhalant use. Particularly common lifetime disorders are major depression and antisocial personality disorder. In addition, psychiatric disorders are highly comorbid, with approximately one in seven lifetime inhalant users meeting the DSM-IV criteria for six or more lifetime nonaddictive mental disorders, and more than one in five inhalant users meeting the criteria for three to five of such disorders. Female inhalant users were more likely than male users to meet the criteria for dysthymia and anxiety disorders, while male inhalant users were more likely than female users to have an antisocial personality disorder. Early onset of inhalant use was strongly associated with an increased likelihood of having multiple mental disorders, particularly mood and personality disorders. On average, inhalant users tend to have an earlier age of onset of mood or anxiety disorders than noninhalant users. Regarding the temporal ordering of various disorders, onset of phobia typically precedes the onset

of inhalant use, whereas mood and other anxiety disorders on average are likely to develop subsequent to inhalant use initiation.

Medical Comorbidities and Mortality

Inhalant use is associated with increased morbidity and mortality. Most inhalants are very toxic to organs, and inhalant users are at risk for an array of long-lasting adverse or even fatal medical consequences, including substantial cardiac, renal, hepatic, and neurological morbidity or mortality. The liver and the heart are the organs most commonly affected by volatile inhalants. Sniffing highly concentrated chemicals in solvents or aerosol sprays can induce irregular and rapid heart rhythms, which can result in heart failure and death within minutes of a session of prolonged sniffing (i.e. sudden sniffing death). Inhalation of nitrites can not only increase the risk for HIV-related risky sexual behaviors but also has adverse effects on the immune system by impairing immune functioning and suppressing resistance to infection. In illicit drug users, daily use of nitrite inhalants (poppers) is also associated with overdose mortality.

Inhalant use is particularly devastating to adolescents with respiratory problems because it can not only produce adverse effects on the respiratory system through irritation or inflammation of breathing passages but can also exacerbate existing respiratory conditions. Recent research data from the NSDUH show that 4–5% of adolescents who used inhalants in the past year also had one or more respiratory conditions (pneumonia, bronchitis, asthma, and sinusitis) in the same period of time. These research data, however, cannot discern whether inhalant use leads to respiratory conditions.

Causes of death related to inhalant use may include suffocation, aspiration, choking, accidental injuries (e.g. car accidents, drowning, fire, trauma), or adverse drug–drug interactions; death can result from either acute (e.g. sudden sniffing death syndrome) or delayed (e.g. cardiomyopathy, central nervous system toxicity, hepatocellular carcinoma, renal toxicity) adverse effects. Recent research data from 60 poison control centers (the NPDS) in the United States provide important information about mortality associated with inhalant use. The mortality rate is defined as the number of deaths per 1000 single substance use cases involving the product. Butane (58 deaths per 1000 cases), propane (26 deaths per 1000 cases), and air fresheners (22 deaths per 1000 cases) have the highest mortality rate, followed by nitrous oxide (14 deaths per 1000 cases), carburetor cleaners (9 deaths per 1000 cases), and fluorocarbons/Freon® (9 deaths per 1000 cases).

The vast majority of inhalant cases reported to the NPDS are adolescent boys, suggesting that boys might tend to use more harmful inhalant products or to engage in heavier or more chronic inhalant use. Girls are most likely to use air freshener, hair spray, and nail products (e.g. nail polish and remover), and the latter two categories have a very low rate of fatality from the analysis of the poison control data. As a group, inhalants have a fatality rate of 5.5 deaths per 1000 cases, which is much higher than the fatality rates (less than 1 death per 1000 cases) for cases of pharmaceutical substances or nonpharmaceutical exposures from the NPDS. Thus, inhalants appear to be more lethal to poison control center cases than other substances.

PREVENTION AND TREATMENT

Prevention

Given the serious, or even fatal, medical consequences resulting from inhalant use, and data showing that use can lead to harmful consequences, prevention efforts should begin with a renewed public information campaign as was done in the 1990s. Because household products and office supplies subject to inhalant use and abuse are omnipresent, a broad and concerted approach that incorporates prevention efforts by schools, communities, parents, and health care professionals are recommended to enhance the general population's knowledge of the serious health consequences of inhalant use and to increase early identification of at-risk subgroups or new onset inhalant users to reduce adverse health effects.

Education by means of a school-based drug abuse curriculum is considered an important component for primary prevention of substance use, and efforts should be made to make certain that inhalant use is included. School staff have the opportunity to identify students who show behavioral or psychological risks for inhalant-related problems and to work with parents of at-risk students. Informing parents and at-risk children and youth about the dangers of inhalant use (e.g. sudden death, burns, and serious brain or liver damage) can decrease experimentation with inhalants. Pediatricians or family physicians can also play an important role in prevention efforts (e.g. education about the dangers from inhalant use, early identification of inhalant users, brief intervention, and referrals to appropriate health care providers) because they see children and youth routinely for physical checkups and often have well-established relationships with family members.

Treatment

According to data from 60 poison control centers in the United States, the majority (56%) of inhalant cases were treated in a health care facility (mainly emergency departments), 10% of cases were admitted to critical care units, 7% to noncritical care units, 8% to psychiatric units, and 20% received an unknown level of care. Inhalant abusers often do not seek treatment for inhalant abuse, and only when inhalant use results in life-threatening or serious consequences does the user present to a health care facility. Medical management starts with providing life support to stabilize the patient and address any acute injury or toxicity. Subsequent treatment needs and plans will depend on the history of physical, mental, and substance abuse status. There are presently no effective reversal agents for inhalant intoxication.

Further, little is presently known about substance abuse treatment needs and successful treatment modalities for inhalant users; clinicians rely on available approaches to substance use problems, such as motivational enhancement techniques, cognitive behavioral therapy, family therapy, or 12-step facilitation. As shown from this review, inhalant abusers are not only affected by multiple substance abuse and mental health problems but might also have developed negative physiological and neurological damage from repeated inhalant use. These multiple comorbid problems pose challenges to effective treatment. Unfortunately, treatment for inhalant abuse or dependence is among the least-studied areas of treatment research. There are few programs designed specifically for inhalant abuse treatment. Thus, access to effective care is limited.

In conclusion, inhalant abuse can lead to serious morbidity and mortality. There is a clear need to increase research efforts on effective prevention and treatment approaches specific to addressing inhalant abuse and dependence.

CHAPTER

74

Ketamine

Jan Copeland, Paul Dillon

National Cannabis Prevention and Information Centre, University of New South Wales, Sydney, NSW, Australia

OUTLINE

INTRODUCTION

Ketamine is a short-acting, noncompetitive *N*-methyl-D-aspartate (NMDA) receptor antagonist that acts as a dissociative anesthetic with analgesic and amnestic properties. It has been used for humans and animals since the 1960s and its first reported use as a recreational drug was in the early 1980s. Both popular and research accounts indicate that the recreational use of ketamine has widened in the context of nightclubs, dance parties, and raves. Clinicians and researchers noted that some nonmedical users sought dissociative, hallucinatory experiences. By the end of the 1970s, the United States Food and Drug Administration (FDA) was becoming concerned about the sale of ketamine on the street. By the early 1980s a wide range of unauthorized preparations were available in the United States including capsules, powder, crystals, tablets, and solutions, in addition to the authorized injectable forms. Solutions sold on the street in the United States have gone by many names such as K, Kay, Jet, Super Acid, 1980 Acid, with powders known as Green, Purple, Mauve, Special LA Coke, Super C, and K. Other street names have included Vitamin K and most recently, Special K.

Ketamine is available as a liquid, pill, or powder, and can therefore be snorted, swallowed, smoked, or injected. It is typically snorted in measures known as bumps. Bumps are small snorts usually measured by

Principles of Addiction, Volume 1

a tiny spoon provided within the lid of the container in which it is purchased.

HISTORY OF KETAMINE

Ketamine hydrochloride is marketed as a short-acting, general anesthetic for human and veterinary use. Reports have indicated that ketamine, or Special K as it is also known, is being used in social rather than medical and scientific settings in many parts of the world. It was first synthesized by Calvin Stevens in 1962. Early clinical studies on ketamine with human volunteers found it to be more effective and shorter acting than phencyclidine (PCP), with fewer emergence symptoms and less toxicity. The drug was first manufactured in the United States in the 1960s as Ketalar. It was described as a dissociative anesthetic with analgesic and amnesic actions. Use of ketamine as a surgical anesthetic escalated when it gained popularity on the battlefields of Vietnam. It was promoted as a dissociative anesthetic because of its ability to induce a lack of responsive awareness, not only to pain but also to the general environment. It is believed that the drug selectively interrupts association pathways of the brain before producing somesthetic (the consciousness of having a body) sensory blockade.

PHARMACOLOGICAL AND TOXICOLOGICAL EFFECTS OF KETAMINE

Ketamine is 2(2-chlorophenyl)-2-(methylamino)-cyclohexanone, an arylcycloalkylamine. It is structurally related to PCP and cyclohexamine. Ketamine is a noncompetitive NMDA receptor antagonist that interferes with the action of excitatory amino acids including glutamate and aspartate. It occurs in racemic form and also as an *S* enantiomer. Ketamine is manufactured by the chemical industry for use in pharmaceutical products using the precursors cyclopentyl bromide, *o*-chlorobenzontrile, and methylamine. Due to the complicated multistep synthesis, and the difficulty of obtaining the necessary precursors and numerous solvents and reagents, ketamine sold illicitly for recreational use appears to be mostly obtained by diversion of legitimate supplies of either the bulk drug or its pharmaceutical preparations.

Ketamine has a plasma half-life of 2–4 h. It is highly lipid soluble and has a distribution half-life of approximately 7–11 min. Ketamine is metabolized in the liver within the cytochrome P_{450} system with formation of water-soluble conjugates. Some of the metabolites, namely norketamine, have some potency but do not penetrate the central nervous system sufficiently to cause hypnosis. Ketamine is typically administered in doses of 1–2 mg kg^{-1} intravenously over 1–2 min or 4–5 mg kg^{-1} intramuscularly. Studies of the pharmacokinetics of ketamine report similar plasma concentration profiles for the same dose administered orally, sublingually, and in suppository preparations with nasal preparations having the highest relative concentration of the noninjecting routes of administration.

While ketamine has analgesic effects it is not reversed by naloxone. The synthetic alpha$_2$-adrenergic antagonist, atipamezole hydrochloride, is used in veterinary medicine to reverse the effects of medetomidine and ketamine anesthetics in a range of animals. There are no reports of its use in humans. At this stage, therefore, there is no agent available to reverse the effects of ketamine in humans.

PATTERNS OF USE

That ketamine-related data are not individually reported in the World Drug Report epidemiology of illicit drug use is testimony to its low level of use in general populations of most participating countries. It was not reported in the triennial Australian National Drug Strategy Household Survey until 2004. That year, 0.3% reported having used ketamine in the previous 12 months, compared with 0.2% in the 2007 survey. In the latter survey, the average age of initiation was 24.0 years (23.8 males; 24.3 females). The typical use pattern was once or twice a year (51.1%) but 6% used ketamine between daily and weekly. The other drugs most commonly reported as being used concurrently with ketamine were alcohol (73.5%), sildenafil citrate (Viagra®) (53.6%), and cannabis (24%).

In 1994, however, ketamine was listed in the Australian Illicit Drug Report for the first time. This is an Australian national annual survey of injecting drug users. An additional annual survey of regular ecstasy users has reported a decline between 2003 and 2009 from 26% of participants reporting having used ketamine in the previous six months in 2003 to only 10% in 2009.

The British Crime Survey shows that less than half of 1% of all respondents reported the use of ketamine in 2007–08, and that there was no statistically significant change in this figure compared to the previous year. Surveys of nightclub patrons in the United Kingdom, however, have reported an increase in ketamine use from 25 to 40% from 1999 to 2003. A study in 2009 found increased use in 9 out of 20 studied areas (London, Birmingham, Newcastle, Ipswich, Bristol, Blackpool, Portsmouth, Nottingham, and Sheffield) and that ketamine users were experimenting with stronger doses, including injecting the drug.

One of the few population level data collections to include ketamine is the US Monitoring the Future Study, an ongoing study of the behaviors, attitudes, and values of American secondary school students, college students, and young adults. The 2009 trends for 12th graders reported a reduction in annual ketamine use from a peak of 2.6% in 2002 to 1.7% in 2009.

The use of ketamine in Asia appears to be relatively more common. A Taiwanese study reported that ketamine was detected in 47% of the urine samples obtained from a study of those attending rave parties but in only 2% of the urine of police detainees. A recent study of drugged drivers involved in nonfatal driver casualties in Hong Kong reported that ketamine was the most commonly detected substance, being found in 45% of participants. In Shanghai and neighboring cities, ketamine was more frequently detected (0.03%) than 3,4-methylenedioxymethamphetamine (MDMA) (0.1%) in the serum of drivers involved in motor vehicle accidents and traffic violations.

The most recent Drug Abuse Warning Network report on trends in drug-related emergency department visits for 1994–2001 reports a 3474% increase in the number of drug mentions for ketamine from 19 in 1994 to 679 in 2001. More recently, from 2005 to 2008, the number has stabilized to between 300 and 344 ketamine mentions per year.

EFFECTS OF KETAMINE

Ketamine has systemic effects on a number of organ systems. The predominant effect of ketamine on the cardiovascular system is thought to be due to decreased catecholamine reuptake leading to increase in arterial blood pressure and cardiac output 2–4 min after intravenous injection and 10–20 min after intramuscular injection. A recent study has reported that ketamine reduces left ventricular systolic and diastolic functions among those with ischemic heart disease.

Ketamine may cause an increase in cerebral blood flow, oxygen consumption, and intracranial pressure. Animal studies, however, have demonstrated a marked neuroprotective effect, mediated by antagonism of the NMDA channels on central neurons, and may have promise in the future management of cerebrovascular accidents. Upper airway reflexes are usually maintained when ketamine is administered in addition to bronchodilation. Apnea has been seen with ketamine use but is generally associated with rapid and/or large intravenous doses. Additional effects are seen in the gastrointestinal tract (increased salivation), the immune system (a significant reduction in leukocyte activation during sepsis), and the eyes (initial rise in intraocular pressure, eye movements throughout surgery, and preservation of the corneal reflex).

Key Psychoactive Effects of Ketamine

In one of the earliest studies of the recreational use of ketamine, it was reported that the drug was viewed by most of the users in the study as a safe, potent hallucinogen with a short duration of action and an equal balance between positive and negative effects. Self-administration was titrated to achieve the desired amount of dissociative sensations, hallucinations, and transcendental experiences. Respondents reported ataxia, slurring of speech, dizziness, mental confusion, blurred vision, anxiety, hyperexcitability, and insomnia, amongst other effects.

In a later study that examined the subjective effects of ketamine, seven male volunteers were given between 5 and 12 doses of ketamine intermittently over a period of 18 months. They used approximately 10–25% of the anesthetic dose, believing this to reflect the dose level that occurs during the emergence period. The authors describe a series of phenomena experienced by most of the participants: a sensation of light throughout the body; novel experiences concerning body consistency (e.g. feeling as though they are made from wood or plastic); grotesquely distorted shape or size of body parts; sensation of being weightless and floating or hovering; colorful visions (including geometric patterns and figures); absence of sense of time; sudden insights into the nature of the existence or the self; strong feelings of association with others in the environment; and out-of-body experiences.

Subsequent studies of the psychedelic effects of ketamine in healthy volunteers have reported that these effects are dose related. Anecdotal evidence indicates that many users of other club drugs have hesitated to use it, due to either bad personal experiences or horror stories relayed to them by others. Some users may describe visits to the K hole or K ride as it is known in Asia, as a place referring to where users are when under the influence of ketamine. The K-hole experience appears to vary with the individual, but six main categories of mental effects produced by ketamine have been identified: the perception of contact with aliens; the perception of entry into information networks; access into alternative realities; personal and creative problem solving; out-of-body near-death states; and tantra-like enhancement of sexual activity.

Ketamine can sometimes reproduce the features of a near-death experience (NDE), including buzzing/ringing/whistling sounds at the beginning, travel through a dark tunnel into light at a high speed, the conviction that one is dead, apparent telepathic communion with God, intense visions, and out-of-body

experiences. A survey of 50 ketamine users who reported experiencing an NDE reported that it typically occurred in their first few occasions of use with the most frequently noted features being altered perception of time (90%), strong sense of detaching from their own body (88%), and a sense of peace and joy (76%). It should be noted that an NDE induced by ketamine does not necessarily mean that the person is physically near death.

Psychosis

The role of the NMDA neurotransmitter system in relation to psychosis is not completely understood, however, pharmacological, postmortem, and clinical studies have implicated the NMDA system has been implicated in the pathophysiology of schizophrenia. The psychotic states induced by NMDA antagonists such as ketamine have been described as being similar to schizophrenia. The hallucinogenic effect of ketamine arises, at least in part, from its capacity to disrupt thalamocortical gating of external and internal information to the cortex. Deficient gating of sensory and cognitive information is thought to result in an overloading inundation of information and subsequent cognitive fragmentation and psychosis. Animal studies have shown that treatment with ketamine leads to an increase in D2 receptor binding in the hippocampus and a decrease in glutamate receptor binding in the frontal cortex with no change in D1 receptor binding. The density of dopamine receptors was increased in the striatum and 5-hydroxytryptamine transporters were increased in the striatum, the hippocampus, and the frontal cortex.

Laboratory studies of subanesthetic doses of ketamine in humans report that it produces behaviors similar to the positive (e.g. hallucinations and thought disorder) and negative (e.g. detachment, amotivation, and blunted affect) symptoms of schizophrenia, elicits alterations in perception, impairs performance on tests of vigilance, verbal fluency, and the Wisconsin Card Sorting Test, evokes symptoms similar to dissociative states, and preferentially disrupts measures of frontal lobe function such as delayed word recall, sparing immediate recall, and postdistraction recall. Ketamine also exacerbates the core psychotic symptoms in patients with schizophrenia and is not blocked by antipsychotic drugs such as haloperidol.

As a result ketamine is a useful model of schizophrenia and is being used to increase our understanding of the illness and to develop new treatments.

Depression

A growing body of preclinical research implicates the NMDA class of glutamate receptors in the pathophysiology of major depression and the mechanism of action of antidepressant treatments. A small study of those with diagnosed major depression reported robust decrease in depressive symptoms, emerging progressively over 3 days, following low-dose ketamine infusion. There are studies currently being conducted in the United States on the use of ketamine as treatment for bipolar disorders.

Teratogenic Effects

Ketamine crosses the placenta easily and concentrations in the fetus are approximately equal to those of the mother. There is accumulating evidence from in vitro and in vivo experiments that suggests that tonic stimulation of NMDA receptors is vital for the survival of developing nerve cells. The NMDA receptor can be pharmacologically blocked by drugs such as alcohol and ketamine, among other drugs. This alters the glutamate and γ-aminobutyric acid (GABA) transmission that suppress neuronal activity and cause neuronal death in the developing brain. While there are no human studies, animal studies suggest that the duration of ketamine exposure in 7-day-old rat pups increases neuronal degeneration of the developing rat brain.

Safety Profile

Ketamine has a wide margin of safety. The predominant adverse reaction is emergence phenomena post anesthetic for which the risk factors are age, female gender, noisy environment during recovery, prior personality disorders, and excessive dreaming. The experience of emergence phenomena is not associated with dose. Other side effects include a transient rash predominantly on the face and neck, and nausea and vomiting. A reasonably conservative safety ratio of 35 for snorted ketamine and a somewhat higher margin for oral administration has been reported.

THERAPEUTIC VALUE OF KETAMINE IN HUMANS

Ketamine has broad areas of application and is a rapidly acting, relatively safe parenteral analgesic and anesthetic agent that has been in clinical use for more than three decades. It is the only injectable anesthetic that induces increase in arterial pressure and heart rate. Although the respiratory and pharyngeal reflexes are sometimes momentarily depressed after injection of substantial quantities, they are usually maintained during the period of unconsciousness. The drug is therefore suitable for short anesthetic and surgical procedures especially in the absence of a trained anesthetist, although the latest Parke-Davis data sheet stresses that

a trained professional should be present, together with resuscitation equipment. It is particularly useful in developing countries and remote country areas where a doctor may be working alone.

The major concern is the emergence phenomena. Psychic disturbances after ketamine anesthesia have been reported to occur in about 15–40% of adult cases, depending to some extent on how these terms are defined. Other drugs, such as diazepam, lorazepam, and propofol, have been given together with ketamine in an attempt to reduce or abolish these phenomena, with some success. Psychological techniques are also effective in reducing complaints. The emergence phenomena have led to less medical use than was originally anticipated, but ketamine is still to be found in many general hospitals in most countries. It is also currently widely used in veterinary medicine. A number of clinical uses of ketamine have been suggested. Ketamine appears to be best used in the young (less than 10 years old) and the old (over 60 years) as these groups have reported fewer emergence reactions (Radford, 1996). Recent studies have confirmed the effectiveness of ketamine in a variety of pediatric and diagnostic procedures via caudal or intramuscular routes of administration.

In addition to anesthesia and sedation, ketamine is used as an analgesic for acute postoperative pain, painful procedures, and more controversially for chronic or neuropathic pain. Analgesic doses of ketamine have been associated with dose-related declines in mood, conscious perception, and intellectual performance. Recent studies also report the successful use of patient controlled analgesia with morphine and ketamine following spinal and hip surgery in adults. An early stage descriptive study of the use of topical ketamine in the management of postherpetic neuralgia suggests it shows promise in the management of this painful condition.

Ketamine has also been used as an experimental treatment for complex regional pain syndrome, which is a severe, chronic pain condition characterized by sensory, autonomic, motor, and dystrophic signs and symptoms. The treatment involves one or two cycles of a 10-day, inpatient intravenous infusion for 4 h daily in high doses. While there have been promising findings, the studies to date have been open label and the evidence base is yet to be developed.

There is mixed evidence on the effect of ketamine on epilepsy and seizure disorders. Ketamine has been reported as both a pro- and anticonvulsant. Recently, ketamine has been recommended for use with electroconvulsive therapy as it has been shown to prolong seizure duration with more rapid posttreatment reorientation. A larger body of evidence, however, suggests that it displays anticonvulsant and neuroprotective properties but should be used with caution over prolonged periods of time.

Studies conducted in the 1950s and 1960s suggested that psychedelic drug-assisted psychotherapy might be an effective treatment for alcohol dependence. In the 1990s, these findings were used as a partial basis for ketamine-assisted treatment of alcohol dependence. This is known as ketamine psychedelic therapy (KPT). The same author reports on the use of ketamine psychotherapy for heroin addiction, where dose was found to be related to treatment outcome at 2 years. These are controversial treatments that are yet to be used outside Russia.

In the current environment of growing concern about bioterrorism, the neuroprotective and antiepileptic activities of ketamine have led to suggestions that it may be a useful tool in the management of nerve agent poisoning such as sarin.

KETAMINE-RELATED MORTALITY

There are very few deaths by pure ketamine overdose recorded (i.e. not also involving a drug such as alcohol). Of 87 ketamine-linked deaths in New York City, none was purely due to the use of ketamine. Parke-Davis have reported that there are cases of accidental injections with ten times the amount required for surgery, with no obvious lasting effects. The principal physical dangers of most nonmedical uses are currently believed to arise mainly from the setting, or an interaction between the user and the setting of use, as ketamine can leave the user in a confused state. This can, for example, result in burns, falls (sometimes fatal), drowning, death by hypothermia from lying outside in winter, traffic accidents, and becoming a crime victim (e.g. drug rape). A recent paper reported the case of an emergency medical technician who died of a combination of asphyxia and intoxication with administered intravenous ketamine in an autoerotic accident.

There are two reports in the literature of deaths by pure ketamine overdose. One described as a homicide for homosexual ends. The other described a middle-aged woman who took the drug daily for 7 months.

KETAMINE-RELATED MORBIDITY

There is an extensive list of possible physical effects of ketamine that may be seen as adverse by the user, or that may be directly harmful. Some of those of principal concern in a nonmedical use context are difficulty with walking and balance resulting in falls, numbness, slurred speech, dizziness, visual problems, nausea, headaches, spasms, and twitches. A recent study found

that, consistent with the animal studies, frequent ketamine use produces long-lasting impairments in episodic memory and aspects of retrieval from semantic memory even when other drug use is taken into account. A later study reported that when retested 3–4 years later following significant reductions in levels of ketamine use, semantic memory impairments associated with ketamine use were reversible. The effects upon schizotypal symptoms and perceptual distortions may, however, persist.

The use of ketamine has been linked with a range of unpleasant mental effects including anxiety, panic attacks, flashbacks, posttraumatic stress disorder, persistent perceptual changes, mania, depression, suicide, insomnia, nightmares, night terrors, an unpleasant feeling of being unreal or that the world is unreal, paranoid delusions, persistent hallucinations, automatic behavior, and fragmentation of the personality and aggression.

A study of 23 recreational users noted a high incidence of flashbacks and attentional dysfunction, but exactly what was meant by flashbacks is not defined. Large anesthetic studies do not confirm the finding and generally conclude that ketamine is usually devoid of significant persistent effects once the drug and its metabolites have cleared the body. For example, in a study of 1400 patients given ketamine as an anesthetic for surgical procedures, three had prolonged hallucinations, none lasting beyond 3 weeks. In no case did hallucinations begin after a period of normality, which is integral to the World Health Organisation (1992) definition of flashbacks.

A 2009 study of the consequences of chronic self-administration on the neurocognitive function and psychological well-being involved 150 individuals. The study over a period of 1 year compared levels of ketamine use frequency (frequent ketamine users, infrequent ketamine users) with abstinent users, polydrug using controls, and drug-free controls. Among frequent ketamine users, increasing use was correlated with decreasing cognitive performance as measured by spatial working memory and pattern recognition memory tasks. Assessments of psychological well-being also showed greater dissociative symptoms among frequent users and a dose–response effect on delusional symptoms.

Until recently, there had only been reports that ketamine could cause toxic changes in the rat brain. A Chinese study of 41 ketamine-dependent individuals compared with 44 healthy controls found white matter changes associated with ketamine use in the bilateral frontal and left temperoparietal cortices. These changes were correlated with the severity of ketamine use. These findings suggest a microstructural basis for the changes in cognition and experience observed among those using ketamine for prolonged periods. The similarities of these changes to those observed in chronic schizophrenia, moreover, have implications for the glutamate model of the illness. The use of ketamine with other neurotoxic drugs like alcohol is an additional cause for concern.

Urological and Upper Gastrointestinal Effects

A number of series of case reports have recently identified physical health consequences of ketamine use. A review of 233 ketamine-related presentations to 15 Hong Kong emergency departments reported that the most common presenting symptoms were impaired consciousness (45%), abdominal pain (21%), lower urinary tract symptoms (12%), and dizziness (12%).

A retrospective study of 64 heavy ketamine users explored the effects on the upper gastrointestinal tract. When those with other gastrointestinal conditions were excluded, 37 participants were studied. Of these, 28 (75.7%) reported upper gastrointestinal symptoms including epigastric pain and vomiting. It was further reported that despite medications, symptoms tended to persist unless ketamine use ceased.

A more concerning consequence of ketamine use that has been newly identified is so-called ketamine bladder syndrome, which was first described in 2007. Clinicians from Canada described nine patients who were daily ketamine users and who presented with severe dysuria, frequency, urgency, and gross hematuria. At cystoscopy, all patients had severe ulcerative cystitis. Clinicians in Hong Kong reported a similar presentation of ten street ketamine users diagnosed with ulcerative cystitis.

This unwanted effect of ketamine has also been reported among pediatric patients in less than 2 weeks after commencing use for chronic pain. The largest study to date was conducted in Hong Kong and reports on 59 ketamine users with moderate to severe lower urinary tract symptoms. Patients had frequency rates from 15 to 90 min between voids. Functional voiding capacity was between 20 and 200 ml, which represents a dramatic decrease in bladder capacity. Upon cystoscopy, 71% of these patients showed various degrees of bladder mucosal inflammation similar to that seen in interstitial cystitis. Histological examination showed a largely denuded bladder epithelium and granulation of the lamina propria infiltrated by lymphocytes and eosinophils. Most patients showed detrusor over activity at very low bladder infusion volumes. Even more concerning is the documentation of severe kidney effects among these individuals, where 51% showed unilateral or bilateral hydronephrosis on renal ultrasonography and 7% had features suggestive of papillary necrosis. Similar case series are now being reported in the United Kingdom and other regions of China.

The urologists treating this disabling condition have also reported on the apparent difficulty their patients experienced in abstaining from ketamine use. A group in Taipei reported that of ten consecutive patients with ketamine bladder syndrome, where clear advice and multidisciplinary support was provided to cease their ketamine use, at 12 months follow-up only 3 had been able to do so successfully.

KETAMINE DEPENDENCE

There is a substantial amount of popular literature describing ketamine as having a marked potential for giving rise to nonphysical dependence and case studies in the medical literature are accumulating. Many of these early reports of ketamine dependence were among those with access to the drug such as anesthetists and veterinarians.

The Australian National Minimum Dataset of Clients of Specialist Drug and Alcohol Treatment Services records no identified episodes of care for ketamine as the principal drug of concern in its collection over the past decade. The comparable dataset in the United States reported a total of 229 mentions in 2006 where in only 82 was ketamine the primary drug of concern. While this appears to indicate that ketamine is either used by only a small number of individuals or that it is unlikely to cause dependence sufficient to drive treatment seeking, it may be that, as there is no evidence-based intervention for ketamine-related problems, that they are not admitted to treatment services.

There is evidence from animal studies to support the view that ketamine can give rise to a dependence syndrome without physical withdrawal phenomena. This resembles cocaine dependence without the crash after use. Ketamine is also self-administered in rats and nonhuman primates.

A recent Australian study of 100 recreational ketamine users found that around one in five (22%) of participants reported physical tolerance to ketamine. This is consistent with reports of tolerance to ketamine following multiple anesthetics.

There have been at least two reported case histories of inpatient withdrawal from ketamine with observed psychotic symptoms. One case also included reports of a number of previously experienced ketamine withdrawal symptoms such as chills, autonomic arousal, lacrimation, restlessness, nightmares, and psychological craving with ketamine being used to relieve the symptoms.

There is no research literature on the management of ketamine abuse or dependence. Case histories of ketamine withdrawal report the use of benzodiazepines for the management of anxiety and insomnia and vitamin supplements. There are some generic descriptions of potentially useful interventions that suggest an abstinence-oriented approach similar to that used for psychostimulants.

PUBLIC HEALTH ISSUES ASSOCIATED WITH KETAMINE USE

In 1980, nonmedical unauthorized experimentation with ketamine was first reported in Australia. The authors believed that use of the drug was largely confined to medical circles. Since that time, anecdotal evidence indicates that the nature of users has become much more varied.

In Australia, ketamine is often marketed in small glass vials with small spoons to measure accurate doses. The spoon is contained in the cap of the bottle, much like a snuff spoon. Other bottles have a self-contained measurer in the cap, which when turned over leaves a measured amount, which can then be snorted as bumps; very few ketamine users snort the drug in lines. This may result in lower doses per snort than its use in lines as is seen more commonly internationally. The effects of differing methods of insufflation on health outcomes have not been examined.

Ketamine appears to be obtained from the diversion of legitimate supplies (veterinarians and pharmaceutical companies) or is imported from overseas. Ketamine can be bought over the counter in some Asian countries. Ketamine sold illicitly is often converted from a liquid form to a powder utilizing a simple evaporation process. The liquid ketamine is dried in a variety of ways (microwave oven or sun-dried) until a residue remains. This crystal residue is ground into a powder, leaving a fine powdery material similar to cocaine and heroin. In this form, it is far more convenient and more marketable than the injectable drug.

Evidence from the United States indicates that, up until 1996, ketamine was usually not adulterated with other substances. Of all the ketamine submissions to the US Drug Enforcement Agency (DEA) regional laboratories in that period, there was only one instance of this type of dilution recorded. However, this situation may well have changed when price and demand rose sufficiently to make such practices profitable.

Both popular and research accounts indicate that the recreational use of ketamine has widened in the context of nightclubs, dance parties, and raves. This has caused concern as ketamine is an anesthetic. One study concluded that it was totally inappropriate to use ketamine as a dance drug. The reasons for this were factors such as set and setting, the rapid onset of the drug, and the intensity of the experience as a whole. The respondents believed that using ketamine in a noisy, busy, or crowded environment was potentially dangerous and

that use should be confined to a familiar and secure place, such as one's home. All users had been unprepared for the intensity and nature of the effects when they first used the drug. In a study of the toxic effects of club drugs, it was concluded that the "single most risk-producing behavior of club drug users is combining psychoactive substances, usually involving alcohol."

The use of ketamine and other party or club drugs is reportedly associated with an increased incidence of unsafe sex among gay men on the circuit party scene in the United States. This is clearly a public health issue in the spread of blood-borne viruses and other sexually transmitted diseases. A small study of high-risk youth injecting ketamine in New York City also reported that its use was associated with a range of high-risk injection practices such as group injection with shared paraphernalia. Recent surveys among this sentinel group, however, have shown declines in the levels of ketamine (and other drug use) between 2002 and 2007.

An Australian study reported a number of ketamine-related problems among their sample of nonmedical ketamine users. While only one in five stated that they had ever experienced severe side effects as a result of ketamine use, more than one-third (38%) reported having to deal with someone else who had suffered badly following ketamine use. More than half (58%) of those interviewed had experienced the K hole and this was related to increased exposure to the drug – having used more than 20 times. The most commonly reported problems were employment related (20%). These included vagueness affecting work performance and lesser volume of work being produced. Additional problems reported included relationships (5%), financial (5%), and legal (1%). Of the five participants reporting relationship problems, none also reported financial problems but three of the five also reported work-related problems. Twenty-two participants reported at least one problem, five reported two problem areas, and one reported three problems areas. Ketamine has been sold in the rave scene in the United Kingdom as a key component in fake MDMA (ecstasy) tablets. There are also reports of ketamine being sold as ecstasy in Australia, or used as a cutting agent in other drugs such as cocaine, amphetamines, and heroin.

THE LEGAL STATUS OF KETAMINE

Ketamine is scheduled in many jurisdictions. Below are some examples of the legal status of ketamine internationally.

Australia

Ketamine is scheduled differently within and between countries. Below is a brief overview of the legal status of ketamine in a number of key jurisdictions. Within Australia prior to December 2003 ketamine was a scheduled drug in New South Wales under the Poisons and Therapeutic Goods Act, which meant that there were strict regulations on the sale and distribution of the substance. In response to increasing trends in ketamine use, the government added it to the list of prohibited drugs in New South Wales. This means that it has now been listed under the Drug Misuse and Trafficking Act 1985, ensuring that tougher penalties are in place for dealing with its illicit use. New penalties for those caught manufacturing or supplying the drug include fines between AU$5500 and AU$550 000 and anywhere from 2 years to life imprisonment or both. These penalties particularly apply to veterinary and medical practitioners who have an authority to purchase ketamine for legitimate purposes and then supply it to others for illicit use. Similar laws apply in some other states of Australia, however, in other states it remains legal to possess ketamine.

Canada

Ketamine is Schedule 1 in Canada, pursuant to a February 2004 notice that it "is an analog of phencyclidine (PCP), and is, therefore, captured as item 14 in Schedule I of the CDSA and item 14 in the Narcotic Control Regulations (NCR)." Affected researchers were expected to have complied with the Schedule 1 protocol for the handling of ketamine by August 31, 2005.

China

Ketamine is a Class II psychiatric drug; trade is limited to licensed wholesalers and retail sales are prohibited. In July 2004, the state of Sichuan placed ketamine in Class I; other provinces are expected to follow suit.

Mexico

Ketamine is a Category 3 drug under Mexico's General Health Law; Category 3 drugs "have a therapeutic value but constitute a problem for the public health." Medicines Administration Regulations restricts the acquisition of ketamine to licensed veterinarians only and sets strict rules regarding the management and follow-up of the products.

Netherlands

Ketamine is treated as a medication and is not in List 1 or 2 in the Netherlands.

United Kingdom

Prior to January 1, 2006, ketamine was not controlled in the United Kingdom under the Misuse of Drugs Act, making it legal to possess. However, sales and distribution were controlled under the Medicines Act making it illegal to sell or distribute without a license. Ketamine became a Class C drug on January 1, 2006, following a 2004 report to government that recommended moving ketamine into Class C.

United States

Ketamine was unscheduled until August 1999. In early July 1999, the DEA added ketamine to Schedule III with an emergency ruling that took effect on August 12, 1999. It is now a federal offense to possess ketamine in the United States without a license or prescription. Since that time, ketamine has been scheduled in many individual states, and laws are pending in many more. Where ketamine is not scheduled in a specific state, all prosecutions for possession or sales occur at the federal level.

SUMMARY

In conclusion, as levels of ketamine in the general population appear to be very low, the harms reported by recreational users are not excessive, adulteration is rare, and the mortality rate is low. Ketamine does not appear to pose a risk to public health at this time. At the individual level, many of those who experiment find the effects aversive and do not persist. The harms that require further investigation are the association with unsafe sex and injecting behaviors, the neurotoxic effects, and use in situations where there is a heightened risk of accidental death when the user's cognition is grossly impaired. It is recommended that the usual harm minimization strategies; especially not to use the drug when alone, not to concurrently use other neurotoxins such as alcohol, to be in a physically safe environment, and to use safer injecting techniques; should be observed when using ketamine.

PCP phencyclidine

Glossary

Bumps bumps are a measure of ketamine that is a small snort usually measured by a tiny spoon provided within the lid of the container in which it is purchased.

K hole this is a slang term for a state of dissociation from the body that may mimic the phenomenology of schizophrenia. The K-hole experience appears to vary with the individual and includes intense hallucinations and perceptual distortions.

CHAPTER

75

Anabolic-Androgenic Steroid Use and Dependence

Gen Kanayama, Harrison G. Pope, Jr.
McLean Hospital, Belmont, MA, USA

OUTLINE

DEFINITION OF ANABOLIC-ANDROGENIC STEROIDS

The anabolic-androgenic steroids (AAS) are a family of hormones that includes testosterone, the naturally occurring male hormone, together with numerous synthetic derivatives of testosterone that have been created over the last 70 years. As their name implies, AAS have both anabolic (muscle-building) properties and androgenic (masculinizing) properties; there are no AAS that can produce one of these effects without the other. AAS must not be confused with other types of steroids, such as corticosteroids. Corticosteroids are a separate family of hormones that includes the natural hormone cortisol, together with many synthetic derivatives of cortisol; corticosteroids have a similar chemical structure to AAS, but very different biological actions. In particular, corticosteroids do not lead to muscle gain, and thus are not used by athletes or by other illicit drug abusers.

HISTORY

As early as the late nineteenth century, the noted physician Brown-Séquard injected himself with an extract that he had prepared from testicles of guinea pigs and dogs, and noted a subjective improvement in energy and virility. However, it appears that his preparation actually contained no active ingredients. It was not until the 1930s that testosterone was ultimately synthesized by chemists in Germany (see Fig. 75.1 for a chronology of this and subsequent events). Over the next decade, dozens of synthetic derivatives of testosterone were created, yielding the family that we now call AAS. It is rumored that Hitler gave AAS to some of his troops during the 1940s in order to make them more aggressive, although no written documentation of this story seems to exist.

Also in the 1940s, physicians began to prescribe testosterone and other AAS to male patients, especially in attempts to treat symptoms of depression in aging

men. A substantial literature appeared in that decade, reporting considerable success in using testosterone and its relatives as antidepressant medications. One study even reported that the efficacy of testosterone in depression was comparable to that of electroconvulsive therapy. However, by the early 1950s, the discovery of other antidepressant medications, such as the tricyclic antidepressants and monoamine oxidase inhibitors, eclipsed the use of testosterone as an antidepressant, and there were few additional publications on this topic over the next several decades.

By the 1950s, athletes had begun to discover the remarkable efficacy of AAS for sports, including particularly sports involving muscle mass and strength, such as weightlifting, power lifting, and field events such as the shot put. Perhaps the first well-documented case of AAS use was by the Russian weightlifting team at the world championships in Vienna, Austria, in 1954. By the 1960s, AAS use was widespread throughout elite athletes around the world, and by the late 1960s, AAS were officially banned in the Olympics. Formal drug testing for AAS was first instituted at the Olympic games in Montréal in 1968.

By the 1960s, AAS also became virtually mandatory for professional bodybuilders, since these drugs permitted bodybuilders to attain a degree of muscle mass far beyond that attainable by any natural human being. Bodybuilding shows and magazines began to proliferate; the Mr Olympia contest was initiated in 1962, and many other bodybuilding competitions followed. Still, most people in the general public were not aware of the extraordinary anabolic potency of AAS, and as recently as 1977, the American College of Sports Medicine published a position paper stating that AAS were not effective for muscle gains – a statement that was retracted 10 years later.

Through the end of the 1970s, AAS use remained largely in the domain of elite competitive athletes. Then, starting in about 1980 in the United States, AAS began to percolate out of the athletic world and onto the street. Larger and larger numbers of rank-and-file weightlifters, many of whom had no competitive athletic aspirations at all, began to discover AAS and to use these drugs. This evolution was fueled in part by the appearance of various underground guides offering information about how to use AAS, how to perform injections, and what results to expect. The first of these guides, the *Underground steroid handbook*, appeared in 1981, and quickly went through increasingly expanded revised editions. The 1980s also witnessed a surge in Western media images of supermuscular males, appearing in comic strips, advertisements, television dramas, and Hollywood movies such as *Rambo* and *Conan the Barbarian*. Even boys' action toys, such as GI Joe in the United States and Action Man in the British Commonwealth, have become steadily more muscular over the last several decades.

By the 1980s, epidemiologic studies in the United States began to appear, reporting AAS use in 3–11% of male high school students (see further details below). Since that time, illicit AAS use has continued to spread through young American men up to the present. Even using conservative estimates, at least 2 million American men have now used illicit AAS at some time in their lives. In European countries, widespread illicit AAS use began to appear about a decade behind the United

States; since the 1990s, studies in the United Kingdom, Scandinavia, and more recently elsewhere in Europe have documented lifetime AAS use in 2–6% of boys and young men.

Concern about AAS use has led to increasing legislation to try to prevent the spread of AAS, especially in the United States. In 1989, the United States Congress enacted laws making it a felony to sell AAS, and in 1991, Congress passed the Steroid Trafficking Act, placing AAS under the jurisdiction of the United States Drug Enforcement Administration, with increased penalties even for possession of AAS. Within a short time after 1991, domestic production of AAS within the United States was largely eliminated. Currently the legal status of AAS in other countries is variable; for example, in the United Kingdom it remains legal to possess a personal supply of AAS, whereas sale of AAS is illegal. In many other European countries both possession and sale of AAS are illegal. Despite regulation, however, illicit AAS use continues to flourish, because with the rise of the Internet, AAS can be purchased from countries where they remain legal, and interdiction of such shipments is difficult. Thus, it seems likely that illicit AAS use will remain a widespread form of substance abuse for the foreseeable future.

Returning to legitimate medical uses of AAS, it is notable that the therapeutic use of testosterone has enjoyed a renaissance of interest since the 1990s. Several factors appear to account for this change. First, it has been found that testosterone and other AAS are effective for treating the wasting syndrome associated with human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), and testosterone is now widely prescribed for this purpose. Some controlled studies also suggest that testosterone exerts antidepressant effects in individuals with HIV/AIDS. Second, testosterone has now been marketed in the form of patches and gels that allow the drug to be administered without the necessity for injections (which had previously been required because testosterone is ineffective when taken by oral administration). The appearance of these formulations has made testosterone administration more user friendly, thus likely stimulating more widespread prescription. Third, there has been increased psychiatric interest in the antidepressant properties of testosterone, with several studies suggesting that testosterone may be of value in men with dysthymia or major depression – an observation harking back to the early reports of the 1940s described above. In recent decades, there has been increasing interest in the use of testosterone and other AAS to counteract the natural decline in testosterone that occurs in aging men. The merits of this treatment continue to be debated, with cautious medical practitioners at one extreme noting that the long-term hazards of testosterone replacement remain poorly understood, and with sometimes questionable antiaging specialists at the other extreme offering testosterone and other AAS to virtually any customer, even in the absence of clear medical indications.

In summary, both the licit and illicit use of AAS have expanded substantially in the last few decades. The remainder of this chapter focuses almost entirely on illicit AAS use, which represents one of the newest and most rapidly evolving major forms of substance abuse worldwide.

PREVALENCE OF ILLICIT AAS USE

The great majority of illicit AAS users are young men, mostly ranging in age from 18 to 40 years. Girls and women rarely use illicit AAS, since women typically do not desire to become highly muscular, and women are also vulnerable to the masculinizing effects of AAS, such as deepening of the voice, beard growth, and masculinization of secondary sexual characteristics. Not surprisingly, therefore, very few published studies have actually recruited and personally evaluated any female AAS users, and even the largest such study recruited only 25 such cases. Surprisingly, however, many anonymous surveys of high school students have quoted seemingly high rates of AAS use among girls as young as 12 or 13 years old. Upon inspection, it appears that these studies likely have produced large numbers of false-positive responses because of ambiguously worded questions about steroid use. For example, anonymous questionnaires may use a question such as, "have you ever used steroid pills or shots without a doctor's prescription?" However, this question does not distinguish between illegal AAS used for muscle growth, as opposed to corticosteroids that are widely used for legitimate medical purposes, or over-the-counter supplements from health food stores that a student might erroneously believe are steroids. Thus, a young girl may answer "yes" to the steroid question when in fact she has simply used hydrocortisone cream for poison ivy, or corticosteroids in an asthma inhaler, or because she has used a nutritional supplement that she erroneously believes was a steroid. A recently published analysis of anonymous survey questions, covering studies performed in the United States, Europe, Australia, and Brazil, has concluded that the true rate of genuine AAS among girls is likely less than 0.5%.

Among young boys below age 18 years, it is likely that AAS use has also been overestimated by many anonymous surveys, although there is no doubt that

some boys of high school age do in fact use genuine AAS either for athletic purposes or for improving personal appearance. After correcting for possible false-positive responses on anonymous questionnaires, it seems likely that the true rate of AAS use in boys below the age of 18 years is about 1–3%. However, a number of studies suggest that the onset of AAS use in men occurs after age 18 years, with a peak in the early 20s. Thus the great majority of AAS users are men between about 20 and 40 years of age. It follows that among men who have reached their late 20s, the prevalence of lifetime AAS use may be considerably higher than 1–3%. At the least, it seems reasonable to estimate that there are at least 10 million men – primarily in the United States, Scandinavia, British Commonwealth countries, other European countries, and Brazil – who have used AAS at some time in their lives. Importantly, because of the fact that illicit AAS use did not become widespread until after 1980, it follows that the oldest members of this illicit AAS-using population – those who first initiated AAS use as youths in the 1980s – are only now reaching middle age. These middle-aged men, comprising both former AAS users and some still-current users, represent effectively the leading edge of an epidemiologic bubble. As these aging AAS users reach middle age, and enter the age of risk for various medical complications of AAS, it appears likely that we may witness a substantial rise in public health problems associated with illicit AAS use. By analogy, imagine that widespread smoking of cigarettes did not appear until 1980, and that most of the older cigarette smokers were only approaching middle age today. In this hypothetical scenario, one might hear of occasional cases of lung cancer or emphysema, but the full magnitude of risk conferred by cigarette smoking would not yet be appreciated. It is possible that an analogous situation exists with AAS use, and that we will witness a substantial increase in AAS-induced medical problems over the next decade or two.

By contrast with the West, AAS use is rare in most Asian countries such as China or Japan. This difference is likely attributable to differences between Eastern and Western cultural attitudes toward muscularity and masculinity. In the West, muscularity has been a feature of male heroes and gods for thousands of years, as illustrated, for example, by Greek statues of Herakles and the other Titans, or the muscular gods of Norse mythology such as Thor and Vulcan. By contrast, China and Japan have no comparable ancient muscular gods or heroes, and muscularity is not associated with masculinity in the same way. In Confucian tradition, for example, a masculine man is someone who has intellect, integrity, and force of character, but not bulging muscles. Similarly, Japanese gods and heroes are typically shown fully clothed in artwork and statuary, without any of the added muscle that one would see in Western art or statues. Thus, it seems likely that differences in cultural traditions have helped to insulate the East against widespread illicit AAS use.

AAS DEPENDENCE

AAS are usually consumed in courses, colloquially called cycles, which typically extend from a few weeks to a few months in duration, separated by drug-free intervals. It is widely believed by AAS users that the drugs are more effective when taken in discrete cycles than when taken on a continuous basis, perhaps because there is less tolerance to their muscle-building effects, although it is not clear that this belief is scientifically justified. Another important consideration is the fact that exogenous AAS suppress the body's hypothalamic–pituitary–gonadal (HPG) axis, thus suppressing endogenous testosterone production. When AAS are used in cycles, the HPG axis can recover during the spaces between cycles, thus restoring endogenous testosterone production to normal.

Many illicit AAS users are content to ingest only a few cycles of AAS in a lifetime, with a cumulative total lifetime AAS exposure of only 6–12 months. It has become increasingly recognized, however, that AAS can create a dependence syndrome, in which some individuals begin to use AAS almost continuously, with little or no space between cycles, often for years of cumulative lifetime exposure, despite adverse medical, psychiatric, and social consequences. AAS dependence differs in some ways from dependence upon classical drugs of abuse, because AAS do not generally produce a high of intoxication in the manner of drugs such as alcohol, cannabis, or opioids. Thus, AAS do not yield the immediate reward of classically intoxicating drugs, but instead a delayed reward of increased muscularity and enhanced bodily appearance. We will discuss the mechanisms of this dependence syndrome in greater detail in the next section below.

Field studies of illicit AAS users in the United States, United Kingdom, and Australia have attempted to estimate the prevalence of AAS dependence in various populations. On average, these studies estimate that about 30% of male AAS users exhibit a dependence syndrome, meeting criteria for dependence similar to those postulated for other forms of substance dependence in the standard diagnostic nomenclature. However, it should be recognized that this estimate may be influenced by selection bias, since individuals with AAS dependence are perhaps more likely to be encountered in field studies recruiting study participants from gymnasia and other similar venues, whereas nondependent individuals, who perhaps used AAS only briefly, might be

underrepresented in such samples. Nevertheless, even if one assumes that the prevalence of dependence is substantially below 30%, it still appears that well over 1 million individuals, and perhaps even several million worldwide, have developed this syndrome. From a public health perspective, this group is of greatest interest, since it likely accounts for the great majority of the morbidity and possible mortality associated with AAS use in much the same manner as other drugs, such as alcohol, where the majority of the pathology is concentrated in the minority of users who display the highest levels of consumption.

MECHANISMS OF AAS DEPENDENCE

AAS dependence has not been studied in nearly as much detail as other forms of classical drug dependence, and indeed arguably represents the least-studied major form of substance dependence in the world. Nevertheless, available studies suggest that there may perhaps be at least three separate mechanisms whereby AAS dependence can develop. As summarized in Fig. 75.2, these include (1) an anabolic pathway, where individuals with muscle dysmorphia might become dependent on AAS for their muscle-building effects; (2) an androgenic pathway, where men might use AAS to self-treat hypogonadism from AAS withdrawal; and (3) a hedonic pathway, where AAS dependence may arise via mechanisms shared with classical addictive drugs. Each pathway, if supported, would suggest specific clinical treatments (see Fig. 75.2).

The anabolic pathway arises from the ability of AAS to stimulate muscle growth. A substantial literature has shown that individuals with concerns about their body image and muscularity may be particularly vulnerable to using AAS, since these drugs answer to these concerns and provide a rapid and often dramatic increase in muscularity. In particular, it has been shown that a substantial number of men suffer from a form of body dysmorphic disorder termed muscle dysmorphia, in which they become pathologically concerned that they do not look muscular enough. Muscle dysmorphia has also sometimes been called reverse anorexia nervosa, because individuals with this disorder may perceive themselves in the mirror as small and frail, even though they are actually large and muscular, which is the reverse of the pattern seen in classical anorexia nervosa, where girls may perceive themselves as being fat when they are actually thin or even emaciated.

At first it might be assumed that AAS use would help to resolve individuals' concerns about muscularity, but paradoxically, such individuals may often become even more obsessed with muscularity as they grow bigger on AAS, such that they never feel muscular enough. Therefore, they continue to ingest repeated cycles of AAS, sometimes in escalating doses, and may develop anxiety if they begin to lose even a small amount of muscle upon discontinuing AAS. For example, it is not uncommon to hear anecdotally from AAS users that they resumed using AAS much more quickly than intended after a previous cycle, because they developed intolerable anxiety that they might be losing muscular size.

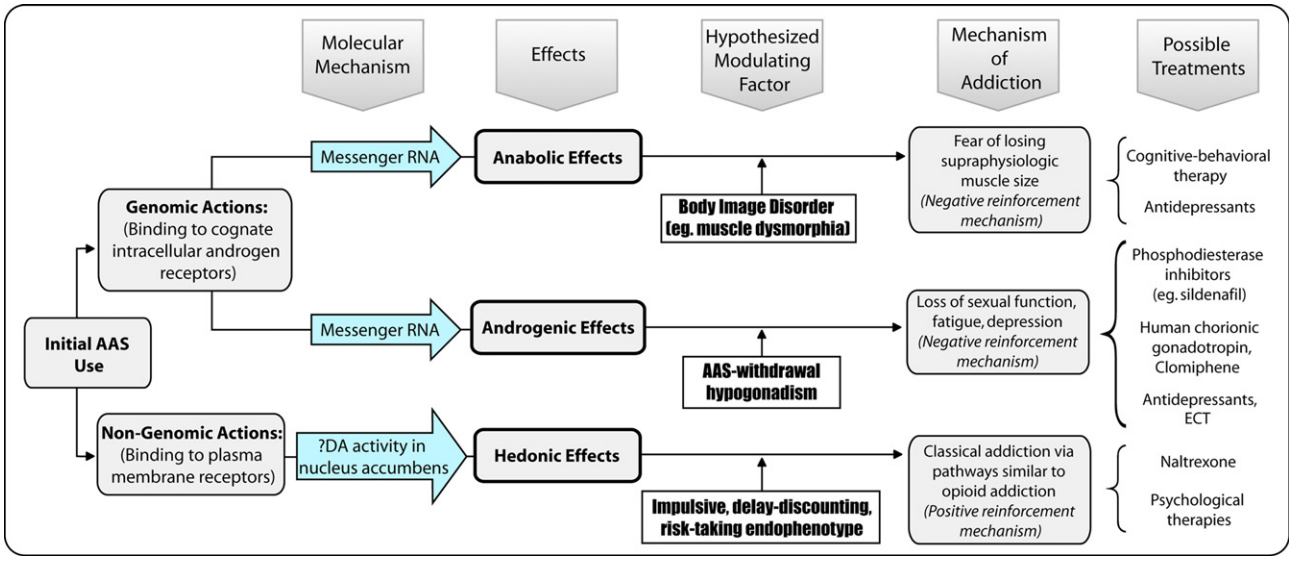

FIGURE 75.2 A model illustrating three possible mechanisms for the evolution of AAS dependence, together with potential treatment strategies to address these mechanisms. DA, dopamine. *Adapted from Kanayama, G., Brower, K.J., Wood, R.I., Hudson, J.I. and Pope, H.G. (2010). Treatment of anabolic-androgenic steroid dependence: emerging evidence and its implications.* Drug and Alcohol Dependence *109, 6–13.*

Although there have been no specific studies addressing the treatment of muscle dysmorphia associated with AAS dependence, many studies have addressed the treatment of other forms of body dysmorphic disorder. It has been found that both cognitive behavioral therapy and serotonergic antidepressants (e.g. serotonin reuptake inhibitors and norepinephrine-serotonin reuptake inhibitors) show efficacy in body dysmorphic disorder, and thus it follows that these modalities may also be helpful for AAS-dependent individuals who experience pathological body image concerns. However, these speculations remain to be tested.

The androgenic pathway to AAS dependence arises from the neuroendocrine effects of AAS. As mentioned earlier, testosterone and other AAS suppress the HPG axis, leading to testicular atrophy and decreased production of testosterone and spermatozoa in males. If a man stops AAS, particularly if he stops AAS abruptly after a long cycle, he will be very likely to become hypogonadal, because the HPG axis may require weeks or months to regain normal functioning. Indeed, several reports have described AAS users who exhibited hypogonadism lasting for more than a year after discontinuing AAS.

Although AAS users rarely describe an explicit craving for AAS in the manner of individuals experiencing, say, alcohol or cocaine withdrawal, they frequently experience dysphoric symptoms associated with AAS-withdrawal hypogonadism. These may include fatigue, decreased sex drive, hypersomnia, loss of appetite, decreased enthusiasm for activities, and in some cases severe depression. It appears that serious depressive symptoms are an idiosyncratic effect of AAS-withdrawal hypogonadism, in that a majority of individuals do not develop marked depression, even when profoundly hypogonadal, whereas a small minority develop pronounced depression, sometimes associated with suicidal ideation or outright suicide attempts. In any case, the dysphoric symptoms associated with hypogonadism, whether they be mild or severe, likely induce some individuals to resume AAS use in order to self-treat these symptoms, thus leading to repeated AAS use and ultimately to dependence.

Because illicit AAS use is a relatively new phenomenon, as noted above, many physicians are unfamiliar with the treatment of hypogonadism in AAS users. An evolving literature suggests that it is important to recognize and promptly treat hypogonadism in these individuals, especially when they have expressed a desire to stop their drug use, because such treatment may help to prevent them from resuming AAS. A variety of neuroendocrine treatments exist for this purpose. For example, exogenously administered human chorionic gonadotropin mimics the effects of pituitary luteinizing and follicle-stimulating hormones, thus stimulating the testis to resume production of testosterone and spermatozoa more rapidly. The drug clomiphene in turn mimics the effects of hypothalamic-releasing hormones and thus stimulates pituitary secretion of luteinizing and follicle-stimulating hormones, also aiding in the restoration of normal HPG axis functioning. Although many psychiatrists and other substance abuse professionals are unfamiliar with such neuroendocrine treatments, patients with AAS-withdrawal hypogonadism can easily be referred to endocrinologists for management of this problem.

A third pathway to AAS dependence might be called the hedonic pathway. Persuasive evidence for this pathway arises from animal studies, which have found that laboratory animals show a preference for AAS, even though these animals are presumably not concerned with their muscularity or with the threat of becoming hypogonadal. For example, rats and mice display conditioned place preference for AAS, in that they prefer to spend time in an environment where they have previously received AAS as compared to a comparable environment where they have not. Even more compelling are recent studies showing that male hamsters self-administer testosterone and other AAS, even to the point of death in some cases. Importantly, self-administration occurs even when testosterone is administered directly into the cerebral ventricles; this finding indicates that self-administration is not dependent on some peripheral effect of testosterone (e.g. via an effect on muscle or joint pain), but is attributable to a central effect in the brain.

The mechanism of AAS self-administration in animals remains incompletely understood. However, several lines of evidence suggest that this self-administration is mediated by binding of drug to plasma membrane receptors in the brain, rather than by the classic genomic effects of AAS whereby AAS enter the cell nucleus and bind to intracellular androgen receptors. More specifically, animal studies suggest that there may be metabolites of the parent AAS that bind to receptor sites on the nucleus accumbens, producing hedonic effects analogous to those produced by classical addictive drugs. Interestingly, hamsters intoxicated with testosterone after self-administration exhibit a state somewhat similar to opioid intoxication, suggesting possibly similar mechanisms. Furthermore, pretreatment of hamsters with opioid antagonists, such as naltrexone, blocks intracerebroventricular testosterone self-administration, again suggesting that opioidergic mechanisms may mediate this process.

Several observations in human AAS users appear to parallel the observations from animal studies. In one of the earliest case reports of AAS dependence, the investigators found that an AAS-dependent individual exhibited opioid-like withdrawal symptoms when

challenged with naloxone, even though this man had apparently never used opioids. In another more recent study, the investigators evaluated consecutive men admitted to an opioid detoxification facility and found that nearly 10% of them appeared to have been introduced to opioids via their initial use of AAS. These men typically reported that they had first learned about using opioids from friends at the gym, and had purchased their first illicit opioids from the same drug supplier from whom they had purchased AAS. Another study examined sequential men admitted to a generic substance dependence treatment facility and asked all of them about prior history of AAS use. Among patients reporting opioids as their drug of choice, a past history of AAS use was much more common than among patients reporting other forms of drug use such as alcohol dependence. Finally, a recent field study compared AAS-dependent men, nondependent AAS users, and comparison weightlifters reporting no history of AAS use. The men with AAS dependence reported a strikingly higher lifetime prevalence of opioid abuse or dependence than the other groups, again suggesting that AAS and opioids possibly produced similar hedonic effects in these men. Interestingly, the chronological sequence of AAS and opioid use in these men was variable; opioid abuse or dependence occurred before, during, and after AAS use in different individuals, suggesting that neither form of drug abuse necessarily led to the other, but rather that they might arise from a common underlying mechanism (Fig. 75.3).

The implications of these latter findings for treatment of AAS dependence remain uncertain, because there are as yet no major studies of treatment of AAS dependence in the literature. Certainly, it seems reasonable to speculate that therapies effective for opioid and other substance dependence might also be effective for AAS dependence. Such therapies might include motivational therapies in the early stages of treatment to address denial and minimization, followed by psychological therapies such as supportive-expressive therapy, contingency management, and behavioral couples therapy or behavioral family counseling. It seems likely that couples therapy might be particularly useful in such cases, since women may suffer physical and emotional abuse from male AAS-using partners.

Another, more provocative possibility is that use of an opiate antagonist, such as naltrexone, might be helpful for AAS dependence. It has already been shown that long-acting preparations of naltrexone may be effective in the treatment of alcohol dependence, perhaps by blocking the effects of endogenous opioids that are released following the ingestion of alcohol. By analogy, naltrexone might also block endogenous opioid-like effects mediated by AAS. To our knowledge, however, this approach has not yet been attempted in individuals with AAS dependence.

HAZARDS OF AAS DEPENDENCE

Although many forms of addiction are well established as harmful and deserving of treatment, the hazards of AAS dependence are still poorly understood. Indeed, widespread opinion in the AAS-using community and in websites and discussion groups from the bodybuilding underground has questioned whether AAS use is seriously harmful. Similarly, prominent reports in the lay media and even articles from some scientists have argued that warnings about the dangers of AAS are exaggerated; some have sometimes even labeled these warnings as steroid hysteria. Indeed, AAS use is sometimes portrayed as part of a healthy athletic lifestyle, rather than as simply a form of illicit drug

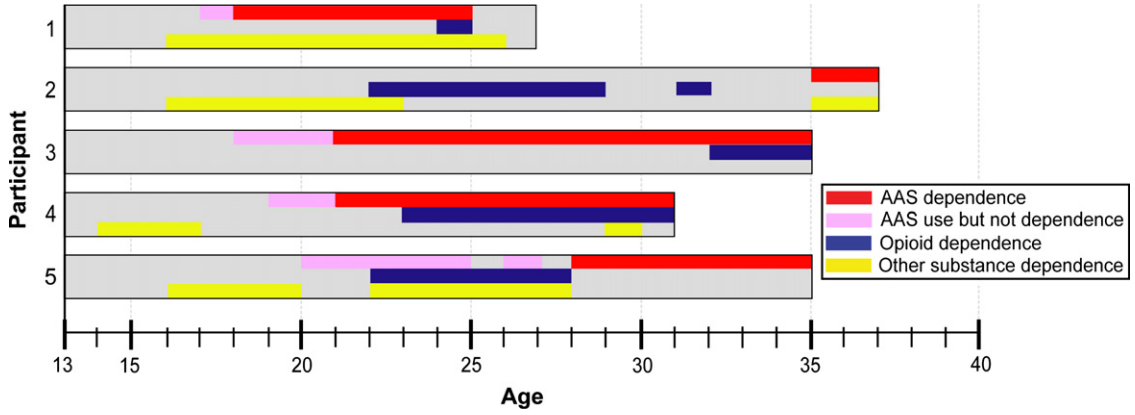

FIGURE 75.3 Illustrations of the time course of AAS abuse and dependence, together with other forms of substance abuse or dependence, in five representative men with AAS dependence. *Adapted from Kanayama, G., Hudson, J.I. and Pope, H.G. Jr. (2009). Features of men with anabolic-androgenic steroid dependence: a comparison with nondependent AAS users and with AAS nonusers.* Drug and Alcohol Dependence *102, 130–137.*

use – a portrayal that belies the fact that many AAS users ingest large amounts of classical illicit drugs as well.

However, these lenient attitudes about AAS have been increasingly challenged by evidence of serious medical and psychiatric adverse effects from long-term exposure to these drugs. Perhaps the most extensive medical evidence surrounds the cardiovascular effects of AAS. There is also evidence of adverse medical effects on other organ systems, such as the liver and kidneys. In addition there is substantial evidence that AAS can produce adverse psychiatric effects.

Cardiovascular Effects

AAS produce a range of cardiovascular effects, which appear to be responsible for substantial morbidity and even premature mortality. First, AAS can produce hypertension in some individuals, especially when these drugs are used in massively supraphysiologic doses, as is often the case when they are used illicitly. AAS also can increase red blood cell production, resulting in polycythemia, accompanied by an increased risk of thrombosis. In both the scientific literature and the anecdotal experience of the authors, these effects may lead to apparently thrombotic events, such as transient ischemic attacks, cerebrovascular accidents, and myocardial infarction.

AAS may also affect cardiac electrical conduction, although the literature is inconsistent with regard to this finding. In one recent study, for example, AAS users showed significantly longer PR intervals and QRS intervals as compared to otherwise similar weightlifters who denied AAS use. This finding suggests that AAS users may display impaired cardiac electrical propagation. Given the association between such electrocardiographic abnormalities and the risk for pathologic arrhythmias in other populations, together with reports of unexplained arrhythmias and sudden death in AAS users, this finding is of some concern.

Even more ominous are findings associating AAS use with myocardial toxicity. A growing literature has suggested that AAS use may be associated with impaired myocardial contraction, as reflected, for example, in a decreased left ventricular ejection fraction. One recent study found that 10 (83%) of 12 long-term AAS users displayed a left ventricular ejection fraction below the accepted limit of normal (55%) as compared to only one (14%) of seven comparison weightlifters reporting no AAS usage. AAS users have also been reported to exhibit diastolic impairment, as reflected by lower early diastolic transmitral blood flow velocity (E-wave) and early peak tissue velocity (E') with preserved or increased late diastolic filling, as evidenced by late diastolic transmitral blood flow velocity (A-wave) and peak tissue velocity (A'). The clinical significance of these findings remains incompletely understood, but a number of anecdotal reports in the literature have described frank cardiomyopathy in AAS users, and it seems plausible that some of this pathology may be irreversible.

Finally, AAS use is associated with dyslipidemia. In individuals ingesting markedly supraphysiologic doses of AAS, especially orally active AAS, levels of high-density lipoprotein cholesterol may fall dramatically – sometimes to less than 10 mg dL^{-1} – whereas levels of low-density lipoprotein cholesterol may rise. These alterations in lipid levels almost certainly have serious atherogenic potential, although again the full clinical significance of these effects remains unknown. Certainly there are many anecdotal reports of myocardial and cerebral infarctions in individuals with known or probable AAS use who were only in their 30s or 40s, and it seems likely that some of these may have been attributable to premature atherosclerotic changes. One small preliminary imaging study has shown striking increases in coronary artery calcium in bodybuilders with long-term AAS exposure, but these findings remains to be replicated in larger investigations.

It is difficult to estimate the overall threat posed by the many cardiovascular effects of AAS use. One study in Finland examined 62 men who had placed highly in power lifting contests in 1977–1982 and compared them to matched population controls. Eight of the 62 men had died – a rate much greater than in the general population – and three of these died of myocardial infarction, which the authors speculated was likely associated with AAS exposure. Similarly, a Swedish pathological study found chronic cardiac changes in 12 (35%) of 34 medicolegally investigated deaths of male users of AAS.

As discussed earlier in this chapter, the older members of the illicit AAS-using population are only now entering middle age, and thus it seems likely that the above cardiac effects will become more manifest as this population moves into the age of risk. Thus, the cardiac effects of long-term AAS exposure represent an area urgently in need of further study.

Effects on Other Organ Systems

Long-term exposure to supraphysiologic doses of AAS may also produce deleterious effects on other organ systems. For example, a substantial literature has shown that orally active AAS may exhibit hepatotoxicity, as evidenced by inflammatory changes, peliosis hepatis (the formation of blood-filled cysts in the liver), and the development of various forms of liver cancer. Although the association between these effects and AAS use is very well documented, these effects appear to be relatively rare. Interestingly, public warnings about

the dangers of AAS often emphasize hepatotoxicity, out of proportion to the actual prevalence of these phenomena. Our experience suggests that a possible reason for this misplaced emphasis is the fact that many AAS users exhibit substantial elevations of liver enzymes, such as alanine aminotransferase, aspartate aminotransferase, and lactic dehydrogenase. However, these same enzymes are also present in skeletal muscle, and muscle trauma from a hard workout in the gymnasium can produce marked elevations in these indices, even in individuals with no liver disease. Thus, it seems likely that many practitioners have misinterpreted elevations in these enzymes as suggestive of AAS-induced hepatotoxicity when in fact they are not. A more specific test is the γ-glutamyl transaminase (GGT), an enzyme present exclusively in liver and not in skeletal muscle. In studies of AAS users conducted by the authors, GGT has almost always been within the normal range, suggesting that AAS-induced hepatic inflammation is rare.

A potentially more serious concern is nephrotoxicity. Massive muscle breakdown occurring in AAS-using weightlifters may lead to rhabdomyolysis and myoglobin-induced renal failure. One recent report has described focal segmental glomuleronephritis in ten long-term AAS users, possibly attributable to a combination of postadaptive glomerular changes, driven by increased muscle mass, and to a potential direct nephrotoxic effect of AAS. These renal complications may be largely reversible if AAS are discontinued, but may go unrecognized in AAS users for prolonged periods.

The effects of AAS on the prostate are less clear. Although it has been widely believed that supraphysiologic levels of testosterone or other AAS might potentiate or exacerbate prostate cancer, there are as yet only two individual case reports of prostate cancer in middle-aged bodybuilders with possible AAS use, and both of these reports appeared about 20 years ago. The absence of more recent reports argues against an association between AAS use and prostate cancer. Moreover, some authorities have recently argued that it is a myth that androgen administration can stimulate prostate cancer, even though it is universally acknowledged that reduction of androgen levels can slow the progression of existing prostate cancer. In any event, at present, it appears that the dangers from the prostatic effects of long-term AAS exposure rank well below the dangers from the cardiac and renal effects of these drugs.

Psychiatric Effects

A substantial literature has now described psychiatric effects of AAS. Unlike the medical effects discussed above, many psychiatric effects are not contingent upon long-term exposure and may occur even in some individuals with relatively brief AAS experience. The principal psychiatric effects of AAS include manic or hypomanic syndromes during AAS exposure, and depression during AAS withdrawal.

Manic or Hypomanic Effects

As early as 1985, it was reported that AAS use could apparently induce hypomanic symptoms, including euphoria, hyperactivity, hypersexuality, and impaired judgment. Many studies appeared over the next 10 years, documenting hypomanic or frankly manic symptoms in some AAS users, occasionally even accompanied by psychotic symptoms, such as grandiose or paranoid delusions. These effects appear to be dose related; individuals using only modestly supraphysiologic doses of AAS (up to 300 mg of testosterone or equivalent per week) have rarely been reported to show such symptoms, while individuals in the mid-range of dosage (300–1000 mg of testosterone equivalent per week) show a somewhat higher prevalence, and those in the upper range (greater than 1000 mg of testosterone equivalent per week) appear most likely to exhibit such effects. In one study, for example, 7 (28%) of 25 illicit AAS users taking more than 1000 mg of testosterone per week reported symptoms meeting criteria for a hypomanic or manic episode, as opposed to only 1 (7%) of 14 individuals using less than 300 mg per week.

Starting in about 1990, a number of reports also appeared suggesting that hypomanic symptoms in AAS users might include unusual irritability, aggression, or even violence. Several reports described individuals with no apparent past history of psychiatric disorder, violent behavior, or criminality who became uncharacteristically aggressive and committed violent crimes, including murder or attempted murder, while under the influence of AAS. In several forensic cases around the United States, the issue of involuntary intoxication with AAS was even raised as a possible defense, albeit with mixed results.

Several writers have questioned whether AAS play an etiologic role in the development of hypomanic or aggressive symptoms. For example, it might be argued that aggressive individuals are more prone to take AAS in the first place, and that their behavior does not represent a biological effect of the drugs. Similarly, expectational factors or sociocultural effects of being in the gym subculture might plausibly explain such behavior. However, these concerns have now been addressed by four blinded investigations, in which supraphysiologic doses of AAS (equivalent to 500 mg of testosterone per week or greater) were administered to normal volunteers. In the four studies, collectively comprising 105 individuals administered AAS, 5 (4.8%) developed hypomanic or manic symptoms

during AAS exposure, even though they did not exhibit such symptoms on placebo or at other times in their lives. Since these observations were obtained under blinded conditions, it appears that these effects cannot be explained purely on the basis of psychological or expectational factors, and indeed represent a biological effect of AAS. However, it remains unclear why occasional individuals are highly vulnerable to these mood-altering effects, while most individuals do not develop such symptoms despite ingesting identical doses under similar conditions.

Major Depression

As we have noted earlier, major depression may sometimes develop in the context of AAS-withdrawal hypogonadism, and this effect, like the hypomanic effects just discussed, appears to be an idiosyncratic phenomenon that affects only a minority of individuals. Again, the reasons for this idiosyncratic response remain unknown, but it is well recognized that some men will occasionally develop pronounced depressive symptoms, sometimes associated with suicidal ideation or occasionally even completed suicide, typically after stopping a prolonged cycle of AAS use. One report has described successful treatment of four cases of AAS-withdrawal depression using the antidepressant fluoxetine; another report described a case resistant to antidepressant medications, but ultimately responsive to electroconvulsive therapy. As we have noted earlier, it is probably important to treat AAS-withdrawal hypogonadism with neuroendocrine therapy, while remaining alert to the possibility that some individuals will occasionally exhibit serious depression requiring psychiatric intervention over and above endocrine treatment.

FUTURE PROSPECTS

Of the many forms of addiction discussed in this volume, dependence on illicit AAS is one of the least studied and least understood. This dearth of evidence is partly attributable to the fact that AAS use is a relatively recent form of illicit drug use, as discussed above, and also attributable to the fact that AAS users rarely seek treatment. Indeed, AAS users are frequently distrustful of health professionals and often report that they have never disclosed their AAS use to any doctor that they have seen. Similarly, there have been relatively few investigators who have successfully recruited and personally evaluated large numbers of illicit AAS users. Although there are numerous animal studies of AAS, anonymous questionnaire studies asking about AAS use, Internet surveys of AAS users, and studies on programs to prevent AAS use, there are only a modest number of studies in which actual illicit users have been assessed in person.

However, it is possible that this situation may change over the next decade, as increasing numbers of men with AAS dependence grow old enough to experience adverse effects from prolonged exposure to these drugs, and consequently may be induced to seek treatment when they would not have done so earlier. Such men might perhaps come to the attention of cardiologists as a result of cardiomyopathy or atherosclerotic disease, to nephrologists as a result of real disease, or to endocrinologists and psychiatrists as a result of prolonged hypogonadism and possible associated major depressive disorder. It will likely become important for clinicians in these various disciplines to become familiar with AAS dependence and its effects, so that they can quickly identify such patients and refer them for appropriate treatment.

At present, as we have noted above, experience with treatment of AAS dependence is very limited, although possible modalities of treatment are already apparent, as also discussed earlier. The next decade will likely see a substantial increase in our knowledge of this area, as this form of dependence becomes better known.

Prescription and Over-the-Counter Medications

Jessica L. Eaddy

Clinical Neuroscience Division, Medical University of South Carolina, Charleston, SC, USA

OUTLINE

INTRODUCTION

The nonmedical use of prescription and over-the-counter (OTC) medications is a serious public health concern. Prescription medications are drugs approved by the US Food and Drug Administration (FDA) that require an individualized prescription written by a licensed health care professional. The most commonly abused prescription medications, which are the focus of this chapter, include pain relievers (i.e. opioids), stimulants, and sedatives/tranquilizers. OTC medications refer to all FDA-approved medications available directly to consumers without a prescription. These drugs are considered to be relatively safe, effective, and involve minimal risk when taken as directed. OTC medications containing pseudoephedrine, antihistamines, or dextromethorphan (DXM), in particular, are discussed. See Table 76.1 for a list of generic and trade names of common prescription and OTC medications.

Prescription medications are some of the most commonly abused substances. Each year, the National Survey on Drug Use and Health (NSDUH) assesses persons in the United States aged 12 years or older regarding the use of illicit drugs. The NSDUH asks about marijuana/hashish, cocaine (including crack), inhalants (e.g. nitrous oxide, amyl nitrite, cleaning fluids, gasoline, spray paint, other aerosol sprays, glue), hallucinogens (e.g. lysergic acid diethylamide (LSD), phencyclidine (PCP), peyote, mescaline, psilocybin mushrooms, ecstasy), heroin and prescription drugs (e.g. pain relievers, tranquilizers, stimulants, sedatives). In 2009, approximately 22 million Americans (i.e. 8.7% of the United States population) reported using an illicit drug in the past month. With regard to the nonmedical use of prescription medications, 7.0 million Americans (e.g. 2.8% of the United States population) reported past month use. Some data

TABLE 76.1 Generic and Trade Names of Common Prescription and OTC Medications

Generic name	Brand names
Opioids	
Buprenorphine	Subutex, Buprenex
Codeine	Phenergan with Codeine, Empirin with Codeine, Robitussin A-C, Tylenol with Codeine, Actifed with Codeine, C Tussin, Cheratussin, Zodryl
Hydrocodone	Vicodin, Vicoprofen, Anexsia, Dolorex Forte, Hycet, Liquicet, Lorcet, Lortab, Maxidone, Norco, Polygesic, Xodol, Zydone, Hycodan
Hydromorphone	Dilaudid, Palladone, Hydrostat, Hydromorph
Fentanyl	Ionsys, Duragesic, Sublimaze, Actiq, Fentora
Levacetylmethadol (LAAM)*	OrLAAM*
Levorphanol	Levo-Dromoran
Meperidine	Demerol
Methadone	Diskets, Dolophine, Methadose
Nalbuphine	Nubaine
Opium tincture	Generic only; no brands available
Oxycodone	Dazidox, ETH-Oxydose, Endocodone, OxyIR, Oxycontin, Oxyfast, Percolone, Roxicodone
Pentazocine	Fortral, Talwin, Talacen, Fortwin
Propoxyphene	Darvon, Darvocet, PP-Cap
Remifentanil	Ultiva
Sufentanil	Sufenta
Tapentadol	Nucynta
Tramadol	Ultram, Ultracet
Sedatives-hypnotics	
Barbiturates	
Amobarbital	Amytal
Glutethimide	Doriden
Mephobarbital	Mebaral
Methaqualone*	Quaaludes
Pentobarbital Sodium	Nembutal
Phenobarbitol	Solfoton, Luminal
Secobarbital	Seconal
Thiopental	Pentothal, Trapanal
Benzodiazepines	
Alprazolam	Xanax, Niravam
Chlorazepate	Gen-Xene, Tranxene
Chlordiazepoxide	Librium
Clonazepam	Klonopin
Diazepam	Valium, Valrelease, Dizac, Zetran, Diastat
Estazolam	ProSom
Flunitrazepam*	Rohypnol*
Flurazepam	Dalmane
Halazepam	Paxipam
Lorazepam	Ativan
Midazolam	Versed, Dormicum, Hypnovel
Oxazepam	Serax
Prazepam	Centrax
Quazepam	Doral
Temazepam	Restoril
Triazolam	Halcion
Nonbarbiturate sedative-hypnotics	
Chloral hydrate	Notec, Somnote, Felsules
Eszopiclone	Lunesta
Ramelteon	Rozerem
Zaleplon	Sonata
Zolpidem	Ambien
γ-Hydroxbutyrate (GHB)*	Xyrem*
Stimulants	
Dexmethylphenidate	Focalin
Methylphenidate	Ritalin, Concerta, Metadate, Methylin, Daytrana
Amphetamines	
Amphetamine–dextroamphetamine mixtures	Adderall, Biphetamine* Dexamphetamine
Dextroamphetamine sulfate	Dexedrine, Dextrostat, ProCentra
Lisdexamfetamine dimesylate	Vyvanse

TABLE 76.1 Generic and Trade Names of Common Prescription and OTC Medications—cont'd

Generic name	Brand names
Methamphetamine hydrochloride	Desoxyn
Analeptics	
Doxapram	Dopram
Modafinil/armodafinil	Provigil, Nuvigil
Anorexiants	
Benzphetamine	Didrex
Diethylpropion	Tenuate
Fenfluramine*	Redux*
Phendimetrazine tartrate	Bontril
Phentermine*	Adipex,* Fastin*
Sibutramine*	Meridia,* Reductil*
OTC drugs	
Decongestants	
Ephedrine**	ePHEDrine Sulfate, Am-Ephed, Amesec, Amphetrazine, Kondon's Nasal, Mudrane, Primatene, Theodrine, and others
Phenylephrine	Sudafed PE, Sudogest PE, Dimetapp, Triaminic, Vick's Sinex, and others
Pseudoephedrine**	Sudafed, Sudogest, Dimetapp (Maximum Strength), Sudophed, Simply Stuffy, and others
Antihistamines	
Dimenhydrinate	Dramamine, Tryptone
Diphenhydramine	Benadryl, Simply Sleep, Nytol, Midol, AllerMax, Theraflu strips, and others
Doxylamine	Aldex, Doxytex, Nitetime, Nytol, Sleep Aid (Doxylamine), Unisom
Diet aids	
Ephedra*	Diet Pep,* Metabolife, Gen-Fen, Herbal Majic, Twinlab Ripped, Trim Easy Plus
Antitussives	
Dextromethorphan	Coricidin, Robitussin, Delsym, Alka-Seltzer, Dimetapp, Triaminic, Theraflu, Nyquil

** The drug has been removed from the market.*
*** Regulation varies by state; minimum federal requirement that consumer present photo identification to purchase.*

suggest that among youth aged 12–17 years old, females are more likely than males to use prescription medications nonmedically, but among individuals 18 years or older, males report higher prescription medication use than females. This gender difference may also vary by the type of medication.

Each day in the United States, an estimated 8500 individuals initiate illicit drug use for the first time (see Fig. 76.1). Over half of all new initiates are less than 18 years old and approximately half are female. Among new initiates, a substantial amount (28.6%) begin illicit drug use by consuming a prescription medication, the most common of which are pain relievers (17.1%).

In contrast to other commonly abused substances in society, such as alcohol and cocaine, prescription and OTC medications are unique in that their consumption is endorsed or prescribed by health care professionals. For many individuals, these medications serve as a primary treatment for certain medical conditions and represent a legitimate means of improving physical health and well-being. However, this is only true when the medications are used exactly as directed. Because these medications are FDA-approved and many are prescribed by health care professionals, some individuals develop a false sense of safety regarding their use and erroneously believe that the severity and risk of negative side effects is lower with prescription and OTC medications compared with other substances. Teenagers and young adults, who often have a sense of being invulnerable, are particularly susceptible to this erroneous perception of prescription and OTC drugs as being safe.

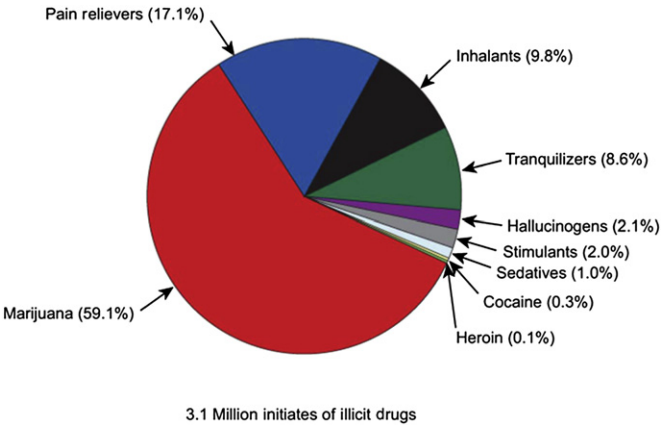

FIGURE 76.1 Specific drugs associated with initiation of illicit drug use among 3.1 million past year illicit drug initiates aged 12 years or older. From Substance Abuse and Mental Health Services Administration (2010). Results from the 2009 National Survey on Drug Use and Health: Volume I. Summary of national findings. Rockville, MD: Office of Applied Studies, NSDUH Series H-38A, HHS Publication No. SMA 10-4856 Findings.

RISK AND PROTECTIVE FACTORS

Table 76.2 includes a list of factors that may increase the risk of nonmedical prescription and OTC medication use. For example, individuals who initiate substance use at an early age, have a family history of alcohol or drug addiction, and aged 18–25 years are at increased risk of misusing prescription and OTC medications. Individuals with other substance use disorders or co-occurring psychiatric symptoms such as depression, anxiety, attention deficit hyperactivity disorder (ADHD) and eating disorders are also at increased risk. Such individuals may use the medications in an attempt to self-medicate their psychiatric symptoms. Women, in particular, may use stimulants in an attempt to lose or maintain weight. A history of childhood trauma (e.g. sexual or physical assault) or neglect may also increase the risk of nonmedical prescription and OTC medication use. Numerous studies demonstrate a strong correlation between exposure to early-life adversity, such as trauma and violence, and elevated risk for addiction as an adult. Finally, living with someone who uses prescription and OTC medications may also increase risk. Data regarding pain medication misuse show that one of the most common sources for obtaining pain relievers is family and friends. Young adults may be given a prescription medication by well-intentioned but ill-informed family members to help with a physical condition (e.g. a mother may give her teenage daughter one of her own prescription pain relievers to sooth a migraine headache or menstrual cramps). Furthermore, risk is increased when living with a user of prescription medications, even when that use is legitimate. Simply having access to these drugs is a risk factor. Caregivers should store all prescription and OTC medications securely to keep others in the home safe. Appropriate storage involves keeping medications somewhere out of reach (e.g. in a high, cool, and dry location) rather than in a medicine cabinet where anyone who enters the home can access the drugs.

TABLE 76.2 Risk and Protective Factors

Risk factors
Younger age (e.g. 18–25 years old)
Early initiation of substance use
Family history of addiction
Easy access to drugs
Male gender (except among youth, girls outnumber boys in nonmedical use of prescription drugs)
Juvenile delinquency/gang involvement
Societal discrimination (on basis of race, ethnicity, education, sexual orientation, etc.)
Comorbid psychiatric conditions, such as other substance use disorders, mood and anxiety disorders, posttraumatic stress disorder, ADHD, and eating disorders
Low socioeconomic status and poverty
Conflict in interpersonal relationships
History of interpersonal violence, childhood sexual abuse, or other traumas
Sensation-seeking personality characteristics and poor impulse control
Chronic medical problems or frequent surgical procedures (specific to prescription opioids)
Protective factors
Stable family and interpersonal relationships
Strong social support network consisting of nonusing peers
Coping skills (anxiety management, problem solving, emotion regulation skills, etc.)
Religious and spiritual practices
Commitment to academic achievement
Participation in child, adolescent, and family support programs offering tutoring, social competency skills, and alternative positive activities for at-risk youth
Supportive, drug-free friends, and romantic partner

SPECIFIC MEDICATIONS

The following sections briefly address the approved medical uses, mechanisms of action, symptoms of intoxication/withdrawal, and treatment of the most commonly abused prescription medications: opioids, stimulants, and sedative/tranquilizers. Commonly abused OTC medications are briefly discussed at the end.

Prescription Opioids

Medical Uses

Prescription opioids are most often prescribed as analgesics for acute pain relief and degenerative chronic pain conditions (e.g. cancer, rheumatoid arthritis). In addition to their analgesic properties, opioids are also used as anesthetics during surgical procedures and as antitussives to suppress coughing. Various opioids (e.g. methadone, buprenorphine, naltrexone) have also been approved for detoxification and treatment of opioid dependence, as discussed later in this chapter. Although less frequent, prescription

opioids are approved for the treatment of severe diarrhea.

Neurobiology

Opioids work through a complex set of interactions involving multiple neurotransmitter systems within several brain circuits. Chronic use of opioids results in neuroadaptations within these brain areas. Like most drugs of abuse, opioids activate dopaminergic neurons in the mesocorticolimbic and nigrostriatal pathways of the brain. Thus far, studies have focused primarily on the action of opioids within the mesocorticolimbic pathway, which contains dopaminergic neurons originating in the ventral tegmental area (VTA) and projecting into the nucleus accumbens (NAc), amygdala, prefrontral cortex (PFC), and ventral pallidum. The pedunculopontine nucleus is a structure unique to the reinforcing effects of opioid use. Neurotransmitters that specifically activate opioid receptors throughout the body are also important in the acquisition and maintenance of opioid dependence. For example, growing evidence indicates that cannabinoid receptors (CB1s) may play an important role in opioid addiction. One study found that when CB1s were deactivated, rodents no longer self-administered morphine.

Pharmacology

Opioid drugs bind to receptors in the brain that are activated by naturally occurring, endogenous chemicals called opioid peptides. Opioid peptides include (1) endorphins, (2) endomorphins, (3) enkephalins, and (4) dynorphins. Endorphins, specifically β-endorphins originating in the hypothalamus, are responsible for the high or euphoric state produced by opioids. They also produce symptoms of drowsiness, respiratory depression, and analgesia. Enkephalins are spread throughout the body. Within the brain, enkephalins are involved in pain management, respiratory regulation, and may also play a role in the reinforcing properties of opioids. Within the gastrointestinal tract, enkephalins are responsible for digestive function and are associated with the constipating side effect of opioid use. Although dynorphins produce analgesia, they also cause anxiolytic symptoms, anhedonia, confusion, and sweating.

Opioid peptide neurotransmitters can have a variety of psychological and physical effects, depending on what type of receptor(s) they bind to, binding affinity for the receptor, and how strongly they activate the receptor once attached. The exact role of each receptor is still under investigation; however, several generalizations can be made at this point. Mu (μ) opioid receptors are primarily responsible for the subjective euphoria and rewarding properties that users may experience from taking opioid drugs. Blocking or removing μ opioid receptors in rodents dependent on opioids decreases self-administration of opioid drugs and reduces the amount of time rodents spend in areas that remind them of past opioid use (i.e. conditioned place preference). In addition to rewarding effects, μ opioid receptors produce analgesia, pupil constriction, and respiratory depression. Kappa (κ) opioid receptors produce a subjective dysphoric state, pupil constriction, spinal anesthesia, sedation, and stress-induced analgesia. These receptors are also responsible for the hallucinogenic properties of some opioids (e.g. pentazocine, nalbuphine). Dynorphins appear to have a high binding affinity to the κ receptors. The delta (δ) receptors are currently the least understood receptor class, but appear to have analgesic properties.

When an opioid drug binds to a receptor, one of three events can occur. The drug can serve as an antagonist, full agonist, or partial agonist. Drugs that serve as antagonists bind to receptors but do not activate them. Instead, they block other opioid peptides from binding to and activating the receptor. Opioid antagonists that have a high binding affinity for a particular receptor can actually displace opioid agonists from the receptor site, thereby functionally deactivating the receptor and reversing any previous effects. Naltrexone, an opioid antagonist approved for the treatment of opioid dependence, functions in this manner. Drugs that act as opioid full agonists mimic opioid peptides by fully activating the receptors to which they bind. Partial agonists bind to the receptor but do not fully activate it. Pharmacotherapies such as buprenorphine work by competing with agonists at the receptor site and binding tightly to the receptor. However, once attached to the receptor, these partial agonists fail to activate the receptor with the same intensity as an opioid agonist. Partial agonists activate receptors enough to prevent severe withdrawals and cravings, but do not provide the full range of effects that opioids provide, including the rewarding euphoric effects.

Dopamine (DA) is a neurotransmitter critical to modulating the motivational aspects of reward-based behaviors. DA levels are increased in the VTA and NAc when opioid agonists bind to opiate receptors. Opioid agonists trigger a decreased activation response from γ-aminobutyric acid (GABA) interneurons. As these interneurons pump out less GABA (an inhibitory neurotransmitter), the presynaptic dopaminergic neuron is disinhibited. Decreased inhibition allows this dopaminergic neuron to release more DA into the synapse. Increased releases of DA and endorphins are responsible for most of the symptoms of opioid intoxication. Likewise, decreased DA levels within the mesolimbic pathway during opioid

withdrawal are responsible for the dysphoric symptoms following cessation of chronic opioid use. For a detailed discussion of the neuropharmacology of opioids.

Symptoms of Intoxication and Withdrawal

Symptoms of opioid intoxication vary by drug, dosage, and route of administration. Typical intoxication symptoms include

- euphoria,
- nausea,
- drowsiness (nodding off),
- constipation,
- pupil constriction,
- impairments in attention, memory, and social functioning.

High doses of opioids may cause an initial euphoria followed by apathy, dysphoria, slurred speech, respiratory depression, decreased heart rate, and possible coma or death. Risk of death by overdose and respiratory depression is a major concern, especially when opioids are combined with antihistamines, sedatives (e.g. barbiturates, benzodiazepines) or alcohol. For example, promethazine (e.g. Phenergan) is a popular antimimetic prescription drug that can be mixed with codeine or oxycodone for recreational use and referred to as sizzurp.

Acuity of intoxication is partially dependent on the route of administration. For example, rapid release oxycodone (OxyContin) in a crushed form provides a more intense intoxication than extended release capsules that are metabolized in the digestive tract. Injecting or snorting crushed pills produces a quick flood of neurotransmitters in the DA reward pathway system, whereas opioids that are gradually released (i.e. transdermally administered) closely resemble endogenous processes in the brain.

Symptoms of opioid withdrawal generally follow the opposite course of symptoms of opioid intoxication. Acute opioid withdrawal symptoms can occur as soon as 2.5 h after intake and last up to 4 days. Withdrawal symptoms resemble influenza and include

- insomnia,
- dysphoric mood,
- nausea and vomiting,
- diarrhea,
- muscle pain and aches,
- yawning,
- lacrimation or rhinorrhea (i.e. runny eyes or nose),
- pupil dilation, piloerection (i.e. goose bumps), or sweating,
- fever,
- involuntary leg movements.

Residual withdrawal symptoms following heavy opioid use, such as anhedonia, anxiety, insomnia, and drug craving can continue for months after cessation. Withdrawal symptoms are a main cause of relapse, as many individuals return to opioid use in an attempt to relieve or prevent uncomfortable withdrawal symptoms.

Treatment

The combination of psychotherapy and pharmacotherapy is most effective for the treatment of opioid use disorders. Behavioral therapies can help strengthen coping skills, enhance motivation for change, improve social functioning, address maladaptive cognitions and behaviors, and assist patients in building a substance-free life, and social support system. A range of behavioral models may be used, including cognitive-behavioral, harm-reduction, voucher-based contingency management, relapse prevention, and traditional, abstinence-based 12-step models. Pharmacotherapies work in conjunction with behavioral therapies to ameliorate the physiological symptoms of withdrawal and craving, thereby helping to prevent relapse.

The first step of treatment is often opioid detoxification, which may occur in a medically monitored facility or under physician supervision in an office-based setting, depending on the level of addiction. Several treatment options exist for opioid detoxification. Opioid replacement therapies substitute an opioid agonist (e.g. methadone, buprenorphine) and slowly taper the dose until the patient no longer requires any opioid agents. A second option is to use a nonopioid agent (e.g. clonidine) to decrease elevated noradrenaline (NE) levels present during withdrawal, which mitigates withdrawal symptoms. A third option is to shorten the length of the opioid withdrawal syndrome via a rapid or ultrarapid detoxification process. Withdrawal is induced and accelerated by administering an opioid antagonist to quickly displace the remaining drug from the receptor. Nonopioidergic drugs are typically given to treat subsequent withdrawal symptoms. This relatively new form of opioid detoxification is controversial in terms of safety and long-term efficacy. Critics argue that the procedure is unsafe due to the potential for cardiorespiratory complications and aspiration while under anesthesia.

Medication-assisted treatments for opioid dependence consist of opioid replacement therapies, opioid antagonists, and mixed opioid agonist–antagonists. LAAM and methadone maintenance are the two full agonist replacement therapies approved by the FDA in the United States. Low doses of these opioid agonists are administered to patients at regularly scheduled intervals in conjunction with psychotherapy. Of these two replacement therapies, methadone has been the preferred treatment since 2001 when the FDA

administered a warning that LAAM may cause cardiac arrhythmia. LAAM has since been withdrawn from the market. For further information regarding methadone maintenance as a treatment for opioid dependence, *see* Methadone Maintenance.

Buprenorphine (Subutex®) is a partial agonist commonly used in the treatment of opioid dependence. It works as a partial agonist at the mu receptor while simultaneously serving as an antagonist at the kappa receptor. Since buprenorphine does not fully activate the mu receptor, it can precipitate withdrawal among individuals who chronically abuse high doses of opioids. Buprenorphine combined with naloxone, an opiate antagonist (Suboxone®) is frequently used to prevent misuse (e.g. injection of the drug to get high or selling it on the street) and to treat opioid dependence. Antagonists such as naltrexone or nalmefene can also be useful in the treatment of opioid dependence, as they have low abuse liability. For more information regarding the use of antagonists for the treatment of opioid dependence, *see* Antagonists for the Treatment of Opioid Dependence.

Central Nervous System Depressants

Medical Uses

The central nervous system (CNS) depressant drug class is frequently referred to as the sedative-hypnotic drug class and includes a wide spectrum of prescription medications used to induce anesthesia and treat anxiety, sleep, and seizure disorders. Barbiturates, benzodiazepines, hypnotics, and tranquilizers are included in this group. Barbiturates are approved for use as anticonvulsants, hypnotics, and sedatives. Benzodiazepines are used to treat anxiety disorders and alcohol withdrawal. When taken as prescribed at low to moderate doses, benzodiazepines offer many of the same beneficial effects as other sedative-hypnotics without the severe side effects and overdose potential. However, dependence on benzodiazepines can develop after chronic use. Dependence occurs primarily in populations with preexisting vulnerabilities to substance use disorders and is more likely evidenced by physiological withdrawal symptoms following cessation of use (i.e. physiological dependence) rather than positive reinforcing properties obtained during use. Compared to other medications with abuse potential (e.g. opioids and amphetamines), benzodiazepines have a relatively safe and low abuse profile.

Neurobiology

CNS depressants increase the inhibitory neurotransmitter GABA, which serves to decrease neuronal firing. GABA and benzodiazepine receptors are located in most synapses throughout the brain. Due to the pervasive expression of these receptors, it is difficult to isolate specific neural circuits activated by benzodiazepine and GABAergic agents. However, specific symptoms of intoxication and withdrawal are modulated by multiple neurotransmitter systems acting within different brain structures. For example, increased inhibition in the Papez circuit of the limbic system and basolateral amygdala may be responsible for the anxiolytic response during drug use and subsequent anxiogenic response during withdrawal. Barbiturates are believed to have a particularly strong effect on the mesencephalic reticular activating system. If synapses are activated postsynaptically by barbiturates, their receptors may be found on neurons in the cuneate nucleus, substantia nigra, and thalamus. Presynaptic activation of these agents occurs in the spinal cord. The most prominent neurotransmitter systems activated during CNS depressant use are GABA and glutamate. Some CNS depressants, such as glutethimide (Doriden), produce anticholinergic effects as well.

Pharmacology

GABA receptors are located in the majority of the synapses in the CNS and play an important role in neuronal firing (e.g. seizure disorders), regulating emotion, and controlling cognition, pain, sleep, and motor function. GABA has three receptor types: GABAa, GABAb, and GABAc. Benzodiazepines activate GABAa receptors, which are primarily responsible for the anxiolytic effects at low doses, sedation at moderate doses, anesthetic properties at high doses, and fatality in the case of overdose. Different GABAa receptor subtypes are responsible for different drug effects, meaning that one receptor subtype is responsible for the sedating effects of a drug while another produces anxiolytic effects.

A glutamatergic hypothesis has been proposed, suggesting that augmented GABA inhibitory neurotransmission produces a compensatory increased glutamatergic excitatory response. Sudden withdrawal of benzodiazepines reduces GABAergic neurotransmission while there is still a residual enhanced glutamatergic response remaining. This excess glutamate may be responsible for the anxiogenic and epileptic symptoms possible during benzodiazepine withdrawal.

Benzodiazepines also have their own class of receptors in the brain, which is subdivided into three receptors types: BZ1, BZ2, and BZ3. A close relationship exists between GABA and BZ receptors, such that activation of BZ receptors can in turn produce a stronger inhibitory response from GABAa receptors. Recent studies have shown that drugs classified as nonbenzodiazepine hypnotics activate the same receptors as benzodiazepines, despite significant differences in their chemical structure.

Barbiturates activate GABAergic synapses in addition to increasing the binding affinity of benzodiazepine and GABA receptors. GABAa receptors in particular appear to be the primary site of augmented inhibitory action for barbiturates. In addition, barbiturates block the glutamate subreceptor α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA). Inhibiting the AMPA subreceptor of this excitatory neurotransmitter at least partially accounts for the anticonvulsant property of barbiturates.

The primary difference between barbiturates and benzodiazepines is the mechanism by which they open ion channels. Barbiturates cause the channel to open for a longer period of time, whereas benzodiazepines cause the channel to open more frequently. This difference in phamacodynamics partially explains why barbiturates are more likely to cause an overdose. For further information regarding the neuropharmacology of benzodiazepines, *see* Neuropharmacology of Benzodiazepines.

Intoxication and Withdrawal Syndrome

Symptoms of CNS depressant intoxication include

- decreased anxiety,
- subjective feelings of well-being and confidence,
- lowered inhibitions,
- decreased heart rate and blood pressure,
- depressed respiration (arrested respiration at high doses),
- poor concentration,
- confusion,
- dizziness,
- sedation and fatigue,
- impaired coordination, memory, and judgment.

While under the influence of CNS depressants, particularly benzodiazepines, learning is impaired and memory loss for events that took place while intoxicated may occur. Combining CNS depressants with alcohol or another sedating substance increases the risk of loss of consciousness and fatalities. Two drugs from this class, γ-hydroxybutyrate (GHB) and flunitrazepam (Rohypnol), are especially dangerous. Since GHB and flunitrazepam (also known as date-rape drugs) are colorless, odorless, and can be easily dissolved into liquids, they are used by sexual perpetrators. Once ingested, these drugs act quickly to induce memory loss. Withdrawal symptoms from CNS depressants include

- anxiety,
- agitation,
- tremors,
- nightmares,
- insomnia,
- anorexia,
- nausea and vomiting,
- orthostatic hypotension, and
- fever.

If left untreated, withdrawal symptoms may escalate to delirium, disorientation, hallucinations, and seizures. Withdrawal from CNS depressants may be life threatening if doses are not appropriately tapered. Medically supervised detoxification is necessary. The onset of withdrawal symptoms for short-acting CNS depressants (e.g. pentobarbital, meprobomate, methaqualone) occurs 12–24 h after the last dose, while withdrawal from longer-acting CNS depressants (e.g. phenobarbital, diazepam) does not begin until 24–48 h after the last dose.

Treatment

Detoxification from CNS depressants should be medically monitored due to the elevated risk of seizures. Chronic use of high doses of benzodiazepines or other depressants increases the risk for a severe withdrawal syndrome. In order to minimize the severity of withdrawal symptoms, doses of benzodiazepines or pentobarbital can be gradually tapered. Long-acting barbiturates, most commonly phenobarbital, can be substituted for short-acting agents and the long-acting medications are slowly withdrawn. In addition, anticonvulsants such as carbamazepine or valproate can be substituted to treat withdrawal symptoms.

Aside from available detoxification strategies and pharmacologic treatment for withdrawal symptoms, there are no identified evidence-based psychotherapies specifically targeting the treatment of CNS depressant use disorders. For a discussion of evidence-based practices for treating generalized addictive disorders and further information regarding pharmacotherapies for sedative dependence, *see* Evidence-Based Treatment and Medications for sedative dependence.

Stimulants

Medical Uses

Included in the stimulant class are amphetamines, analeptics, anorexiants (also referred to as anorectics), and methylphenidates. Of these, the most commonly abused stimulants are amphetamines and methylphenidates. Amphetamines were originally developed as a diet pill to decrease appetite and increase the breakdown of adipose tissue. Amphetamines have since been approved for the treatment of narcolepsy and ADHD. Methylphenidate and dexmethylphenidate have also been approved for the treatment of ADHD. Methylphenidate has an additional approved clinical indication for the treatment of narcolepsy.

The analeptics are most often misused for their cognitive enhancing properties. Modafinil and armodafinil are approved for the treatment of narcolepsy, obstructive

sleep apnea-hypopnea syndrome, and shift-work sleep disorder. Doxapram is another analeptic used to stimulate respiration following drug overdose, postoperative anesthesia, and chronic obstructive pulmonary disease. The anorexiants are approved as a short-term treatment for obesity when combined with caloric restriction. Many of the drugs in this class (e.g. sibutramine, fenfluramine, phenmetrazine, phentermine) have been discontinued in the United States due to adverse cardiovascular side effects and concerns about abuse potential. For information about methamphetamine, *see* Methamphetamine Addiction.

Neurobiology

The therapeutic effects of stimulants stem from increased activation in the prefrontal cortex, limbic structures, and hypothalamus. Among other functions, the hypothalamus is important for regulating stress, arousal, feeding, blood pressure, and autonomic activity. Imaging studies have revealed that individuals with narcolepsy have structural abnormalities in the hypothalamus, whose interaction with other limbic structures such as the cingulate cortex may be responsible for cataplexy, a predominant symptom of narcolepsy. In addition, the hypothalamus and its functional connectivity to limbic and cortical structures are important in controlling food intake. The hedonic component of obesity has been linked to limbic and cortical structures, such as the nucleus accumbens, ventral tegmental area, orbitofrontal cortex, and amygdala.

ADHD correlates with deficits in frontocortical areas, specifically in structures responsible for impulsivity, attention, and motor activity. Likewise, brain imaging studies have revealed that methylphenidate, a popular ADHD pharmacotherapy, increases activity in the orbital and medial prefrontal cortices. Increased levels of dopaminergic and noradrenergic neurotransmission within cortical, limbic, and hypothalamic structures are likely responsible for mitigating symptoms in ADHD, obesity, and narcolepsy. The intensity of the hedonic effects of stimulants is related to the increase of extracellular DA in mesocorticolimbic pathways (i.e. reward pathways of the brain).

Pharmacology

Stimulants work by activating the sympathetic nervous system, primarily through increasing the levels of DA and NE available in the synapse. When taken as prescribed, stimulants slowly increase neurotransmitters in a manner that mimics endogenous processes. However, when taken in excess or through alternative routes of administration (e.g. crushing and snorting), DA and NE flood the synapses and produce symptoms of intoxication. This rapid increase is caused by higher levels of DA and NE being released into the synapse while reuptake of these neurotransmitters is decreased. Within frontocortical structures, DA functions as an inhibitory neurotransmitter, so stimulant pharmacotherapies enhancing DA release decrease impulsivity, increase attention, and improve vigilance. Anorexiants such as sibutramine increase serotonin levels in addition to DA and NE.

The pharmacological means by which armodafinil and modafinil operate are unclear. Although evidence regarding modafinil's influence on dopaminergic and noradrenergic neurotransmission remains under study, it appears that some level of interaction exists. One hypothesis is that modafinil acts through DA release to stimulate adrenergic receptors. However, the exact mechanism of action is difficult to identify, as modafinil appears to interact with dopaminergic, serotonergic, noradrenergic, GABAergic, orexinergic, histaminergic, and glutamatergic neurotransmission on varying levels.

Intoxication and Withdrawal Syndrome

Prescription stimulant medications have the same mechanism of action as other psychostimulants (e.g. cocaine) and their symptoms of intoxication closely resemble those of other stimulants. Intoxication symptoms include

- enhanced confidence and feelings of well-being,
- increased heart rate, blood pressure, respiration, and body temperature,
- constricted blood vessels,
- dilated bronchioles,
- increased arousal, alertness, and energy,
- euphoria,
- decreased appetite, and
- elevated blood sugar.

Much like cocaine, amphetamines can induce psychosis, including symptoms of paranoia, hallucinations, and delusions. Chronic, long-term use of stimulants can produce stereotyped, repetitive behaviors due to continual locomotor stimulation. Extremely high doses can induce cardiac arrest. Another subtle but dangerous effect of amphetamines is the increase in body temperature. When used to enhance physical performance, the increased body temperature combined with extreme exertion can be fatal. Tolerance to certain effects of stimulants, such as suppression of appetite, develops rapidly after consistent predictable intervals of use. Dangers of overdose are especially high when these drugs are taken via alternative routes (e.g. smoking, injecting, crushing, and snorting). In addition, the negative side effects of stimulants can be masked when they are combined with opioids such as heroin, rendering speed balling a hazardous combination.

Adhering to a routine daily schedule of prescribed stimulant medication dramatically decreases the risk of

addiction. Relatively few individuals who are prescribed stimulant medications for ADHD develop abuse or dependence. Although dependence on ADHD medications is a significant concern, some research shows that the likelihood of developing a future substance use disorder is lower for individuals treated pharmacologically for ADHD compared with individuals with untreated ADHD.

Although withdrawal from stimulants is not life threatening, symptoms of the crash following the high are often so dysphoric that it results in relapse. Anhedonia and craving are particularly strong after chronic stimulant use cessation. In addition to anhedonia, symptoms of withdrawal include

- excessive sleep or insomnia,
- vivid, disturbing dreams,
- depressive symptoms,
- psychomotor retardation or agitation, and
- increased appetite.

Treatment

Pharmacological treatments for amphetamines and other stimulants target symptoms of withdrawal, stimulant-induced disorders, or co-occurring psychiatric disorders. Similarly, detoxification from stimulants consists primarily of supportive measures, ensuring that the person is in a safe environment and treating individual withdrawal symptoms. Medication development for amphetamine dependence is described in Medication Development for Amphetamine Dependence.

With regard to behavioral therapies, contingency contracting is frequently used in the treatment of stimulant dependence. This operant conditioning intervention is based on a mutually agreed contract between clinician and client, stating that the client agrees to perform certain behaviors. Failure to perform these behaviors may result in aversive consequences, whereas successful performance leads to rewards. Urine drug screens are often an important component of this intervention. Prize incentives contingency management for substance abuse treatment is an evidence-based practice utilizing contingency contracting to treat individuals with stimulant and cocaine dependence. Participants draw chips from a bowl designating they have won a prize valued between $1 and $100. As patients perform more desirable behaviors (e.g. negative urine drug screen tests), the number of chips they are allowed to draw from the bowl increases. The matrix model is another evidence-based practice approved for the treatment of stimulant abuse and dependence. The intervention uses group and individual therapy sessions to provide psychoeducation, teach relapse prevention skills, enhance self-esteem, and offer social support.

Over-the-Counter Medications

The nonmedical use of OTC medications is becoming increasingly popular among adolescents and young adults, in particular, due to the accessibility, perceived safety, legality, lowered social stigma, and the financial affordability of these drugs. Slang terms such as pharming (i.e. the selling and use of OTC medications for recreational purposes) and sheeting (i.e. measuring use in terms of number of full cards of medication consumed rather than number of gel capsules per card) have arisen to describe practices within this subculture. Minimal research is available on the abuse and dependence syndromes resulting from chronic use of OTC medications.

Medications containing ephedrine and pseudoephedrine were initially released as OTCs but are now behind-the-counter (BTC) medications. As production of methamphetamine from ephedrine and pseudoephedrine surged in the mid-2000s, the Drug Enforcement Administration (DEA) changed federal legislation regarding the distribution of these products in an effort to reduce drug diversion. Regulation of ephedrine and pseudoephedrine sales varies by state; however, federal law requires that anyone purchasing ephedrine or pseudoephedrine must present photo identification in addition to providing a name, address, date/time of purchase, and signature to the pharmacist. Some states refuse to sell ephedrine-containing products except within inpatient hospital settings.

Ephedrine is currently FDA-approved for the treatment of asthma. This medication, also known as herbal X-tacy, was initially sold as a weight-loss enhancer and illicitly distributed as a safe ecstasy substitute. Unlike amphetamines, ephedrine does not cross the blood–brain barrier as easily, so it produces fewer subjective symptoms except when abused at high doses. However, the stimulant effects of ephedrine on the cardiovascular system are problematic and misuse has led to fatalities, especially when combined with monoamine oxidase inhibitors. Pseudoephedrine is a nasal and sinus decongestant that increases release of noradrenaline and constricts blood vessels in the nasal passage. Commonly known as Sudafed®, it also has limited subjective effects except when taken at high doses. Because of the regulation of ephedrine and pseudoephedrine, pharmaceutical companies have begun substituting phenylephrine for pseudoephedrine. Although phenylephrine may produce giddiness and restlessness at high doses, it cannot be diverted for methamphetamine production. Currently, many phenylephrine and pseudoephedrine products share the same brand names (refer to Table 76.1); however, products containing phenylephrine as the active ingredient are available OTC, whereas pseudoephedrine-containing products are available BTC.

DXM is an antitussive/expectorant combination contained in over 140 OTCs. When taken as prescribed, it is a relatively safe drug with few side effects. It suppresses the cough center in the medulla and serves as an agonist to sigma receptors. This poorly understood receptor class was originally categorized as an opioid receptor; however, its structural and functional differences have now designated it as its own class. DXM's actions on sigma receptors may contribute to the drug's dissociative and hallucinogenic properties at high doses. At low doses, DXM serves as a glutamate antagonist. Taken in significantly higher than recommended doses, it serves as an *N*-methyl-D-aspartate (NDMA) antagonist and serotonin agonist. Although this drug has minimal side effects when taken as prescribed, there have been multiple reports of fatalities among young adults due to overdose of DXM. Symptoms of intoxication for DXM include stupor, hyperexcitability, and euphoria. At high doses, DXM may produce nausea, vomiting, pupil dilation, hallucinations, delusions, seizures, paranoia, irregular heartbeat, hyperthermia, coma, and death. Combining DXM with sedatives, selective serotonin reuptake inhibitors (SSRIs), or antihistamines is especially dangerous.

Antihistamines serve as antagonists to histamines at the H1 receptor, but also interact with dopaminergic, serotonergic, noradrenergic, opioidergic, and acetylcholinergic systems. They are usually available OTC in low doses. Antihistamines are often abused in conjunction with other drugs to produce an augmented high. For example, tripelennamine is often combined with opiates, particularly pentazocine (in a mixture referred to as T's & Blues) to produce a euphoric rush similar to heroin. Diphenhydramine is contained in a number of cold and flu medications including Benadryl, Theraflu strips, and Midol, which are frequently used for recreational purposes in conjunction with alcohol or other sedatives. Dimenhydrinate, commonly marketed as Dramamine®, is sometimes abused for its euphoric and hallucinogenic properties. Other antihistamines include doxylamine (e.g. Nyquil, Alka-Seltzer), Nytol, and Compoz. Many of these drugs contain alcohol and intensify the effects of alcohol or other sedatives when used in combination with other drugs.

SUMMARY

Over the past decade, the nonmedical use of prescription and OTC medications has increased significantly and is a serious public health concern. In contrast to other commonly abused substances in our society, prescription and OTC medications are unique in that their consumption is endorsed by health care professionals, they serve as a primary treatment for certain medical conditions, and they represent a legitimate means of improving physical health for many patients. Because of this some individuals, in particular teenagers and young adults, develop a false sense of safety regarding the nonmedical use of prescription and OTC medications. Early treatment typically involves detoxification and the management of withdrawal symptoms, a common cause of relapse. While further research on the development of evidenced-based treatments for nonmedical prescription and OTC medication use is clearly needed, a combination of pharmacotherapy and psychotherapy is recommended.

SEE ALSO

Methamphetamine Addiction

Glossary

Abuse a maladaptive pattern of use leading to clinically significant impairment or distress as evidenced by one or more DSM-IV diagnostic criteria in the past 12 months (e.g. recurrent failure to fulfill major obligations at work, school, or home; recurrent use in situations in which it is physically hazardous; continued use despite having recurrent social or interpersonal problems caused or exacerbated by the use).

ADHD attention deficit hyperactivity disorder.

AMPA α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid.

Antagonists drugs that bind to receptors but do not activate them, thereby blocking the receptor and preventing activation from other chemicals.

Behind-the-counter medications (BTCs) US FDA-approved medications that require photo identification, contact information, and signature in order to purchase.

DA dopamine.

Dependence often used synonymously with addiction. A maladaptive pattern of use that indicates a loss of control and clinically significant impairment or distress, as evidenced by three or more DSM-IV diagnostic criteria in the past 12 months (e.g. tolerance, withdrawal symptoms, persistent desire, or unsuccessful efforts to cut down or quit, taking more of the substance than was planned).

DXM dextromethorphan

Evidence-based practice (EBP) an intervention tested and accepted by consensus or expert review and demonstrated to yield a specific clinical outcome (i.e. objective, concrete, measurable change in client status follows implementation of practice).

FDA US Food and Drug Administration

Full agonists drugs that bind to receptors and fully activate them, thereby closely mimicking endogenous processes.

GABA γ-aminobutyric acid.

GHB γ-hydroxybutyrate

LAAM levacetylmethadol.

LSD lysergic acid diethylamide.

Misuse incorrect use of a medication (e.g. taking more than was prescribed, taking it more often than was prescribed, using it for a purpose other than that for which it was prescribed).

NAc nucleus accumbens.

NE noradrenaline.

Nonmedical use the use of a medication that was not prescribed by a physician or was used only for the experience or feeling it caused.

Over-the-counter medications (OTCs) US FDA-approved medications available directly to consumers without a prescription.

Partial agonists drugs that bind to receptors but do not activate them with the same intensity as endogenous chemicals or full agonists.

PCP phencyclidine.

PFC prefrontral cortex.

Pharming a slang term used to describe the distribution and use of prescription and OTC medications for recreational purposes.

Physiological dependence tolerance for a medication, emergence of withdrawal symptoms upon cessation of the medication, or continued use of the medication to prevent withdrawal symptoms. Note that a person could have physiological dependence on a medication but not be addicted to it (see definition for Dependence).

Prescription medications US FDA-approved medications that require authorization (i.e. a prescription) from a licensed medical professional in order to purchase.

Pseudoaddiction Drug-seeking and other behaviors that are phenotypically consistent with psychological dependence but actually result from insufficient treatment (e.g. lack of pain relief). Once the condition is adequately treated, the drug-seeking and other related behaviors cease.

VTA ventral tegmental area.

OUTLINE

TOBACCO: AN INTRODUCTION

The use of tobacco dates back thousands of years. It is cultivated from two main species of tobacco plant (*Nicotiana tabacum* and *Nicotiana rustica*) originating in the Americas and West Indies. There are numerous ways in which tobacco can be consumed, and there are important differences between smoked and smokeless tobacco, and between different forms of delivery device. However, the focus here is on smoked tobacco (e.g. cigarette) as this is the most common form of tobacco consumption and is associated with the greatest degree of dependence and ill-health. Nicotine is the primary psychoactive constituent of tobacco, and is thought to underlie many of the behavioral and addictive properties of tobacco use. However, nicotine is only one of around 4000 compounds that are released when tobacco is burned. Therefore, although nicotine is considered to be the most important constituent of tobacco, it does not underlie all of the effects of smoking and cannot fully explain the smoking phenomenon. For example, smoking is more widely abused than other methods of nicotine delivery (e.g. chewed tobacco), and nicotine replacement therapies (NRTs) have limited efficacy in

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00077-2

helping people to quit smoking suggesting that nicotine is not the only factor important in smoking dependence. In addition, the main adverse long-term effects of smoking, including respiratory and cardiovascular disease are predominantly related to non-nicotinic compounds in tobacco, such as carbon monoxide and tars.

When tobacco is smoked, nicotine is taken into the lungs and is quickly absorbed into the bloodstream and distributed throughout the body. It readily crosses the blood brain barrier, first entering the brain around 10–15 s after inhalation. Given the speed of activation, smoked tobacco is the most popular vehicle of recreational nicotine administration. However, nicotine is effectively absorbed via other areas of the body, including through membranes in the mouth (cheeks and gums), nasal membrane, and through the skin (transdermal), all of which have been used as sites of absorption for NRTs.

Nicotine is primarily metabolized by the liver (around 70–90%) and excreted in urine. A special enzyme called Cytochrome P450 2A6 (CYP2A6) transforms nicotine into its principal metabolite, cotinine. The elimination half-life is approximately 2 h, although this can vary depending on several factors such as the frequency and heaviness of smoking and individual differences in metabolism (e.g. degree of CYP2A6 activity).

Nicotine binds to nicotinic acetylcholine receptors both in the central nervous system and the periphery. It acts largely as a stimulant drug, increasing heart rate and blood pressure and initiating release of epinephrine (adrenaline) from the adrenal glands. Stimulation of these receptors in the brain has been associated with increased psychomotor activation and improved cognitive function, particularly working memory and sustained attention, although these effects appear to vary across individuals and are also task dependent, with generally better outcomes being observed on relatively simple mental performance tasks rather than complex problem solving. Nicotine administration has also been shown to increase calmness and reduce tension in abstinent smokers, often leading to the belief that smoking is anxiolytic. Somewhat paradoxically to this, smokers generally display higher levels of anxiety than non-smokers, indicating that the anxiolytic effects associated with abstinence may be a reversal of withdrawal-related tension. This is supported by the fact that nicotine is a stimulant (rather than sedative) drug that often induces feelings of heightened arousal and tension when administered acutely to non-smokers.

Importantly, like the majority of recreationally abused drugs, nicotine also stimulates activation of the reward pathways in the brain, which accounts for at least some of the rewarding properties of smoking. In higher doses, nicotine is toxic and can induce a plethora of aversive symptoms including vomiting, dizziness, excessive sweating and salivation, tremors, and seizures. However, cases of nicotine overdose are extremely rare, and tend to occur through non-volitional intake rather than excessive smoking (e.g. accidental swallowing or exposure to high levels of nicotine when harvesting tobacco). Early use of nicotine can induce nausea and vomiting, possibly due to activation within the area postrema (the area of the brain that controls vomiting), although tolerance to this effect occurs quickly with repeated use.

THEORY OF ADDICTION

The process by which smokers become addicted to tobacco is quite well understood. Nicotine plays a pivotal role. Cigarettes are the dominant and most addictive form of tobacco. When the smoke is inhaled nicotine is absorbed rapidly via the large surface area of the lungs and transported to the brain where it attaches to 'nicotinic acetylcholine receptors'. This has different effects in different parts of the brain but one area that is of particular importance is a part of the midbrain called the 'ventral tegmental area (VTA)'. When nicotine attaches to receptors in the VTA it leads to an increased rate of firing of neurones originating in this area. Some of these neurones project to a part of the forebrain called the 'nucleus accumbens (NAcc)'. The nerve terminals in this area release another neurotransmitter called dopamine. This dopamine release causes the smoker's brain to pay attention to what activity it had just performed and the situation, and strengthen the impulse to engage in that activity when the same situation arises. This does not require conscious awareness and in that sense is 'automatic'. Thus the smoker experiences urges to smoke in situations where smoking has occurred in the past and these can be very strong.

Repeated exposure to nicotine in this way also has a chronic effect on the brain which leads smokers to experience a kind of 'nicotine hunger' – a drive to smoke – when nicotine concentrations in the brain are depleted. Thus even in situations where smoking has not occurred, smokers may feel a need to smoke.

In addition to this, adaptation to nicotine leads the brain to experience a range of adverse withdrawal symptoms when nicotine concentrations become depleted. These include: irritability, depressed mood, restlessness, difficulty concentrating, sleep disturbance, and increased appetite. There is also usually rapid weight gain. This has two effects. One is that the adverse experiences create a need to smoke to relieve them. The second is that the repeated experience of mood disturbance and relief by smoking creates a strong expectation that smoking

helps with stress, regardless of how that stress is generated. Thus when smokers experience a stressful situation which may be months or years after they have stopped smoking, they will often feel a need to smoke.

In summary, nicotine from tobacco (and particularly when delivered rapidly via cigarettes) establishes (1) urges to smoke in situations where smoking has occurred in the past, (2) a drive to smoke when brain nicotine concentrations are depleted, and (3) a need to smoke to avoid unpleasant mood and physical symptoms together with an expectation that smoking will help with stress.

There is considerable variation between individuals and over time in susceptibility to these effects. Moreover, there is reason to believe that a range of other factors can exacerbate or mitigate the development and expression of dependence. Thus smokers can develop a strong 'smoker identity' to which they are attached and the sense of belonging to a social group of smokers can motivate continued smoking. It has also recently been hypothesized that the effects of nicotine may be dependent on, or amplified by, the presence of monoamine oxidase inhibitors (MAOIs) which are present in cigarette smoke. Most smokers report that they enjoy smoking but this does not appear to play a role in leading them back to smoking if they try to stop.

EPIDEMIOLOGY OF SMOKING

Tobacco use prevalence has steadily decreased since the middle of the last century in the developed world, standing at around 20–30% in many Western countries, but is stagnating or still increasing in the developing world; the vast majority of smokers now live in developing nations or nations in transition. Consequently, the worldwide population of smokers is estimated to reach 1.7–1.9 billion by 2020, more than ever before.

Tobacco use is initiated at a young age; most smokers will have started before their 18th birthday. Adolescent smoking rates vary considerably from country to country but unlike adult smoking rates, there is currently no clear trend for changes in adolescent smoking prevalence. Smoking rates also vary with age; while smoking is less common in both young and old age, prevalence peaks somewhere before middle age. This is primarily due to two factors; less dependent smokers start to give up smoking as they grow older, while more dependent smokers continue to smoke and as a consequence start to die prematurely from middle age onwards, resulting in a bell-shaped distribution of smoking prevalence across the human life span.

Globally, smoking is more common among men than women but this gender gap has much reduced in the developed world, having virtually disappeared in countries like Australia. Whilst female smoking prevalence is still much lower in developing countries, this is likely to change with shifts in social and cultural conventions and targeted marketing by tobacco companies.

Besides gender, there exist a number of other important socio-demographic determinants of smoking such as ethnicity. Taking the United Kingdom as an example, smoking prevalence among minority ethnic groups as a whole is somewhat lower than among the general population but much higher in some ethnic minorities, notably those originating from the Indian subcontinent. Moreover, gender biases for smoking also persist in ethnic minority groups; for example, in the Asian community in the United States smoking prevalence among men is three times higher, and in the Hispanic community two times higher, than among women.

One of the strongest determinants of tobacco use is socio-economic status (SES), but the direction of this relationship is variable. In some countries, usually those with weak tobacco control measures and less public awareness of the consequences of smoking, cigarette consumption is still mostly determined by income, leading to a positive correlation between smoking and SES. However, in countries where awareness of the negative impact of smoking is high, there is a negative relationship between smoking and SES. It appears that better-off smokers are not more likely to attempt to stop, but are more likely to succeed in giving up smoking, possibly due to deprived smokers lacking adequate financial, emotional, and environmental resources to aid smoking cessation.

PUBLIC HEALTH ISSUES

Tobacco smoking is the largest avoidable cause of death, disability, and social inequality in life expectancy in the developed world, and with the growing epidemic of smoking throughout the developing world is set to become the biggest avoidable cause of disease globally. Smoking killed about 5 million people in 2006, and is projected to kill about 10 million in 2025. Although smoking prevalence has been declining in many developed countries over recent decades, the reverse is true in many other countries. As a result, the majority of the burden of tobacco-related deaths over the coming decades will occur in low- and middle-income countries. Where smoking is currently prevalent, smoking typically accounts for up to one in five of all deaths.

Half of all regular cigarette smokers die from a disease caused by their smoking, typically losing about 10 years of life. Smoking causes over 50 fatal illnesses and a range of chronic diseases, but the majority of deaths from smoking arise from three causes: cardiovascular disease,

lung cancer, and chronic obstructive pulmonary disease (COPD); the majority of deaths from lung cancer, and of chronic obstructive disease in the developed world, are due to smoking. Globally, smoking caused about 1 in 10 deaths, but in countries where adult smoking is prevalent this proportion rises to 1 in 5 or more. Passive smoking is also a significant cause of death and disability among adults wherever smoking is prevalent, and although precise numbers are less certain than for active smoking, in Europe for example, deaths caused by passive smoking are equivalent to about 10% of the total attributable to active smoking. Passive smoking is also a major risk factor for death and disease in children, including fetal death, sudden infant death, lower respiratory infection, asthma, middle ear disease, and meningitis. Smoking also contributes to poverty and economic disadvantage as well as ill-health. Preventing smoking is therefore a major global public health priority.

VULNERABLE GROUPS

A number of vulnerable groups exist with regard to smoking prevalence which are a priority for tobacco control worldwide. Some have been discussed previously (for example those in lower socio-economic groups and in ethnic minority groups). Other vulnerable groups include those with mental health issues, prisoners, pregnant women, and adolescents.

Mental Health

The significance of tobacco smoking in those with mental illness is substantial. Issues related to the increased prevalence of smoking and severity of tobacco dependence, and the resulting impact on the lives of smokers with a mental illness have been confirmed in numerous international studies, notably in the United States, Australia, and New Zealand. Patients with mental illness are up to three times more likely to be smokers than the general population with smoking prevalence reaching over 70% for some severe disorders such as schizophrenia. Smokers with mental illness are likely to be heavier, more dependent smokers and have smoked for longer than smokers in the general population. Frequent and heavy smoking has detrimental impacts on the physical health of individuals with psychiatric conditions. It is responsible for a large proportion of the excess mortality experienced by those with mental health problems. With smoking being gradually denormalized in the general population, its current persistence and entrenchment in mental health settings contribute to a widening of tobacco-related health gaps in a highly vulnerable population. Those with mental health disorders are often as motivated to quit as the general population but face difficulties due to their high level of dependence and a lack of knowledge on the part of health professionals as to the link between smoking, mental illness, and treatments. Difficulties to address the 'smoking culture' in mental health settings such as those above and possible steps forward have recently been identified in national and international research.

Pregnancy

Smoking is the single largest modifiable risk factor for adverse outcomes in pregnancy and prenatal death. Women who smoke during pregnancy are more likely to be young, single, of low income and low educational attainment. Smoking has been linked to a number of serious health problems, including but not limited to ectopic pregnancy, increased risk of miscarriage, complications during labor, low birth weight, and stillbirth. In addition, an estimated 40% of all infant deaths have been estimated as being attributable to smoking. Babies born to mothers who smoke during pregnancy are more likely to suffer from poor intellectual development and physical growth and are more likely to have respiratory ailments. Smoking prevalence throughout pregnancy varies considerably around the world, but as examples figures of between 6 and 25% have been reported across Europe, 15–20% in both Australia and the United States and around 30% in South Africa. It is important to continue to encourage as many women as possible to quit smoking during pregnancy to minimize the health risks listed above.

Prisoners

A 1997 national survey of prisons in England and Wales revealed a smoking prevalence of 85% among male remand prisoners. Smoking plays a significant role in the prison setting, in particular as a relief from boredom and stress and for fostering a sense of group membership in an environment where smoking is very much the norm. These reasons also make cessation in this environment extremely difficult. Canada, Australia, and the United States are examples of countries which have introduced legislation against smoking in prisons which may contribute to reducing the prevalence, although the rulings have often come under challenge and in some cases have been overturned.

Adolescents

Adolescent smokers are of concern as they are the group who will have the largest impact on smoking prevalence in the future, and are also more likely to

drink alcohol or take illicit drugs in addition to tobacco use. Experimentation is an important predictor of future use, with the vast majority of regular smokers taking up the habit in adolescence. Reducing smoking among young people presents a challenge for health professionals as reasons for smoking are multi-faceted and largely driven by the home and social environment.

GENETICS

Despite decades of research to develop effective smoking-cessation treatments, a large proportion of smokers who attempt to quit fail, so that any improvement in the currently modest success rates achieved by smokers attempting to quit would have the potential to afford a considerable improvement in public health. There is substantial inter-individual variation in the level of nicotine dependence among cigarette smokers, as well as in therapeutic response to smoking-cessation pharmacotherapies. These observations have prompted a growing interest in genetic research to determine (1) whether individual differences in smoking behavior may be due to genetic influences and (2) whether the efficacy of different pharmacotherapies for the treatment of nicotine dependence is influenced by inherited variation in drug metabolizing enzymes and drug targets.

Genetic effects are known to influence smoking behavior, including cigarette consumption, but the identification of genetic variants robustly associated with smoking behavior phenotype has proved elusive. Recently, however, a number of genome-wide association (GWA) studies have provided robust evidence that single nucleotide polymorphism (SNP) variants with the *CHRNA5-A3-B4* gene cluster (which encodes the α5, α3, and β4 nicotinic acetylcholine receptor subunits) on chromosome 15q24 are associated with heaviness of smoking. Research in this area has reported an association with the rs16966968/rs1051730 SNPs (which are highly correlated and used interchangeably) with each additional copy of the risk allele associated with approximately one cigarette per day increased smoking quantity, corresponding to approximately 0.5% of phenotypic variance. Recently, a number of large collaborative efforts have replicated this association, and identified additional loci which appear to be associated with different aspects of smoking behavior, including smoking initiation, heaviness of smoking, and smoking cessation.

To date, only a limited number of pharmacogenetic studies of smoking-cessation pharmacotherapies have been published, principally investigating first-line medications such as NRT and sustained-release bupropion. A smaller number of studies investigated second-line medications such as venlafaxine. These pharmacogenetic analyses have typically focused on candidate genes in the dopamine, serotonin, and opioid pathways, or on genes coding for drug metabolizing enzymes (e.g. *CYP2A6* and *CYP2B6*).

It is clear that these findings are too preliminary to support the translational application of these findings to the clinical practice of smoking-cessation pharmacotherapy at the present time. In particular, there is a need for very large studies explicitly designed to examine pharmacogenetic pathways, implementing genome-wide analyses rather than focusing on single or a small number of variants. Newer medications (e.g. varenicline), as well as current second-line medications for smoking cessation (e.g. nortriptyline), will require investigation, and such studies should investigate associations with tolerability and side effects, given that there may exist sub-groups of individuals who respond well to certain medications which are typically not well tolerated.

The cost-effectiveness and acceptability of genetic testing, both among patients and clinicians, will also require investigation. Any additional costs generated by the consultation time required when providing feedback on the results of a genetic test may serve to render tailored intervention less cost-effective than the current model, despite the very low (and falling) costs of genotyping *per se*. There are several issues here, including assessing the clinical utility of such a treatment model, considering the preparedness of primary care physicians to implement such a model, determining the acceptability of such testing among patients, and ensuring that appropriate legal and regulatory frameworks are in place to ensure privacy and protect against genetic discrimination (e.g. by insurers).

Can we therefore know whether pharmacogenetics will ever help smokers quit? At present, the answer is "no", although there is some early promise. We will need to know a great deal more before we can begin to translate pharmacogenetic findings into practice, not the least of which is to determine which of those findings to date represent replicable, robust associations with treatment response. However, the pharmacogenetic investigation of smoking cessation has value beyond simply the potential for translation into clinical practice, and the implementation of tailored or personalized therapy. Such research can provide important insights into the mechanisms of nicotine addiction and smoking cessation, including response to pharmacotherapy.

TREATING TOBACCO DEPENDENCE

The idea that some smokers can become dependent on tobacco and may require treatment to stop smoking started to gain wider currency only in 1970s. The

awareness of health risks of smoking became widespread, a large number of smokers were quitting, and a special category of smoker became increasingly visible: someone who is highly motivated to stop but unable to do so.

A considerable number of psychological treatments were proposed, using mostly behavioral and some cognitive elements. A typical treatment program required smokers to monitor their smoking behavior, identify the most important cigarettes, and replace smoking with alternative coping strategies and behaviors. Despite the intuitive validity of this approach, little evidence emerged suggesting that any of the specific behavioral interventions are actually helpful in facilitating long-term abstinence. One exception to this was a method of aversive or 'rapid' smoking. This requires smokers to take frequent puffs on a series of cigarettes (typically one puff every 10 s) until smoking becomes aversive. The method seems to have an active ingredient and modest efficacy. It was superseded by NRTs in 1980s.

There are several NRT products currently available, including nicotine chewing gum, transdermal patch, nasal spray, lozenge, 'inhalator', and sublingual tablet ('microtab'). The first three of these were innovative when they first appeared, with the gum pioneering the new approach to treatment, the patch providing a user-friendly option and a potential for achieving higher nicotine concentrations, and the spray increasing the speed of nicotine delivery. Since 1980s, however, the field has been stagnant, with new products simply mimicking the delivery profile of the tried-and-tested gum.

The existing NRTs when combined with multi-session support almost double the success rates of the behavioral treatments, but overall their efficacy remains limited, reaching some 15% 1-year abstinence rates in studies with strict outcome criteria. Note that in this field, the choice of outcome definitions (e.g. validated or not, point prevalence versus sustained abstinence, etc.) has a stronger influence on reported 'success rates' than the methods used.

The anti-depressant bupropion was discovered to help smokers quit in the 1990s. Its efficacy is considered overall similar to NRT, but it seems to have a striking effect in some smokers. Compared to NRT, which has virtually no contraindications and no side effects other than local irritation, bupropion has contraindications and can cause insomnia and seizures. It remains popular in United States but in Europe, where UK tabloids ran a scare campaign against it, it is now used only rarely.

The selective α4β2 nicotinic acetylcholine receptor partial agonist varenicline has been available since 2006. It is more effective than bupropion and seems to be also more effective than NRT, at least in the short term. About a third of users experience nausea, but this is usually mild and does not deter smokers from carrying on. Media reports of erratic behavior and suicide in smokers using the drug led to warnings in the labeling, but data available so far suggest these were coincidences of the type to be expected in any medication used by millions of people.

All three medications show efficacy largely only when accompanied by behavioral support. Key elements of this appear to be a supervision of the actual quit date, regular monitoring of abstinence, ensuring patients understand what to expect from the medication and how to use it to its best advantage, reassurance regarding withdrawal discomfort, and maintaining patients' motivation to remain abstinent. In the United Kingdom and in an increasing number of other countries, the current prevailing approach to treating smokers is the Withdrawal Oriented Treatment (WOT), which combines pharmacological aids and motivational support.

CLINICAL TRIALS

There are two types of clinical trials: comparative and non-comparative. In the early phases of testing a pharmacotherapy for addiction, researchers use non-comparative trials to examine the effect of different doses on psychological and physical indices. Such trials can suggest a medication might be effective, but cannot provide definitive evidence. For this we need a comparative clinical trial where two or more treatments are given to participants and the frequency of occurrence of the outcome compared.

Although pharmacotherapy trials are relatively straightforward to describe, lots of trials in tobacco addiction concern psychological, behavioral, or societal interventions. These are often described as complex interventions. This means that the whole is more than the sum of the parts or that the various components depend on each other for their efficacy. Testing complex interventions follows a process similar to testing pharmacotherapy, described in the UK Medical Research Council Framework for Complex Interventions.

The huge variety of types of interventions and the phases of development make it impossible for all trials to be run the same way. However, the final test of any intervention is whether it can prevent people taking up tobacco or help people stop (or sometimes reduce) their use of tobacco and thus overcome their addiction. For this reason, the main academic society in the field, the Society for Research on Nicotine and Tobacco, has proposed guidelines to help researchers show that interventions work. For example, addiction is a relapsing disorder and the large majority of people who are

abstinent at one point in a treatment trial for addicted smokers will relapse. Thus the Society proposes that trials should show that participants have been abstinent for at least 6 months. This long-term criterion is much less important in prevention trials where, except in special populations, the majority will not take up smoking in the near future.

An important aspect of the analysis of clinical trials in addiction or in other fields is the intention to treat principle. Randomization of a sufficient number of participants ensures reasonable balance of both the known and unknown predictors of outcome (confounders). All other things being equal, both groups have an equal chance of the outcome occurring. In a treatment trial, participants whose attempt to stop smoking is failing and who abandon the program are unlikely to attend a clinic and are less likely to respond to attempts by the researcher to follow them up. Thus assessing the outcome in only those that attend follow-up is biased. We have empirical data from a typical treatment trial that smokers who decline follow-up are smoking. Thus, to cope with the missing data, we impute that people not followed up are smoking and there are detailed coding processes called the Russell Standard. This process does not work so well in some contexts: for example, people who are quitting using an Internet site are much less likely to be followed up but the assumption that they are all smoking is probably wrong. On the other hand, the assumption that those who are followed up have the same smoking experience as those who decline to be followed is also wrong. This issue is also not clear in prevention trials, where most children who are not followed are probably not smoking but data indicate that they are more likely to smoke than children who are followed up.

Another issue in tobacco addiction trials is that we can and usually do seek to confirm smoking status by biological tests. It is cheap and easy to measure exhaled carbon monoxide in smokers or do other tests on blood, urine, or saliva which would indicate active smoking. In a typical treatment trial, participants feel a strong pressure to maintain abstinence and when they fail to achieve it, feel pressure to claim this. Even more important, this sense of pressure can vary between the arms of the trial because, in behavioral trials, blinding is impossible, and, in trials of pharmacotherapy, participants can usually feel the effect of the medication so blinding is not completely successful. Consequently biological confirmation is helpful. Again, in trials where participants have little or no relationship with a therapist, the pressure to lie is lower and the feeling of wanting to prove abstinence makes biological confirmation harder to achieve and less necessary.

There are a large number of trials in prevention and treatment of tobacco addiction and the results of many of these trials are summarized in the Cochrane reviews by the Tobacco Addiction Review Group. This gives the best evidence of efficacy of both clinical and public health interventions in prevention and treatment of tobacco addiction.

TOBACCO POLICY AND CONTROL

In order to '*protect current and future generations from the devastating health, social, environmental and economic consequences of tobacco consumption and exposure to tobacco smoke reduce tobacco use internationally*' and in recognition of the globalization of the tobacco epidemic, the World Health Organization developed the world's first public health treaty, the Framework Convention on Tobacco Control (FCTC). Adopted by the World Health Assembly in 2003, it entered into force in February 2005 and since that time, 171 Parties (countries) have demonstrated political commitment not to undermine it, making it one of the most popular treaties in the history of the United Nations. The FCTC sets out a comprehensive strategy for reducing tobacco use and its harm. In its preamble it states that it represents a '*paradigm shift in developing a regulatory strategy to address addictive substances; in contrast to previous drug control treaties, the WHO FCTC asserts the importance of demand reduction strategies as well as supply issues*'.

There is a substantial evidence base that the optimum way to reduce tobacco use and disease in populations is through implementing a comprehensive tobacco control strategy involving a variety of different policies. The implementation of these evidence-based policies will have important health benefits which will save money for health services and most are relatively inexpensive and easy to implement. Nevertheless, the tobacco industry and its front groups routinely challenge tobacco control policies in the hope that this will deter other countries from adopting them.

A comprehensive strategy needs to be aimed at reducing uptake, increasing cessation of tobacco use and reducing the harmfulness of tobacco use to others and to those users who cannot or will not stop. The World Bank emphasized the importance of fiscal policies to increase the price of tobacco. It also demonstrated that encouraging existing tobacco users to stop is a better strategy for reducing the mortality caused by smoking over a relatively short time frame (the next few decades), rather than concentrating on preventing uptake among new users. In order to help as many tobacco users in a population to quit, policies and strategies with wide reach are required (such as price rises and mass media campaigns or media advocacy) as well as more intensive individual strategies, such as smoking-cessation clinics, which will reach fewer people but have a much greater

efficacy. Harm reduction policies have the least consensus, apart from measures to protect people from the risks of breathing other people's smoke. To achieve the latter, prohibiting smoking in work and public places has been shown to reduce exposure to the harmful effects of cigarette smoke and have an immediate impact on hospital admissions for heart attacks within a year of coming into effect.

Demand reduction strategies in the FCTC include: taxation policies which increase the price of tobacco over and above inflation on a regular basis; protection from exposure to tobacco smoke (such as smoke free public places); packaging and labeling of tobacco products (large pictorial health warnings are shown to be the most impactful); widespread education and public awareness; prohibition of tobacco advertizing, promotion, and sponsorship; regulation of the contents of tobacco products and of tobacco product disclosures; and the provision of tobacco dependence interventions. Supply reduction provisions include curtailing the illicit trade in tobacco products, reducing sales to and by minors and provision of support for economically viable alternative activities to tobacco growing and manufacture. Finally, the FCTC also includes a provision to address liability issues.

Monitoring tobacco policy implementation is important and a tobacco control scale has been developed to measure country progress with implementation of FCTC tobacco control policies. Article 14 of the FCTC states that countries who are signatories to the treaty should develop evidence-based treatment guidelines and take effective measures to promote adequate treatment for tobacco dependence. To date, however, relatively few countries have introduced smoking treatment programmes as part of their health care systems. One exception is the United Kingdom where a national network of smoking-cessation services now exists.

Given the widespread availability of cessation services, the United Kingdom provides an interesting example of how tobacco polices have been developed and implemented. In the United Kingdom, smoking-cessation services were developed on the basis of guidance originally published as a special edition of the journal *Thorax*. This guidance reviewed the effectiveness and cost-effectiveness of interventions to treat tobacco dependence and recommended that specialist clinics be established offering a combination of NRT (at the time, the only available stop smoking medication) and behavioral support. In 1998, the UK government published a white paper on tobacco entitled *Smoking Kills*. This proposed the development of a national network of cessation services delivered by the UK National Health Service (NHS). These services were initially piloted in areas of deprivation in England from 1999 and rolled out across the United Kingdom from 2000. The *Thorax* recommendations provided the basis for subsequent government guidance for the services, originally published in 2000. The services provide a combination of behavioral support from a trained adviser, delivered either one to one or in groups in a range of health service and community venues for between 6 and 8 weeks on average. Behavioral support is combined with access to a range of NRT products and/or bupropion or varenicline. All medications are available on prescription at little or no cost to the smoker.

Since their establishment around 4.7 million smokers have set a quit date with the services in England. Of these, 2.5 million have reported that they stopped smoking in the short term (4-week post quit date) with 1.6 million of these successful quit attempts confirmed by biochemical validation (CO monitoring). Research has examined the longer-term effectiveness of the services, finding a validated 1-year quit rate of 14.6%. This equates to a fourfold increase in the chances of quitting compared with trying to stop unaided. This is equivalent to around 680 000 smokers stopping in the longer term amongst all those who have accessed the services in England since their establishment.

Research has also demonstrated that smoking-cessation services can be effective in reducing inequalities in health. The evidence base to guide the development of interventions to reduce inequalities is extremely limited, but treatment for tobacco dependence provides one of the only clear examples of what works. Studies have demonstrated that smoking-cessation services are effective in reversing the inverse care law (that states that health care is more readily available to affluent than deprived groups). They do this by reaching and treating proportionally more smokers in disadvantaged areas than in more affluent areas. One study examined quit rates amongst 1.5 million NHS stop smoking service clients that had used the services between 2003 and 2006. This found that although smokers from poorer areas were less likely to be successful in quitting, the services were treating a far higher proportion of these smokers. This resulted in a reduction in absolute and relative gaps in smoking rates between disadvantaged and more affluent areas – thereby making a contribution to reducing inequalities in health caused by smoking.

To date, smoking-cessation services have largely been established in developed countries such as the United Kingdom where smoking rates may be higher and where the health care system is well developed. In developing nations, there is some evidence that the integration of tobacco dependence treatment into existing programs such maternity services or clinics to treat tuberculosis, or HIV/AIDS, for example, may be

a more effective way of reaching smokers than through specialist cessation services.

TOBACCO MARKETING

Why do so many young people still take up smoking? Why do so many continue with the habit for decades thereafter and, in many cases, until it kills them? And why do both phenomena persist despite widespread knowledge of the hazards involved and the best efforts of public health? Scientists cite dozens of psycho-social and biological factors, including demographics, peer pressure, parental modeling, economics, disadvantage, gender and, of course, addiction – all of which interact in a complex and damaging system that demands massive and multi-faceted effort to counteract it. However, a much simpler explanation is that smoking continues to thrive because a handful of large, multinational tobacco corporations use their marketing muscle to ensure that it does.

For many, the word marketing is synonymous with mass media advertising, and this can be a powerful tool. The Marlboro Cowboy and Joe Camel brand images are just the visible tip of a beguiling iceberg. Billboards and press ads are combined with a host of other less obvious communications, including sports and arts sponsorship, digital media, merchandising, point of sale display, and pack design. The latter two have become increasingly important in jurisdictions like the United Kingdom and Australia which have banned other sorts of advertising.

This mix of 'marketing communications' is nested within the rest of the marketing effort of product design, distribution, and pricing, with the combined aim of making an offering to smokers and potential smokers that is as attractive, ubiquitous, and as affordable as possible. So young and old are perpetually tempted to try, and continue consuming, an appealing array of beautifully packaged and displayed tobacco products. This effort is strategically and coherently deployed for many years (the Lucky Strike brand, for instance, is a 100 years old) and the physical offering is developed into a much broader and emotionally satisfying brand. Hence a bit of dried leaf in a paper tube becomes an evocative lifestyle choice and powerful statement of identity – and the alchemists' dream of turning base ingredients into gold is fulfilled.

But the tobacco marketers' work is not complete. They have read John Donne, understand that no man (or woman) is an island, and that social context has a big impact on individual choice. They therefore put just as much effort into influencing the behavior of stakeholders, policy makers, and power-brokers as they do into influencing the behavior of teenagers, but in this case, rather than starting to smoke, they want them to resist tobacco control measures such as marketing restrictions or smoke free ordinances; to treat their industry with respect and to encourage pro-tobacco social norms. Thus the tobacco industry recruits not just individuals but the system to its cause.

SUMMARY

Nicotine is considered to be the main addictive ingredient in tobacco. It reinforces smoking behavior by indirectly stimulating dopamine transmission in the reward pathways of the brain. Furthermore, chronic nicotine administration induces neurobiological changes that manifest in an aversive withdrawal syndrome when abstinent that motivates the individual to smoke in order to avoid a negative physiological and emotional state.

Smoking is the most popular vehicle of recreational nicotine consumption, due to its fast pharmacological action. However, smoking is associated with numerous negative health consequences, including cancers, cardiovascular disease, and respiratory illness. Increasing awareness of the risks, and heightened social stigmatization of smoking in recent years, may explain the steady decrease in smoking rates in developed countries, although rates are stagnating or increasing in developing countries. Within societies, smoking is particularly prevalent or problematic among certain groups. For example, individuals of low SES, adolescents, pregnant women, and mental health patients are particularly vulnerable.

Numerous psychological treatments have been proposed to treat nicotine dependence, using behavioral and cognitive techniques. More recently, pharmacotherapies have proved efficacious, particularly when combined with behavioral support. The most common are NRT, bupropion, and varenicline. Of these, varenicline is generally considered the most effective, although there is individual variability in the response to these drugs, and cessation rates remain low. In order to improve cessation rates, there has been growing interest in genetic research to further understand individual variations in smoking behavior and response to treatment, which could result in the introduction of targeted cessation treatments, although the cost-effectiveness of such interventions has been questioned.

In recognition of the need to reduce smoking rates and smoking-related harms, tobacco control strategies are being increasingly developed and enforced throughout the world. These include increasing the taxes, restricting smoking in public-areas, incorporating health warnings on packets, and increasing the availability of smoking-cessation services. Legislative restrictions have also been placed on the marketing of tobacco products in

order to reduce the allure of cigarettes to current smokers but also to non-smokers that may be tempted to smoke.

Acknowledgment

The authors are all members of the UK Centre for Tobacco Control Studies, a UKCRC Centre for Public Health Excellence. Funding from the British Heart Foundation, Cancer Research UK, the Economic and Social Research Council, the Medical Research Council, and the National Institute of Health Research, under the auspices of the UK Clinical Research Collaboration, is gratefully acknowledged.

Glossary

Bupropion an atypical anti-depressant drug that is also a licensed smoking-cessation pharmacotherapy due to its ability to reduce the severity of smoking craving and withdrawal symptoms.

Chronic obstructive pulmonary disease (COPD) a life-threatening respiratory disease characterized by chronic obstruction of lung airflow.

Cytochrome P450 2A6 (CYP2A6) one of the Cytochrome P450 enzymes. Involved in the metabolism of nicotine to its primary metabolite cotinine.

Cytochrome P450 2B6 (CYP2B6) one of the Cytochrome P450 enzymes. Involved in the metabolism of nicotine to its primary metabolite cotinine.

Dopamine one of the catecholamine neurotransmitters in the brain. Plays an important role in the reward systems of the brain.

Genome-wide association (GWA) studies methodological approach employed in genetic epidemiology. Involves analysis of genetic markers across the whole genome (i.e. full set of chromosomes). Used to identify associations between genetic variations (i.e. genotypes) and specific phenotypes of interest (e.g. disease, personality traits).

Monoamine oxidase inhibitors (MAOIs) a class of chemicals that increase the levels of monoamine neurotransmitters by inhibiting the enzyme that metabolizes them (monoamine oxidase). Used clinically to treat depression.

Nicotine replacement therapy (NRT) family of smoking-cessation pharmacotherapies that involve administration of nicotine by non-smoking means. Common varieties include: transdermal patch, lozenge and gum.

Nortriptyline an anti-depressant drug that has also been used to aid smoking cessation. Generally less prescribed than other pharmacotherapies for smoking as its use is commonly associated with side effects.

Nucleus accumbens (NAcc) brain region within the forebrain that is part of the mesolimbic dopamine pathway and plays an important role in motivation and reward.

Point of sale the physical location at which goods are bought/sold, such as a shop checkout.

Point prevalence the number of cases within a clinically relevant category (e.g. smoking abstinent) when measured at a specific point in time.

Single nucleotide polymorphism (SNP) genetic variation within a DNA sequence that occurs when a single nucleotide in a genome differs between individuals or between paired chromosomes in the same individual.

Varenicline a nicotine receptor partial agonist used as a smoking-cessation pharmacotherapy. Acts by reducing nicotine withdrawal and the pleasurable effects of smoking.

Venlafaxine an anti-depressant and anti-anxiety drug that has shown to be beneficial as a smoking-cessation aid, particularly when paired with other pharmacotherapies such as nicotine replacement therapy.

Ventral tegmental area (VTA) sub-cortical brain region where the dopaminergic cell bodies of the mesolimbic reward pathway are located.

Withdrawal Oriented Treatment (WOT) a therapeutic approach to smoking cessation that focuses on helping nicotine-dependent individuals overcome the negative consequences of nicotine deprivation.

CHAPTER

78

Caffeine and Caffeinated Energy Drinks

Andrew Paul Smith

Centre for Occupational and Health Psychology, School of Psychology, Cardiff University, Cardiff, UK

OUTLINE

BACKGROUND

The effects of caffeine have been widely studied and a number of recent reviews cover different outcome measures. Indeed, the present author has written a number of reviews of the behavioral effects of caffeine and has suggested that a cost–benefit analysis is an appropriate way of organizing the literature. The first part of this article will summarize research which demonstrates beneficial effects of caffeine. Earlier reviews suggested that the behavioral effects of caffeine are often positive except when one considers very large doses and sensitive individuals. The issue of dependence and negative effects associated with withdrawal clearly represent an area where one needs to assess possible costs of caffeine consumption. Consumption of energy drinks by children has become an important recent issue. These drinks often have high levels of caffeine and are being consumed by a potentially vulnerable sample. An overview of our current knowledge of these two topics will be given in the second part of the article.

Considerable detail about sources of caffeine, the pharmacology of caffeine, and levels of consumption is available elsewhere. The next section provides a very brief summary of these topics. Caffeine (1,3,7-trimethylxanthine) is a member of a class of naturally occurring substances termed methylxanthines. Plasma levels of caffeine peak 15–45 min after ingestion and the half-life is between 5 and 6 h. A variety of factors influence the metabolism. For example, in pregnant women the half-life can increase to 18 h. Oral contraceptive use

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00078-4

increases the half-life to 11 h whereas in cigarette smokers the half-life is only about 3 h which may account for the high level of consumption found in this group.

Caffeine acts by blocking the effects of the naturally occurring neuromodulator adenosine. This produces an increase in central nervous system (CNS) activity which is associated with changes in many neurotransmitter systems. Caffeine has other CNS effects (e.g. influencing blood flow to the brain). Many of these CNS effects of caffeine are unlikely to occur with the amounts consumed by humans.

Caffeine occurs naturally in a number of foods, is employed as a food additive, and is added to medications. It occurs naturally in coffee, tea, and cocoa and the exact amount present will depend on growing conditions and preparation. Some rough approximations of the caffeine content of products are: filter coffee – 100–150 mg (5 oz cup); instant coffee – 50–60 mg; tea – 35–45 mg; milk chocolate – up to 15 mg; dark chocolate – up to 35 mg. It is also added to soft drinks (e.g. Cola 40 mg in a 12 oz serving). Higher amounts are added to energy drinks (70 mg+). Caffeine is also added to over-the-counter (OTC) medications (e.g. to analgesics, usually in the region of 30–50 mg per tablet). Caffeine tablets can also be purchased and the recommended dose to increase alertness is 100–200 mg. Several estimates suggest that average intake is about 200 mg per day. Problems usually only occur when excessive amounts are consumed (500 mg a day plus) and these problems usually take the form of an increase in anxiety. Some individuals are very sensitive to effects of caffeine and even small amounts can cause adverse reactions. Most individuals control their consumption of caffeine. For example, consumption usually occurs when alertness is reduced (e.g. early in the morning; after prolonged work; after lunch) and is reduced at times when high alertness is undesirable (e.g. before going to sleep).

BENEFICIAL EFFECTS OF CAFFEINE

In a recent review of the literature on possible beneficial effects of human caffeine consumption, Michael Glade concludes that moderate amounts of caffeine lead to the following benefits:

1. Increased energy availability.
2. Increased daily energy expenditure.
3. Decreased fatigue.
4. Decreased sense of effort associated with physical activity.
5. Enhanced physical performance.
6. Enhanced motor performance.
7. Enhanced cognitive performance.
8. Increased alertness, wakefulness, and feelings of energy.
9. Decreased mental fatigue.
10. Faster reactions.
11. Increased accuracy of reactions.
12. Increased ability to concentrate and focus attention.
13. Enhanced short-term memory.
14. Increased ability to solve problems requiring reasoning.
15. Increased ability to make the correct decisions.
16. Enhanced cognitive functioning capabilities and neuromuscular coordination.

CAFFEINE AND SPORTS PERFORMANCE

A recent position paper on caffeine and sports performance from the International Society of Sports Nutrition can be summarized as follows:

1. Caffeine is effective for enhancing sport performance in trained athletes when consumed in low-to-moderate dosages (~3–6 mg kg^{-1}) and overall does not result in further enhancement in performance when consumed in higher dosages ($\geq$9 mg kg^{-1}).
2. Caffeine exerts a greater ergogenic effect when consumed in an anhydrous state as compared to coffee.
3. It has been shown that caffeine can enhance vigilance during bouts of extended exhaustive exercise, as well as periods of sustained sleep deprivation.
4. Caffeine is ergogenic for sustained maximal endurance exercise, and has been shown to be highly effective for time-trial performance.
5. Caffeine supplementation is beneficial for high-intensity exercise, including team sports such as soccer and rugby, both of which are categorized by intermittent activity within a period of prolonged duration.
6. The literature is equivocal when considering the effects of caffeine supplementation on strength-power performance, and additional research in this area is warranted.
7. The scientific literature does not support caffeine-induced diuresis during exercise, or any harmful change in fluid balance that would negatively affect performance.

CAFFEINE AND SLEEP DEPRIVATION

The American Academy of Sleep Medicine has examined the efficacy and safety of caffeine use during sleep loss and their main conclusions are summarized below:

The most commonly reported measure used to study this topic is the ability to stay awake or fall asleep. Fourteen out of 15 studies reviewed have shown increased wakefulness measured by sleep latency tests following ingestion of caffeine by sleep-deprived volunteers.

Choice reaction time performance of sleep-deprived individuals has been improved by caffeine in eight studies. Similarly, working memory performance of sleep-deprived individuals has been shown to be improved by caffeine in over 10 studies. The effects of caffeine during sleep loss have been examined over a dose range from 75 to 1200 mg per 24 h. Recommended doses are usually in the range of 200–300 mg, mainly because side effects are more prevalent with higher doses. Caffeine administration typically improves performance during sleep loss as compared with placebo, but performance and alertness often continue to decline even when caffeine is given due to further sleep loss, circadian rhythms, and caffeine half-life.

Subjective alertness decreases with sleep loss and ratings of fatigue increase. Studies that have monitored mood typically show that caffeine ameliorates these subjective changes with a similar time course to that seen for performance variables. However, some studies have not obtained these results and it has been suggested that some "subjective tolerance" to caffeine may develop with prolonged testing.

Studies have generally shown that doses of 200–300 mg caffeine produce few side effects whereas higher doses (600 mg+) may increase mild symptoms (e.g. gastrointestinal upset, nervousness, muscle twitching). Based on these findings, the review concluded that caffeine can increase alertness and improve performance at doses of 75–150 mg after acute restriction of sleep and at doses of 200–600 after a night or more of total sleep loss. Caffeine is unlikely to have major disruptive effects on sleep that follows 8 h or longer after administration. Prolonged administration is not recommended due to the increasing likelihood of side effects with high doses.

CAFFEINE AND SUSTAINED MILITARY OPERATIONS

A number of studies have examined effects of caffeine in sustained military operations. Harris Lieberman and colleagues conclude that "When cognitive performance is critical and must be maintained during exposure to severe stress, administration of caffeine may provide a significant advantage".

Other research has examined beneficial effects of caffeinated tube food on pilot performance during a 9-h simulated U-2 mission. The results showed that the caffeinated tube food (200 mg caffeine consumed every 4 h) maintained cognitive performance at baseline levels over a 9-h overnight period. Research has considered both cognitive and physical performance measures in sustained operations (e.g. performance during 27 h of sustained wakefulness in Special Forces personnel). The results showed that caffeine (200 mg caffeinated gum administered on three occasions) maintained performance of a reconnaissance vigilance task and also improved running times compared to placebo. A similar study was conducted over a period of 4 days and three nights of sustained operations. The results showed caffeine maintained both vigilance and physical performance during sustained operations that require periods of overnight wakefulness and restricted opportunities for daytime sleep.

CAFFEINE AND SHIFT WORK

A recent review has considered the effects of caffeine for preventing injuries, errors, and cognitive problems caused by impaired alertness in persons doing shift work. Thirteen trials were included but none measured injury, two measured error, and the remaining trials assessed cognitive performance. The trials assessing the impact on errors found that caffeine significantly reduced the number of errors. Caffeine improved concept formation and reasoning, memory, orientation, attention, and perception. The results were largely from studies involving young participants under simulated conditions and further research is needed on older workers and real world shift work. The authors conclude that "Based on the current evidence, there is no reason for healthy individuals who already use caffeine within recommended levels to improve their alertness to stop doing so."

CAFFEINE AND SAFETY AT WORK

Research by the author has examined the impact of habitual caffeine consumption on performance and safety at work. In the first study volunteers, all of whom were regular caffeine consumers, rated their alertness and carried out a simple reaction time task before and after work on a Monday and Friday. Caffeine consumption during the day was recorded and volunteers were sub-divided into low and high consumers on the basis of a median split (220 mg day^{-1}). The results showed that those who consumed higher levels of caffeine reported significantly greater increases in alertness over the working day and a significantly smaller slowing of reaction time.

The second study involved secondary analyses of a database formed by combining the Bristol Stress and Health at Work and Cardiff Health and Safety at Work studies. In the first analyses associations between caffeine consumption and frequency of cognitive failures were examined in a sample of 1253 white-collar workers. The second set of analyses examined associations between caffeine consumption and accidents at work in a sample of 1555 workers who were especially at risk of having an accident. The results from the second study demonstrated significant associations between caffeine consumption and fewer cognitive failures and accidents at work. After controlling for possible confounding factors, it was found that higher caffeine consumption was associated with about half the risk of frequent/very frequent cognitive failures and a similar reduction in risk for accidents at work. Overall, the results from the three analyses confirmed that caffeine consumption may have benefits for performance and safety at work.

CAFFEINE AND HUMAN ERROR

Other research by the author has involved secondary analyses of a large epidemiological database to examine associations between caffeine consumption and cognitive failures (errors of memory, attention, and action) in a non-working sample. Associations between caffeine consumption and physical and mental health problems were also examined. After controlling for possible confounding factors significant associations between caffeine consumption and fewer cognitive failures were observed. Overall, the results show that caffeine consumption may benefit cognitive functioning in a non-working population. This confirms earlier findings from working samples. This beneficial effect of caffeine was not associated with negative health consequences.

CAFFEINE AND DRIVING

A number of studies by Jim Horne and colleagues have examined (1) the efficacy of 200 mg caffeine with restricted and completely sleep-deprived drivers, (2) an energy drink containing caffeine with sleep-restricted drivers, and (3) "a functional energy drink" and sleep-restricted drivers. The results from these studies showed that caffeine generally reduced the impaired driving performance that was seen in sleepy drivers given placebo.

Others have extended these results by examining the effects of sleepiness and caffeine on real-life driving. Extended driving and sleepiness resulted in an increase in lane crossing, which was reduced by 200 mg caffeine. As shown in previous sections of this chapter, fatigue can be induced in a number of ways. One study involved 1 h of simulated driving before and after either caffeine or placebo. In addition, volunteers carried out a battery of tasks measuring subjective alertness and sustained attention. Caffeine reduced steering variability (which in real-life driving may lead to lane crossing) and led to an increase in subjective alertness and improved cognitive vigilance. This suggests that results found after caffeine with artificial laboratory tasks may be applicable to real-life activities involving similar functions.

Driving performance can be impaired by a number of factors, the most widely studied being alcohol. One study examined whether caffeine would reduce an alcohol-induced impairment of simulated driving. The results suggested that caffeine may increase alertness and improve reaction time after alcohol use but will not completely counteract the alcohol impairments seen in driving.

Jack James and colleagues argue that many of the effects of caffeine seen in studies of driving can be interpreted in terms of reversal of the effects of caffeine withdrawal. One method of distinguishing a benefit of caffeine from a reversal of caffeine withdrawal is to compare caffeine consumers with non-consumers. There is a need to do this using an epidemiological approach to examine associations between caffeine consumption and road traffic accidents.

Research by the author has examined a community sample from South Wales ($N = 6648$). These respondents provided information on involvement in road traffic accidents. 3.6% of non-consumers of caffeine were involved in a road accident requiring medical attention compared to only 2.2% of caffeine consumers. Logistic regressions, including demographic, lifestyle, and psychosocial characteristics showed that consumption of caffeine nearly halved the risk of being in a road accident (odds ratio [OR] = 0.58 confidence intervals [CI]: 0.35, 0.98). This result confirms previous research showing that caffeine reduces the risk of accidents (at work) and supports the existing literature and information campaigns about the positive benefits of caffeine for road safety.

CAFFEINE AND DEMENTIA

Several epidemiological studies have examined associations between consumption of caffeine and dementia. A recent systematic review and meta-analysis considered nine cohort and two case control studies. The outcomes examined were Alzheimer's disease (four studies), dementia or cognitive impairment (two studies), and cognitive decline (three studies). The

summary relative risk for the association between caffeine intake and the different cognitive measures was 0.84 [95% CI: 0.72–0.99]. This suggests a trend toward a protective effect of caffeine but the large methodological heterogeneity across a small number of studies precludes more definitive conclusions.

CAFFEINE AND ANXIETY AND DEPRESSION

Caffeinism refers to a constellation of symptoms associated with very high caffeine intake that are virtually indistinguishable from severe chronic anxiety. Caffeinism is usually associated with daily intakes of between 1000 and 1500 mg. However, it appears to be a rather specific condition and there is little evidence for correlations between caffeine intake and anxiety in either nonclinical volunteers or psychiatric outpatients. Other research has investigated whether caffeine is capable of increasing the anxiety induced by other stressors. It has been found that 400 mg of caffeine increased anxiety when paired with a stressful task. However, other research has not been able to provide any evidence of interactive effects of caffeine and stress.

Recent research has shown an association between ADORA2A and DRD2 polymorphisms and caffeine-induced anxiety. Adenosine receptors functionally interact with dopamine receptors in the brain. Functional polymorphisms in the genes for either adenosine or dopamine receptors may, therefore, affect responses to caffeine. A recent study found that 50 mg caffeine did not increase anxiety in any individuals whereas 450 mg caffeine increased it in the majority of the volunteers. With a dose of 150 mg caffeine anxiety was associated with ADORA2A and DRD2 polymorphisms.

In contrast, moderate caffeine intake has been associated with fewer depressive symptoms and a lower risk of suicide. This effect of caffeine on depression may have other knock on effects with regards to health. The author conducted secondary analyses of a large epidemiological database ($N = 2750$) to examine associations between caffeine and both chronic and acute health outcomes. Many of the initial associations between caffeine and health were no longer significant when potential confounders were examined. However, caffeine consumption was still significantly associated with reduced depression in the final regressions. Caffeine consumption was also associated in a dose response fashion with fewer upper respiratory tract symptoms. This suggests that caffeine may influence the immune system, either directly, or by reducing depression (a well-established risk factor for immunosuppression). Other research by the author has shown that caffeine removes the malaise (fatigue, psychomotor slowing) associated with minor illnesses such as the common cold.

CHRONIC HEALTH EFFECTS OF CAFFEINE CONSUMPTION

It is important to conduct a cost–benefit analysis when considering the effects of caffeine. Benefits usually refer to behavioral outcomes and costs reflect possible long-term health effects. Caffeine has been linked with a range of possible health problems but most of these associations are not significant when confounding factors are adjusted for. Indeed, in recent years the trend has been for suggestions that caffeine may have health benefits. It has been suggested that studies of caffeine have played a key part in defining the role of adenosine receptors, phosphodiesterases, and calcium release channels in physiological processes. Caffeine and various analogs, the latter designed to enhance potency and selectivity toward specific biological targets, are potential therapeutic agents for intervention in Alzheimer's disease, asthma, cancer, diabetes, and Parkinson's disease.

CAFFEINE: AN ATYPICAL DRUG OF DEPENDENCE

Roland Griffiths and colleagues have suggested that caffeine is an excellent model compound for understanding drugs of abuse/dependence. Caffeine can be shown to act as a reinforcing agent, a criterion for dependence, under certain conditions. However, the level of responding is lower than that maintained by addictive drugs such as cocaine and amphetamine and there is little or no evidence for upward dose adjustment. Indeed, it is unclear about the contribution of desirable stimulatory effects and undesirable withdrawal symptoms in the reinforcing properties of caffeine.

It has been suggested that caffeine shares four behavioral pharmacological effects with classic drugs of abuse/dependence: reinforcing effects, discriminative/subjective effects, tolerance, and physical dependence. Similarly, it has been suggested that there are some people who report a compulsive pattern of caffeine use and are physiologically dependent on caffeine and there is evidence that just under 20% of caffeine users show some degree of dependence although this is small compared with nicotine (90% of users show dependence) and at a similar level to alcohol (where 14% show a lifetime prevalence of dependence). The most important issue is the severity of the harmful consequences associated with dependence. Compared to nicotine or alcohol the risks associated with moderate

caffeine consumption are generally low. Although caffeine fulfills some of the criteria for drug dependence and shares with amphetamines and cocaine a certain specificity of action on the cerebral dopaminergic system, the methylxanthine does not act on the dopaminergic structures related to reward, motivation, and addiction.

CAFFEINE WITHDRAWAL

Caffeine withdrawal is typically associated with symptoms of headache and drowsiness. These symptoms generally begin slowly, maximize after 1–2 days and are over within a few days. Many of the early studies of this topic used small samples and if one adjusted for the number of analyses carried out one would find few significant effects. The studies also have other undesirable features (e.g. in one study – the subjects were also the authors of the paper). The frequency of caffeine withdrawal has been examined in a population-based survey and in a controlled, blinded experiment. In the survey of over 11 000 people, 61% reported daily caffeine consumption and 11% of the caffeine consumers reported symptoms upon stopping caffeine. When volunteers were unaware that the focus of the study was caffeine withdrawal, reports of symptoms associated with withdrawal were less frequent. Indeed, in another double-blind study by the present author, caffeine withdrawal was associated with an increase in reports of headache but those who continued to consume caffeine also reported more headaches as the study progressed. Volunteers in this study were not very good at discriminating whether they were in the caffeine or no caffeine groups and this suggests that symptoms of caffeine withdrawal may only be apparent if volunteers know that caffeine has been withdrawn. Such a result was obtained in further research by the author which suggests that the dependence associated with caffeine may largely reflect the knowledge that caffeine has been withdrawn rather than a pharmacological dependence.

BENEFICIAL EFFECTS OF CAFFEINE OR REMOVAL OF NEGATIVE EFFECTS OF WITHDRAWAL?

Overall, the previous sections confirm that the effects of caffeine on performance are largely beneficial. However, this view has been questioned by Jack James who argues that the beneficial effects of caffeine are really only removal of negative effects produced by caffeine withdrawal. The author has argued against this general view of caffeine effects on a number of grounds. First, it cannot account for the behavioral effects seen in animals or non-consumers where withdrawal cannot occur. Second, caffeine withdrawal cannot account for behavioral changes following caffeine consumption after a short period of abstinence or the greater effects of caffeine when arousal is low. Finally, claims about the negative effects of caffeine withdrawal require closer examination as they can often be interpreted in ways other than caffeine dependence (e.g. expectancy). Indeed, in most of the studies that have demonstrated increases in negative affect following caffeine withdrawal, the volunteers have not been blind but have been told or even instructed to abstain from caffeine. This is clearly very different from the double-blind methodology typically used to study effects of caffeine challenge.

The view that beneficial effects of caffeine reflect degraded performance in the caffeine-free conditions crucially depends on the strength of the evidence for withdrawal effects. Jack James states that “there is an extensive literature showing that caffeine withdrawal has significant adverse effects on human performance”. If one examines the details of the studies cited to support this view one finds that some of them do not even examine performance, and that where they do, any effects are selective, not very pronounced, and largely unrelated to the beneficial effects of caffeine reported in the literature.

Peter Rogers and colleagues have reviewed a number of studies of caffeine withdrawal and performance. They conclude that “ in a review of recent studies we find no unequivocal evidence of impaired psychomotor performance associated with caffeine withdrawal”. Indeed, they found that caffeine improved performance in both deprived volunteers and non-consumers. Furthermore, other studies which suggest that withdrawal may impair performance can be interpreted in other ways than deprivation (e.g. changes in state).

The effects of caffeine withdrawal are still controversial. One study showed that caffeine withdrawal impaired short-term memory performance but caffeine ingestion had no effect. In contrast, research by the author has shown that caffeine improved attention in both those who had been deprived of caffeine for a short period and those who had no caffeine for 7 days. Other studies suggest that effects of withdrawal are restricted to mood and that performance is unaltered. Like many areas of caffeine research, some of the effects that have been attributed to withdrawal are open to other interpretations. For example, some studies have compared days when mid-morning coffee was either caffeinated or de-caffeinated. Caffeine consumption was associated with better performance and mood. The authors interpret this as a negative effect of caffeine withdrawal whereas one could equally interpret it as a positive effect

of caffeine. Other studies of caffeine withdrawal effects have methodological problems such as the lack of pre-drink baselines or failure to consider possible asymmetric transfer when using within subject designs.

Caffeine withdrawal has been widely studied because it is meant to provide crucial evidence on whether caffeine is addictive or leads to some kind of dependence. The most frequent outcome measure has been reporting of headache, but mood has been examined in other studies. Research has shown that caffeine deprivation led to increased reporting of stress by heavy coffee drinkers. This has been confirmed in another study which showed that caffeine withdrawal was associated with feelings of fatigue and decreased feelings of alertness. Indeed, results show that about 10% of volunteers with a moderate daily intake (235 mg day^{-1}) reported increased depression and anxiety when caffeine was withdrawn. Other research has examined the effects of varying time periods of caffeine deprivation (90 min, overnight and 7 days) on mood. The results showed that overnight caffeine deprivation produced dysphoric symptoms and these mood effects were reduced, but still present, after longer term abstinence. However, close examination of the results does not support this conclusion with only one of the 17 mood scales showing a significant effect.

Recent research in this area has been concerned with two main topics, namely what underlies the increase in symptoms following caffeine withdrawal, and, secondly, whether the positive effects of caffeine reflect removal of negative effects of withdrawal. Peter Dews and colleagues have considered factors underlying caffeine withdrawal and conclude that "non-pharmacological factors related to knowledge and expectation are the prime determinants of symptoms and their reported prevalence on withdrawal of caffeine after regular consumption".

In contrast, some researchers still suggest that caffeine only has beneficial effects on performance when the person has had caffeine withdrawn. One study reported that caffeine improved performance on a sustained attention task and increased rated alertness when volunteers had been caffeine deprived but had no such effects when they were no longer deprived. However, the results showed an effect of order of treatments with those who received caffeine first continuing to show better performance even when subsequently given placebo.

Research by the author has examined effects of caffeine in the evening after a day of normal caffeine consumption. Caffeine improved performance which casts doubt on the view that reversal of caffeine withdrawal is a major component underlying effects on performance. Further evidence against the caffeine withdrawal explanation comes from recent studies of non-consumers. These studies not only detected few negative effects of withdrawal but also showed that caffeine improved the performance of both withdrawn consumers and non-consumers, a finding that argues strongly against the withdrawal reversal explanation.

Other research has compared the effects of caffeine following abstinence and normal caffeine use. Caffeine had a greater effect on mood in the abstained state. The authors also suggest that choice reaction time showed a similar effect although this would not be significant if adjustments were made for multiple statistical tests. Other aspects of performance showed significant effects of caffeine in both abstained and normal caffeine consumption conditions. Failure to adjust for multiple testing is a common problem in this area of research. In addition, it is often unclear why specific sample sizes or tests are used. Consideration of these factors leads to a very different interpretation of some of the literature. For example, Heatherley and colleagues claim that cognitive performance is only improved by caffeine after 8 h of abstinence. Adjustment for multiple testing shows that none of the effects of caffeine are significant which reflects the low power of the study and failure to covary baseline data. Similarly, claims that 9 to 11-year-old children show negative symptoms of withdrawal which are reversed by caffeine do not hold up when adjustments are made for the number of statistical tests conducted.

A review of caffeine withdrawal has been conducted by Roland Griffiths with a view to validate specific symptoms and signs and to define important features of the syndrome. The review covered 57 experimental and 9 survey studies. Symptoms associated with caffeine withdrawal were: headache, fatigue, decreased energy, decreased alertness, drowsiness, depressed mood, difficulty concentrating, and irritability. The incidence of headache was 50% and the incidence of clinically significant distress was 13%. The onset of symptoms occurred 12–24 h after abstinence, with peak intensity at 20–51 h and for a duration of 2–9 days. Abstinence from even low doses (e.g. 100 mg day^{-1}) produced symptoms. Unfortunately, this review was selective and studies which suggested a different view of caffeine withdrawal were excluded. In addition, there was no attempt to distinguish between negative effects of withdrawal and positive effects of caffeine. For example, certain studies are interpreted in terms of negative effects of caffeine deprivation when they could actual be interpreted in terms of positive effects of caffeine ingestion. This review does not look at the details of the studies and, as stated above, many effects of caffeine deprivation are no longer significant when adjusted for multiple statistical tests.

Recent research has demonstrated that acute caffeine abstinence produces changes in cerebral blood flow

velocity, EEG, and subjective effects. These vascular effects of caffeine withdrawal are clearly very different from behavioral effects of caffeine which are thought to reflect changes in a variety of neurotransmitter systems. Astrid Nehlig and colleagues present evidence that in animals caffeine does not trigger metabolic increases or dopamine release in brain areas involved in reinforcement or reward. A single photon emission computed tomography (SPECT) assessment of brain activation in humans showed that caffeine activates regions involved in the control of vigilance, anxiety, and cardiovascular regulation but did not affect areas involved in reinforcement and reward.

TOLERANCE

Developing tolerance is a hallmark of substance abuse and dependence. In adults, caffeine-induced tolerance has been shown for some, but not all, outcomes and only in a sub-set of consumers.

CROSS-SENSITIZATION

Cross-sensitization is the process by which taking one drug enhances the response to other drugs with the same neurobiological mechanisms. It has been suggested that caffeine may increase sensitization to nicotine although the correlation between caffeine use and smoking may reflect the faster metabolism of caffeine by smokers. There is no clear relationship between caffeine use and cocaine in humans and if anything, cocaine users are less likely to consume caffeine than non-cocaine users.

CAFFEINE AND CHILDREN AND ADOLESCENTS

Ingestion of caffeine from naturally occurring sources has been largely restricted to adults but it is now added, sometimes in large quantities, to drinks that are consumed by children. Our knowledge of the effects of caffeine on the behavior of children needs to be extended by further research. The current position on this topic can be briefly summarized as follows.

Older studies of the behavioral effects of caffeine on children have shown similar effects to those observed in adults. Effects in children are often smaller than those observed in adults which may reflect the smaller doses consumed.

It is generally agreed that caffeine intake by pregnant women should be kept at a low level (below 200 mg) because of the possible impact on birth problems and reduced body weight of the child. However, there is no evidence showing that caffeine consumption during pregnancy or childhood influences brain development.

A recent review has shown that caffeine containing drinks are now regularly consumed by children. Indeed, some caffeinated products are even marketed to children as young as 4 years old. Our knowledge of effects of caffeine on children is very limited and further research is needed in the area because children may be more sensitive to negative effects of caffeine than adults. This research should examine possible caffeine dependence and also caffeine intoxication. Caffeine intoxication is characterized by the following symptoms: restlessness, nervousness, excitement, insomnia, flushed face, diuresis, and gastrointestinal complaints. It is likely that low consumers of caffeine, such as children, may experience caffeine intoxication following consumption of a high dose (as found in some energy drinks). No empirical studies have been conducted to examine whether children and adolescents develop tolerance to the effects of caffeine. Surveys suggest that 41.7% of teenagers reported tolerance to caffeine and 77.8% reported symptoms of withdrawal. Consumption of caffeinated soft drinks is also associated with poor diet, excess weight, and dental caries.

There is a growing literature that suggests that caffeine use in adolescents and young adults is associated with impulsivity, risk taking, and sensation seeking. Unfortunately, due to the correlational nature of these studies, it is not possible to determine the direction of causality.

ENERGY DRINKS

Energy drinks represent the fastest growing sector in the beverage industry. These drinks often contain five times the amount of caffeine as soft drinks and may also contain taurine, riboflavin, pyridoxine, and various herbal derivatives. Most energy drinks also contain sugar in an amount that exceeds recommended daily allowances. Studies of the effects of energy drinks on behavior confirm that they increase alertness and attention, improve simulated driving when sleepy and can reduce sleepiness in night workers. However, energy drinks that also contain alcohol (6% by volume) have been shown to impair a global measure of cognitive functioning. Energy drinks have also been shown in laboratory studies to increase heart rate and blood pressure.

Energy drink consumption can lead to caffeine intoxication especially in children. Deaths attributed to energy drink consumption have been reported in Australia, Ireland, and Sweden. Health care providers

report the following effects after consumption of energy drinks: dehydration, accelerated heart rates, anxiety, seizures, acute mania, and strokes. The risk of caffeine intoxication may be greater for energy drinks than for other sources of caffeine due to inadequate labeling, advertising, and the consumer demographics.

Energy drinks are often combined with alcohol to increase the positive effects of alcohol ingestion and counteract the depressive effects. This can lead to increased alcohol intake and an increase in adverse events due to alcohol. Indeed, combining energy drinks with alcohol gives the person a false sense of control. Recent research has investigated the extent to which energy drink consumption was a risk factor for alcoholism. The results of a study of over 1000 university students showed that weekly or daily energy drink consumption was associated with more frequent and greater consumption of alcohol. This, of course, could be due to alcohol consumption influencing energy drink consumption rather than the other way around.

CONCLUSIONS

In conclusion, there are many beneficial effects of caffeine and negative effects are restricted to consumption of high doses by susceptible individuals. Caffeine is almost certainly the most widely used drug of dependence in the world. Despite this, the evidence of morbidity associated with caffeine consumption is slight. Research on caffeine tells us little about the harmful effects of drugs of dependence and shows that caffeine dependence *per se* is not a problem.

Food Addictions

Mark S. Gold, Richard L. Shriner

College of Medicine, University of Florida, Gainesville, FL, USA

OUTLINE

DEFINITION

Establishing a workable definition for food addiction is of paramount importance to understanding one of the world's most pressing epidemics, obesity. This definition must also lend greater definition to other forms of food addiction such as binge eating, bulimia, anorexia, and other maladaptive relationships with food. If food is to be seen as a putative agent for addiction and obesity, then we must simultaneously entertain it in a framework not unlike other substances of addiction. A working definition of food addiction should identify a distinguishing set of characteristics that sets it apart from normal eating. It must clearly outline a distinct pattern of behavior that is truly unhealthy (i.e. maladaptive) over space and time. Such a definition is offered below. Importantly, food addiction (like other addictions) involves a dual biasing valence of both perception (i.e. a highly valued [rewarding] substance) and behavior (i.e. craving/dependency), which reliably sets up the abuser and food addict to predictably suffer a set of unhealthy outcomes.

In terms of *Diagnostic and statistical manual of mental disorders 4th edition text revision* (DSM-IV-TR), researchers have argued that food (like gambling) is indeed an addictive substance. They argue that food fulfills the seven DSM-IV-TR criteria of substance dependence. This includes three or more of the following seven criteria realized over a period of at least 12 months: (1) tolerance, (2) withdrawal, (3) the substance is taken in larger amounts for a longer duration than initially intended, (4) attempts are made to cut back on the substance, (5) excessive time is spent pursuing, using, or recovering from the substance, (6) there is curtailment of other activities because of use of the substance, and (7) there is the continued use of the substance despite adverse consequences that are caused by the substance.

In terms of practical clinical interventions, we offer the following working definition for food addiction:

> *Food addiction represents a pervasive and enduring pattern of both food perception and food-related behavior (leading to either excessive food ingestion or aversion) whose dual valence (i.e. perception and behavior) biases interaction with food in harmful and unhealthy ways. Such a biasing and unhealthy valence toward food continues, despite knowledge of its harmful consequences. Food addicts usually present both a tolerance (i.e. a need to increase participation in their harmful relationships with food over space and time) as well as a form of withdrawal (i.e. an inability to escape their addiction with food without suffering undue anxiety, craving, or other adverse neurochemical reactivity [which may include depression or anger]) when deprived of access to addictive foods. This latter emotional and behavioral reactivity must reliably occur during efforts to either alter or disrupt the food addict's harmful and maladaptive pattern of eating.*

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00079-6

The advantage of this definition is that unlike other forms of addiction, ultimate food sobriety (defined later) is clinically understood to be neither absolute nor static, but rather relative and dynamic. Using this sort of dynamic conceptualization of living in balance with food (instead of being captured by its pathological valences causing fixed weight gain, pathological weight flux or loss) the term Living with Food seems justifiable and clinically useful. This living or healthy coexistence with food involves a state of dynamic interaction that implies neither dependency nor addiction, but rather food sobriety and health. Such sobriety connotes a new, dynamic, and more resilient relationship with food that allows for a healthy acquisition and maintenance of weight over space and time. This is done by balancing those valences that would otherwise cause a person to tend toward pathological patterns of eating. Such pathological patterns having genetic, anatomic, neurochemical, psychological, and environmental roots and triggers, are described under the rubric of disordered eating. These disorders include a spectrum reaching from obesity to binge eating to bulimia and then on to anorexia. This newly formulated, dynamic definition of food addiction paves the way for the study of the entire spectrum of disordered eating under a common defining schema, from excessive weight gain (obesity), to periodic weight gain (binge eating and/or bulimia), to excessive weight loss (anorexia).

MAGNITUDE OF THE PROBLEM

If we assume that food addiction plays a potent role in obesity (an assumption that now appears quite plausible) and obesity is the single most common cause of type 2 diabetes mellitus (T2DM), then food addiction may be the most singularly important addiction of our time. In this way, food addictions will continue to vex scientists, minions of public health policy, insurance companies, the Federal Government, and tax payers who will be asked to cover an ever-escalating health care budget as more graduate into the ranks of obesity. Here are some sobering statistics.

By 2018, more than 43% of US citizens will be obese. Morbid obesity is one of the fastest growing disease states. The National Council on Compensation Insurance found that

- obese claims were roughly three times more expensive;
- added treatments related to obesity can balloon cost differences by as much as 30 times;
- workers who are morbidly obese filed 45% more claims, missed eight times more work, and experienced medical costs five times higher than nonobese counterparts.

The world picture in terms of obesity and food addictions (especially for high carb/high fat food (cafeteria style or highly palatable food)) is no better. Rates of obesity have tripled in the last 20 years in the developing world with 10% of the world's children currently overweight or obese. Countries facing the greatest challenges include the Middle East, Pacific Islands, Southeast Asia, and China. Amongst major world powers, McDonalds (in 6 out of 11 countries) is the favorite fast food chain, with China favoring Kentucky Fried Chicken (KFC). In terms of obesity, the body mass index (BMI) for US children at the 95th percentile is below that in China. Australian and UK women are rapidly approaching the BMIs found in US women. Amongst children in the major countries of the United States, United Kingdom, Australia, and China, Chinese children have gained the marginally highest, some 5-point increase in BMI since 1991. Three things are now self-evident: (1) the major type of diabetes is T2DM, (2) T2DM is largely preventable through weight loss, and (3) T2DM is the number one cause of death in the United States. Hence, the cycle of obesity, diabetic misery, and death tells us food addictions play an ever more critical role in the survival of our species. This cycle goes on and on unabated. The *Morbidity and Mortality Weekly Report* (MMWR) August 2010 report found that rates of obesity have increased by 1.1% since 2007, negating any prior reports of a leveling off of the obesity epidemic.

SUPPORTIVE EVIDENCE

Supportive evidence for food addiction comes from the following lines of research:

- Genetic
- Neuroanatomic/neuroimaging
- Neurochemical
- Stimulus/reward paradigms
- Psychological research
- Clinical case examples

Genetic

Genetic contributions to food addiction seem plausible given the fact that addiction has an estimated heritability of 50–70%. Various researchers have described how such genetic factors are at play in the dysmorphic syndromes of Prader-Willi, Cohen, Carpenter, and others, as well as leptin/receptor mutation, β3 AR mutation and the overexpression of neuropeptide Y (NPY). Each one of these genetic syndromes

results in obesity and can be seen to exacerbate food addictions in the individuals that are so afflicted. As described later in the neurochemical section, dopamine plays a critical role in addiction. The neurogenetics of dopaminergic receptor supersensitivity and brain reward circuitry continues to emerge. For example, a plethora of animal models are being used to elucidate the role that genetics plays in both animal and human vulnerability to addiction in terms of their responsiveness to food or cocaine.

Neuroanatomic/Neuroimaging

Neuroanatomic and neuroimaging studies that are germane to understanding food addiction continue to be developed. Investigators have shown how (using positron emission tomography [PET] and [^{18}F]fluorodeoxyglucose [FDG]), morbidly obese patients have increased metabolism in the somatosensory cortex. They have also showed using PET and FDG in normal weight individuals how increased dopamine increases metabolism in the orbitofrontal cortex and is directly involved with the perception of hunger and desire for food. Using group averaged images of [^{11}C] raclopride PET scans, these same researchers have been able to show that obese rats have marked diminution of dopamine transporter levels compared with nonobese controls. This suggests downregulation of the dopamine (D2/D3) receptor function in obese subjects. This has been replicated in humans. Over the last decade, we now have a greater appreciation for the science of food addiction, including two distinctive food addictive pathways involving: (1) the homeostatic and (2) the reward (or hedonistic) circuits of the brain. Functional magnetic resonance imaging (fMRI) studies have revealed how food craving is activated specifically through three distinct areas of the central nervous system (CNS): hippocampus, insula, and caudate.

Neurochemical

Shadowing the progress of understanding food addictions through neuroimaging of the brain, our neurochemical understanding of food addition and disordered eating continues to be elucidated. In terms of the recent worldwide obesity epidemic, this includes how appetite control and energy balance have been adversely affected by large amounts of high energy-dense foods (e.g., high fructose corn syrup [HFCS]), increased exposure to powerful food cues (e.g. television advertising), together with sedentary lifestyles to create an imbalance between repletion signals versus reward-driven brain inputs leading to obesity. Researchers are focusing on the processes of bingeing, withdrawal, craving, and sensitization that can be used to define food addiction (as well as addictions in general). Again, investigators have found the three key neurotransmitters (dopamine, opioids, and acetylcholine) play a pivotal role in the development and maintenance of food addiction through time. Currently, a major focus of study involves the role that intermittent excessive carbohydrate/cafeteria style (fast food) ingestion may have on binge eating. Specifically, rats exposed to excessive amounts of sugar, which were then denied access to such sugar, tended to engage in binge eating over time, versus rats that were given continuous access to such high carbohydrate food (see below).

Continuing along this line of investigation, binge eating is also associated with stress. Together with an intermittent exposure to palatable foods (e.g. eating fast foods on an intermediate basis), the evolution of binge eating resulting in the exacerbation of weight seems to reliably involve opioid chemistry interaction within the nucleus accumbens of the brain, along with specific dopamine inputs. Increasingly, animal models for the neurochemistry of food addiction (especially involving sugar) are proving the existence of a craving–bingeing–withdrawal–craving cycle. Researchers in the area of food addiction have described how sugar bingeing works through the combined inputs of dopamine interacting with acetylcholine to affect the net output of γ-aminobutyric acid (GABA), all within the nucleus accumbens. Then, this GABA neurochemical traffic goes on to mediate either approach (increased appetite) or avoidance (decreased appetite). In this way, acetylcholine may work to oppose the stimulating effects that dopamine has on appetite. Interestingly, these same researchers found that although both sugar and fat can be associated with bingeing, only sugar was associated with the classic signs of withdrawal, as one would expect from a truly addictive substance.

Stimulus/Reward Paradigms

Stimulus/reward paradigms involving neurobiological pathways and putative neurochemical agents for food addictions are now solidly in play. Again, investigators have shown the significance of addiction to food and brain reward systems. They argue that opioid-based neuropharmacology may underlie the mechanisms behind our current over consumption of palatable (i.e. high carb/high carb, high fat) foods. In general, most research points to the fact that opioid stimulation increases the pleasurable aspects of food, while opioid antagonists do the opposite. At least for carbohydrate craving, opioids may decrease oxytocin-mediated satiety (oxytocin normally turns off carbohydrate

cravings). Thus, opioids may help to mediate the food reward value of carbohydrates. This includes sugar-induced upregulation of μ-opioid and D1 dopamine receptors, along with an increase in release of dopamine in the nucleus accumbens. In fact, in rat models, sucrose is often chosen over cocaine. As we just alluded to above, an emerging body of research suggests that sugar can be highly addictive, causing both craving and bingeing in animal subjects who are denied access to it. To be sure, studies of rats who have been exposed to intermittent schedules of high-dose sugar followed by its sudden removal, can display frank withdrawal (i.e. increased motility, nervousness, etc.) after the opioid antagonist naloxone is administered to them. In humans, opiate-dependent individuals on methadone maintenance report higher consumption of sweets than control subjects.

Lastly, in terms of stimulus/reward paradigms, food addictions (including binge eating and obesity) highlight that time and space may play an important part in obesity and food addictions, as we suggested in our definition of food addiction given at the end of the last section. Specifically, the effects of some food stimulus early in our lives may have an effect later in life vis-à-vis the way we live with food. A recent study was able to demonstrate that if mice were exposed early in their development to high carbohydrate chow, although they did not immediately gain weight, later on in their development they did show increased obesity (over controls) when these same mice were given access to highly palatable food. Thus, early exposure to sugar may have an enduring effect (and/or influence upon) our capacity to suffer from obesity later in life.

Psychological Research

Another area of evidence that supports food addiction involves psychological research. This involves whether psychological mechanisms play a part in food addictions, albeit as modified by genetic and epigenetic mechanisms. Research is now giving us an interesting glimpse into the possible inputs that psychobiological factors such as reward sensitivity and impulsivity may have on food addictions and obesity/eating disorders. Investigators have recently outlined how genetic inputs to dopamine function (hence food motivation) are translated by way of polymorphisms of the D2 receptor (Taq1A), which may have direct impact on obesity and food addiction. The Taq1A+ allele has reduced brain dopamine function compared with the A1 allele since those with the Taq1A+ allele have a 30–40% reduction in D2 receptor density in the striatal region. This has been related to reduced mesolimbic brain dopamine, therefore, a deficient ability to experience natural reward. Given that patients with Taq1A+ allele function have a hypoactive reward system, these same individuals may be susceptible to low food stimulus/reward functionality. Thus, these same individuals may need to consume larger amounts of food to achieve the same measure of reward that those with A1 allele function require. This leaves Taq1A+ allele cohorts at risk for over ingestion and obesity. At least for some individuals with a high BMI, this has been confirmed. The μ-opioid receptor gene (OPRM1) has been extensively studied for drug abuse. This distinct genotype may be higher in binge eaters, but perhaps not in obese individuals without binge eating disorder.

Other studies have examined the psychological effects on obesity and food addiction that carbohydrates may have on female subjects suffering depression. As we mentioned in our definition at the end of the last section, individuals suffering from food addiction may undergo both anxiety and/or depression when they face the prospect of food withdrawal. This, of course, forms the withdrawal component within the definition of food addiction. Investigators have been able to show that after inducing dysphoric mood in overweight female subjects, carbohydrate beverages (but not taste-matched protein substitutes) were able to effectuate an antidepressant effect. In other words, carbohydrates (in contrast to matched taste proteins) were able to assuage the carbohydrate cravings these dysphoric females were suffering from, suggesting that carbohydrate ingestion medicates mildly dysphoric mood.

Clinical Case Examples

The last area of evidence that supports the existence of food addiction involves clinical case examples in general medicine; specifically, how stress and stress-related medical disorders may be involved with carbohydrate cravings and addictions. As we stated earlier, stress plays a crucial role in animal models of binge eating. To this end, if rats are exposed to food restriction alone, they did not tend to overeat. But if one adds the stress of foot shock trauma, these same rats tend to significantly over ingest, especially palatable foods high in carbohydrates and fat. In studies showing this effect, rats needed a primer of at least three restriction/refeeding cycles (see earlier discussion on intermittent exposure to sugar and bingeing), as would be the case in humans for those trying to diet by intermittently restricting their food intake. This is, of course, the same phenomenon we discussed earlier in the rats who were intermittently given access to high carbohydrate chow, followed by restriction. Again, such animals were shown to be at high risk for the eventual development

of binge eating. High stress reactivity binge type eating has also been shown in humans.

Food and drugs have cross tolerance in the laboratory and food, especially sugar, is used to calm withdrawing cigarette smokers and addicts. Actual clinical case examples of how food addiction and stress may play a part in everyday medicine comes from research involving models of stress, allostasis, and chronic diseases. The literature on allostatic load refers to the consequences of sustained or repeated activation of mediators of allostasis. Allostasis (literally other balance) is invoked when specific effectors are activated because organismal homeostasis (literally similar balance) is threatened. An example of such an effector might be an interleukin called IL-6, which is a proinflammatory marker in the body. Such inflammatory markers are released when the body undergoes stress. Such stress-induced inflammatory markers tend to be associated with a simultaneous immune response that forces the egress of cortisol from the adrenal gland (perhaps to counteract such effectors). In turn, cortisol can go on to stimulate appetitive function since it has an orexigenic influence on the hypothalamus. Living within this environment, the organism is predisposed to increased hunger, dopamine release, and (as we have learned earlier) increased motivation to seek out food. Thus, stress can through allostatic load, lead to both direct and indirect reactivities in the body that then go on to induce disturbances of appetite and invariably weight gain. In fact, waist to hip ratio (a measure of obesity) as well as glycosylated hemoglobin (a measure of excess blood glucose) are two important indicators of allostatic load.

A real-world clinical example of how food addiction, allostatic load, allostasis, and orexigenia might find its way into our lives is found in the disorder called metabolic syndrome. This disorder (again really a syndrome) exists when a patient suffers from at least three of the following: (1) hypertension, (2) hypertriglyceridemia, (3) decreased high-density lipoprotein fraction, (4) hyperglycemia; and (5) obesity. In the case of food addiction, continued cravings for especially high carbohydrate substances continue to inflame body effectors (e.g. IL-6, tumor necrosis factor (TNF), etc.) ultimately causing the exhaustion of insulin-producing cells in the pancreas leading to the number one cause of diabetes, T2DM. Regardless, these sorts of metabolic imbalances can lead to obesity and diabetes, which increase the vulnerability of an individual to stress, which creates a vicious cyclical mechanism between stress, food addictions, obesity, diabetes, leading to more stress. As if this were not enough, stressful life events are known to accelerate the course of diabetes in adverse ways. Since diabetes costs approximately 2.5 times more than any other disorder to treat, diabetes, obesity, food addiction, and runaway health care costs remain inextricable from one another.

T2DM AND WHY FOOD ADDICTIONS MATTER

A Model of Pro-inflammation and Energy Misalignments

The reason food addictions matter, at least in terms of their impact on obesity and medical economics in general, is that obesity is so insidiously and directly associated with T2DM, the number one killer in the United States, if not soon the entire world. Certain endocrinologists have pointed out that food (in particular, HFCS) and other substances of addiction (e.g. ethanol) have many metabolic perturbating and allostatic (see earlier discussion) disease-contributing effects in common. These same endocrine researchers convincingly argue that both HFCS and ethanol (EtOH) can contribute to hyperlipidemia, hepatic inflammation, and hepatic (if not also skeletal) insulin resistance. This leads to increasing feedback-mediated hyperinsulinemia (i.e. to compensate for insulin receptor resistance (insensitivity) in order to preserve organismic metabolic integrity) which eventually exhausts β-cell pancreatic function, often leading to T2DM, if not eventually type 1 diabetes in selected individuals.

When it comes to food addiction and its impact on obesity, research is teasing out a common thread between foods of abuse and their impact on several key metabolic, endocrine, and neuroendocrine pathways. These processes and pathways seem to involve the following unraveling of healthy hepatic metabolic eustasis (meaning literally good balance):

- exotic (not previously available to *Homo sapiens*) nutrient energy excess (e.g. HFCS);
- ensuing perturbations of hepatic metabolic function;
- stimulation of proinflammatory species leading to hepatic insulin resistance;
- overwhelmed metabolic pathways that stimulate hepatic gluconeogenesis;
- overwhelmed metabolic pathways that stimulate hepatic dyslipidemia;
- resultant hypersecretion of insulin which favors development of T2DM;
- resultant hypersecretion of insulin which favors fatty acid storage;
- skeletal muscle insulin resistance/hyperlipidemia that decreases energy expenditure;
- net weight gain due to decreased fatty acid mobilization from adipocyte to muscle;
- long-term leptin resistance caused by hyperlipidemia causing further hyperphagia;

- hyperuricemia from excess ADP breakdown causing NO causing blood pressure;
- all of the above contributing to metabolic syndrome and preventable death.

The most potent exotic source of nutrition that has arrived on the landscape of the modern *Homo sapiens* is HFCS. This inflaming source of energy causes several specific perturbations in hepatic function that have been identified by key researchers in the study of endocrinology and obesity. These same researchers have done a masterful job of pointing out the similarities between the addictive substrate EtOH and HFCS. Specifically, how each of these two addictive substances can cause proinflammatory changes, possible reactive oxygen species (ROS), dyslipidemia, and ensuing insulin resistance. EtOH, by altering GABA and opioid transmission within the ventral tegmental area and central areas of the amygdala, activates dopamine neurotransmission. As we mentioned earlier, the stimulation of both opioid and dopamine receptor function is the same thing that carbohydrates (including fructose) are capable of doing and is a prerequisite for defining a substance as addictive.

In this way, sugar, EtOH, HFCS, and other potential addictive substances affect not only peripheral organs, but central nervous nuclei as well. Collectively, these and other addictive substances have been shown to cause the stimulation of a host of proinflammatory substances. Such substances are known to be perturbated in an allostatic fashion, which collectively reflect a state of metabolic dysresiliency called the metabolic syndrome. Woven into this syndrome is diabetes, obesity, hypertension, and dyslipidemia, all reflecting a state of hyperoxidative distress. During such states of oxidative organismic dysfunction, adiponectin levels drop while IL-6, TNF, and other proinflammatory markers are increased. In terms of food addictions, it is this state of metabolic dysfunction or stress (what we have chosen to call metabolic dysresiliency) that identifies a state of abuse for the obese food addict.

The qualifier (and/or proinflammatory quantifier) that outlines a state of abuse in terms of food addiction is found in the net energy expenditure variables that lead to either metabolic resiliency (when energy intake and energy expenditure are resiliently matched to maintain an adaptive dynamic weight called eubaria) or when they are in nonresilient allostasis reflecting a maladaptive weight that is either hypobariac (e.g. anorexia) or hyperbariac (e.g. obesity). A heterobariac weight would be found in the bulimic individual who although maintaining a normal weight is nonetheless still living in a state of dysresiliency that betrays underlying metabolic distress. This is why these individuals often suffer from neuropsychiatric disease states that reflect hypothalamic–pituitary–adrenal axis abnormalities (e.g. increased level of corticotropin-releasing factor) such as depression and/or anxiety.

At least for the hyperbariac conditions such as simple overweight and obesity, food addictions that lead to a state of abuse invariably lead to metabolic dysresiliency and dysfunction. These metabolic dysresilient states are often, unfortunately, self-sustaining since they tend to disturb and upset the normal balance of anorexigenic/orexigenic endocrine feedback (e.g. food addictions causing obesity, block leptin, hence the body's normal anorexigenic responsiveness, etc.).

With reference to the term sobriety, it follows that food sobriety would reflect a state of eubaria and/or metabolic resiliency. To that end, we can define the term food sobriety in the following way:

> *Food sobriety is a dynamic state of interactivity with food that maintains a healthy balance of resilient metabolic function that is free of significant symbolic (relational) or hedonistic (addictive) skew.*

In terms of obesity and T2DM, such a healthy balance of metabolic function or metabolic resilience can be defined as a ratio of insulin to glucagon that is kept in a dynamic (pulsatile) adaptive flux. This flux is necessary for normal hepatic and pancreatic function to work in healthy synergy with one another. This is reflected by a pattern of food ingestion that creates a normal adiponectin and a low proinflammatory oxidative state. To be sure, research has found that the normal healthy pancreas releases insulin in a dynamic, somewhat chaotic fashion that is pulsatile and continuously adaptive, in a nonlinear fashion. This is, of cours, a state much different than that emulated by taking pills or injections to regulate insulin via pharmaceuticals. Even insulin pumps cannot possibly totally emulate this nonlinear continuously adaptive, unpredictable moment to moment resilient flux of insulin versus glucagon that the native healthy pancreas is able to engineer. Therefore, all present and future medical interventions must emphasize the importance of salvaging and restoring native hepatic and pancreatic functioning whenever possible. This, of course, is not always possible, often making permanent and ongoing pharmacotherapy mandatory, if not lifesaving.

Clinical Presentation

The clinical presentation of food addiction is obviously both global and omnipresent. Food addictions start with the way we offer nutrition and take care of our children and end in nursing homes and hospitals, which are, even now, overwhelmed by growing numbers of patients dying of metabolic syndrome and T2DM. We need to do a better job of early intervention,

translational medicine, and more aggressive treatment in terms of patient and physician information sharing, dietary intervention, exercise incentivization, stress/wellness intervention, and psychobiological/psychological evaluation and treatment.

The most important initial assessment in the diagnosis of patients suffering from food addiction is the history and physical examination. At our obesity clinics at the University of Florida, patients are asked to fill out an extensive bariatric data packet. This packet includes background data on current stresses, past stresses (including childhood trauma), past medical and surgical history, past psychiatric history, participation in either Overeaters Anonymous, Alcoholics Anonymous, Weight Watchers, or other fellowship programs, past and current medication, a figurine analysis of the patient's perceptions of their body image, a patient-generated narrative of their self-image, a thorough life–weight profile beginning in childhood up until the present, a canvassing of types of foods eaten, frequency and amount, assessment of binge eating and other eating disorders (e.g. laxative, diuretic abuse, self-induced vomiting, etc.), a list of all diets and diet supplement/diet pill pharm trials, a sleep apnea assessment, inquiry about reasons patient feels they are overweight, and a series of brief psychiatric rating scales. The packet is quite easy to fill out and provides our staff with invaluable data that might otherwise not be assayed.

Next, patient's blood and urine are carefully assessed, including a complete fasting metabolic panel, complete blood count, thyroid functions, fasting insulin, and C-reactive protein. Each patient's QUICKI score is calculated to assess a raw estimate of insulin resistance. In addition, we may or may not obtain IL-6 and adiponectin titers . After obtaining suitable blood and urine chemistries, weight, electroencephalogram, etc., to assay for disturbances in metabolic function, all our patients are given a cognitive assessment, which helps us discern exactly how they negotiate health care information under stress.

Using a cognitive assessment tool allows today's modern bariatrician to interact with patients in terms of their own biases and unique modes of interacting with food. These biases can often be shown to interfere with a patient's capacity to overcome their food addiction. Patients should be taught how certain foods, along with their time/space ingestion patterns (see earlier discussion on intermittent schedules of feeding) can lead to hedonistic problems with food, which can then lead to binge eating and other maladaptive ingestion patterns. Finally, patients should be taught how ingesting large quantities of carbohydrates (especially HFCS) can create metabolic problems with food sobriety given their capacity to upset insulin to glucagon ratios and damage hepatic metabolic function.

Giving patients the capability of focusing upon their relationship problems with food sobriety, cognitive tools (such as the IGS-rooms tool we have developed at the University of Florida) helps patients identify their maladaptive relationship patterns not only with food, but also with their relationships with others (at home, at work, and at play). As we mentioned in the section involving the pivotal role that stress plays in maladaptive eating, without such a cognitive assessment and enrollment in group fellowship intervention, patients tend to remain in maladaptive relationships with food. This may be why the vast majority of diets fail over time. These patients, without adequate medical translation tools, have not engineered a complete transformation in their metabolic, addictive, and relationship interactions with food. This makes food sobriety difficult, if not impossible.

After completing a cognitive assessment, patients should undergo a thorough dietary evaluation that helps to quantify and qualify the exact ratios of fats, proteins, and carbohydrates they are ingesting in a typical day. Effort should be made to assist the patient in minimizing their exposure to HFCS as well as large quantities of EtOH for reasons clearly spelled out above. This is exactly why food addiction programs fit comfortably alongside alcohol and other polysubstance abuse interventions. Next, any underlying neuropsychiatric dysfunctions should be addressed via pharmacological and/or psychotherapeutic intervention.

Whenever possible, patients should be offered group fellowship interventions. Such group interventions can explore maladaptive patterns of thinking and relating to food. These patterns are then reset into more resilient or adaptive complexes. The group process can then reinforce through group fellowship an enduring participation and validation of more resilient and adaptive interactions with food. Since much of the literature on food addictions seems to support the notion that high carbohydrate/cafeteria style foods (especially when periodically curtailed in repetitive attempts at dieting) create more binge eating than weight loss, programs should generally support continuous feeding throughout the day. The overall goal with patients should be to achieve a relatively low carbohydrate/reasonably high protein/reasonable medium chain fatty acid diet. Supplementing a patient's diet with low carbohydrate/reasonably high protein whey protein shakes also seems worthwhile. Rapidly absorbed proteins such as whey protein have been shown to help mitigate hunger. Such a low carbohydrate/high protein caloric source does not tend to aggravate insulin production. Finally, in order to mitigate ongoing inflammation, omega 3 fish oil augmentation would seem advisable in patients wishing to mitigate the proinflammatory responses secondary to their obesity.

The typical food addict is often a patient who has T2DM and/or a patient who is manifestly obese. This includes bariatric surgical patients (who usually have BMI >40 kg m^{-2}). However, clinicians will also discover food addictions in heterobariac patients (defined above), whose BMI is between 17.5 and 25 kg m^{-2}. Obviously, such patients may suffer from either borderline anorexia nervosa (i.e. just above 17.5 kg m^{-2}) or bulimia (with a normal BMI). In addition, binge-eating patients are obviously found nested within general obese patient populations, representing (conservatively) some 5% of these patients. It has been suggested by various investigators that binge eaters have more intrinsic neuropsychiatric disturbances than those who suffer from non–binge-eating obesity. Others who may suffer from food addictions include patients with polycystic ovaries syndrome, chronic pain (especially those who suffer from concomitant problems with opioid addictions), chronic pulmonary disease, various plegic or paretic disorders leaving them wheelchair bound, patients who are cardiovascular compromised, female rather than male (worldwide, females tend to be more obese than their male counterparts), postpartum patients, etc. Interestingly, certain investigators have shown that morbid obesity is often not associated with alcoholism. Overeating may compete with alcohol for brain reward sites, making alcohol ingestion less reinforcing.

Current Treatments

The treatment of food addiction is complicated by the diagnosis. Are there one or many types of food addictions? Is fat preference and overeating a different or related form of sugar and desert-loving food addiction? Only additional research will tell. Multimodal treatment is the norm, extending from group fellowship intervention, to individual psychotherapy, to strategic diet targeting, to focused exercise to bariatric surgical intervention to specific target psychopharmacology. The various antiobesity pharmacologic reagents (A-OPRs) are as diverse as the organs these drugs seek to influence to carry out their anorexigenic response.

In terms of the CNS, A-OPRs include bupropion, the serotonin noradrenaline reuptake inhibitor (SNRI) antidepressant (Wellbutrin). This antidepressant effectuates weight loss via its pro-opiomelanocortin (POMC) activator properties. More recently, naltrexone (an opioid receptor antagonist) has been coupled with bupropion to augment bupropion's POMC activator potency. The anticonvulsants topiramate (Topomax) and zonisamide (Zonegran) have shown some success. Phentermine (Adipex) is a stimulant but only has US Food and Drug Administration (FDA) indications for short-term use only. Unfortunately, patients usually quickly regain weight after discontinuation of the drug. Sibutramine (Meridia) is a central norepinephrine/serotonin reuptake inhibitor whose use is limited by possible hypertensive side effects. Together with orlistat (see below), sibutramine is the only FDA-approved medication for weight loss. Rimonabant (Acomplia) is an endocannabinoid type 1 inhibitor that was taken off the market because of significant neuropsychiatric side effects including suicidal ideation. More recently, DOPA 3 agonists have been in development and may have potential value in impulsive behavioral diatheses such as cigarette addiction. Some investigators are now considering these same reagents in the treatment of binge eating.

In terms of the gut, orlistat (Xenical) is a lipase inhibitor that impairs the digestion of fat causing some degree of malabsorption and weight loss. Its use is limited by the emergence of fatty stools and bowel leakage. Experimental A-OPRs in various phases of development include obinepitide (a dual analogue of PYY3-36 from the distal gut's L cells and PP from the F cells of the pancreas), GLP-1, OXM (Oxyntomodulin, which contains glucagon and is a potent central acting anorexigenic agent), and others. Metformin (Glucophage) blocks hepatic gluconeogenesis and may help to mitigate the harmful effects that excessive hyperinsulinemia has on leptin function (as we outlined above). Unfortunately, because it does block hepatic gluconeogenesis, metformin will invariably prevent a patient from re-establishing normal metabolic resiliency after they lose sufficient weight. Therefore, it is one of those reagents that is often taken off board in our patients who achieve food sobriety.

Bariatric surgery is perhaps the most definitive and effective intervention used to treat patients suffering from morbid obesity (BMI >40 kg m^{-2}) and/or patients with a BMI of 35 kg m^{-2} or greater who also suffer from metabolic syndrome. At least for gastric bypass surgery, it is felt that the anatomic rearrangements so engineered by the surgery help to decrease the influence of the gastric hormone ghrelin (which stimulates appetite at the level of the hypothalamus) and increase the output of GLP-1 and PYY, which have the opposite effect.

The Diabetic Prevention Study found metformin to be inferior to simple diet and exercise, which represent the ultimate medicinal to fight obesity and prevent T2DM. This is why weight loss means everything to the patient with T2DM or obesity and (at least for obese patients), their food sobriety demands loss of weight. In order to achieve this, many clinicians and researchers are recommending we re-examine our assumptions about the vital role that certain food stuffs play (including HFCS, EtOH in significant quantities, etc.) and the vital role that exercise plays, in stemming the tide of the obesity epidemic. The importance of considering the levels of metabolic (homeostatic), addictive (hedonistic), and relational

(symbolic) drives in patients needs to be integrated into antiobesity/food addiction research and intervention strategies.

Without a consideration of all three of these levels of intervention (metabolic, addiction, and relational), simple metabolic revisions are often trumped by addictive attractions (e.g. episodic bingeing on chocolate) or conflicted relational issues (e.g. divorce creating stress and binge eating). Therefore, it is vital that the clinician deals with the entire triad of metabolic–addictive–relational aspects of obesity. Again, this is exactly why the vast majority of weight interventions fail.

FUTURE RESEARCH

The future of research in terms of food addictions will only grow in time. First, research on evidence-based diagnostic interviewing and division into treatment-relevant subgroups is required. In the meantime, the Center for Medicaid and Medicare Services realizes the extraordinary costs of doing nothing. In terms of A-OPRs, the field is wide open. Research on epigenetic modifiers of metabolism will clarify how to more effectively triage those patients who might benefit from a specific gut peptide (such as a ghrelin blocker or GLP-1 modifier), a leptin gene-splicing intervention that ups the level of sensitivity of the leptin hypothalamic receptor, or perhaps a β-3 adipocyte agonist that more effectively uncouples energy expenditure, etc. The potential putative agents for weight loss are more or less endless as are potential genetic interventions in the future. In addition, there is a need to better research more effective bariatric surgical techniques given the likelihood that morbid obesity will only worsen over time.

There is also a need to further research our understanding of how human cognitions dealing with stress lead to increased vulnerability to food addictions. This approach needs to be cross culturally relevant. We also need to understand how to better motivate our patients to want to lose weight and afford them the supportive informational structures in order to do so. Social networking will expand in terms of importance, as will research on how to better integrate multispecialty interventions (so-called bundling) for patients suffering from food addictions.

Gambling

Tony Toneatto

University of Toronto, Toronto, ON, Canada

OUTLINE

EPIDEMIOLOGY OF PROBLEM GAMBLING

Several epidemiological studies measuring the prevalence of problem gambling have been conducted and show lifetime prevalence rates ranging between 0.4 and 2%. With rates of pathological gambling hovering around 1% in North American surveys, the rate approaches 4% when subclinical or problem gamblers are included. Elevated rates of comorbidity have been found repeatedly in epidemiological research, as well as in studies of treatment-seeking samples. The prevalence of problem gambling appears to be lowest among older adults and highest among younger adults.

CLASSIFICATION OF PROBLEM GAMBLING

Pathological gambling was introduced into the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III) as a "disorder of impulse control, not elsewhere classified" and comprised seven criteria predominantly related to the financial consequences of gambling (of which three needed to be met for a diagnosis), an inability to resist impulses to gambling, and negatively affected family, vocational, and personal pursuits. A differential diagnosis of antisocial personality disorder was also specified.

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00080-2

A major shift in the conceptualization of pathological gambling was reflected in DSM-III-R with a set of criteria strongly resembling substance use disorders. Nine symptoms defined the syndrome (of which four needed to be met for a diagnosis) consisting of preoccupation with gambling; gambling more than intended to; withdrawal symptoms when unable to gamble; tolerance as expressed by increasing amounts of money spent; chasing financial losses; efforts to reduce or stop gambling; disrupted social or occupational obligations; sacrifice of important social, occupational, or recreational pursuits; and continued gambling despite growing personal losses. Antisocial personality disorder, mania, and hypomania were specified as differential diagnoses.

In the fourth edition of DSM, 10 criteria defined the syndrome, of which five needed to be met for a diagnosis. As with DSM-III-R, several criteria resembled symptoms of substance dependence: preoccupation with gambling; tolerance (i.e. increasing the frequency and/or amount of money wagered); withdrawal (i.e. feeling restless or irritable when unable to gamble); difficulty stopping/reducing gambling; and sacrificing other activities (social, occupational, or leisure) as a result of gambling. The remaining criteria included chasing lost money, relying on gambling to cope with negative mood, lying about or hiding gambling, engaging in illegal activity to support gambling, and relying on others for financial relief. A manic episode was specified as a differential diagnosis. There were several differences from the previous edition of the DSM with the inclusion of gambling as a means of coping with dysphoric mood, committing illegal activities to obtain money for gambling, and relying on others to provide gambling-related financial relief in DSM-IV. Several symptoms related to the disruption of social, occupational, and personal functioning in DSM-III-R were collapsed into one criterion in DSM-IV.

As work progresses toward the fifth edition of DSM scheduled for release in 2013, the substance use disorders Workgroup of the American Psychiatric Association's DSM committee has recommended shifting pathological gambling from Impulse Disorders Not Otherwise Specified to a new category, Addiction and Related Disorders. This recommendation is based on the elevated rates of comorbidity regularly observed between substance use disorders and pathological gambling; phenomenological similarities between addiction and problem gambling; neurobiological, neurochemical and genetic commonalities; and the adoption of similar treatment approaches. In addition, the Workgroup has suggested that the name of the disorder be altered as the term "pathological" may be considered pejorative. "Disordered gambling" is being suggested as an alternative label. While DSM-IV lists 10 criteria for pathological gambling and statistical analyses identify a single underlying construct for the 10 symptoms, the criterion related to committing illegal acts (e.g. forgery, fraud) to finance gambling, which was introduced in DSM-IV, is infrequently endorsed and contributes minimally to classification accuracy. As a result, this criterion may be eliminated in DSM-V.

In addition, the Workgroup is considering modifying the cut-off score for determining a diagnosis. Currently, the cut-off for a diagnosis of pathological gambling requires endorsement of 5 of the 10 DSM-IV symptoms. However, it is not clear that this cut-off is the most valid. Although possessing face validity, it has received only limited psychometric testing. The Workgroup, based on several studies, suggests four symptoms may be sufficient to diagnose pathological gambling.

In summary, the Workgroup has suggested that listing pathological gambling among the addictive disorders section, reducing the criteria from 10 to 9, and the diagnostic cut-off from 5 to 4 should improve screening, diagnosis, treatment, and research into problem gambling.

THEORETICAL MODELS OF PROBLEM GAMBLING

Models of problem gambling have often glossed over individual differences between diverse forms of gambling, reflecting an implicit assumption that the diverse phenomenology of gambling behavior represents an unimportant variation of a more fundamental underlying process. Results of individual differences, treatment outcomes, and prevalence are typically reported in an aggregated fashion and rarely analyzed or presented by subtype of gambling. This approach to problem gambling research may present a significant barrier to a better understanding of problem gambling, its prevention, and treatment. As increasingly diverse types of gambling become available within society, the choice of game will likely be made on the basis of multiple biological, psychological, social, and cultural variables. Subtyping of problem gamblers may thus be important to increase our understanding of the assessment, cause, treatment, and natural history of problem gambling.

Choice of Gambling Activity

Given the wide availability of different forms of gambling, the choice of which games(s) to play is affected by multiple developmental, psychosocial, and demographic variables. Factors affecting the choice of

gaming may have important implications for the development of awareness, prevention, and therapeutic interventions. For example, few studies separate out slot machines and video poker even though slot machines are games of pure chance and video poker involves a degree of skill. There may be significant differences in the characteristics of those who participate in, and those who develop problems with, specific types of gambling. For example, "skill" games (e.g. track, sports) tend to be preferred by men and games that promote dissociation and narrowing of attention (e.g. electronic games, slot machines) appear to be preferred by women. In addition, games vary tremendously in terms of the speed of play, size of bet, prize structure, frequency of wins, and the role of skill.

Although each type of gambling may be conceptually distinct from another and may require different approaches to treatment, most theoretical models of problem gambling have tended to be nonspecific with respect to the type of gambling, emphasizing the putative mediating or latent variables that may underlie diverse gambling forms and generally disregarding phenomenology.

Some studies have reported differences based on gambling type. For example, gamblers on horse racing, slot machines, and mixed form gamblers treated residentially did not differ on measures of boredom proneness, depression, and sensation seeking. However, reaction times of slot machine gamblers tended to be quicker for slot machine-related words and slower for track-related words with the reverse pattern observed for racing gamblers. In a comprehensive study, treatment-seeking gamblers were compared on the basis of their preferred gambling activity (i.e. sports, racing, cards, slots, lotteries) differed in South Oaks Gambling Screen (SOGS) scores (i.e. racing gamblers the highest), gambling frequency (i.e. lottery players the highest), money wagered (i.e. racing gamblers the highest), years of problem gambling (i.e. racing gamblers the highest), and Gamblers Anonymous (GA) participation (i.e. least likely by lottery players) as well as in patterns of psychiatric illness and addiction. Horse/dog race gamblers tended to be less educated, men, and older with an earlier onset of gambling. Demographic variables also distinguished the gambling subtypes. Sports gamblers tend to be younger men with relatively higher rates of addiction comorbidity. Electronic gaming gamblers (e.g. slot machines) were more likely to be female and older with higher rates of psychiatric comorbidity and later onset of gambling. The lottery gamblers tended to have both alcohol and other psychiatric comorbidity and the highest frequencies of gambling.

Gender appears to affect the choice of gambling activity. Women preferred nonskill/nonstrategic forms of gambling such as bingo and slot machines, whereas men preferred skill/strategic types of gambling such as sports and track gambling. Gambling choice may also reflect gender differences in motivation for gambling (i.e. emotional dampening versus excitation).

Many have suggested that there are at least two main subtypes of gamblers: (1) overstimulated gamblers, who are attracted to types of gambling that may soothe or diminish dysphoric emotional states by engaging in games that promote dissociation or narrowing of attention (e.g. slot machines, electronic gaming) and (2) understimulated gamblers, who are drawn to games that provide stimulation and arousal (e.g. sport betting, race track betting, craps). These two models have been incorporated into the Pathways Model, a synthesis of the available knowledge on the determinants and variables associated with developing problem gambling, including the data on the biological correlates of gambling. Three main pathways that lead to problem gambling have been distinguished: behaviorally conditioned (BC), emotionally vulnerable (EV) (i.e. overstimulated), and antisocial impulsivist (AI) (i.e. understimulated) gamblers. The Pathways Model assumes all gamblers, independent of pathway, will be influenced by gambling availability, operant (i.e. schedules of reinforcement) and classic (i.e. stimulus control) conditioning, and irrational beliefs.

The EV gambler generally demonstrates higher rates of mood and anxiety symptoms, proneness to abuse psychoactive substances, relies on gambling to cope with negative mood, poor problem-solving skills, higher levels of psychological distress, fewer legal problems, and dysfunctional family history. Women tend to have a greater representation among the EV subtype, consistent with studies that have found affective disorders and escape gambling more prominent among female problem gamblers.

The BC gamblers are sensitive to irrational and distorted beliefs about gambling, show evidence of poor decision making, often lack any concurrent psychiatric comorbidity, do not have a familial psychiatric history, and tend to show lower severity of gambling problems. BC gamblers may often be underrepresented in treatment-seeking populations.

The AI gambler tends to show the highest severity of gambling and substantial psychopathology, have lower educational attainment, are predominately male, and show evidence of neurochemical and neurological disturbance. Character dysfunctions are common in this subtype, especially those associated with antisocial personality, impulsivity and attention deficits, addictive behavior, suicidality, criminality, and low frustration tolerance.

SCREENING AND DIAGNOSING PROBLEM GAMBLING

Accurate identification of disordered gambling is aided by the growing development of assessment instruments specific to gambling pathology. Available tools establish the severity of problem gambling (i.e. degree of involvement, consequences associated with gaming behavior) with the goal of classifying the gambler along a continuum of severity and/or making a diagnosis. Many of the same measures are also used as screening devices to distinguish problem gamblers from nonproblem gamblers.

Screening Measures

One of the earliest instruments to screen for problem gambling, the Twenty Questions (GA-20Q), was developed within GA. Evidence for the reliability and concurrent, convergent, and predictive validity data for the GA-20Q in three independent samples involving 456 participants (two samples of problem gamblers in treatment and a nontreatment sample of problem gamblers) has been established. Classification analyses indicated that the 20Q is comparable with the DSM-IV diagnostic criteria for pathological gambling in specificity, sensitivity, and rates of false-negatives and false-positives.

The SOGS was developed in the mid-1980s and is arguably the most-well known self-report screening tool for gambling pathology. The use of the SOGS has extended from a screening instrument to nonclinical populations and prevalence surveys, raising questions about the psychometric properties and classification accuracy of the SOGS under these conditions. Furthermore, development of the SOGS items was based on the DSM-III and DSM-III-R criteria, and do not reflect the evolution of criteria observed in DSM-IV. Attempting to address concerns with the SOGS and develop a more appropriate measure of problem gambling for use in the general population, the Canadian Problem Gambling Index (CPGI) offers a more "holistic view of gambling" within a social context. The CPGI consists of three main sections: gambling involvement, problem gambling assessment, and correlates of problem gambling (including familial history of gambling); and yields five categories of gambling behavior (ranging from nongambling to problem gambling). Initial studies indicate that the CPGI demonstrates good reliability and validity.

For clinicians and researchers interested in a very brief self-report instrument using DSM-IV criteria, the Lie/Bet questionnaire contains only two items (e.g. need to bet more money, lie about gambling). A three-item version of the National Opinion Research Center DSM Screen for Gambling Problems (NODS), consisting of symptoms related to loss of control, lying, and preoccupation (the "CLiP"), and requiring 1 min to administer has been developed. The CLiP has excellent sensitivity and specificity, and identified almost all pathological gamblers and problem gamblers diagnosed by the full NODS. Recently, a three-item measure, the Brief Biosocial Screen (BBS), has been developed to detect gambling disorders among gamblers in the general household population and treatment seekers. The three symptoms reflect the neuroadaptive aspect (i.e. withdrawal), psychosocial characteristics (i.e. lying), and social consequences (i.e. obtaining money to gamble from others) of gambling. The BBS has been shown to have high sensitivity and high specificity.

Diagnostic Measures

Currently there is no well-established, structured, clinical interview for assessing problem gambling. However, the Diagnostic Interview for Gambling Severity (DIGS) and the Diagnostic Interview Schedule (DIS) Pathological Gambling Module (GAM-IV) have encouraging reliability and validity. Excellent sensitivity and specificity of the DIGS in classifying pathological gamblers in the general population has been reported.

The NODS, a DSM-IV–based telephone screening measure to identify problem gambling has been assessed as a potential outcome measure for gambling treatment studies. Internal reliability was fair to good. The factor structure revealed three subfactors: measuring negative behavioral consequences, preoccupation/impaired control over gambling and tolerance, and withdrawal/relief gambling. The NODS total score correlates moderately with gambling behavior and outcome and the SOGS. The NODS displayed good reliability, concurrent and discriminant validity, and may be a clinically useful screen for gambling problems among patients with substance use disorders.

Practical Issues in Selecting Instruments

There is considerable variability in screening and assessment instruments ranging from as few as two items and only minutes to administer to extensive interviews requiring over an hour to administer. Some instruments can be self-administered; others must be administered by clinicians. Although some measures only indicate the severity of a gambling problem, some measures yield a diagnosis. The SOGS tends to yield higher false-positive rates. DSM-based measures may produce higher false-negative rates, missing individuals with milder gambling problems. The SOGS is ideal when the goal is to identify possible gambling problems; the NODS is to be indicated if the goal is to derive a diagnosis of pathological gambling.

RISK FACTORS AND PROBLEM GAMBLING

Recent efforts to increase our understanding of the psychology of problem gambling has focused on a number of risk factors, including the role of negative affect (depression and anxiety), personality factors (sensation seeking, impulsivity, boredom proneness, extroversion, locus of control, narcissism, and antisociality), concurrent disorders (overlap between gambling pathology and mood disorders, substance misuse, and attention-deficit hyperactivity disorder), gender differences, and the role of cognition (including metacognition).

Very few risk factors for problem gambling have been well established (i.e. supported by more than two studies). Some risk factors with supportive evidence include demographic variables (age, gender), cognitive distortions (erroneous perceptions, illusion of control), sensory characteristics, schedules of reinforcement, and psychiatric comorbidity (obsessive–compulsive disorder, drug abuse), and criminal activity. Relevant research is highlighted below.

Demographic Variables

Age

Age and gambling disorders have consistently been shown to be negatively correlated. Younger people tend to show higher rates of problem gambling than older adults. The earlier the onset of gambling, the greater the probability of developing a more severe gambling disorder. In a longitudinal study of males of low socioeconomic status (SES) beginning at age 11 years, three groups were identified: an early-onset/high gambling involvement, late-onset/high gambling involvement, and a low gambling group. Anxiety and impulsivity during childhood and early adolescence distinguished the early-onset and the nonproblem groups, with the late-onset group falling in between. Gender differences in gambling preferences have been found among adolescents, with boys preferring skill games (e.g. cards) and girls preferring lotteries. Older adults may prefer games that are less competitive and demand fewer cognitive and attentional resources such as bingo, lotteries, and slot machines.

Gender

Men have consistently been shown to comprise a higher proportion of problem gamblers in most jurisdictions throughout the world. An important gender difference has been the "telescoping effect": the observation that women appear to experience a different illness course than men. The interval between the onset of gambling and its recognition as a problem appears to be shorter for women. Gender differences in motivation have also been reported. Women's motivation to gamble was more likely to be associated with feelings of loneliness and dysphoria and escape from personal or family problems, whereas men gambled more for action, excitement, and arousal, and to win money. Electronic gaming machine gambling, in particular, may induce dissociative states that women may rely on to escape from other life problems to a greater degree than men. In a study of treatment-seeking gamblers, a higher proportion of the electronic gaming machines and bingo gamblers were women and a higher proportion of the horse racing, legalized betting, and card gamblers were men.

SES

Lower SES, unemployment, low educational achievement, and low income have been consistently associated with higher rates of problem gambling. Minority status and SES were found to be significantly associated with gambling problems after controlling for gambling behavior, addictive behavior, and other sociodemographic variables. SES may also interact with type of gambling; that is, electronic gaming machine (e.g. slot machines) players tended to be of lower SES than roulette players.

Marital Status

Problem gamblers are more likely to be divorced than nonproblem gamblers. Lower rates of problem gambling among married individuals compared with the divorced or separated have been shown in Swedish, Norwegian, and Australian samples. There is also evidence that married problem gamblers may be more likely to seek treatment.

Psychiatric Disorders

Mood

The association of pathological gambling with depressive mood is one of the most studied risk factors for pathological gambling. Investigations in this area have produced mixed results, with some research initiatives unable to establish a connection between depression and gambling. In contrast, several studies have highlighted the high rates of co-occurrence of gambling and depressive symptoms. Epidemiological studies have reported up to 50% of problem gamblers may have a lifetime mood disorder.

Studies that have assessed directionality between mood and gambling find that the gambling disorder typically precedes the onset of depression. Affective symptoms were equally likely to either precede or follow the onset of a gambling problem in a sample of treated pathological gamblers.

Anxiety

Epidemiological studies have reported up to 40% of problem gamblers may have a lifetime anxiety disorder, with even higher rates among treatment-seeking gamblers (Ibanez et al., 2001). Older samples tend to have high rates of lifetime anxiety disorder (47.5%), obsessive–compulsive disorder (37.5%), and panic disorder (27.5%). Similarities between problem gambling and obsessive compulsiveness have been specifically noted, particularly the preoccupation with gambling and the amount of time spent developing gambling strategies. Obsessive–compulsive factors in lottery and scratch ticket gamblers also showed that pathological gamblers endorsed more symptoms of obsessive compulsiveness compared with recreational gamblers.

Substance Use

Comorbidity between gambling pathology and substance use disorders has often been observed. The majority of pathological gamblers in a national sample of 43 000 respondents had a lifetime alcohol use disorder and 38% had a lifetime drug use disorder. Substance abusers with a gambling problem reported increased levels of somatization, obsessive compulsiveness, interpersonal sensitivity, and paranoia. Problem gamblers with a history of treatment for substance abuse reported more depression, hallucinations, suicidal ideation and attempts, and difficulty controlling violent behavior over their lifetime versus gamblers with no previous treatment for substance abuse.

The relationship between lifetime diagnoses of drug dependence or mood disorder and gambling treatment outcomes in a sample of quit (either with or without formal treatment) gamblers followed up for up to 5 years was studied. Those with lifetime drug diagnoses were less likely to have established a period of abstinence for more than 3 months in duration. Those with a lifetime history of a mood disorder also took longer to establish 3 months of abstinence. Comorbid addictive and mood disorders predicted shorter-term, but not longer-term, gambling abstinence. These results illustrate the importance of assessing lifetime comorbid disorders, which clearly complicate the recovery process for pathological gambling.

Individual Differences

Sensation Seeking

Individuals who are underaroused, prone to boredom, hypomanic, or depressed may value the stimulation and excitement associated with waging higher amounts of money and participating in higher-risk gambling activities; this has often been proposed as an important individual difference between problem gamblers. Sensation seeking has been among the most commonly investigated personality factors among problem gamblers but the results have been unequivocal. Correlation between higher needs for arousal and stimulation and preference for riskier bets has been observed in undergraduate gambling. In a sample of community-recruited problem gamblers, some aspects of sensation seeking (i.e. the boredom susceptibility) were found to correlate significantly with severity of gambling but negatively correlated in a study of pathological gamblers. Horse race gamblers (a "skill" game) sought heightened arousal but electronic gaming machine players (a chance game) appeared to seek dampened arousal. Among youth, sensation seeking was associated with gambling frequency but not with the development of a gambling disorder.

Physiological Arousal

Physiological "rush" or excitement when gambling has often been proposed as a major reinforcing stimulus for gambling. This appears to be supported by research with sports, horse race and dog race gamblers who showed increases in blood pressure and heart rate while gambling. Many studies have demonstrated increased levels of arousal in problem gamblers, especially in ecologically valid settings. In the latter studies, the effects were enhanced when the gamblers played in a real casino versus a laboratory setting. However, not all studies have found a relationship between arousal and problem gambling or even between objective and subjective reports of arousal. Winning during slot machine play was associated with an increased heart rate. An increase in heart rate during electronic machine gambling was observed but only when winning. The positive correlation between winning and heart rate did not require that the gamblers actually needed to ultimately win money.

The inconsistent results in the arousal/sensation-seeking literature, similar to other constructs discussed in this chapter, can be accounted for by a multitude of methodological differences (i.e. measure of arousal, type of gambling, setting, psychometric instruments, demographics, gender). As noted elsewhere, the inclusion of heterogeneous samples of gamblers often introduces variability in the results.

Cognitive Variables

A substantial body of work is devoted to the role of cognitive factors in pathological gambling. Two major beliefs seem to describe the problem gambler's irrational cognition. *Primary illusory c*ontrol, the irrational belief that the gambler can control the outcomes of gambling events, has been distinguished from secondary illusory control, the irrational belief that the gambler can predict the outcomes of gambling events.

Even games that are ostensibly completely random such as slot machines can elicit irrational beliefs about control and prediction. These core beliefs yield a wide array of irrational or maladaptive beliefs about gambling outcomes that have been well described in the literature.

The raw frequency of erroneous perceptions may not distinguish problem gamblers from nonproblem gamblers, at least in a sample of video lottery players. Pathological gamblers were more convinced of the truth of their erroneous perceptions than the nonproblem gamblers. Although the nonproblem gamblers demonstrated a reduction of confidence in their erroneous perceptions as their play continued, the pathological gamblers showed a trend toward increasing confidence over time. These results suggest a role for a metacognitive level of analysis of gambling cognition.

Educating university students on probability theory (e.g. odds) through the use of gambling examples produced differences in the ability to calculate gambling odds and resistance to irrational gambling-related mathematical beliefs compared with those who were instructed on probability theory generically (i.e. without the aid of gambling-related examples). Surprisingly, however, there was no effect on gambling behavior. Mathematical knowledge related to gambling did not translate into a modification of gambling behavior. In another study, individuals who were reminded about the independence of events reported a decreased motivation to pursue playing roulette and made fewer erroneous perceptions.

Early Childhood Experiences

Rates of abuse and neglect among problem gamblers are higher than among nonproblem gamblers. Almost two-thirds of gamblers attending a residential treatment facility reported a history of emotional trauma, 40% reported a history of physical trauma, and 24% a history of sexual trauma, mostly during childhood. All females reported some form of abuse compared with 61% of the males. A positive history of childhood trauma was associated with suicidal, addictive, and psychiatric symptoms.

Influence of Parental Gambling

Adult problem gamblers have reported higher rates of gambling behavior by their parents compared with nonproblem gamblers. In a study of high school students, probable pathological gamblers reported higher likelihood of parental gambling, suicide attempts, alcohol and drug misuse, and peer pressure susceptibility. The transmissibility of gambling-related irrational beliefs in nonproblematic video lottery play was demonstrated in a study that found the father's gambling-related cognitions and behaviors were most strongly correlated with their offspring's gambling behavior. In another study, subjects took greater monetary risks while playing video lotteries in the presence of an accomplice who had expressed erroneous cognitions about gambling but not in the presence of an accomplice who had expressed rational beliefs. These results may help explain how childhood exposure to gambling environments affect gambling behavior later in life.

PSYCHOLOGICAL TREATMENT OF PROBLEM GAMBLING

The psychological treatments that have been evaluated in controlled trials can generally be classified as brief and cognitive-behavioral in orientation. The focus has generally been placed on directly modifying gambling-related behaviors and cognitions, and in developing behavioral and cognitive coping skills to reduce gambling frequency, gambling expenditures, or urges using problem-solving, practical, and pragmatic approaches. Several reviews of the controlled treatment literature have shown cognitive-behavioral treatment (CBT) approaches to be supported with the best empirical evidence, although this finding generally reflects the fact that non-CBT studies tend to be evaluated less frequently. The better-designed cognitive-behavioral studies have obtained long-term improvements in gambling of between 50 and 75%.

CBT

Cognitive-behavioral techniques to treat pathological gambling have included alternative activity planning, problem solving, limit setting, social skills, communication training, relapse prevention, stimulus control, and in vivo exposure. Individually administered response-prevention treatment was superior to group cognitive therapy or the combined treatment at the 1-year follow-up with no group differences between the active treatments for any of the other dependent variables (e.g. frequency of gambling). The addition of cognitive therapy was not found to be differentially more effective than behavioral treatment or a combined CBT.

Slot machine gamblers who were first treated with stimulus control and in vivo exposure followed by response prevention until abstinent was achieved were subsequently randomly assigned to one of three relapse prevention (RP) modalities: individual RP, group RP, and no-treatment control. Significant differences in abstinence rates between the two RP groups (which did not differ) and the no-treatment control group

emerged at 3 months after treatment and were maintained throughout the 12-month follow-up.

Due to high attrition, compliance enhancements (e.g. follow-up letters, positive reinforcement, increased self-efficacy) were added to a cognitive-behavioral intervention. Subjects who received the compliance enhancement completed the eight-session program at a higher rate (65%) compared with those randomly assigned to the standard CBT (35%) but there were no group differences on measures of improvement (e.g. SOGS, % net monthly income gambled) or at the 9-month follow-up.

Node-link mapping-enhanced cognitive-behavioral therapy (CBGT mapping) was compared with 12-step facilitated (TSF) treatment. A wait-list control group was also included. The group treatments resulted in significant improvements on the dependent measures, while the wait-list group showed little change. Improvements were found on DSM-IV criteria, self-efficacy, and gambling episodes. Both intervention groups sustained treatment gains at the 6-month assessment but demonstrated no significant differences in terms of gambling outcomes. Relatively few TSF members attended GA, indicating that attending GA meetings may not be necessary for treatment to be effective.

Eight sessions of CBT or the 12-step treatment-oriented approach (based on the first five steps of GA) were compared in a quasiexperimental research design. At 12 months after treatment, there were no group differences on key gambling variables (e.g. frequency, abstinence rates, money wagered) in an analysis of completers, with both treatments significantly reducing the frequency and amount of money spent on gambling. Participants who attended more sessions and chose an initial abstinent treatment goal seemed to achieve better outcomes.

In one of the largest evaluations of CBT, pathological gamblers were randomized to GA, GA referral plus a self-directed CBT manual (eight chapters), or GA referral plus individual CBT (eight sessions) with a 12-month follow-up. Primary outcome variables were symptom severity scores, days of gambling, and money gambled. Patients in the GA referral plus individual CBT group had significantly greater improvement than patients in the GA referral only group on all primary outcome measures and greater longer-term benefits relative to the other two groups.

An integrated 14-week treatment for comorbid problem gambling, anger, and substance use randomized to either treatment of anger and addictions or treatment-as-usual (TAU) for gambling and substance use showed that the integrated anger and addiction treatment showed significantly less gambling after treatment and at follow-up and less trait anger and substance use at the 1-year follow-up.

A sample of inpatient pathological gamblers treated with CBT found over half of the sample abstinent at the 1-year follow-up and an additional 16.3% were abstinent until the last 3 months of the follow-up. However, the low follow-up response rate of just over half of the initial sample (i.e. 52%) limits the generalizability of the study. Patients who relapsed reported higher psychological distress at the end of treatment and at follow-up and lower quality of life at follow-up.

Cognitive Treatments

Although treatments targeted at correcting cognitive distortions are effective, it is too early to tell whether treating cognitive distortions is a prerequisite for successful gambling treatment outcomes. Research on cognitive pathology specific to different types of gambling is underway (e.g. slot machines; lottery players), but much more is necessary before the cognitive characteristics of different types of gambling and their role in the course of problem gambling is understood.

Several randomized control studies attest to the efficacy of cognitive treatment for problem gambling. Cognitive intervention targeting erroneous beliefs found significant reductions in gambling severity, frequency of gambling, and amount wagered compared with the wait-list control group in several studies with results maintained at a 12-month follow-up in some studies and up to 2 years in others.

Although cognitive distortions among problem gamblers have been well established, less is known about whether treating cognitive distortions is more effective than other therapeutic approaches to gambling. Four brief, six-session, homogeneous treatments for problem gambling (i.e. cognitive, behavioral, motivational, minimal intervention) were compared in a sample consisting primarily of middle-aged, unmarried, underemployed men recruited from the community. The results demonstrated that a cognitive approach was not superior to the three other treatments, which did not explicitly address cognitive distortions. There are likely multiple pathways to therapeutic change that may not necessarily require the modification of gambling-related cognitive psychopathology.

Brief and Motivational Interventions

In recent years brief treatments for problem gambling emphasizing brief motivational interventions (BMI) have emerged. A unique aspect of BMI is the willingness to acknowledge and accept ambivalence about modifying gambling behavior. A firm commitment for change is not insisted upon, and participants are encouraged to discuss the pros and cons of gambling. BMI encourages the exploration of the values and principles that govern

their life without demanding change or assigning judgment.

Combining BMI with CBT may help reduce dropout rates. A brief minimal intervention for gamblers compared a self-help manual with the manual plus telephone/postal contact. The manual-only group reduced the number of gambling sessions per week and dollars wagered per week for the 6 months after receiving the manual, whereas the manual/interview subjects showed a reduction between the interview and 3 months only.

Two versions of a self-help manual based on CBT (i.e. mailing the self-help manual versus preceding the mailing of the manual with a telephone BMI reviewing assessment information and enhancing commitment to change) were compared with a wait-list control group. Significant reductions in gambling behavior were reported by 84% of subjects over the 1-year follow-up period. An initial superior outcome demonstrated by the BMI plus manual group over the manual-only group was evident at the 3-month follow-up but not at 12 months, except for gamblers with less severe gambling.

The efficacy of a single BMI session compared with a no-treatment control interview showed that the BMI condition significantly reduced gambling expenditure and gambling days per month and led to less emotional distress than the control condition at the 1-year follow-up. However, problem gambling severity decreased (as measured by the SOGS and CPGI) in both conditions. The provision of the self-help manual, which the no-treatment control received, may have reduced between-group differences.

A comparison of four groups of non–treatment-seeking gamblers (no-treatment control, 10 min of brief personal feedback and gambling advice, a 50-min motivational enhancement session, or one session of motivational enhancement plus three sessions of CBT) showed that those in the brief advice condition showed significantly decreased gambling compared with the no-treatment control group during the 6-week study period. No additional gains were made in the remaining 9 months of the follow-up period. The motivational enhancement group did not differ from the control group. Those in the motivational enhancement plus CBT group were no different from the control group during the 6-week study period, but were significantly better on some outcome measures throughout the 9-month follow-up period.

A comparison of four sessions of motivational interviewing (MI) and eight sessions of CBT with a wait-list control found both treatments were superior to the control group on a measure of severity (i.e. NODS) and depression but on no other outcome measure. There were no differences between MI and CBT post-treatment or throughout the follow-up period although both treatments showed significant within-treatment gains. High rates of attrition (mean of 5.6 out of eight CBT sessions attended; mean of 0.9 sessions out of four MI sessions attended) compromised the generalizability of the findings. In this study, the no-treatment control group made significant gains on the basis of non–treatment-related factors (i.e. due possibly to intrinsic motivation natural recovery).

Subtyping and Treatment Outcome

Treatment-seeking pathological gamblers were classified according to the subtypes described in the Pathways Model and evaluated as to whether there would be a differential benefit from CBT or GA referral through a 12-month follow-up. Compared with BC gamblers, EV gamblers had higher baseline psychiatric and gambling severity, and were more likely to have a parent with a psychiatric history. AI and EV gamblers experienced greater gambling severity throughout treatment than BC gamblers, but all three subtypes demonstrated similar positive responses to treatment and improved at similar rates. As a result, the EV and AI subtypes demonstrated greater problem gambling severity post-treatment and during the follow-up period relative to BC gamblers due to higher gambling severity before treatment. Subtyping problem gamblers according to the Pathways Model may not be useful for making specific treatment recommendations.

Meta-analysis of CBT

Meta-analyses of CBT or variants show that three forms of CBT (generic CBT, MI, or combined MI/CBT) demonstrated large and significant effect sizes through follow-up periods of up to 2 years, suggesting the enduring effects of CBT despite variability in populations being treated, recruitment methods, gambling severity, treatment type, outcome measures, and study design. Although this result lends support to the use of CBT, it cannot be used to claim that other treatments would be ineffective. Few studies directly compare two different treatment modalities.

Although the heterogeneity of gambling problems may preclude a single therapeutic approach to CBT, this modality was effective regardless of the type of problem gambling at both the 3- and 6-month time windows. This indicates that there is a common mechanism underlying gambling behavior that can be targeted by CBT regardless of how the gambling behaviors are phenomenologically expressed. An alternative pathway for the clinical efficacy of CBT is that gambling behaviors are not directly affected by CBT at all. Comorbid psychiatric syndromes (e.g. mood, anxiety) may improve first

with a concomitant reduction in gambling behaviors as a consequence. Metaregression effects suggest that treatment outcome is independent of the therapy length. This is encouraging for brief therapeutic programs as several studies have demonstrated that a one-session, motivational intervention could perform as well as longer (i.e. six sessions) CBT.

A closer study of efficacious treatments for problem gambling reveals that they tend to be multimodal, combining cognitive, behavioral, and motivational interventions. Thus, it is difficult to evaluate which class of interventions is the most effective in effecting clinical change. This can be a serious weakness in the formulation of optimally effective treatment for problem gambling given the brief duration of contact between problem gamblers and the treatment system and high attrition rates among gamblers in treatment. To maximize the impact of treatment and reduce the risk of noncompliance, dropout, and relapse, treatments should strive to include only those interventions that have been empirically supported.

PHARMACOLOGICAL TREATMENTS OF PROBLEM GAMBLING

A wide variety of medications have been evaluated for their efficacy in the treatment of problem gambling. Two classes of medications have received considerable experimental investigation: opioid antagonists and antidepressants.

Opioid Antagonists

Two opioid antagonists, naltrexone and nalmefene, have been studied in several double-blind, placebo-controlled, randomized trials. Naltrexone-treated patients were more likely to improve (75%) compared with patients in the placebo condition (24%). Effects on actual gambling behavior were not reported in either study. Post hoc analyses in one study further support the hypothesis that pharmacological manipulation of the opiate system may target core symptoms of pathological gambling. However, naltrexone was not superior to placebo in reducing alcohol and gambling behavior in a concurrently comorbid population of alcohol-dependent/abusing pathological gamblers.

Antidepressants

Several antidepressants have also been evaluated with mixed results. Fluvoxamine and paroxetine have been shown to reduce gambling expenditure and time spent gambling in double-blind placebo-controlled studies. As no data on actual gambling behavior were collected, it is not known whether paroxetine actually modified gambling behavior. Fluvoxamine was compared with topiramate, an anticonvulsant that targets gamma-aminobutyric acid (GABA)ergic and antiglutamatergic mechanisms, in a randomized, blind-rater comparison study. Rates of abstinence were equal in both groups (75%) but the rate of attrition was much higher in the fluvoxamine group (50%) compared with 20% in the topiramate group.

Based on the available research, there is no compelling empirical evidence for the efficacy of any medication except for naltrexone. To date, no medication has been approved for pathological gambling by the US Food and Drug Administration.

SUMMARY OF TREATMENT EFFICACY

Review of the best-designed treatment studies indicate that CBT and pharmacological treatments for gambling can be judged as possibly efficacious. No specific modality or intervention has been found to be unequivocally effective by at least two independent research teams. The significant findings for CBT have usually been reported in comparison with wait-list controls and less often against other credible treatments. CBT, even when delivered via a manual and involving only minimal therapist contact, has the most empirical support compared with no treatment. Among the medications that have been studied, there is some limited support for naltrexone. However, it is not possible to determine which specific type of CBT or medication is most effective or whether CBT is more effective than other treatment options.

The issue of attrition remains an important methodological issue to consider in evaluating treatment efficacy, given its common occurrence. Among gambling treatment studies published between 1982 and 2005, rates of attrition in pharmacological treatment studies ranged from 11 to 40% (in short-term studies) and from 48 to 59% (in long-term studies). Between one-third and one-half of subjects in psychosocial treatment studies dropped out of treatment; the rates of attrition in community multimodal treatments ranged between 29 and 83%. GA treatment studies showed similar rates of attrition (i.e. 50–69%). Although there is evidence that more treatment is generally associated with better outcomes, some recent work has challenged this finding.

Placebo/nonspecific response to treatment by problem gamblers has often been identified as a factor common to both pharmacological and psychosocial treatments. High rates of placebo response rate (up to 72%) have been reported. The average rate of placebo response among pathological gamblers is estimated to be ~40%. Observations that one-third of early treatment

dropouts and treatment referrals who did not engage in treatment were abstinent from gambling at the 6-month follow-up suggest that placebo or nonspecific response can account for the benefits of treatment. Nonblinded studies with nonequivalent control groups are more likely to overestimate treatment effects by including nonspecific effects with the specific benefits of treatment.

Implications for Delivery of Treatment

With the prevalence of concurrent addiction and psychopathology common among gamblers well established, appropriate screening for such comorbidity and determination of the primary disorder should influence decisions about appropriate treatment (most likely a combination of psychological and pharmacological therapies). Very little research has investigated the outcomes following the combination of validated psychological therapies and medications.

For gamblers who do not have a concurrent disorder, the initial intervention should strive to increase the individual's commitment to treatment and resolve treatment-disrupting ambivalence as much as possible through BMI. Motivational treatments may serve this purpose and thus reduce the relatively high rates of dropout found in most gambling treatment studies. The high attrition rates suggest that more effort must be made to strengthen the client's motivation to change.

With strengthened motivation, the available empirical research suggests that CBT, generally brief and delivered on an outpatient basis, seems to be the most effective treatment. Concurrent pharmacotherapy (i.e. naltrexone, selective serotonin reuptake inhibitors) remains promising as an adjunct to psychosocial treatment, but is insufficiently empirically validated at the present time.

OUTLINE

DEFINING CYBERSEX

As Internet has become a popular medium all over the world, more and more individuals are engaging in various kinds of sexual exchanges online. Cybersex, Internet sex, net sex, or computer sex refers to an enormous range of real-time sexual encounters by using computer-mediated interactive technologies. This rapidly growing phenomenon has drawn much attention due to its novelty since the 1990s.

Cybersex can be defined as a subcategory of online sexual activity where Internet is used for sexually gratifying activities. In the computer-mediated communication environment, cybersex participants engage in various sexual experiences, and Internet has become a virtual playground for sexual encounters. Cybersex is a kind of interactive erotic experience, which usually involves two or more participants having sexual exchanges online with the purpose of sexual arousal and stimulation.

Participants connected remotely via a computer network interact with one another through sexually explicit messages, such as typed text, live video, and various digitized sexual content, written, auditory, or visual. Cybersex is commonly performed in Internet chat rooms and on instant messaging systems. Newsgroups and online role-playing games can also be the starting points for cybersex. Individuals engage in cybersex in many ways but basically, two forms are most prevalent: text cybersex and televideo cybersex. Cybersex users engage in simulated sex talk while online for the purposes of sexual pleasure and may or may not include masturbation. Cybersex can either be a goal in itself or may serve as a first step toward a real-life encounter. Related activities include phone sex with people met online, and online affairs that progress to skin-to-skin sex.

TEXT CYBERSEX

Text cybersex refers to a form of role-playing in which the participants pretend they are having actual sexual relations through real-time written communication of

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00081-4

erotic-sexual content. The conversations vary, ranging from flirting and talking dirty, to very detailed descriptions of having intercourse.

In text cybersex, participants try to get mutual stimulation by describing their sexual fantasies in detail and responding to their chat partners. Through online chat, people type out their appearances, erotic actions, utterances, touches, feelings, and happenings to one another. In this way, text cybersex participants make online chat to be a personalized interactive arena for sexual experience by provoking, constructing, and playing out sexual encounters.

To a certain degree, the online "hot" chats or sex talk can be seen as extensions of telephone sex and party lines. Similar to telephone sex, text-based cybersex is purely communicative, without co-present bodies and actions. While different from phone sex, there can even be no spoken words. Thus, text cybersex is a form of co-authored erotica interactively crafted by anonymous participants in a process of communication.

The use of language in text cybersex is often creative, since the whole experience depends on the exchange of detailed and intimate typed conversations. The quality of a cybersex encounter typically depends on the participants' abilities to evoke a vivid, visceral mental picture in the minds of their partners. Text cybersex participants usually draw from a vast repertoire to describe the enormous range of bodily sensations which typically accompany sex, such as appearances, expressions, gestures, odors, and physical sensations, which may require expansive vocabulary and an active imagination based on some communicative and sexual literacy. Some participants may also exchange pictures or short movies of themselves or erotic pictures and movies found on the web to accompany the otherwise text-based communication.

TELEVIDEO CYBERSEX

Although televideo cybersex entails considerable text communication as well, there are significant differences between the two. In televideo cybersex, participants can see and respond to one another in real time, by using web cameras and client software. Therefore, in addition to "hot" chat, televideo participants can see each other in live streaming video, including what they look like, what they are (or are not) wearing, where they are, their moment-by-moment expressions, and what they are doing (often to themselves). In this way, televideo cybersex participants can be regarded as simultaneously live erotic performers and consumers, casual voyeurs, and exhibitionists all at once.

As part of sex, stripping and being seen naked is an erotic experience in televideo cybersex. Some participants are excited just because someone wants to see their naked bodies. Dennis Waskul, an expert in cybersex from the field of sociology, suggests that to a certain extent, televideo cybersex can be seen as a loose form of semi-public nudity. Unlike nude beaches, nudist resorts, and Finnish saunas, where nakedness is anti-erotic, the nude body in televideo cybersex is intentionally displayed in an explicitly sexual manner for the purposes of giving and receiving sexual attention and/or arousal. For the majority of participants, televideo cybersex involves a kind of looking-glass eroticism. The viewing pleasures for televideo cybersex participants include both the live moving images of the bodies of other people and the interactive exhibitional imagination. The interactivity of being watched is exciting, fun, and erotic for televideo cybersex users.

Different from the for-profit live webcam performances or services, televideo cybersex refers to those casual and usually anonymous televideo sexual encounters among participants who do it for enjoyment, for sex, and for free, without considering internet service provider (ISP) fees, cost of the digital camera, and cost of the client software. Couples, either heterosexual or homosexual, sometimes connect with each other or other couples in televideo cybersex, but more often, these erotic encounters occur between people who do not know one another and whose interaction is merely for the purposes of casual and immediate sexual gratification.

CYBERSEX AND REAL-LIFE SEX

With the transmission of sexual fantasies via the Internet, for some individuals, cybersex becomes the online equivalent of engaging in sex in real life. Cybersex is such a distinctive kind of sexual activity that it seems to contradict the conventional definition of sex with interaction between physical bodies. The major difference between cybersex and real-life sex is that participants are making virtual love, since it is a cognitive and emotional exchange rather than a physical one.

Different from real-life sex, individuals do not interact directly with the bodies in cybersex. Therefore, the physical barriers which can be found in real-life sex are not present in cybersex. Participants engaging in cybersex create new configurations of sexual experience within the interaction through words and images. By taking away the physical aspect of sex, cybersex is an act of communication with both sides participating to keep the fantasy alive; therefore, it is usually less one-sided than many sexual relationships in real life.

Generally, cybersex can be more spontaneous and adventurous than real-life sex. It is often much easier

to meet someone online in cyberspace than in real world offline. In the real world, it may take days, weeks, or months to cultivate a sexual relationship, while things progress more rapidly online. People often get to the point much faster in their cybersexual encounters, and take more risks than in a traditional face-to-face setting.

Cybersex can be a way for some participants to express themselves sexually in a way in which they may not feel comfortable in a real-life relationship. Anonymity regarding self-disclosure and intimacy is a key factor to consider when studying differences or similarities between cybersex and real-life sex. Typically, persons who engage in cybersex find each other on the Internet and have never met before in real life. Participants feel less inhibited to express their sexual desires due to the anonymity, and they collaborate on a rich sexual fantasy.

Cybersex allows real-life partners who are physically separated to continue to be sexually intimate. In geographically separated relationships, cybersex can have an important function in sustaining the sexual dimension of a relationship in which the partners see each other only infrequently face to face. Although some cybersex participants may develop long-term relationships or even intimate real-life relationships offline, most of the time cybersex experience is anonymous, fleeting, and casual.

APPEALS OF CYBERSEX

The Internet has several characteristics that make it an attractive venue for sexual pursuits. It is widely accessible, affordable, legal, available in the privacy of one's own home, anonymous, and does not put the user at direct risk of contracting a sexually transmitted disease. Other factors include convenience, escape, and social acceptability. In addition, the ability of people using the Internet to approximate, or experiment with, different aspects of sexuality or sexual practices online may also be important. The Internet may allow for sexual experimentation in a forum that seems safer. Unlike print, video, and film pornography, cybersex is interactive, through real-time exchanges of words, pictures, and videos. This enables people to experiment with, and experience, an activity closely, without actually engaging in physical sex, to become psychologically and physically (in an autoerotic sense) familiar in the context of a virtual encounter.

Although cybersex may be regarded as virtual compared to those real face-to-face sexual experiences with interactions between corporeal bodies, it can be meaningful and sometimes even highly valued by some participants, more than a novel masturbatory innovation. Cybersex has become so popular because participants regard it as safe sex, full of fantasy appeal, and sometimes with therapeutic values.

SAFE SEX

The absence of physical bodies promotes the perception of cybersex as a safe alternative to real-life sexual encounters. Cybersex can satisfy sexual desires without the risk of sexually transmitted disease or pregnancy. Cybersex participants can have various kinds of sexual activities by just sitting safely behind their personal computers, and without talking to each other if they do not want to. It can be a physically safe way for young people to experiment with sexual thoughts and emotions. In addition, people with long-term ailments including HIV can engage in cybersex as a way to safely achieve sexual gratification without putting their partners at risk.

Anonymity can provide security and be a protector and a liberator. Participants regard the Internet as a safe technological medium to express or explore different aspects of their sexuality in almost complete anonymity. By taking advantage of the anonymity of cybersex, participants feel safe to share sexual intimacy online. Participants can delete or create a new screen name, if any adventure becomes unpleasant or uncomfortable. Therefore, cybersex becomes a safe outlet for interests and desires which are difficult to be expressed in real life. Anonymity can also help unsociable or stigmatized people because there are no social sanctions, embarrassment, or fear of negative reactions. In addition, the distance afforded by computer-mediated technology adds one more element of safety for the cybersex participants, because cybersex can always stop at the keyboard.

FANTASY APPEAL

Cybersex offers a private, safe, and anonymous way to explore fantasies. The excitement from taking risks without anyone finding out can be part of the appeal of cybersex for some participants, and some cybersex participants may find it erotic just by not knowing who is really on the other end. Anonymity as an important element of cybersexual experiences gives cybersex participants greater sexual freedom. It could be sharing secret sexual fantasies or creating an interactive sex novel. Cybersex provides an opportunity for people to explore and express their most private sexual fantasies. Because of the anonymity, cybersex participants live out their fantasies by doing whatever

they want and taking any identity they wish with no inhibitions.

Another important element of the eroticism of cybersex is that it offers opportunities for participants to playfully toy with alternative vicarious experiences, which they would not or could not try in real life, or in other cases have no intention of trying offline. There are endless possibilities in cybersex for identity change, such as a different gender, race, or even species. Cybersex creates an opportunity for participants to try kinds of sexual fantasies, which are normally hidden or controlled in real life. Compared with real-life sexual encounters, it is relatively easy to find someone to share personal sexual fantasies online.

For some participants, cybersex provides a novel mechanism for them to explore and cultivate sexuality. By exploring cybersex, experimenting and receiving real feedback from partners become quite easy due to anonymity. Some cybersex participants claim that they have learned new sexual techniques and turn-ons, which expand their repertoire of sexual behaviors. By acting out of fantasies, cybersex may help some participants' real sex lives.

THERAPEUTIC VALUES

Some cybersex participants think the enjoyable sexual experiences online also have therapeutic values. For example, some individuals may have a long-standing conflict between internal desires and outside pressures, for fear of punishment or social rejection. For some participants, cybersex can be a way to explore their hidden sexual desires, or free their suppressed sexual desires and needs, which they would never express in real world. It can be a tremendous relief for them. Some ethnographic studies of the online bondage, discipline, sadomasochistic (BDSM) subculture suggest that cybersex may be freeing and helpful in terms of identifying and enacting parts of the person that would otherwise never have surfaced.

As another way to connect to people or to achieve intimacy, cybersex experiences can grow to be a source of comfort for some participants. Relationships can be formed online, such as regular cybersexual encounters, and may become more real as they progress from "hot" chat in the virtual world to direct contact in the real world. For some people, the attention they receive in cybersexual experiences can serve to increase appreciation for and assessment of themselves, and make them feel sexy and attractive.

As for some cybersex participants, it is the escape appeal that entices them go online. They go online to escape the demands and responsibilities in real life for a short time. Besides, without the emotional baggage of performance anxiety in real-life sex, the pressure of having to perform or please a partner seems to disappear in cybersex. Some cybersex participants may have deeper problems in their own primary relationships, and cybersexual experiences may improve their sex life in the real world.

RISKS OF CYBERSEX

Although participants point out a variety of sexual and other personal benefits from online sexual experiences, cybersex also has some potential risks. Online sexual problems include the full range of difficulties that people can have when engaging in cybersex. This would include negative financial, occupational, legal, relationship, and personal repercussions from cybersex. These problems may result from a one-time incident or a pattern of excessive involvement, and the consequences might range from feelings of guilt to loss of a job or a relationship.

EMOTIONAL RISKS

In some cases, engaging in cybersex may pose some emotional risks. Cybersex participants may try something that goes beyond his or her normal comfort range. Some online survey found that cybersex seduces some users into crossing boundaries into sexual thinking, fantasy, longing, and activities in which they may do not want to participate. Some cybersexual encounters can be quite psychologically damaging. Moreover, the issue of sexually related Internet crime, such as cyberstalking, sexual harassment, and molestation may also be imported into cybersex. Some researchers have suggested that the use of cybersex may be counterproductive to normal, healthy sexual development in certain individuals.

Cybersex is usually associated with no necessary commitments. Many people participate in cybersex just for enjoyment, without any intention to take the relationship further. While some individuals enjoy cybersex because of the lack of commitment, others may find this disappointing. For someone who has built an intimate relationship with his/her cybermate, a sudden loss may occur when one individual disappears without warning and the relationship ends abruptly. Someone may feel hurt and angry when he/she goes online find his/her cybermate has vanished, leaving no trail to follow. Such a sudden loss or cyber breakup can be emotionally upsetting. Therefore, for those who are seeking a long-term committed

relationship, they need to be careful when getting too emotionally involved.

CROSSOVER INTO REAL LIFE

The speed and capabilities of the Internet when combined with sexuality have produced far-reaching social impacts beyond the confines of cyberspace. Some cybersex activities may progress to offline sexual encounters with other people. One concern that has become a focal point of social and political action is access by minors to cybersex. Some adolescents may try cybersex as a form of sexual gratification by engaging in various kinds of online relationships, which can be dangerous if they lead to real-life activities, such as underage sex.

Cybersex allows individuals to try out sexual fantasies free of sexual boundaries and limits; however, some extreme fantasies tap into taboo areas. Researchers have studied criminal and deviant use of the Internet and posited that the instant gratification of cybersex provided certain reinforcement for the operationalization of sexual fantasies that would otherwise be extinguished. Some scholars warn of the potential for cybersex to be used as a means of luring children into assignations. Online pedophiles typically masquerade as young people.

Cybersex veers away from healthy sexuality when it interferes with normal responsibilities, causes distress, or becomes out of control. Some cybersex users are reported to get further and further into the bizarre, losing interest in their previous sexual activities and partners, and seeking more and more unusual experiences. Researchers have noted the danger of individuals neglecting their real-world relationships by spending increasing amounts of time engaged in virtual relationships. Some participants may be at great risk for developing a cybersex addiction. A number of self-score questionnaires are available to help cybersex participants judge whether their online activities are causing problems.

Cybersexual experiences can undermine or destroy marriages. Debate continues on whether cybersex is a form of infidelity. Many cybersex participants tend to treat cyberaffairs as nothing more than a harmless form of erotic entertainment since it does not involve physical contact; however, many significant others view cyberaffairs as a definite violation of trust and a serious threat to the marital relationship. In some cases, cybersex can cause such great stress that it can lead to a breakup in real-life relationship. The risks to participants' current relationships in real world need to be considered. Some moral and legal issues may also get involved for those engaging in cybersex.

Another potential risk of cybersex is related to privacy issue. Especially for televideo cybersex, there is the possibility for extreme embarrassment for the participants, since the images can be saved, and even reproduced and distributed. Therefore, with the vulnerability of showing one's face, some televideo cybersex participants choose to keep their face conspicuously absent from images of their body, otherwise cybersexual experiences may carry much emotional weight or pressure in their real life. In addition, the anonymous nature of cybersex permits rather cruel pranks. The intimacy of cybersex may in some cases be rudely shattered by pranksters who solicit cybersex, but with the actual intention to post the logs in public. Many guides for netiquette warn against this.

Another privacy concern is false identity. Role playing and misrepresentation is a typical feature of cybersex. The nature of the Internet as a medium makes it very easy to exaggerate or misrepresent the facts. In cybersex, participants develop various virtual identities, distorting important aspects of themselves and even pretending to be of the opposite sex and of a different age. The virtual identities can go from slight exaggerations or variations to complete fabrications. They are often not easy to detect. Some individuals may feel hurt and ashamed by knowing the true identity of their online partners afterward. When online relationships move from online to offline, in many cases, reality frustrates the fantasy.

CYBERSEX PARTICIPANTS

Researchers propose that not all cybersex users are similar. The majority of participants who engage in cybersex report that their use does not lead to problems in their lives. Nevertheless, for a small but significant minority, cybersex generates serious problems. Studies have been conducted to contribute to an understanding of cybersex participants. Studies led by Al Cooper show that there are three general categories for cybersex users: recreational users, at-risk users, and sexually compulsive users.

Recreational users engage in cybersex exploration more out of curiosity, or for entertainment or experimentation purposes. They are usually satisfied with their online activities, without feeling guilty or ashamed of them. These users engage in cybersex as a casual entertainment and not to an extent that it has any serious negative impact on their life. They tend to maintain reasonable levels of involvement, often become bored or indifferent over time, and decrease or discontinue the activities.

At-risk users have no prior history of sexual compulsivity, yet they may become vulnerable when facing the

accessibility, affordability, and anonymity provided by cybersex, and spend substantial time and energy on cybersex activities. For these participants the power of cybersex interacts with certain underlying personality factors and can lead to patterns and behaviors that, without intervention, may develop into online sexually compulsive behavior. Two subtypes have been described: stress-reactive and the depressive types. The stress-reactive subtype is characterized by the tendency to engage in cybersex during times of high stress. These individuals use cybersex as a temporary escape, distraction, or means of coping with uncomfortable feelings that arise from stressful situations. The depressive subtype seeks relief from depression, dysthymia, and/or chronic difficulties accessing any emotions through their use of cybersex.

The sexually compulsive group is composed of those users who have past or present difficulties with sexual issues in their lives. They, like the others, simply find the Internet to be an effective venue by which to pursue their sexual interests. Unfortunately, their cybersex experiences may escalate the problem, often resulting in clear and significant difficulties in their lives. Sexually compulsive users suffer varying degrees of consequences from their pathological cybersex. In some studies, sexually compulsive users are defined sexual by a compulsivity scale combined with time online, which result in distress and interference with their lives. This group report higher levels of distress around their online sexual pursuits.

In addition, studies have been conducted focusing on specific populations affected by Internet sexuality, including women, gay men, older adults, and clergy. However, as for some other populations, such as lesbians, people with disabilities, and so on, little research is currently available.

CYBERSEX ADDICTION

Cybersex becomes a convenient and relatively safe way to meet powerful psychological forces, such as sex, intimacy and romance; however, the online thrill is potentially addictive. As Internet usage continues to increase, clinicians and therapists report a growing number of clients addicted to cybersex, a form of both Internet addiction and sexual addiction, with the standard problems associated with addictive behaviors. Intoxicating, isolating, integral, inexpensive, imposing, and interactive are aspects of the Internet that appear to be risk factors for cybersex users who have preexisting sexual compulsions or addictions. The anonymity and convenience of cybersex also makes it easy for participants to fall into compulsive use. Beginning with harmless curiosity, cybersex may escalate into compulsive use. Some cybersex participants have frequent erotic encounters online and may border on addiction, finding themselves pressured to engage in frequent cybersexual activities.

Cybersex addiction also features the hallmarks of dependence, including salience, mood modification, tolerance, withdrawal, conflict, and relapse. Salience occurs when cybersex becomes the most important activity in the individual's life and dominates his/her thinking (preoccupations and cognitive distortions), feelings (cravings), and behavior (deterioration of socialized behavior). For instance, even if the individual is not actually online participating in cybersex, he or she may feel preoccupied with going online for cybersex. Some participants may even day-dream about cybersex and look forward to any opportunity to be online for it. Mood modification refers to the subjective experiences that participants report as a consequence of engaging in cybersex and can be seen as a coping strategy, such as the escape appeal of cybersex. Tolerance is the process whereby increasing amounts of cybersex are required to achieve the former mood altering effects. This may mean more hours online for cybersex, a larger number of partners, more bizarre or riskier activities, or going from virtual to actual sexual encounters. Withdrawal symptoms are the unpleasant feeling states and/or physical effects, for instance, the shakes, moodiness, irritability, and so on, which occur when cybersex is discontinued or suddenly reduced. Conflict means cybersex interferes with participants' occupational, social, and/or recreational dimensions of life, including conflicts between the cybersex participants and those around them (interpersonal conflict), conflicts with other activities (job, social life, hobbies, and interests), or conflicts within the individuals themselves (intrapsychic conflict and/or subjective feelings of loss of control), which are concerned with spending too much time engaged in cybersex. Relapse is the tendency for repeated reversions to earlier patterns of cybersex to recur and for even the most extreme patterns typical of the height of excessive cybersex to be quickly restored after years of abstinence or control.

Some scholars have produced a checklist of warning signs for cybersex addiction. These include: routinely spending significant amounts of time in chat rooms and private messaging with the sole purpose of finding cybersex; being preoccupied with using the Internet to find online sexual partners; frequently using anonymous communication to engage in sexual fantasies not typically carried out in real-life; anticipating the next online session with the expectation of finding sexual arousal or gratification; frequently moving from cybersex to phone sex, or even real-life meetings; hiding online interactions from significant others; feeling guilt or shame about online use; accidentally being aroused

by cybersex at first, and now actively seeking it out when online; masturbating online while engaged in erotic chat; and less investment with real-life sexual partners; and preferring cybersex as the primary form of sexual gratification. Based on the *DSM-IV* symptoms of dependence, many screening tools have been designed to help people identify a possible problem with their online sexual behavior, such as the Online Sexual Addiction Questionnaire (OSA-Q) and Internet sex screening test.

There is growing empirical evidence that cybersex addiction exists. Some researchers may not use the term cybersex addiction, although their descriptions of excessive cybersex among the populations they have observed appear to feature the general components of addiction outlined earlier. There is evidence to support the overlap between real-life sex addiction and cybersex addiction. For some participants, cybersex is a continuation of preexisting sexual addiction. Some describe a rapid progression of a previously existing compulsive sexual behavior problem, whereas others have no history of sexual addiction but become rapidly involved in an escalating pattern of cybersex use once they discovered cybersex. For the latter, cybersex is the first expression of an addictive sexual disorder, one that lends itself to rapid progression, similar to the effect of crack cocaine on the previously occasional cocaine user. Some researchers suggest that issues such as isolation and fantasy contribute to at-risk users becoming compulsive.

Studies find that accessing sex on the Internet has the potential to escalate preexisting sex addiction as well as to create new addictive disorders in previously at-risk users. Progression of cybersex addiction is rapid. People who reported a 10-, 20-, or even 30-year history of low-level compulsive sexual behaviors experienced severe life repercussions within a year or two of going online. People addicted to cybersex and related online relationships can experience compulsive usage which means the individual has an intention to stop but inability to do so despite adverse consequences.

In addition, some studies show that both male and female cybersex compulsive users are more likely to use chat rooms, favoring an interactive modality in their sexual pursuits. It may be that the particularly engaging nature of chat rooms may be a slippery slope for certain at-risk individuals in the development of their cybersex compulsivity, or that certain individuals who habituate to less powerful forms of online sexual activities over time gravitate to chat rooms, or that chat rooms are a transitional step from online sexual interactions to meeting and finding face-to-face partners. In any case, the use of chat rooms for sexual pursuits should be a red flag and something to which clinicians should pay particular attention.

Previous studies, usually based on findings from online surveys, document the adverse effects of cybersex addiction on the participant's self-esteem, emotional state, social life, job performance, finances and, in some cases, legal status, when the cybersex involves children or adolescents. Compulsive cybersex use clearly decreases the user's availability to the family. As for the effects of cybersex addiction on partners, they were found to have feelings of hurt, betrayal, rejection, abandonment, devastation, loneliness, shame, isolation, humiliation, jealousy, and anger as well as loss of self-esteem. Thus, it is not surprising that the partner's addiction has been cited as a major factor in subsequent separations and divorce. The reported adverse effects on children include exposure to online pornography, objectification of women and men, or masturbation, involvement in parental conflicts, lack of attention, and breakup of the marriage.

PREVENTION, INTERVENTION, AND TREATMENT

There are already reports of an increase in the number of counselors and therapists seeing people who come in for problems associated with online sexual activities. The extraordinary expansion of computer technology into more and more lives and into all parts of our lives means that cybersex addiction will increase. Cybersex addiction is an extremely potent addiction that must be treated as such. It is usually not just a single family member affected by cybersex, but it can have far lasting effects on partners, children, siblings, and parents. If Internet sex addiction is a viable concept, there are also implications for treatment. At present, treatment programs for sexual addiction include inpatient, outpatient, aftercare support, and self-help groups. There are also family counseling programs, support groups, and educational workshops for addicts and their families to help them understand the facets of belief and family life that are part of the addiction. Some online resources are also available for help, such as Center for Online and Internet Addiction, Internet Behavior Consulting (IBC), and Cybersexual addiction by Sexual Recovery Institute (SRI). However, at present there are very few outlets for the treatment of Internet sex addiction. Clearly there is a need for establishment and evaluation of treatment strategies for online compulsivity/addiction.

Unlike human sexuality, Internet usage is not an innate human need or drive. However, like television and telephone, it has become an essential feature of modern life. Therefore, total abstinence of computer use is probably not the best approach in the long term given the prevalence of computers and Internet use in everyday life. Treatment modalities developed for

treating other addictions, particularly food and sex addictions, are applicable to treating cybersex addiction. Inpatient and outpatient therapy programs can be modified to include cybersex addiction. Inpatient and outpatient treatments vary in intensity, but both include auxiliary treatment such as 12-step groups, peer support, family therapy, medication, and a continuous emphasis on relapse prevention. As for medications for treatment, some cybersex-based paraphilias or hypersexuality can be managed through pharmacological treatment involving anti-psychotic, anti-depressant, and anti-androgenic medications. Depression is a core experience in all addictions; therefore, depression treatment is a central component in the treatment for cybersex addicts. If there is a strong family history of affective disorder and the patient fits diagnosis of the affective disorder and the cybersex addiction, the person may be a good candidate for antidepressant medication. Serotonin reuptake inhibitors (e.g. Paxil or Luvox) are helpful for dealing with depression, anxiety, and compulsive symptoms.

As public and professional awareness of cybersex usage is raised, it becomes increasingly important to understand, assess, and treat this phenomenon. Therapists need to become more informed about the range of sexual activities available on the Internet, the powerful draw of such activities for many cybersex users, the significant adverse consequences that many cybersex users experience, the need to modify self-destructive or illegal behaviors a top priority in therapy, and the importance of considering cybersex addiction a family problem, and involving the spouse or significant other in the treatment process.

Many cybersex participants identify themselves as sex addicts and relate a history of compulsive sexual behaviors antedating their online sexual activities. Therefore, familiarity with current models of treatment for sexual addiction and compulsivity will play a significant role in successful treatment of cybersex compulsives. One option for intervention is the 12-step recovery groups for sexual addiction and/or compulsivity. These groups often assist clients in modifying their compulsive sexual behaviors and interpersonal relationships. In case studies, many respondents reported that what has helped them is attending 12-step sex addiction meetings, daily contact with a 12-step sponsor, individual and couple counseling, and initially, a 90-day abstinence plan. Ideally, the spouse should also attend a 12-step co-sex addict program and as well as individual and couple counseling. Clinicians should be familiar with 12-step groups that are available as an adjunct to individual and group therapies. Training will be needed to help therapists transfer extant knowledge and interventions from work with other sexual acting out problems to the online world, as well as identify and develop methods specifically geared to cybersex issues. In China, Ran Tao's Addiction Medicine Center, inpatient treatment programs are used to jump-start a period of abstinence and a recovery program, especially for adolescent clients. In addition, there are also various online recovery resources, such as online education centers, support groups, and online tests for self-assessment.

Compared with men, female cybersex addicts have additional challenges when they seek help, such as increased shame about the activities, less societal acceptance of women's sexual and cybersexual behaviors, fewer 12-step meetings where women feel comfortable, and lack of knowledge by therapists about cybersex in general and about women's activities in particular.

The results from clinical experience and review of the literature establish that involvement in compulsive cybersex is not a unitary phenomenon. Previous studies find that addictive disorders tend to have their onset in adolescence or young adulthood, but some cases illustrate that cybersex addiction can arise even in later years. Some may have other compulsive behaviors in earlier years, and the powerful lure of cybersex resulted in their switching addictions from others to cybersex. For those with a prior history of compulsive sexual behaviors, the Internet can escalate their addiction and the unmanageability of their lives. Compulsive cybersex is a complex, multifaceted experience that requires several levels of analysis prior to making recommendations for different components of treatment, including assessment, treatment, resources, relapse prevention, and comorbidities.

Some studies find that most of the cybersex abuse patients are married or living with a partner in a committed relationship and primarily college-educated students and professionals, with the youngest age group having most cybersex experience while the oldest group having the least one. Homosexual men were found more likely to have had cybersex compared with heterosexual men, while sexual orientation was found not to have any significant effects on odds ratios for women. When using the number of sex partners during the last year as an indicator of offline sexual activity, having had more than one sex partner increased the possibility of having had cybersex. The results of some online survey showed that a similar proportion of men and women engaged in real-time online sex with another person and significantly more women stated that their online activities had led to real-life sex encounters.

As for psychiatric comorbidities, behavior individuals presenting with substance use disorders and other process addictions, such as pathological gambling or eating disorder, may reveal a concurrent problem with compulsive cybersex. Many compulsive cybersex

patients present comorbid anxiety and affective disorders. In terms of addictive behavior, male cybersex abuse patients were more likely to report chemical dependence, with more males in recovery for alcoholism and more females in active addiction to various drugs (such as benzodiazepines, narcotics, and cocaine). Two-thirds of the women reported an eating disorder, including compulsive overeating and bulimia.

Important future research areas may involve identifying both risk factors and protective factors among those susceptible to Internet sex addiction. The interplay between such factors is likely to be complex, but future research needs to identify the interaction between individual sociodemographic susceptibility risk factors (e.g. gender, age, ethnicity, etc.), psychological risk factors (e.g. personality type, attitude/belief systems, self-esteem), biological risk factors (e.g. genetic predispositions), situational risk factors (accessibility and availability to Internet services, advertising of Internet services, etc.), and structural risk factors (affordability of Internet services, speed of Internet services, etc.).

SUMMARY

Cybersex, as a form of sexual expression accessed through the Internet, is a phenomenon unknown before the mid-1980s. Some characteristics of the Internet explain the appeal of cybersex, such as accessibility (any time, any where), affordability (as inexpensive as a local phone call, and there are a host of ways to get "free" sex), anonymity (people perceive their communications to be anonymous), and escape-friendly.

In both positive and negative ways, cybersex is changing the way people relate. With a powerful fantasy component, many cybersex participants view it as a highly erotic experience. Cybersex provides participants the freedom of sexual expression and experimentation, a way to learn about new sexual techniques, and a means for exploring various aspects of one's sexuality. Cybersex becomes popular also due to its therapeutic values. Although participants can feel less inhibited in cybersex, it is also associated with negative consequences for some users. Cybersex has raised serious legal and social questions, including issues of access, privacy, and morality. Some of the underlying issues are perennial concerns repackaged in novel ways, while other questions are new.

The sexual freedom provided by cybersex may also lead some participants to cybersex addiction. Some investigators have argued that cybersex use ranges along a continuum, extending from adaptive to problematic. The majority of cybersex users who pursue sexual interests online are capable of limiting the time spent in these activities to reasonable levels but many have problems. Empirical evidence indicates that cybersex addiction, with common features similar to other addictive disorders, does appear to exist for some participants. Anonymity, accessibility, and affordability seem to increase the chances for the Internet to become problematic for either those who already have a problem with sexual compulsivity or those who have psychological vulnerabilities rendering them at risk for developing such compulsivity.

For those whose cybersex activities have crossed into compulsivity, adverse consequences for the user and the family can result. This emergent addiction has been reported to ruin individual lives, careers, marriages, partnerships, and families. These individuals are in need of therapeutic intervention for their compulsive use of cybersex, while compulsive cybersex is a complex experience that has yet to be clearly understood. Therefore, as research develops, there will be more evidence-based treatment strategies for cybersex addiction.

Video Game Addiction

Daniel L. King, *Paul H. Delfabbro*, *Mark D. Griffiths*[$]

[*]The University of Adelaide, Adelaide, SA, Australia, [$]Nottingham Trent University, Nottingham, UK

OUTLINE

INTRODUCTION

People can gain many benefits from playing video games. These can be educational, social, and/or therapeutic. However, there is evidence that when played to excess, video games can, in some instances, become addictive, especially online video games where the game never pauses or ends, and can be played at any time of the day. For many, the concept of video game addiction seems far-fetched particularly if their concepts and definitions of addiction involve the taking of drugs. Despite the predominance of drug-based definitions of addiction, there is now a growing number of researchers who believe other behaviors can be potentially addictive even though they do not involve the ingestion of a psychoactive drug (e.g. gambling, exercise, sex, Internet use). Such diversity has led to new, all encompassing definitions of what constitutes addictive behavior.

THE MEANING OF VIDEO GAME ADDICTION

The term video game addiction originated in the early 1980s. Video game addiction refers to a persistent and maladaptive pattern of video game playing behavior. Video game addiction is often regarded to be a type of technological addiction, meaning that the technology has similar addictive effects as psychoactive drugs for some users. This subcategory of addictive behaviors also includes Internet addiction. Whereas many types of addictive behavior are recognized as unique clinical disorders, video game addiction has not been widely accepted. There are two main criticisms of the proposed disorder. The first criticism is that there is currently insufficient empirical research to support the claim that video game addiction is a unique psychiatric disorder. The second criticism is that symptoms of video game addiction may be better accounted for by other

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00082-6

psychopathologies, such as depression. Video game addiction is not currently recognized by mental health authorities such as the American Psychiatric Association and the World Health Organization. Thus, video game addiction remains a contentious and purely theoretical disorder.

The limited empirical research suggests that video game addiction involves a psychological dependency on video games. By definition, the term video game refers to a broad range of electronic games played by manipulating images on a video screen. Video games encompass those played on personal computers, dedicated console systems (e.g. Xbox, PlayStation), handheld consoles (e.g. Nintendo DS, Sony PSP), arcade machines, and other portable handheld devices, (e.g. games played on mobile phones, portable mp3 players, etc.). Video game software varies according to genre and format, but most video games emphasize fast action and strategic play. Video games are understood to be psychologically engrossing, and potentially addictive, because they reward skillful or strategic play with a high score or increased status in the game. While players classified as addicted report very high levels of video game involvement, time spent playing video games is itself not a clinically relevant factor in determining addiction. Relative to other addictive behaviors, the addictive potential of video games is considered to be very low.

FEATURES OF VIDEO GAME ADDICTION

There are a multitude of psychological perspectives on addiction, leading it to be defined in many different ways. However, most models of addictive behavior refer to a persistent and uncontrollable urge to consume a substance or engage in an activity that results in significant personal harm and interpersonal conflict for the user. Thus, video game addiction is often said to be present when individuals have completely lost control over their video game playing and their excessive behavior has had a detrimental effect on all aspects of their lives, and compromises their job and/or educational activities, interpersonal relationships, hobbies, general health, and psychological well-being. These two criteria (impaired control and harmful consequences) are regarded as fundamentally important criteria for addiction. An alternative model of addictive behavior has proposed six features or components of video game addiction. Unless sustained continuously for 3–6 months, these criteria may simply indicate a temporary absorption in video games. The criteria include:

1. *Salience.* This occurs when video game playing becomes the most important activity in a person's life, dominating thoughts (preoccupation and cognitive distortions), emotions (cravings), and behavior (deterioration of normal behaviors). An addicted video game player is obsessed with all aspects of video games and, when not playing, will be anticipating or planning the next playing session.
2. *Mood modification.* This refers to changes in a person's mood state that occur as a result of playing video games. Mood change may involve a subjective feeling of euphoria as well as an increase in physiological arousal (increased heart rate, muscle tension, or shaky hands) or, alternatively, a tranquilizing feeling of calm or numbing sensation.
3. *Tolerance.* This refers to the process whereby increasing amounts of video game play are required to achieve the former mood-modifying effects. Tolerance is evident when players gradually increase the amount of time they spend engaged in video game playing. It could be argued that addicted players build up their tolerance to the point that they end a video game session only when they have become mentally or physically exhausted.
4. *Withdrawal.* These are the aversive mood states and/or physical effects that occur when video game play is suddenly discontinued or reduced. Psychological withdrawal symptoms include feelings of frustration, irritability, and flattened affect. Withdrawal motivates the individual to play video games on a regular basis in order to alleviate the unpleasant feeling states associated with abstinence.
5. *Relapse.* This refers to the tendency for the player to revert back to earlier patterns of video game play, and for even the most extreme patterns, typical of the height of excessive video game play, to be restored quickly after periods of abstinence or moderation. Relapse usually indicates that the individual has lost personal control over their behavior.
6. *Harm.* This refers to the negative consequences of excessive video game play. Harm includes personal psychological distress as well as conflicts with other people (family members and friends) and/or other activities (job, school, social life, hobbies, and interests).

John Charlton, an acknowledged expert on technological addiction, suggests that cognitive salience (preoccupation), euphoria (mood modification), and tolerance may not be reliable indicators of video game addiction but merely signify high engagement, or a type of healthy obsession with video games. Therefore, studies may overestimate the prevalence of problem video game play if high engagement is not properly distinguished from video game addiction. Given these issues of reliability, many addiction specialists maintain that impaired control and harmful effects are the most

appropriate criteria for identifying video game addiction.

PHYSICAL SYMPTOMS

Regular video game use may cause a range of adverse health effects for a small percentage of people, including epileptic seizures, motion sickness, headaches, dry eyes, muscle pains, various repetitive strain injuries, and auditory hallucinations. These relatively minor health complaints are often resolved by reduction of or temporary abstinence from video game play. However, video game addicts may experience more serious and ongoing difficulties due to repetitive use, such as carpal tunnel syndrome and migraine headaches. Other physical symptoms of video game addiction include highly irregular sleeping patterns, including insomnia and hyposomnia that impairs the individual's concentration and attention span. Research studies have shown that longer hours of video game play are associated with general ill-health, poor sleep quality and decreased performance at school and work. In some extreme and isolated cases, individuals have died from heart failure following prolonged video game use.

PREVALENCE

The prevalence of video game addiction is influenced by both the general availability of video game machines and the availability of high-speed broadband connectivity. Highly developed urban cities tend to show higher prevalence rates for video game addiction as compared to regional contexts. To date, very few community-based studies of prevalence have been conducted. Prevalence studies have tended to use special populations, such as high school or university students, making it difficult to generalize the results to other populations. Furthermore, most online studies have used self-selected samples that may artificially inflate prevalence rates. Available research has estimated that the prevalence of video game addiction ranges from 0.3 to 2.3%, although prevalence rates in some areas (e.g. South Korea, Japan) have been reported to be as high as 5%. Higher prevalence rates, ranging from 8 to 15%, have been reported in populations of adolescents and college students, particularly those who play online-enabled video games, such as massively multiplayer online role-playing games (MMORPGs). While these prevalence rates are comparable to and higher than other addictive behaviors, very few video game addicts seek out psychological treatment for their video game playing in their lifetime.

COURSE AND ONSET

Video game addiction typically begins in early adolescence. Early indicators or warning signs of video game addiction include spending most or all available hours playing a video game, diminished job and/or educational productivity, choosing to play video games rather than socialize and/or sleep, lying or being secretive about video game use, and avoiding or no longer participating in other activities in order to spend more time playing video games. Although a few individuals may develop symptoms of video game addiction within a short period of time, for most, the course is more insidious. Years of social video game playing may be followed by an abrupt onset, precipitated by greater exposure to video games or by a stressful life event. For instance, children and adolescents can rapidly develop excessive playing behavior following the introduction of a video game machine to their bedroom or family living room. Similarly, young adults who reside on college campuses are at greater risk of developing problematic video game playing habits due to the flexible, unsupervised, and unstructured college environment, unrestricted access to high-speed broadband, and the multiple stressors associated with the transition to living away from home.

In regard to online video game playing, there is generally a progression in the frequency of playing, the planning required to play, and the organization of peers to play with. These video games pose greater challenges and reward the player less frequently in the later stages. Some levels in online video games may require over 4 h of sustained and uninterrupted play with at least five other players. These playing sessions are therefore likely to interfere with real-life commitments and/or activities. The urge to play video games increases during periods of stress, depression, and/or social isolation. Some people sustain an intense and frequent pattern of playing behavior for many years with a single video game, before eventually burning out and then abstaining from playing permanently. For other individuals, problematic video game playing behavior may manifest itself more irregularly, acting as a coping strategy in response to stressful life events.

DEMOGRAPHIC PROFILE

The typical video game player is a male, between 25 and 30 years old, who plays between 6 and 8 h per week, and who has played video games for over 10 years. Video games are also highly popular among children aged 8–15 years, the majority of whom play between 30 and 60 min per day. Other player demographic profiles have recently emerged. In the last

decade, the video game playing market has diversified following the introduction of casual puzzle games, mobile phone games, and online multiuser games that offer more socially driven playing experiences. These video games have attracted a significant female audience as well as players over the age of 35 years. The most diverse video game playing clientele is found in online multiuser video games, some of which attract millions of players. Males are at least twice as likely as females to play video games during adolescence, and males are more likely to maintain their video game playing into adulthood. Males also report playing video games for at least twice as long as females in an average playing session. Video game addicts in most countries tend to be single men in late adolescence or their early adulthood. Female video game addicts tend to be older than male addicts. Female addicts are also more likely to report a concurrent psychological problem, such as depression or anxiety. With regard to other technological addictions, females report greater engagement with non–video game-related Internet activity, including social networking and online shopping, and they are overrepresented in terms of pathological Internet behavior. The reasons for the lack of female participation in video games include the social stigma attached to female video game players, the hostile and overbearing online behavior of some males toward female players (i.e. females are not often socially rewarded for playing), and the masculine imagery and game-play mechanics in video games themselves (i.e. games are often designed by males for other males).

Cultural differences exist with regard to player preferences for video game activities. In Western countries, including the United States, United Kingdom, and Australia, fast-paced, first-person shooting games are a very popular choice among video game addicts. In Asian countries, like South Korea, Taiwan, and Japan, real-time strategy games tend to be more popular. Specific genres of video games, such as role-playing video games, also differ significantly between Western and Eastern contexts in order to appeal to distinct cultural tastes. The prevalence rates of video game addiction are also significantly higher in Far Eastern countries, such as South Korea and Japan.

INDIVIDUAL RISK FACTORS

Some individuals are more susceptible than others to video game addiction. Individuals with poor time management skills are more likely to engage in persistent and uninterrupted video game play. Dispositional factors that have been linked to increased risk of video game addiction include neuroticism, trait anxiety, sensation seeking, compulsiveness, low self-esteem, and depression. It is thought that these factors moderate the effects of self-regulatory mechanisms on an individual's behavior. For instance, anxious individuals hold self-imposed expectations and beliefs that cause apprehension, fear or worry about their environments. These individuals are attracted to video games because the games alleviate anxiety (fear and panic) by providing a safe and predictable retreat from the real world. Parenting style constitutes another risk factor for video game addiction. Authoritative, emotionally distant and unsupportive parents raise children at risk of developing an attachment to video games to satisfy friendship and self-esteem needs. Case study evidence suggests that adolescent video game addicts initially use video games as a maladaptive way of coping with social pressures (bullying or lack of social support), or with unreasonably high expectations to succeed at school. Older video game addicts often report using video games to escape from feelings of dissatisfaction toward work or a close relationship. Video game playing escalates over time as these problems worsen or remain unresolved. Psychophysiological research suggests that excessive computer game playing is maintained through sensitization of the mesolimbic dopaminergic system (the brain pathway that activates feelings of reward), along with a motivational component of reward of specific computer game-related cues. This means that individuals addicted to video games become more sensitized to the cues and rewards of video games over time, making it increasingly difficult to reduce their involvement.

VIDEO GAME STRUCTURAL CHARACTERISTICS

Some video games may have greater addictive potential than others due to their structural characteristics. Structural characteristics refer to the features of the video games that initiate, develop, and maintain player involvement over time. Video game characteristics vary between different video game systems or platforms. For example, the within-game features of arcade video game machines differ significantly from dedicated video game consoles. Early forms of video game play were conceptualized as a nonfinancial form of gambling, due to the structural similarities between video game arcade machines and electronic gambling machines. Both types of machines feature colorful graphics and sound effects, in-game rewards and bonuses for winning moves, digitally displayed scores of correct behavior, and a rapid span of play, negotiable to some extent by the skill of the player. Arcade machines also feature a high-score board, or a socially ranked score that encourages players to compete and outscore their opponents. Studies in the

1980s identified a minority of adolescents who played pay-to-play arcade machines on a regular basis, sometimes absconding from school to play. These players spent disposable income, including lunch and travel money, on the machines, and would often steal money from their parents and/or others in order to finance their video game playing habit. Using a standardized test of pathological gambling (with the term gambling replaced by video game playing), researchers found that some of these adolescent players met the criteria for addiction.

Modern video games are more structurally complex than early arcade machines. Some researchers have proposed five main categories of features to explain the psychological appeal of video games. These include: (1) social features (i.e. the socializing aspects of video games, such as communication features that facilitate social networking), (2) manipulation and control features (i.e. the ways in which a player can interact with and control in-game properties using a physical control scheme and create a sense of mastery and control over the game), (3) narrative and identity features (i.e. the ways in which the player can take on another identity in the game and become a part of an interactive storytelling experience), (4) reward and punishment features (i.e. the ways in which players are reinforced for skillful play (i.e. winning) and punished for losing), and (5) presentation features (i.e. the esthetic qualities of a video game, such as how the game looks and sounds to the player). The reward and punishment features have the strongest association with excessive video game playing behavior. Similar observations have been made in problem gambling research, specifically in regard to electronic gambling machine play. Operant conditioning theory suggests that the frequent and variable reinforcement schedules in video games make them highly psychologically engrossing and resistant to behavioral extinction. The expectation of large rewards and intermittent smaller rewards leads to rapid and persistent playing behavior. Many video game addicts repeatedly perform a small action in a video game in order to obtain a large reward over time. This practice is known among players as grinding, and it can take up a large portion of their video game playing time.

The social aspects of video games can also influence excessive playing behavior. Research has consistently found higher rates of video game addiction in online multiuser video games as compared to single-player video games. A study in the United States found that over 80% of players of first-person shooting games belong to a regular playing group (or clan), and players were primarily motivated by the opportunity to compete against other players. MMORPGs differ from other types of games in that they feature a large interactive game world shared by hundreds, sometimes thousands, of other players. In MMORPGs, players assume the role of a character (usually in a fantasy or science-fiction setting) and take control of many of that character's actions. These actions may involve completing quests or missions (alone or in the company of others) in return for in-game items or other rewards, or competing against other players in organized competitions. MMORPGs are distinguished from other types of video games by the number of players, and by the game's persistent virtual world, which continues to exist and change while the player is away from the game.

In many video games, particularly MMORPGs, players can join social groups (clans or guilds) that enable them to compete against or cooperate with others. The social obligations of these online groups and the unpredictable nature of the video game itself require players to spend long, uninterrupted periods engaged in the video game. Those individuals who fail to play the game at required times or exit the game prematurely may incur an in-game penalty or be ostracized by other members of the group. Therefore, MMORPG addicts often experience significant social pressures to play regularly and limit their absence from the video game. About 9% of the total video game playing population plays MMORPGS, but the prevalence rate of video addiction is reported to be as high as 15% in samples of MMORPG players.

ASSESSMENT

While psychometric scales for assessing video game addiction are currently in use for research and assessment purposes, many have not been clinically validated. Studies of video game addiction in the 1980s used an adapted version of the DSM-III-R criteria for pathological gambling, with the term video game playing substituted for gambling. Individuals who met four or more of the nine criteria were classified as pathological video game players. Some researchers have criticized this approach for its assumption that problem video game playing can be categorized as an impulse disorder. Further, some pathological gambling criteria do not translate easily to video game playing behavior, such as chasing financial losses and increasing gambling bets. A number of self-report measures of video game addiction have been developed since the 1990s. Some of these measures have been based on the updated DSM-IV-TR criteria for pathological gambling, or the ICD-10 criteria for problem gambling, or self-report measures of other addictive behaviors. However, these tests have generally not been cross-validated using a clinical sample of persons classified by trained mental health professionals as addicted to video games. Some researchers have therefore argued that many tests for assessing video game addiction misclassify individuals

as addicted when they are not. This may explain the relatively high prevalence rates of video game addiction reported in some studies.

TREATMENT

Unfortunately, there are currently no evidence-based treatments for video game addiction. There are some specialist addiction treatment clinics (e.g. in The Netherlands, China, Korea, United States) but details of the therapeutic programs have not been published in the academic literature. It would appear that most of the treatment clinics utilize a diverse range of interventions, as do those individual practitioners who have written on the issue (in academic journals and Internet published articles). Cognitive behavioral approaches, in conjunction with family and marital therapies, are often cited as appropriate for treating video game addiction. Therapeutic techniques such as self-monitoring, galvanic skin response biofeedback-assisted relaxation training, in vivo exposure, and response prevention techniques have been used effectively to reduce video game overuse. Since there is very little empirical research into the long-term effectiveness of these programs, it is difficult to establish their credibility. There is currently no proven role for psychotropic medication, although pharmacological treatment has been clinically trialled for the treatment of Internet addiction. A study in the United States in 2008 found that the antidepressant drug escitalopram significantly improved symptoms of impulsive-compulsive Internet usage disorder. Escitalopram has been used previously to treat major depressive disorder, social anxiety disorder, and panic disorder, as well as addictive behaviors including pathological gambling and kleptomania. Some less-conventional treatments for video game addiction have been documented in the popular news media. Most notably, electric shock therapy for video game addiction was being administered to adolescent patients in military hospitals in China, and this practice was discontinued in 2009. Overall, further research is required to establish the therapeutic efficacy of any and all treatment programs directed at excessive gaming.

RESEARCH ISSUES

Research into video game addiction is in its infancy and therefore has a limited knowledge base. A large proportion of video game addiction research involves self-report surveys of players from within university student populations. There is a lack of longitudinal research in this area, which has made it difficult to establish empirically whether excessive video game use represents a stable problem behavior that is maintained on a long-term basis. Furthermore, there is a paucity of in-depth qualitative research on the unique features of video game addiction, including the cognitive and behavioral mechanisms underlying the behavior. Many researchers have criticized the various measures and criteria used to assess video game addiction. The main problems with tests used to identify video game addiction is that they often (1) have no measure of severity to differentiate clinical from subclinical cases, (2) have no consistent temporal response frame, (3) overestimate the prevalence of problems, and (4) take no account of the context of video game use in the person's life. Furthermore, the common practice of using convenience samples in video game addiction research, including first-year university students and users on video game-related Internet sites, may give rise to issues of validity and generalizability of findings. The main disadvantages of self-report methods in video game addiction research include social desirability biases that affect participants' responses to sensitive questions and issues of veracity and reliability of responses due to poor memory recall.

There are some advantages of online self-report methods targeted at video game players including (1) ease of participant recruitment and confirmed presence of the target group under study, (2) collapsed geographical boundaries that may increase numbers of participants in the target group, (3) improved time and cost efficiencies (i.e. allows relatively large-scale samples to be surveyed quickly and efficiently at a fraction of the cost of pen and paper equivalents with no travel needed by either the researchers or the participants), and (4) facilitated data collection and manipulation (e.g. automated data inputting). Online surveys can be particularly useful in gauging opinions from a target group at any particular point in time. The nature of the online medium fosters a relatively high degree of anonymity can be maintained, and video game players may feel more comfortable and thus more likely to disclose personal information when answering sensitive questions on their computer rather than in a face-to-face situation.

CONCLUSION

Based on empirical research, there appears to be little evidence of serious acute adverse effects on health from moderate play. Adverse effects are likely to be relatively minor and temporary. Most will resolve spontaneously as a result of reduction in the frequency of play. Excessive players are the group most at risk of developing more serious problems although further research is required to ascertain the long-term consequences of this activity. There is also a need to determine the

incidence and prevalence of clinically significant problems associated with video game play in the broader population. Epidemiological research would aid in addressing this current gap in knowledge. It is also unclear why so few individuals seek psychological help or treatment for problems arising from excessive video game play. It may be that the detrimental effects of video game addiction are less severe as compared to other addictions, such as gambling, meaning that fewer addicted users believe that some form of assistance is warranted. The predominantly male demographic of video game players may also be less prone to seek treatment, as males are known to be much less likely than females to seek help for a psychological problem. Other factors such as cost, convenience, or a perceived lack of compassion or understanding may also deter video game addicts from seeking psychological help. Worldwide, there are currently very few practitioners who specialize in the treatment of video game addiction. With the growing popularity of video games and the expansion of broadband services, video game addiction is a mental health field that is likely to attract further academic debate and empirical scrutiny.

Exercise Dependence

Jeremy Adams

Eclectic Consulting Pty. Ltd., Altona, VIC, Australia

OUTLINE

EXERCISE DEPENDENCE DEFINED

Exercise dependence represents a behavioral dependence on regular exercising. Exercise dependents typically exercise excessively, and this excess often results in physical and/or psychological and emotional harm. Commonly, diagnosis of exercise dependence requires that a person exercise daily without taking rest days, be likely to have experienced illness or injury as a result of his or her exercising, exercises intensely and for long durations, spends a large proportion of his or her time planning and thinking about exercising, exercises stereotypically (e.g. at the same time or in the same way) and, when unable to exercise, experience irrational thoughts and feelings (e.g. "If I don't exercise today I'll get fat"), as well as withdrawal symptoms (e.g. mood swings, aches and pains, dry mouth).

Despite a lack of evidence regarding the prevalence of exercise dependence, it appears that the condition is relatively rare, with approximately 1% of exercisers experiencing serious consequences from their excessive exercising. Nevertheless, upward of 10% of exercisers exhibit symptoms, presenting a risk for progression to a more serious condition and its potential consequences (see below). The most potentially serious consequence of exercise dependence on a person's health is overtraining, a physiological condition that results from excessive exercising without adequate rest between exercise sessions. Other consequences of exercise dependence include psychological, sociological, and vocational harm, including onset of anxiety and depression (especially in the absence of regular exercise), disruption to personal relationships, and the inability to work effectively.

Along with other nonchemical dependencies, exercise dependence is not presently recognized by the American Psychiatrists' Association's *Diagnostic and Statistical Manual* – fourth edition-text revision (DSM-IV-TR). Despite some controversy (see below), it is widely agreed by exercise-dependence researchers, however, that the condition is legitimate and represents a behavioral dependency rather than, for example, an eating disorder. Consequently, a variety of exercise-dependence diagnostic criteria have been proposed (see Measurement and Diagnosis of Exercise Dependence and Table 83.1).

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00083-8

TABLE 83.1 A Comparison of Contemporary Exercise Dependence Diagnostic Criteria

Author(s)	Diagnostic criteria
de Coverley Veale (1987)*	• Obsession with exercising in a way that is habitual and stereotyped • Noticeable withdrawal symptoms when unable to exercise (e.g. mood swings, irritability, insomnia) • The dependence results in substantial distress or impairment in physical, social, occupational, or other important areas of functioning • The preoccupation with exercise is not better accounted for by another mental disorder (e.g. as a means of losing weight or controlling calorie intake as in an eating disorder)
Ogden, Veale, and Summers (1997)†	Primary exercise dependence • Narrowing of repertoire leading to stereotyped pattern of exercise with a regular schedule once or more daily • Salience with the individual giving increasing priority over other activities to maintaining the pattern of exercise • Increased tolerance to the amount of exercise performed over the years • Withdrawal symptoms related to disorder of mood after cessation of exercise schedule • Relief or avoidance of withdrawal symptoms by further exercise • Subjective awareness of a compulsion to exercise • Rapid reinstatement of the previous pattern of exercise and withdrawal symptoms after a period of abstinence Secondary exercise dependence • As above, but with the associated presence of an eating disorder
Hausenblas and Symons Downs (2002)‡	Clinically significant impairment or distress, as manifested by three or more of the following: **1.** *Tolerance*: defined as either a need for increased amounts of exercise to achieve the desired effect, or diminished effect with continued use of the same amount of exercise **2.** *Withdrawal*: as manifested by either the characteristic withdrawal symptoms for exercise, or the same (or closely related) amount of exercise is engaged in to relieve or avoid withdrawal symptoms **3.** *Intention effects*: exercise is often taken in larger amounts or over a longer period than was intended **4.** *Lack of control*: there is a persistent desire or unsuccessful effort to cut down or control exercise **5.** *Time*: a great deal of time is spent in activities necessary to obtain exercise **6.** *Reduction in other activities*: social, occupational, or recreational activities are given up or reduced because of exercise **7.** *Continuance*: exercise is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the exercise (e.g. continued running despite injury)
Bamber, Cockerill, Rodgers, and Carroll (2003)§	Primary exercise dependence **1.** Impaired functioning The individual shows evidence of impaired functioning in at least two of the following areas: (a) Psychological – e.g. ruminations or intrusive thoughts about exercise, salience of thoughts about exercise, anxiety, or depression (b) Social and occupational – e.g. salience of exercising above all social activities, inability to work (c) Physical – e.g. exercising causes or aggravates health or injury yet individual continues to exercise even when medically contraindicated (d) Behavioral – e.g. stereotyped and inflexible behavior **2.** Withdrawal The individual shows evidence of one or more of the following: (a) Clinically significant adverse response to a change or interruption of exercise habits. Response may be physical, psychological, social, or behavioral (e.g. severe anxiety or depression, social withdrawal, self-harm) (b) Persistent desire and, or unsuccessful efforts to control or reduce exercise Secondary exercise dependence • As above, but with the associated presence of an eating disorder Associated features The following features are indicative but not definitive: **(i)** Tolerance (i.e. increasing volumes of exercising required) **(ii)** High volumes of exercising and, or exercising at least once daily

(*Continued*)

TABLE 83.1 A Comparison of Contemporary Exercise Dependence Diagnostic Criteria—cont'd

Author(s)	Diagnostic criteria
	(iii) Solitary exercising **(iv)** Deception (e.g. lying about exercise volume, exercising in secret) **(v)** Insight (e.g. denial that exercising is a problem)
Terry, Szabo, and Griffiths (2004)**	• *Salience* — this occurs when the particular activity becomes the most important activity in the person's life and dominates their thinking (preoccupations and cognitive distortions), feelings (cravings), and behavior (deterioration of socialized behavior). For instance, even if the person is not actually engaged in the behavior they will be thinking about the next time they will be • *Mood modification* — this refers to the subjective experiences that people report as a consequence of engaging in the particular activity and can be seen as a coping strategy (i.e. they experience an arousing "buzz" or a "high", or paradoxically tranquilizing feel of "escape" or "numbing") • *Tolerance* — this is the process whereby increasing amounts of the particular activity are required to achieve the former effects. For instance, a gambler may have to gradually increase the size of the bet to experience a euphoric effect that was initially obtained by a much smaller bet • *Withdrawal symptoms* — these are the unpleasant feeling states and/or physical effects which occur when the particular activity is discontinued or suddenly reduced (e.g. the shakes, moodiness, irritability, etc.) • *Conflict* — this refers to the conflicts between the addict and those around them (interpersonal conflict), conflicts with other activities (job, social life, hobbies, and interests) or from within the individual themselves (intrapsychic conflict) which are concerned with the particular activity • *Relapse* — this is the tendency for repeated reversions to earlier patterns of the particular activity to recur and for even the most extreme patterns typical of the height of the addiction to be quickly restored after many years of abstinence or control

* *Developed by author.*
† *Based on earlier work by de Coverley Veale (1987).*
‡ *Based on the DSM-IV diagnostic criteria for substance dependence.*
§ *Developed based on a qualitative examination of 56 female exercisers.*
** *Based on Brown's general components of addiction (Griffiths, 1996).*
Adapted from Adams, J., 2009. Understanding exercise dependence. Journal of Contemporary Psychotherapy, 39(4), 231–240.

To date, there has been very little empirical investigation of the prevalence or incidence of exercise dependence or of potential antecedents, such as age, gender, or activity type, frequency, duration, or intensity. Nevertheless, there is some evidence to suggest that exercise dependence affects around 1% of regular exercisers seriously, while up to 10% might be at risk of developing a dependency on exercise. Similarly, it appears that it takes a relatively long time for exercise dependence to develop to a serious condition; around 2 years of regular, intense, long-duration exercise, although it is not yet understood clearly whether certain (e.g. higher) exercise levels are more likely to exacerbate onset. Because it appears to take some time and quite a lot of effort for the condition to develop, exercise dependence is more common in association with physical activities that encourage regular, long, intense exercise bouts such as running or aerobics classes. Likewise, it is thought that, because these sorts of activities generally involve little social interaction (although aerobics is a group activity, it is usually performed without any interaction with the other people in the class), the lack of an obvious point of reference for a healthy participation level could encourage unhealthy involvement levels. Lastly, although more research is required to determine the effects of gender on risk of exercise dependence, it appears that men are more likely to experience primary exercise dependence (see below) whereas women are more prone to exercise dependence as a secondary aspect of an eating disorder (i.e. secondary exercise dependence, see below). It is possible, however, that these differences simply reflect the prevalence of eating disorders by gender; that is, more women than men experience an eating disorder and, therefore, represent statistically the majority of secondary exercise-dependence cases.

Labeling: Exercise Dependence versus Exercise Addiction

Obligatory, excessive exercising is most usually described as a dependence on exercise rather than as an addiction. This distinction results from the psychological and behavioral consequences of the condition: addiction usually refers to a physiological reliance on a substance or behavior, whereas the term dependence is used to describe the consequences of that reliance, such as the presence of withdrawal symptoms in its absence. As such, exercise dependence is usually described based on the effects of excessive exercising (e.g. the compulsive need to repeat the behavior, withdrawal symptoms, and obsessive thoughts in its absence) rather than the physiological effects. Such a distinction notwithstanding, it is not uncommon for exercise dependence to be referred to by a variety of nomenclature throughout the literature, including

exercise addiction. Other examples have included obligatory exercising, morbid exercising, compulsory exercising, and compulsive exercising.

INVESTIGATION OF EXERCISE DEPENDENCE

Historical

The earliest discussion of exercise dependence occurred in the early 1970s, although, initially, researchers regarded the phenomenon as a "positive addiction", on the assumption that, because exercising had physical and psychological benefits, a dependence on exercise should be beneficial. Subsequently, researchers identified cases of psychological and physical harm resulting from excessive exercising, especially in instances where individuals appeared to be exercising in an obligatory fashion. Early descriptions of this behavior were mostly gleaned from studies of runners and labeled in a variety of ways (see above).

Simultaneously, researchers investigating eating disorders identified cases in which patients diagnosed with an eating disorder were also found to be exercising excessively. These instances were labeled "activity-based anorexia" and a relatively large body of literature emerged describing the link between disordered eating and excessive exercising. Little attempt was made, however, to integrate research into exercise dependence with investigation of excessive exercise in association with eating disorders. This separation resulted in a schism within the literature, with subsequent confusion as to whether persons exhibiting a dependence on exercise were "addicted", or manifesting aspects of an eating disorder. In fact, within the eating disorder research, there has been a large amount of skepticism as to whether exercise dependence actually exists independently of an eating disorder, an argument that, to a lesser extent, still continues (see below).

One area in which the majority of these early studies corresponded was their lack of consensus over the condition itself. Not only was there a lack of agreement of the terminology (see above), there was little agreement on the possible antecedents to the condition, let alone its measurement or diagnosis.

Contemporary

In the late 1980s, researchers attempted to align competing ideas about exercise dependence versus manifestations of an eating disorder by proposing the notions of primary and secondary exercise dependence. Briefly, according to researchers, secondary exercise dependence represents a dependence on exercise in combination with disordered eating, whereas primary exercise dependence describes exercise dependence in conjunction with normal or healthy eating (i.e. in the absence of an eating disorder). Both of these terms will be explored in greater detail below. Subsequently, a number of researchers expanded on these terms by investigating both conditions and providing some (albeit controversial) empirical support for the existence of both. As discussed below, however, there is still some contention over the existence of primary exercise dependence as a pathological disorder, as well as a distinct lack of research regarding the risk factors for exercise dependence, its etiology, and its treatment.

NEUROBIOLOGICAL EXPLANATIONS

There has been limited investigation of the potential neurobiological antecedents and correlates of exercise dependence. Nevertheless, several researchers have proposed a variety of mechanisms. Early explanations implicated the endogenous opioid systems, suggesting that exercisers can achieve a "runners' high" through exercise-induced elevations of β-endorphins in the bloodstream. Unfortunately, there appears to be little empirical evidence for this hypothesis. Not only is it unlikely that sufficient levels of β-endorphins would pass through the blood–brain barrier to have a noticeable effect, there have been no reports in investigations of human exercisers that evidence the opiate-induced euphoria attributed to the so-called runner's high. As well, investigations of endogenous opiate levels in sacrificed mice induced to run excessively have shown no evidence of excessive activation of the endogenous opiate systems.

Another proposed explanation for exercise dependence, labeled the "sympathetic arousal" theory, suggests that modifications to the expression of the catecholamines epinephrine and norepinephrine might be sufficient to modify exercise behavior. According to this theory, regular exercising results in greater metabolic efficiency, resulting in a reduction in the basal expression of catecholamines. Because the catecholamines are implicated in general arousal, increases in fitness would result in lower overall catecholamine levels and, therefore, lower arousal. Thus, in order for an individual to maintain his or her arousal levels within a normal range, he or she would need to exercise at increasingly higher intensities and for longer durations and, correspondingly, would experience a substantial drop in arousal levels when deprived of regular exercise. Although this theory is based on sound conceptual reasoning, to date, there have been no empirical investigations either in humans or animals that have provided any evidence to support the notion that tolerance to

catecholamine expression could explain exercise-dependent behavior.

Of greater promise in explaining exercise dependence from a neurobiological perspective is exercise-based modifications to the mesolimbic dopamine system (MDS). The MDS (sometimes referred to as the brain's "pleasure center") is a midbrain pathway that includes the nucleus accumbens and the ventral tegmental area. This system appeared relatively early on in mammalian evolution and exists primarily to reward behaviors related to survival through the expression of dopamine (e.g. feeding, sexual behavior, maternal and paternal behaviors). Among other processes, dopaminergic expression results in subjective feelings of pleasure and contentment, and the experience of these sensations often results both in activation of an emotional response and long-term memory storage of the behavior in question (in order to ensure its repetition). Unfortunately, for humans, the MDS can be activated relatively easily by a range of behaviors, making it possible for nonessential behaviors (e.g. gambling, sex, overeating, exercise) to be experienced as essential. In a similar vein, chemicals that affect dopaminergic cells can effectively 'fool' the midbrain into encouraging their repeated consumption. For instance, cocaine can act as selective dopamine reuptake inhibitor, increasing the amounts of available dopamine and, therefore, reinforcing ongoing cocaine consumption.

Because the brain is able to self-modify in response to environmental and biological changes, increases in available dopamine result in compensation in the MDS to reduce the availability of post-synaptic dopamine receptors. This modification allows the brain to achieve a balanced level of dopamine when levels are raised artificially (e.g. through ingestion of chemical substances, or by engaging in a behavior that stimulates MDS dopamine expression). Problems occur when the substance or behavior that induced the change is withdrawn abruptly. In these instances, MDS modifications to reduce the number of receptors, combined with a reduction in dopamine expression results in substantially lowered available dopamine and can lead to a number of physiological and psychological effects. Most notably for humans, a rapid reduction in available dopamine levels can result in strong cravings for the substance or behavior responsible for elevating dopamine levels artificially.

A second problem with MDS modifications to stabilize dopamine expression following use of a substance or engagement in a behavior, is that the user becomes progressively unable to experience pleasure in the absence of that substance or behavior. In other words, without regular access to the stimulating chemical or activity, other previously pleasurable activities (such as eating, social interaction, sexual behavior, or esthetic stimulation) become decreasingly desirable resulting, eventually, in anhedonia: an inability to experience pleasure except when exposed to the chemical or behavior responsible for the MDS modifications.

There is a relatively large body of evidence that supports the dopaminergic modification theory as a factor in both chemical and behavioral dependencies, as well as in exercise dependence specifically. For example, in comparison to controls, when volunteers were asked to play a video game for monetary reward they showed elevated dopamine expression in the MDS, similar to that seen following amphetamine consumption. Similarly, human exercisers who have ceased exercising voluntarily for a period of time have reported withdrawal symptoms similar to those seen in withdrawal from substances that affect the MDS directly (e.g. cocaine, amphetamines, methamphetamines). More convincing evidence comes from animal models. Investigation of the MDS in mice and rats sacrificed after being induced to exercise excessively (through either running or swimming) has shown substantial reductions in the number of available post-synaptic dopamine receptors, suggesting that exercise can, in fact, modify the MDS over time. Combined with human-based studies which have indicated increased dopamine production post-exercise (especially at high exercise intensities of longer duration), and a number of studies that have described acute elevations in mood post-exercise, it appears that the dopaminergic expression hypothesis provides a relatively convincing explanation for exercise dependence. Nevertheless, until these modifications can be demonstrated directly in human exercisers, this theory will remain speculative.

In addition to the possible activation of dopaminergic systems in exercise dependence, investigation of compulsive voluntary activity in mice when deliberately starved, as well as evidence of a reduction in appetite in mice forced to exercise, has resulted in another possible explanation. According to investigators, this so-called "activity-based anorexia" might represent a dormant survival mechanism that evolved in mammals prior to *Homo sapiens*. Put simply, to protect against starvation during famine, early mammals might have evolved a mechanism that stimulated energy expenditure when calorific intake dropped dramatically. Although counter-intuitive, this behavior might have allowed for migration to an area with better food supplies. Similarly, an automatic reduction in calorific expenditure in conjunction with high-intensity exercise might have allowed for a migrating organism to continue to function without the need to stop and scavenge for food, potentially increasing the chances of finding a food-rich area. In humans, there is certainly a documented relationship between excessive exercising and

disordered (i.e. drastically reduced) eating (see below). Nevertheless, without further convincing neurobiological and behavioral evidence for this theory, it will be difficult to validate.

PSYCHOLOGICAL EXPLANATIONS

Neurobiological explanations can account for a proportion of the factors in explaining exercise dependence. Nevertheless, a variety of psychological variables are also likely to influence the onset, development, and maintenance of exercise dependence. In particular, the positive connotations associated with exercising could be an influencing factor in excessive exercising. Although it is indisputable that regular exercise is of substantial benefit, both physically and psychologically, the mistaken assumption, in a minority of exercisers, that increasing amounts of exercise will result in greater benefits could lead these persons to continue to increase their exercising to an unhealthy level (at which point the physiological processes associated with dependency will have had time to develop). Simultaneously, the social reinforcement associated with exercising (i.e. it is seen widely as a highly positive behavior and rewarded accordingly) could also encourage some exercisers to continue to exercise at unhealthily excessive levels. Speculation notwithstanding, there has yet to be convincing empirical evidence implicating social desirability and reinforcement factors in the onset of exercise dependence.

Another possible psychological factor in the onset and reinforcement of exercise dependence, that has received some empirical investigation and support, is the reinforcing effects of negative withdrawal when exercise is unavailable. A variety of investigators have confirmed the existence of withdrawal symptoms (including mood swings, irrational cognitions, "flu-like" sensations, and anxiety) following exercise cessation in those who exercise excessively. Unfortunately, as with much of the research in this field, there has been little consensus between researchers as to how much exercise participation defines a classification of exercise dependence. Two other problems with this body of research are evident. First, there has been no investigation of the longevity of these withdrawal symptoms and whether they are ameliorated by a reuptake of exercise. Second, because it is difficult to ask those diagnosed with exercise dependence to quit exercising altogether, most of the research on exercise withdrawal has relied on retrospective self-reports from exercisers deprived of their regular exercising by injury. Given that injury can result in psychological trauma the assumption that exercise deprivation and not the injury that explains the supposed withdrawal is premature. Consequently, while it is generally agreed that withdrawal can occur in regular exercisers deprived of their ability to exercise, it is difficult to determine whether these findings relate to exercise dependence *per se*, or simply represent the effects of a forced decline in exercise patterns among committed exercisers.

PRIMARY VERSUS SECONDARY EXERCISE DEPENDENCE

As briefly described above, exercise dependence is best conceptualized as one of two separate disorders: primary and secondary. On the one hand, primary exercise dependence represents a condition in which an individual demonstrates a dependency on exercise (based on diagnostic criteria – see below) in the absence of any eating-related pathology. In other words, in cases of primary exercise dependence, eating is likely to be normal despite excessive, compulsive exercising. On the other hand, secondary exercise dependence represents obsessive exercising in conjunction with disordered eating (such as anorexia nervosa or bulimia nervosa) and might represent an aspect of the eating disorder rather a separate condition. It is not uncommon for exercise to be used as a means of purging or calorific restriction (increasing calorific expenditure to reduce overall calorific balance) in persons suffering from an eating disorder, a fact that has led some researchers to question the notion of exercise dependence in these cases. In other words, because eating disorders often include an element of exercising as a part of the disordered behavior, it is potentially difficult to argue that a dependence on exercise is evident. Such a distinction will require further research. What is not in contention is that eating disorders, with or without an exercising component, invariably result in psychological and physiological harm, and are often associated with comorbid psychopathology, such as depression and anxiety.

Because it has yet to be determined whether it is likely to coexist with psychopathologies, there has been some contention as to whether primary exercise dependence can be classified as a pathological condition. Some researchers have argued that diagnosis of dependence requires that the dependent behavior be associated with some sort of psychological harm, such as psychopathology. For instance, investigation of exercise dependence in female exercisers has resulted in identification of excessive exercising in association with an eating disorder (i.e. secondary exercise dependence) alongside evidence of substantial psychopathology in this group (e.g. DSM-IV TR Axis 1 disorders). These investigators were unable, however, to identify any evidence of psychopathology among those who exercised excessively but who did not show signs of an eating disorder (i.e. primary exercise dependence). Nevertheless, the

use of an exclusively female sample to assess exercise dependence is likely to result in higher rates of eating disorders than one including male participants (reflecting the substantially higher rates of eating disorders among women). Thus, given the finding that, in women, excessive exercising is usually accompanied by disordered eating, it is unlikely that primary exercise dependence would be detected readily in an all-female sample. Subsequently, other researchers have suggested that primary exercise dependence might be more common in male exercisers than in females. Although this notion has received anecdotal support, it still requires empirical demonstration. Future researchers also need to determine whether psychopathology can be detected in persons who exercise excessively and who show signs of dependence.

Psychopathology is not, however, the only form of harm that can result from a dependency. Whether or not psychopathology exists in primary exercise dependence, as is discussed below, there are a number of other potential harmful consequences. Consequently, some researchers have suggested that primary exercise dependence can be classified as a pathological condition in its own right.

POTENTIAL NEGATIVE CONSEQUENCES OF EXERCISE DEPENDENCE

Of particular importance in understanding exercise dependence is the notion of harm as a consequence of the excessive behavior. As with other dependencies, an important aspect in the diagnosis of exercise dependence is that the behavior must have resulted in some form of dysfunction, either psychosocially or physically. Some of these potential outcomes are explored below.

Psychosocial

As with other forms of dependence, excessive exercising is likely to result in reduced psychosocial functioning as the behavior begins to dominate a person's time and other resources. The increasing amounts of time required to sustain an exercise habit is usually associated with a withdrawal of time and energy from other aspects of a person's life, such as his or her commitment to social and romantic relationships, and work and recreational activities. Unlike some other dependencies in which it is possible to obtain a hedonic effect rapidly (e.g. amphetamine use), a large amount of exercise is required to sustain an exercise habit. Although there are no direct investigations of the amount of exercise performed typically in exercise dependence, anecdotal reports indicate that many exercise dependents exercise in excess of 3 h day^{-1}, and spend a large amount of their remaining time planning exercise or engaging in other exercise-related activities.

The main consequence of the large amount of time and energy required to sustain exercise dependence is a large reduction in interpersonal interactions, unless those interactions are exercise related (e.g. relations at a running club or gym). As such, few activities that might have been considered pleasurable pre-dependence are likely to continue. Combined with the likely anhedonia (inability to experience pleasure) that accompanies most dependencies, there is little motivation for those with exercise dependence to engage in activities unrelated to their exercising. Unfortunately, as with many other areas of exercise dependence, there has, to date, been little empirical investigation of its psychosocial consequences.

Physiological

The main physical risk factor from exercise dependence is overtraining, a condition in which an individual exercises to excess, resulting in systemic physiological damage. Physical fitness is, essentially, a physical adaptation to exercise-induced stresses. When exposed to the damage resulting from exercising, over a 24–48-h period without repeated stress (i.e. rest) the body adapts by "overcompensating" in its repairs, slightly increasing the ability of the stressed systems to cope with future trauma (i.e. resulting in stronger muscles, connective tissue and bone, increased blood supply). Over time, these adaptations can result in a substantial increase in fitness levels. If an individual continues to place stress on his or her body, however, by exercising without adequate rest between exercise sessions, he or she will not be able to adapt, and will eventually succumb to exercise-induced damage (i.e. overtraining). Overtraining can result in harm to a variety of physiological systems, including the musculoskeletal, endocrine, cardiovascular, reproductive, and immune systems. As such, overtraining can result in injury, illness, and permanent damage to an individual's ability to reproduce, or to regulate important physiological systems (such as the hypothalamic-pituitary axis, HPA). There have been anecdotal reports of chronic fatigue syndrome (CFS) in association with athletic overtraining and in cases of exercise dependence induced overtraining. Unfortunately for exercise dependents, whereas overtraining in athletes is often detected in time, and modifications made to their training and competitive schedules in order to reduce or reverse the effects, excessive exercisers seldom recognize the signs of overtraining and continue to exercise without reductions in or

modifications to their training, potentially resulting in serious, long-term physiological damage.

MEASUREMENT AND DIAGNOSIS OF EXERCISE DEPENDENCE

A wide variety of instruments purported to measure exercise dependence have been presented in the literature over the last 40 years. As discussed above, researchers investigating exercise dependence have often failed to agree on a definition of the condition, or a set of diagnostic criteria and, consequently, the majority of measurement instruments reflect this lack of consensus. Similarly, until relatively recently, few measures of exercise dependence have been shown to possess adequate psychometric robustness. Thus, it is hard to determine what, exactly, the majority of earlier exercise-dependence measures were actually measuring. Perhaps the most relevant criticism of the majority of exercise-dependence measures is the lack of a set of population normal scores to which individual responses can be compared. Without this information it is hard to determine a "cut off" criteria to determine whether a person is at risk of exercise dependence or not. As well, the majority of measures to date have been developed for a specific exercising population (e.g. runners), or have not been tested across a variety of exercise types, or exerciser experience or proficiency levels. Without this sort of information it is not possible to use these instruments in a way that allows researchers to compare scores across different types of exercise or exercisers. More recently, several instruments have been developed (most notably the Exercise Dependence Scale Revised: EDS-R), which allow for comparison of an individual's scores to normal tables, allowing researchers to estimate exercise-dependence risk more effectively. Work is still required, however, to validate this measure across a variety of exercising types and proficiencies.

In addition to its measurement, since its conceptualization a variety of criteria have been proposed for the diagnosis of exercise dependence. The bulk of these criteria is summarized in Table 83.1. Essentially, there are two sets of criteria: those that are based on the DSM-IV TR criteria for substance abuse, and those that have been developed independently of the DSM. Nevertheless, despite conceptual variations, when comparing the various diagnostic conceptualizations, they appear similar, most likely the result of a stable agreement between researchers regarding the processes, signs, and symptoms of the majority of dependencies (behavioral and chemical). Of note is the fact that several of the diagnostic criteria presented in Table 83.1 are based on theorization about what should be observed in cases of exercise dependence, whereas the remainder are based on actual observations of individuals who have shown evidence of exercise-dependent behavior.

In essence, exercise dependence is diagnosed when the exerciser exercises often, to excess (i.e. on more days than not, at high intensities and for long durations) and stereotypically (i.e. little variation in training regimen), and demonstrates substantial reluctance to any suggested reduction of the level of exercise undertaken, or to missing regular exercise sessions. In addition, exercise dependents find it difficult to control their urges to exercise, and usually experience physical and, or psychological withdrawal (including unwelcome, intrusive cognitions) when unable to exercise. Equally, their dependence reduces their involvement and ability to function in other important life areas, such as emotional, social, and occupational activities. Lastly, their compulsion to exercise is not better explained by another disorder. In the case of secondary exercise dependence (see above), diagnosis is made when the conditions for primary exercise dependence coexist with an eating disorder.

It is up to the individual practitioner or researcher to decide which diagnostic criteria to ascribe to when attempting to identify exercise dependence, however, the more recent suggestions, such as those of Bamber and her colleagues, or Hausenblas and Symons Downs (see Table 83.1), are based on more rigorous investigation of the condition, and represent the end product of an epistemological process, rather than theorization about how exercise dependence ought to manifest.

TREATMENT OF EXERCISE DEPENDENCE

To date, there has been no empirical investigation of the most effective methods for treating exercise dependence. Nevertheless, given the similar likely etiology to other behavioral and chemical dependencies, it is not unreasonable to expect that treatments that have been effective in their treatment would also be of use in exercise dependence. For example, cognitive behavioral therapy (CBT) has been reported to be highly effective in the treatment of a variety of behavioral and chemical dependencies. Likewise, motivational interviewing, a technique developed to treat chemical dependencies, is also likely to be effective in assisting those with exercise dependence, especially for helping to stimulate behavioral change in those who are reluctant to do so.

Practitioners wishing to treat exercise dependence should make themselves familiar with the various

diagnostic criteria, particularly those based on empirical investigation (see Table 83.1), in order to be able to identify the disorder correctly. Because of the possibility of comorbid disorders in conjunction with exercise dependence (e.g. anxiety, depression, eating disorders), practitioners should also ensure that they possess sufficient training in order to be able to treat these problems, or make sure that they are able to refer to someone with appropriate qualifications and experience.

SUMMARY

Exercise dependence is a disorder in which persons exercise excessively and obsessively to a point of dependence and, often injury or illness. Other characteristics of the disorder include withdrawal symptoms when exercise is unavailable, unwelcome, or irrational cognitions concerning exercise (or a lack thereof), a reduction in social and occupational interaction, and reduced functioning in other areas (e.g. interpersonal relationships). Although, to date, there have been no conclusive studies regarding the neurobiological determinates of exercise dependence, it is likely that it is brought about, over time, by exercise-induced modifications to the MDS in the midbrain, activated by sustained, high-intensity exercise.

Despite wide ranging investigation of exercise-dependence spanning some 40 years, until recently there has been little consensus between researchers over its etiology, diagnosis, treatment, or risk factors. There remains contention between researchers as to whether a primary dependence on exercise can, in fact, exist, despite numerous anecdotal reports of such a condition resulting in harmful consequences. Although there have been useful attempts at describing exercise dependence in a variety of exercising populations, including the development of relatively comprehensive and well-reasoned diagnostic criteria, more rigorous and well-planned research is required to determine whether exercise dependence does, in fact, occur regularly in exercisers, what the likely predisposing factors might be, and identification of the best methods for its measurement, diagnosis, and treatment.

List of Abbreviations

CBT	cognitive behavioral therapy
CFS	chronic fatigue syndrome
DSM-IV TR	*Diagnostic and Statistical Manual* – fourth edition – text revision
EDS-R	Exercise Dependence Scale Revised
HPA	hypothalamic-pituitary axis
MDS	mesolimbic dopamine system

Glossary

Dopamine a catecholamine neurotransmitter and neurohormone found largely in the mesolimbic dopamine system comprising portions of the midbrain (including the nucleus accumbens and ventral tegmental area).

Exercise any structured physical activity that results in elevated physical load, including raised heart rate, respiration, and energy consumption.

Exercise dependence a behavioral dependency on exercise categorized by stereotypical exercising, a reluctance to take rest days, exercising despite pain or injury, and a compulsive desire to exercise once or more daily.

Primary exercise dependence exercise dependence independent of any majorly disordered eating.

Secondary exercise dependence exercise dependence concurrent with substantially disordered eating.

Work Addiction

Cecilie Schou Andreassen[*,$]

[*]The Bergen Clinics Foundation, Norway [$]Department of Psychosocial Science, University of Bergen, Norway

OUTLINE

INTRODUCTION

Work addiction [The terms "work addiction," "workaholic," and "excessive work" have sometimes been used in the existing literature to describe the same phenomenon. In this article, I will stick with the term "workaholism," which is consistent with the academic literature on the field of study.], often referred to as workaholism, is defined in many different ways, but most definitions include notions of overindulgence with work, long working hours, working more than what is demanded/expected, prioritizing work over most other activities, enjoyment of work, work compulsiveness, and perfectionism, rigidity, high motivation, resourcefulness, impatience, and self-absorption in work. Thus, the term has both negative and positive connotations. A definition that aims to cover all of the above-mentioned attributes should comprise effective, cognitive, and behavioral elements, as well as positive and less positive aspects.

Since some authors view workaholism in positive terms and others in negative terms, it has been hard to identify one homogenous group of workaholics. Unfortunately, existing typologies rely to a large extent on purely atheoretical rationales that have not been investigated empirically. Scott et al. postulated three types of workaholics: compulsive-dependent, perfectionist, and achievement-oriented. These three types are viewed as stable patterns linked to different antecedents and outcomes, but workaholics can also display a mixed pattern. Robinson proposed four different types of workaholics: the "all or nothing" or "bulimic," who does things perfectly or not at all; the "relentless" who has problems stopping work, is compulsive, and is motivated to work fast and meet deadlines; the "savoring" who obsesses over details to the point of paralysis; and the "attention-deficient" who tends to start many projects but gets easily bored and needs to be stimulated at all times. One central, empirically supported distinction is drawn between workaholics who enjoy their work and workaholics who do not. Spence and Robbins identified these two following types of workaholics: "enthusiastic," who are characterized by high levels of work involvement, driven by an internal pressure to work, and find great fulfillment and pleasure in work; and "non-enthusiastic," who are also highly involved in work-related activities and are driven to work, but who seem not to derive enjoyment from doing so.

ASSESSMENT

In terms of assessment, Spence and Robbins define the concept by identifying three independent dimensions or components that they argue characterize workaholism: high involvement in work (Work Involvement), feeling

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00084-X

driven or pressured to work by an internal motivation (Drive), and lack of enjoyment from doing so (Enjoyment of Work). These three dimensions comprise the Workaholism Battery (WorkBAT), which is clearly the one workaholism measure that has received most empirical attention so far. Evidence for the reliability and validity of WorkBAT has emerged from a number of different sources, based on heterogeneous and cross-cultural samples. The WorkBAT consists of 25 items answered on a 5-point Likert scale ranging from strongly disagree to strongly agree (e.g. "I feel guilty when I take time off work"). The item pool is drawn from a review of existing literature as well as its creators' own hypothesis. To qualify as a workaholic of any kind, there should be high scores on Work Involvement and Drive, whereas scores on the Enjoyment of Work subscale distinguish the two types. Some researchers have followed this dichotomized classification of data when reporting their results, while a few have preferred analyses using the full variance of data. Recently, the original three-factor structure and psychometric properties of WorkBAT have been questioned. Two (Enjoyment of Work and Drive) of the three proposed subscales have consistently met the reliability and validity requirements expected for scales of this type. However, the Work Involvement subscale has failed in several studies to display appropriate psychometric properties, with low internal consistencies and insufficient factor loadings. To address this problem, McMillan et al. have developed and offered evidence for a revised 14-item two-factor (Drive-R, Enjoyment-R) version of the WorkBAT, named WorkBAT-R. A recent study investigating a Chinese version of the WorkBAT in Taiwan actually found support for a five factor solution comprising the following factors: Work Enjoyment, Work Involvement-Enjoyment, Drive-Work Involvement, Drive, and Work Involvement.

However, the first workaholism scale that was developed was the Work Addiction Risk Test (WART). The WART consists of 25 items answered on a 4-point Likert scale ranging from 1 (never true) to 4 (always true) (e.g. "I find myself continuing to work after my co-workers have called it quits"). The construction of the item pool is based on recognized features reported by clinicians working with "workaholics" and their families. High scores on WART (57 and above) indicate workaholism. To a large extent, the item pool covers Type A traits (e.g. impatience, doing multiple tasks simultaneously) and anxiety. When factor analyzing WART, Flowers and Robinson found five separate but correlated factors, which they named Compulsive Tendencies, Control, Impaired Communication/Self-Absorption, Inability to Delegate, and Self-Worth. Several studies, primarily using narrow U.S. samples, have been conducted using WART. Evidence for fairly good psychometric properties has emerged, but the use of a shortened 15-item version in future research has been recommended. Recently, a Dutch version of WART provided support for the original 25-item version and the five factors, but it was concluded that eight items from the Compulsive Tendency (CT) subscale were sufficient to capture workaholism. In a similar vein, another Dutch study reported a strong correlation (0.59) between the Compulsive Tendencies subscale (renamed "Working Excessively") and the Drive subscale from WorkBAT described above. The overall knowledge about the psychometric properties of the WART still remains scarce. The study from Taiwan reported that above Work Enjoyment and Work Involvement were unrelated to the WART sum score, whereas the three other subscales of the WorkBat found in that study all showed positive relationships with the WART sum score.

Another workaholism scale, the Schedule for Nonadaptive Personality Workaholism Scale (SNAP-Work) was developed by Clark. It comprises an 18-item, forced-choice questionnaire. High scores on SNAP-Work are assumed to reflect workaholism. The item pool largely comprises obsessive–compulsive traits (e.g. perfectionism, rigidity, high self-imposed demands). Although the limited amount of studies conducted using this scale has demonstrated good psychometric properties, it has not yet received widespread empirical attention. Significantly, McMillan et al. found a strong correlation (0.61) between SNAP and their revised WorkBAT-Drive subscale.

Recently a new workaholism questionnaire was developed. This is named as the Dutch Workaholism Scale (DUWAS). The DUWAS has two subscales: (1) Working Excessively (WE), which actually consists of five items of the Compulsive Tendencies subscale of the WART and (2) Working Compulsively, which consists of five items from the Drive scale of the WorkBAT. All items are scored along a 4-point rating scale, ranging from 1 (totally disagree) to 4 (totally agree). The DUWAS has shown good psychometric properties in a Dutch and a Japanese sample as well as in a Spanish sample. Interestingly, the DUWAS comprises no items reflecting work enjoyment and the scale constructers regard work enjoyment not to be a constituting element of workaholism.

PREVALENCE

In the wake of globalization, new technology, blurred boundaries between work and other life domains, some authors have suggested that we are witnessing an increase in workaholism. Concerns have been raised about serious consequences of working long hours and excessive work. For example, death from overwork, or "*Karoshi*," has been estimated to account for 10% of all deaths among working Japanese males. As matters stand, claims of an increase

may only reflect the fact that more attention is devoted to the workaholism phenomenon, rather than an increase in its actual occurrence.

Bearing in mind the lack of agreement concerning the conceptualization and measurement of workaholism, prevalence estimates for workaholism consequently vary, are rather conflicting and not entirely clear. As workaholism is claimed to be a stable individual characteristic, it should be rather independent of organizational type or level of performance. According to the attraction–selection–attrition theory, it is still reasonable, to expect that workaholics are attracted to and may be overrepresented in certain work contexts and professions than in others (e.g. managerial and professional work versus clerical and blue-collar jobs). Furthermore, the limited number of studies aiming at estimating the prevalence of workaholism suggests no differences on the basis of background demographics such as marital status, race, or gender. Other researchers claim to have found higher scores on workaholism measures among men and younger workers than among women and older employees. All in all, it is premature to expect proper and well-documented estimates of prevalence rates of workaholism.

WORKAHOLISM AND ANTECEDENTS

In the following, the theoretical and empirical framework for potential antecedents of workaholism will be briefly presented, in addition to other central theories concerning antecedents of workaholism. Some authors have reported a link between workaholism and intrinsic and extrinsic job motivation. This may relate to innate basic psychological needs of autonomy, competence, and relatedness. According to the theory, these three motives are basic motivations for all human behaviors. The workaholic's behavioral pattern can be understood in terms of satisfying these basic needs. For example, when feeling incompetent, the person may work excessively in order to feel more competent, particularly if this motive is given high priority by the individual in question. Internal pressure or obsession with work could therefore be related to unsatisfied basic needs, which may be satisfied through work. According to this theory, need satisfaction is necessary for enjoyment of work. In line with this, Andreassen, Hetland, and Pallesen found that Drive was negatively related to autonomy and that Enjoyment of Work was positively related to autonomy and competence.

Reasoning along these lines, Csikszentmihalyi emphasized the concept of "flow" when describing an optimal work-experience, and it seems relevant to some workaholic types. "Flow-experiences" make individuals lose their sense of time and place and even forget biological needs when they are focused on a work task. Csikszentmihalyi suggested that goals, motivation, and intentions are central to achieving these good and optimal experiences. The theory of flow-experiences may reflect the proposed typologies of the goal-oriented workaholic, the achievement-oriented workaholic, and the enthusiastic workaholic.

Workaholism is considered by some to reflect one or several higher order personality traits. Theorists generally assume that such traits are relatively firmly established, differ between individuals, and affect behavior. It is also believed that most basic personality traits have a genetic basis and are further developed early in life. Three studies have linked workaholism with the Five Factor Model (FFM) of personality. The generic FFM of personality comprises Neuroticism, Extraversion, Openness to experience, Agreeableness, and Conscientiousness. Burke et al.'s study using WorkBAT reported that Drive was strongly and positively related to Neuroticism, whereas Work Involvement and Enjoyment of Work were positively related to Extraversion. Andreassen et al., also using the WorkBAT, found that Work Involvement was positively related to Neuroticism, Extraversion, Openness to experience, and Conscientiousness. Drive was positively related to Neuroticism and Conscientiousness, but negatively related to Agreeableness. Enjoyment of Work was positively related to Extraversion and negatively related to Agreeableness. Clark et al. using the WART found that Neuroticism was the only Big Five trait which was related (positively) to workaholism. Besides Neuroticism, workaholism was positively related to negative affectivity, narcissism, and perfectionism.

Some authors theoretically frame the structure, process, growth, and development of workaholism within addiction theory. Thus, these authors view workaholism as an addiction, comparable to other addictive behaviors such as alcoholism or pathological gambling. Addiction theory comprises two major explanatory models of addictive behavior: the medical and the psychological model. In short, the medical model of addiction emphasizes physical dependence on a substance (internal or external) accompanied by physical symptoms such as increased tolerance, withdrawal, and craving when the supply of the substance diminishes, is absent, or is removed. Based on this model, some authors have suggested that workaholic behavior is somatically stimulated by physiological activation produced by, for example, working against the clock to meet a deadline. In a similar vein, with reference to the psychological model of addiction, it has also been suggested that workaholism is developed and driven by a craving for approval, reward, and recognition rooted in narcissistic traits. Taken together, data supporting these assumptions have so far failed to provide empirical evidence that proneness to addiction is a causal factor in the development of workaholism.

Based on learning theory, the development of workaholism and corresponding behavior can be explained by various principles of learning. As long as the proper reinforcing conditions are present or absent, this model suggests that anyone can be led into or out of workaholism. Following the principles of operant reinforcement, workaholic behavior occurs, is nurtured, and sustained because similar behavior in the past has led to positive outcomes, such as praise and approval from peers, promotion, a good salary, or because the behavior has led to the avoidance of negative outcomes such as conflict at home, unwanted leisure, and socialization. In line with this, workaholism has previously been linked to salary increase and promotions. The principles of social learning can also explain how workaholism is molded. The individual may be influenced by observing the behavior of significant others, such as parents, peers, leaders, and by being exposed to models in the media. At present, however, the learning theory of workaholism remains unexplored.

Also cognitive perspectives on workaholism may add to our understanding of its antecedents. Basic cognitions such as schemata, core beliefs, expectations, attributions, and automatic thoughts are assumed to activate behavior. Thus, if a person holds self-schemata that he/she is a poor achiever, and holds a core belief that hard work equals success, then workaholic behavior may be activated as a result. Self-efficacy or the perceived ability to handle specific situations well may also be relevant in explaining development of workaholism. In general, people are motivated to enhance positive self-evaluations. Thus, when self-efficacy at work is greater than self-efficacy in non-work settings, it may drive the worker to choose work over non-work for the purpose of maintaining a positive self-image and in order to strengthen the sense of mastery. The cognitive perspective on workaholism has to some extent been tested empirically, but more empirical validation is needed. Burke et al.'s study using WorkBAT reported that all three workaholism components were positively related to generalized self-efficacy, with the strongest relation being to Enjoyment of Work.

Furthermore, some people have argued that workaholism should best be understood in terms of family-systems, with the family being the origin of the phenomenon. According to this perspective, workaholism is regarded as the result of certain family dynamics (e.g. over-responsibility, parentified children), affecting the individual within the system. In some cases, long working hours motivated by providing for one's family may reflect over-responsibility. In one study, it was found that students with high scores on the WART perceived their parents as more heavy workers than students with low scores on the WART. Still, as for the other theories discussed so far, the empirical basis for the family-system perspective is scarce.

Although the theories presented here have different explanations of workaholism, they should not be considered mutually exclusive. Workaholism is most probably formed by a variety of antecedents. In short, each theory may add a piece to the puzzle. Most recently, Ng et al. combined parts from several of these theories and proposed that workaholism is the combined result of dispositional traits (e.g. needs, values, traits), socio-cultural experiences (e.g. social learning, cultural emphasis on competence and competition), and behavioral reinforcements (e.g. organizational reward systems).

OUTCOMES AND CORRELATES OF WORKAHOLISM

Workaholism seems to entail both benefits and risks, and potential outcomes are better documented than the antecedents of workaholism. It is important to recognize, however, that outcome research has predominately relied on simple cross-sectional study designs. Both previous and recent research suggests that enthusiastic workaholic features (e.g. work enjoyment) are associated with higher scores on career satisfaction, work engagement, job satisfaction, and low intention to quit their jobs, compared to features characteristic of non-enthusiastic workaholics, who display the reverse relationships. Furthermore, research has found that workaholism in general is related to a broad range of work attitudes such as perfectionism, inability to delegate, and long working hours. This suggests that workaholism may be productive and profit the organization, but it may also result in destructive outcomes for the individual, team, and organization. So far no studies have been conducted on the work performance of workaholics using objective measures of the latter – underlining that spending long hours at work does not necessarily mean good and profitable performance.

Spending a great amount of time on work-related activities seems to be a core element in most definition of workaholism. Since time is a fixed unit, this must have consequences for time spent on non-work activities; thus workaholism may influence the domestic area. Extensive involvement in work, chronic stress, and time pressure, certain coping styles and personality characteristics, an unsupportive organizational climate and poor leadership, etc. have all been postulated as relevant predictors of work–family conflicts. Work–family conflicts are regarded as inter-role conflicts in which the role pressures from the work and family spheres are seen as being incompatible and are linked to negative physiological, behavioral, and psychological outcomes. Work–family conflicts and poor social functioning

outside work have also been proposed as potential consequences of workaholism. However, few studies have been conducted that examine the relationship between workaholism and the work–family interface. The limited number of such studies that have been conducted all conclude that workaholics report a higher degree of work–family conflict than non-workaholics. Bakker et al. using the DUWAS found that workaholism is related to reduced support provided to the partner through work–family conflict. In a recent study differentiating between positive and negative spillover, it was found that Drive was related to negative spillover between work and family, whereas, Enjoyment of Work was related to positive spillover between work and family. Work involvement showed inconsistent relationships with spillover. Although it has been suggested that the relationship between workaholism and work–life imbalance might be moderated by culture, a recent study of Caucasian and Black respondents revealed that cultural origin did not moderate this relationship.

It has further been suggested that workaholism is related to general life satisfaction. Again, since the workaholic's time is primarily devoted to work, how one experiences work will influence how life is experienced. Consequently, since enthusiastic workaholism is associated with passion and positive feelings about work, a large proportion of workaholics' time is spent on pleasurable (work) activities. Unsurprisingly, life satisfaction and purpose in life are reported to be high for these workaholics, whereas non-enthusiastic workaholic features have recently been empirically linked to the opposite pattern. In line with this, Andreassen, Hetland, Molde, and Pallesen using the WorkBAT found that Drive was negatively related to life satisfaction, whereas Work Enjoyment was positively related to life satisfaction. They also found that Drive was negatively associated with job satisfaction and that Enjoyment of Work was positively associated with job satisfaction. In one study using the DUWAS, workaholism was negatively correlated with perceived health and happiness. Chamberlin and Zhang found that student with high scores on the WART reported lower levels of psychological well-being, lower levels of self-acceptance and more physical health complaints compared to student with low scores on the WART. Another study based on the DUWAS showed that workaholism was positively correlated with ill-health and negatively associated with life satisfaction and self-reported job performance. Based on the WorkBAT, Andreassen et al. reported that Drive was positively related to subjective health complaints, while Enjoyment of Work was negatively related to health complaints. As sleep is a complex biological response it is highly vulnerable to stress. Two studies have specifically investigated how workaholism relates to sleep. In one study, subjects with the highest scores on the DUWAS had greater probability than workers with low scores to report insufficiency of sleep, sleepiness at work, and difficulties awakening in the morning as well as tiredness in the morning. In another study based on the WorkBAT, Andreassen et al. found that Enjoyment of Work was negatively related to insomnia whereas Drive was positively related to insomnia.

Generally, it has been argued that workaholism is detrimental to health. In fact, Ng et al. most recently argued that workaholism has both direct and indirect costs in the form of poorer physical and mental health because workaholics do not prioritize protective behavior such as leisure and exercise. The workaholic lifestyle may thus lead to increased blood pressure, cholesterol, poor sleep, etc. There are however no hard data to substantiate such claims, but associations between potential risk factors for illness and disease and workaholism have been postulated. Still, McMillan and O'Driscoll reported similarities in psychological, physical, and general health between workaholics and non-workaholics in their New Zealand study. Thus, more studies on the relationship between workaholism and parameters of somatic health are warranted.

Another potential and suggested consequence of workaholism is "burnout." Burnout is defined as a syndrome of emotional exhaustion, cynicism, and low professional efficacy. Based on the WorkBAT, Andreassen et al. found that Drive was positively related to burnout, whereas Enjoyment of Work showed the opposite relationship to this construct. Moreover, some studies have reported a link between workaholism and potential health risk related to "stress." Specifically these studies have shown that, when experiencing strain in their jobs, individuals scoring high on the Drive dimension or on Compulsive tendencies tend to report an increase in subjective stress-related somatic and psychological symptoms, whereas this response pattern has not been found in individuals with high scores on Enjoyment of Work. In one recent study using the DUWAS in a sample of junior doctors it was found that the relationship between workaholism on the one hand and well-being (job satisfaction, happiness, and perceived health) and burnout on the other was fully mediated by role conflicts.

As the stress response is more dependent on the perception of the stressor than the stressor in itself, the relationship between coping and workaholism should be investigated in future studies. In one study that included measures of coping, workaholism, and health, it was found that workaholism had a direct negative association with poor health (direct path). Workaholism was associated with better health through active coping (indirect path) and with poor health through emotional discharge (indirect path). Hence coping and emotional discharge partially seem to mediate the relationship between workaholism and health.

TREATMENT

Not much is actually known about treatment for workaholism as no controlled treatment/intervention study for workaholism so far has been conducted. Still, some suggestions and recommendations regarding therapy for this condition have been proposed as recently reviewed by Rebecca Burwell and Charles Chen. Inherent in the treatment perspective is the assumption that workaholism primarily represents a negative entity.

Several authors on workaholism have pointed to the fact that many workaholics typically deny their problem. When seen in therapy the workaholics often complain about marital problems and many therefore enters therapy with this focus (e.g. marital therapy).

Telling the workaholic to cut down on the number of working hours is normally warned against, as this is assumed to generate heavy therapeutic resistance. In terms of individual interventions, some argue for modifying the underlying personality factors that are assumed to be at play. In this regard some authors regard workaholism as a symptom of not being able to form authentic bonds to other people. In line with this, work is seen as a way to block out lack of intimacy. It has been suggested that therapy therefore should focus on the emotional consequences of not being able to create deep bonds to other people. One way of working with this may be to conduct cost–benefit analyses concerning the rewards experienced from work and the potential rewards which could be gained by creating deep emotional ties to others. Other authors have emphasized working with specific core beliefs about self, which many workaholics seem to be characterized by. Such core beliefs (e.g. "only when I work hard I will get the attention and love I deserve" and "work performance is the only way to prove my self-worth," etc.) can for instance be targeted and corrected through cognitive therapy. Others have focused more on changing the behavior of the workaholic more than his/her underlying psychological makeup. These approaches typically entail helping clients setting up boundaries between their private and their work arena, for instance, by the use of time management principles (planning how much time to be used at, for instance, work, to self, family, and play). Therapy may also involve identifying triggers (both internal in terms of dysphoric feelings and external in terms of specific situations) for work bouts. Another approach is the Workaholic Anonymous, which advocates a similar 12-step approach used for the treatment of other addictions. A potential effective treatment approach, either by itself or in combination with other approaches, is motivational interviewing (MI). MI represents techniques, including interviews and questions, where the clients themselves discover the negative aspects and consequences of their behavior. Focus is also upon how the clients want their life situation to be and what they can do in order to bring it there. Hence, MI aims at increasing and strengthening the client's motivation for change.

Interventions against workaholism may also comprise the organizational level. Managers are for instance recommended not to set unrealistic expectations for their followers. Managers should also be aware of the importance of themselves as role models, thus a workaholic manager may consequently be a bad example for his/her subordinates. Some companies arrange work–life balance programs in order to prevent and treat workaholism. It may also be important that managers are able to identify workaholic behavior and to encourage the person in question to prioritize recreation and his/her private life.

A newly adopted approach concerning the treatment of workaholism is based upon positive psychology. Within this orientation, focus is not on the shortcomings and problems inherent in human nature, but the emphasis is instead put on strengths and positive human qualities. Positive psychotherapy may involve techniques determining ones strengths and to use one strength in a new way every day for a week. Another technique is the gratitude letter technique where the client is asked to write a letter to someone they have a great gratitude to. The workaholic could for instance write and deliver such a letter to a person whom he or she has ignored due to his/her work investment. Another approach within this perspective is life quality therapy. The client is instructed to rate different life areas in terms of importance. Then the clients are to rate how much satisfaction is derived from each of these areas. The product (importance times satisfaction) yields a score reflecting life satisfaction. Many workaholics may by this method discover that their life quality is low. Quality of life therapy contains several therapeutic techniques aiming at increasing the life quality of the client. These techniques comprise self-care (e.g. exercise and rest), quality time (e.g. relaxing alone), and developing a guiding vision of what matters most in life. Specific interventions for every single life domain have also been developed. The main aim with life quality therapy is to have the workaholic to discover that happiness comes from many other sources than work, paving the way for cutting down on work and prioritizing other important life arenas.

FUTURE RESEARCH DIRECTIONS

The research on workaholism seems still to be in its infancy. Hence several important research questions

remain unanswered. First and foremost the field is in need of conceptual clarifications. The different measures of workaholism have, to a very limited extent, been cross-validated with each other, thus it is not known whether these actually measure the same construct(s). Related to this is the question pertaining to the subdimensions of workaholism. Is workaholism a multidimensional construct with both positive and negative aspects? Some argue, for example, that the term workaholism should be reserved for negative work-related attitudes, cognitions, and behaviors. The term "work addiction" may be a more suitable label for "negative workaholism." In addition, clear demarcations, both on a conceptual as well as on an empirical level, should be made between the term "workaholism" and related and perhaps overlapping concepts such as job satisfaction, job stress, passion toward work, work engagement, and work overcommitment. Consensus about the operationalization of workaholism would allow for comparisons of results across studies, development of norms as well as decisions concerning the use of cut-offs in order to make proper estimates of the prevalence of workaholism in different populations. Unfortunately, the situation in this field seems to suggest that it will take considerable time and effort to reach such a goal.

Future research should also investigate to what degree workaholism represents a rather stable individual characteristic and to what degree it does vary according to the context. As by far the great majority of studies of workaholism are cross-sectional, more studies using longitudinal designs are strongly warranted in order to be able to reveal some potential causal mechanisms concerning antecedents as well as consequences of workaholism. Most studies have also relied on single source of information (self-report only). Thus, studies collecting data from colleges (e.g. 360 degrees evaluation) as well as from marital partners and other family member would be highly welcomed. In addition, very few, if any, studies have linked workaholism to biological data/outcomes, such as immunological, hormonal, and metabolic parameters. Thus, the field is in demand of studies including assessment of such variables. As other non-chemical additions have been shown to be related to specific genotypes, future studies should also investigate whether this is the case for workaholism as well.

Although several therapeutic interventions for workaholism have been proposed, no randomized clinical trial of any workaholism treatment has ever been conducted. Hence, development and empirical investigations of interventions for workaholism should comprise another future research goal within this area. Future studies should also take cultural differences into consideration. Studies have, for example, shown that patterns of work and attitudes toward work differ between cultures in accordance to their emphasize on survival values, self-expression values, and mastery values. Gender differences concerning time devoted to work seem to be greater in masculine than in feminine societies; hence, this dimension should also be taken into consideration in future workaholism research.

Glossary

Agreeableness agreeableness is the tendency to be compassionate and cooperative rather than suspicious and antagonistic toward others.

Antecedent antecedent is a preceding occurrence, cause of event that existed or comes before something else; the antecedent of workaholism.

Autonomy autonomy is a noun and means self-governing. It is having freedom and independence as a person.

Big Five traits Big Five traits or factors (or Five Factor Model; FFM) of personality comprise five broad domains or dimensions of personality, which are used to describe personality in contemporary psychology: Openness, Conscientiousness, Extraversion, Agreeableness, and Neuroticism.

Burnout burnout is a psychological term for the experience of long-term exhaustion and diminished interest.

Cognition cognition is the scientific term for "the process of thought." Usage of the term varies in between disciplines; in psychology, and cognitive science, it usually refers to an information processing view of an individual's psychological functions.

Cognitive psychology cognitive psychology is a subdiscipline of psychology exploring internal mental processes and focuses on topics such as how people perceive, remember, think, speak, and solve problems.

Compulsive Tendency/Compulsive behavior compulsive tendency/compulsive behavior is a tendency or behavior motivated by factors that compel a person to act, sometimes against his or her own wishes.

Conscientiousness conscientiousness is the tendency to show self-discipline, act dutifully, and aiming for achievement; planned rather than spontaneous behavior.

Coping style coping style denotes the general approach in terms of cognitive, affective, and behavioral responses taken by the person for dealing with the anxiety triggering or challenging situations in life.

Correlation correlation is a mutual or reciprocal relationship between two or more variables, a statistic representing how closely two variables co-vary.

Drive drive is one dimension or aspect of workaholism as measured by the frequently used Workaholism Battery (WorkBAT) and reflects working due to feelings of being compelled or driven by inner forces. See Workaholism Battery.

Dysphoric feelings/Dysphoria dysphoric feelings/dysphoria is an unpleasant or uncomfortable mood, such as sadness (depressed mood), anxiety, irritability, or restlessness. Etymologically, it is the opposite of euphoria.

Dutch Work Addiction Scale (DUWAS) Dutch Work Addiction Scale (DUWAS) is a 10-item questionnaire to measure work addiction. The DUWAS comprises two dimensions: Working Excessively and Working Compulsively.

Enthusiastic workaholic enthusiastic workaholic is a workaholic who is characterized by high levels of Work Involvement, Drive, and Enjoyment of Work as measured by the Workaholism Battery (WorkBAT). See Workaholism Battery.

Enjoyment of Work Enjoyment of Work is one dimension or aspect of workaholism as measured by the Workaholism Battery (WorkBAT). See Workaholism Battery.

Extraversion extraversion is the tendency to have energy, positive emotions, surgency, and the tendency to seek stimulation in the company of others.

Extrinsic job motivation extrinsic job motivation comes into play when a person is motivated to work primarily due to factors external to him or her (like money or promotion).

Five Factor Model (FFM) see Big Five traits.

Flow flow is a mental state originally described by Mihály Csikszentmihalyi in which a person becomes fully immersed in a feeling of energized focus, full involvement, and success in the process of the activity.

Intrinsic job motivation intrinsic job motivation occurs when people are internally motivated to work because the work or activity in itself either brings them pleasure, an experience of importance or provides a significant learning opportunity.

Likert scale likert scale is a scale commonly used for response alternatives in surveys in which the respondents specify their level of agreement to a statement by endorsing one of normally five or seven response alternatives. The middle alternative is most often neutral, whereas the others reflect some level of agreement or disagreement with the statement. The scale is named after its inventor, psychologist Rensis Likert.

Motivational interviewing (MI) motivational interviewing (MI) refers to a counseling approach in part developed by the clinical psychologists William R. Miller, PhD and Stephen Rollnick, PhD. It is a client-centered, semi-directive method of engaging intrinsic motivation to change behavior by developing discrepancy and exploring and resolving ambivalence within the client.

Narcissism narcissism trait reflects a general tendency of egotism, vanity, simple selfishness, envy, using and seeing others as objects and self-grandiosity.

Neuroticism neuroticism is the tendency to easily experience unpleasant emotions, such as anger, anxiety, depression, or fear.

Non-enthusiastic workaholic non-enthusiastic workaholic is a workaholic who is characterized by high levels of Work Involvement, Drive, and low Enjoyment of Work. See WorkBAT.

Openness to experience openness to experience is the tendency to appreciate art, emotions, adventure, unusual ideas, and variety of experience.

Operant conditioning/Reinforcement operant conditioning/reinforcement is a form of learning where an individual modifies the occurrence and form of its own behavior due to learning associations between the behavior and its consequence. The consequences are denoted as reinforcement and punishment. Reinforcement increases the frequency of the behavior and is either positive (a positive stimulus occurs following the behavior) or negative (an aversive stimulus disappears following the behavior). Punishment decreases the frequency of the behavior and is either of type I (introduction of an aversive stimulus) or type II, also called penalty (removement of a positive stimulus following the behavior).

Observational learning/Social learning observational learning/social learning is learning that occurs as a function of observing, retaining, and replicating behavior observed in ones environment or other people.

Perfectionism perfectionism is a personality trait manifested by the rejection of personal achievements falling short of perfection, often leading to distress and self-condemnation. It is a disposition to feel that anything less than perfect is unacceptable.

Personality traits personality traits are relatively firmly established general ways of responding, thinking, and feeling and which differ between individuals. Trait theory suggests that basic personality traits have a genetic basis and are further developed early in life.

Positive psychology positive psychology is a recent branch of psychology in which emphasis is put on factors and processes relevant for growth, positive development, achievement, and success.

Psychometric properties psychometric properties are characteristics of tests and other measures of human behaviors, thoughts, or feelings that describe their basic measurement features. Most common psychometric properties express some aspects of the stability or consistency of the instrument (denoted as its reliability) and some aspects indicating whether the instrument measures what it is intended to measure (denoted as its validity).

Schedule for Non-adaptive Personality Workaholism Scale (SNAP) Schedule for Non-adaptive Personality Workaholism Scale (SNAP) is an 18-item questionnaire developed by Lee Anna Clark in 1993 to measure workaholism. The questionnaire largely measures obsessive–compulsive traits.

Self-efficacy self-efficacy is defined in a variety of ways: as the belief that one is capable of performing in a specific manner to attain specific goals, as a person's general belief about their capabilities to produce designated levels of performance that exercise influence over events that affect their lives.

Spillover spillover is the transfer of mood, energy, and skills from one sphere to another. Spillover can be positive as well as negative (e.g. work–family facilitation and work–family conflict) and can operate in both directions (e.g. work-to-family and family-to-work).

Subjective health complaints subjective health complaints are health complaints with few or no objective findings, and which typically include muscle pain, tiredness, mood disturbances, fatigue, headaches, sleep problems, and gastrointestinal complaints.

Twelve-step program twelve-step program is a set of 12 guiding principles outlining a course of action for recovery from addiction, compulsion, or other behavioral problems. The program is normally run by former addicts forming a fellowship.

Work Addiction Risk Test (WART) Work Addiction Risk Test (WART) is a 25-item questionnaire developed by Robinson (1998) to measure work addiction. The questionnaire measures five dimensions of workaholism: Compulsive Tendencies, Control, Impaired Communication/Self-Absorption, Inability to Delegate, and Self-Worth.

Work Engagement work engagement is characterized by energy, involvement, and efficiency, and as a relatively stable condition characterized by vigor, dedication, and absorption.

Work–family conflicts work–family conflicts are inter-role conflicts in which the role pressures from the work and the family sphere are perceived as incompatible.

Work Involvement Work Involvement is one dimension or aspect of workaholism as measured by the frequently used Workaholism Battery (WorkBAT). See WorkBAT.

Workaholic workaholic or work addict is a person obsessively addicted to work, person with a compulsive need to work.

Workaholic Anonymous Workaholic Anonymous is a fellowship of individuals who share their experience, strength, and hope with each other that may solve their common problems and help others to recover from workaholism.

Workaholism workaholism or work addiction is compulsiveness about working and/or working excessively.

Workaholism Battery (WorkBAT) Workaholism Battery (WorkBAT) is a 25-item questionnaire developed by Spence and Robbins (1992) to measure workaholism. The questionnaire measures three dimensions of workaholism: "Work Involvement" (eight items), reflecting the need to spend time efficiently both at work and when off work, blurred boundaries between work and private life and the inability to relax. "Drive" (seven items) reflects internal motivation for work and the frequency of thinking about work. "Enjoyment of Work" (10 items) assesses satisfaction from work.

Shopping Addiction

*Michel Lejoyeux**, *Aviv Weinstein*[$]

[*]Paris 7 University, Paris, France [$]Hadassah Medical Organization, Jerusalem, Israel

OUTLINE

INTRODUCTION AND DEFINITION

Shopping addiction is a frequent and often underrecognized form of behavioral addiction. For shopping addicts, buying becomes uncontrolled and repetitive and leads to severe financial and psychological consequences. Addicts do not buy only items they need or they like. They also experiment craving for buying clothes or other items that they do not use after their purchase. They really need to spend their money and are anxious to miss a good opportunity to buy something. This form of addiction represents a pathological form of a normal behavior, stimulated by advertising and considered as a marker of individual and collective health. First descriptions of shopping addiction appeared in the Roman law to condemn spendthrifts who refused or rapidly spent the legacy of their parents. They refused at the same time transmission of family values and brought their own family about the ruin.

Emile Kraepelin, a century ago, proposed the term oniomania (from the Greek "onios" or "for sale"). According to Eugen Bleuler, shopping addiction could be considered as a type of monomania or instinctive impulse. Monomania was also described as an excessive focusing of attention on one object or issue. In 1960, "prodigality" was added to a French Manual of Psychiatry, defined as an abnormality of the conservation instinct, affecting object properties. More recent and consensual definitions describe shopping addiction as a repetition of excessive and impulsive buying entailing financial and familial problems.

Susan McElroy et al. in 1994 specified benchmarks for shopping in its compulsive dimension. These criteria include many clinical characteristics of addiction. They describe equivalents of craving and withdrawal applied

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00085-1

to shopping behavior. They also exclude buying related to a manic state.

Inappropriate preoccupations with buying or shopping, or inappropriate buying or shopping impulses or behavior, as indicated by at least one of the following:

- Frequent preoccupations with buying or impulses to buy that are experienced as irresistible, intrusive, and/or senseless.
- Frequent buying of more than can be afforded, frequent buying of items that are not needed, or shopping for longer periods of time than intended.
- The buying preoccupations, impulses or behaviors cause marked distress, are time-consuming, significantly interfere with social or occupational functioning, or result in financial problems (e.g. indebtedness or bankruptcy).
- The excessive buying or shopping behavior does not occur exclusively during periods of hypomania or mania.

Other definitions distinguish shopping addiction from normal economic temptations. Impulse shopping is a classical aspect of the consumer's lifestyle and a focal point of considerable marketing management activity. Economic studies found that 27–62% of department store purchases fall into the impulse category. One-third of the people, in the general population, experience shopping impulses. Marketing methods such as development of credit cards, cash machines, instant credit, home shopping networks, and telemarketing make it easier than ever before for consumers to purchase items on impulse. In the modern marketplace, spontaneous urges to buy and consume are normal phenomenon. Everyday consumers receive, via the web or in the real life, these stimulations and need to cope with the impulse to consume, "to have it all now." Bargains and new methods of marketing induce the shopping "spree." Confronted by the array of possibilities, each subject modulates his or her own behavior according to their particular level of impulsivity and frugality. Development of online buying has still increased the risk of shopping addiction. The Internet is becoming a basic feature of global civilization. Informative, convenient, and entertaining, the Internet has changed the ways people shop, work, and spend their leisure time.

Whatever shopping occurs in real life or online, it contains a part of emotion. Valence et al. distinguished four types of "pathological consumers:"

1. The emotional reactive consumer places some importance on the symbolism of the product, frequently presenting compensatory consumption and emotional motives.
2. The impulsive consumer feels a sudden spontaneous desire to buy, living in a state of probable psychological disequilibrium with a conflictual struggle between the id and the superego.
3. The fanatical consumer: He is often interested in only one product and is consumed by a monomania (e.g. either records, books, or clothing). This person displays an enthusiasm and an intense devotion.
4. The compulsive consumer tries to reduce psychological tension and sees the act of buying as a means to reduce this tension or anxiety. He or she often does not seek the possession of goods, but rather the immediate reduction of a state of tension.

According to this classification, shopping addiction concerns subjects who are simultaneously emotional reactive, impulsive, and compulsive consumers. Such subjects are especially sensitive to marketing and social stimulation. Most patients presenting shopping addiction reported that having access to credit cards, money, shopping catalog, online websites or home shopping television programs triggered or increased their compulsive buying.

The two best distinctions between normal urges to buy and shopping addiction are the negative consequences of the behavior and the fact that items bought compulsively are not used as much as expected. Shopping addiction buying must indeed be considered as pathological since it causes personal distress, consequential financial debts, and marital and family disruption. While initially providing some perceived benefits, pathological shopping addiction typically becomes very difficult to stop. It ultimately results in harmful consequences like unmanageable indebtedness or bankruptcy.

EPIDEMIOLOGY

Shopping addiction is primarily a female problem. The typical compulsive buyer is a 36-year-old educated woman. The mean age of onset is 30 years. Clinical studies suggest a beginning of the compulsive behavior as soon as people reach financial independence or earn their first wage. Population-based surveys in the United States show that up to 5% of adults may have shopping addiction. Five million Americans spend excessively. Compulsive buying has significantly risen in developed economies and with the web. A study of 200 women who shopped at a renowned Parisian department store found that 32.5% met criteria for shopping addiction. There was no difference from a control group in age, education level, or professional status. Among 1490 customers of an Internet women's clothing retailer, 17.7% were shopping addicts. In a population of 203 medical students, 11% were shopping addicts.

ADDICTIVE NATURE OF THE DISORDER

Shopping addiction can be included in the "addictive spectrum" due to its clinical characteristics in common with classical addictive disorders. Shopping addicts experiment all signs characteristics of dependence and especially craving, loss of control and social and personal consequences of shopping. *But there are also differences from other behavioral addictions – particularly regarding pleasure or positive reinforcement.*

Intoxication

Most patients describe their shopping experiences as "a high," "a buzz,""a rush." They experience a positive feeling when they buy. Their sensation can be compared with the effect of alcohol or drug intoxication.

Craving

Shopping addicts experience irresistible urges, uncontrollable needs, and mounting tension that could only be relieved by buying. The tension is temporarily assuaged by the purchase but a feeling of guilt quickly replaces the euphoria associated with the purchase. A stimulus (either an internal stimulus, such as emotion, or an external one, such as advertising, stay in a shop, fear of missing a good shopping opportunity) can trigger a thought, which in turn creates a craving. This craving can be strengthened by a permissive thought which leads to an excessive purchase. A person can suffer from a sad mood, in a specific moment. In his mind could appear the idea that he will be less sad if he or she could please themselves with a present. She becomes convicted that buying something will make her happier. A craving for buying something (whatever it is) appears. She has on her mind some "good reasons" to do that, such as "I am worth it"… At the end, the patient enters a shop and buys compulsively items she does not really need. Dependents of online shopping experience craving when they see advertising on their computer screen or when they receive mails suggesting them good affairs to make.

Loss of Control

Shopping addicts consider their purchases as occasions not to be missed. They are often disappointed afterward and become angry when they see the amount of money spent. Compulsive buyers would buy clothes from famous designers and top of the line items in order to impress other people. Loss of control involves in the number of items bought (shoes from all colors available in the shop) or the price unaffordable for them. They also shop online more often than controls do. Buying is also impulsive: the duration between desire to buy and purchase is shorter than for normal buying. Due to this loss of control, purchasing is often a lonely activity. Patients are ashamed of their uncontrolled behaviors and do not want to be seen in a situation of pathological consumption.

Equivalent of Withdrawal

Shopping addicts consider that they miss important occasions to buy items when they cannot go shopping and they regret for the items they did not buy. They feel anxiety and tense comparable to manifestations of withdrawal.

Negative Consequences

Like other addictions, addictive shopping can result in a number of difficulties, including substantial debt, legal problems, personal distress, and marital conflict. More than half of shopping addicts have debts and are unable to make payments. They suffer remarks and reproaches from relatives and friends and more rarely they face criminal or legal proceedings. In most cases, what they spend exceeds what they can afford. Shopping addicts take out loans or revolving credit and soon find themselves trapped in a vicious cycle of debt. They borrow large amounts of money from their friends or family. They make promises to pay back what they know that they cannot fulfill. In some extreme cases, they steal to continue shopping. Friends, relatives, and co-workers don't understand their passion for shopping. They start distrusting them. Shopping addicts become rejected and alienated because of their behavior. They are accused of being irresponsible and they hide what they buy. Relatives are suspicious or overly protective, destroying their credit cards or putting them on an allowance.

OTHER CLINICAL ASPECTS

The nature of products that patients buy during compulsive buying episodes are clothing (95.8%), shoes (75%), jewelry (41.7%), cosmetics (33.3%), antiques (25%), records, CDs (20.8%), cars (16.7%), household items (12.5%), and books (12.5%). Men often buy larger items (e.g. furniture, computers, and stereo equipment) in addition to clothing. Websites recently modified the type of items bought in an addictive manner. Items are often used to enhance both others and one's own image of self. In almost every case, the articles are not bought because they are needed or are a bargain, or even out

of an intrinsic desire for the thing itself. Shopping addicts report that about half of the items purchased during uncontrolled buying episodes were used minimally or not at all. Many patients hoard the items they bought and some gave them away as gifts.

Two basic dimensions are found among shopping addicts: tendency to spend and post-purchase guilt. Tendency to spend corresponds to the six following affirmations:

When I have money, I cannot help but spend part or all of it.

I am often impulsive in my buying behavior.

As soon as I enter a shopping center, I have an irresistible urge to go into a shop and buy something.

I am one of those people who often respond to direct mail offers.

I have often bought a product that I did not need, while knowing that I had very little money left.

I am a spendthrift.

Post-purchase guilt is assessed by the two following items:

At times, I have felt somewhat guilty after buying a product, because it seemed unreasonable.

There are some things I buy that I do not show to anybody for fear of being perceived as irrational in my buying behavior.

The majority of patients describe the course of their addiction as chronic. More rarely, they report that their shopping addiction is episodic, with periods of free of buying symptoms. Patients typically report a mean peak frequency of buying episodes of 17 months with episodes lasting from 1 to 7 h in duration.

Shopping addicts don't seek bargains. They consider their purchases as occasions not to be missed and are often disappointed afterward. They can buy clothes from famous designers and top of the line items in order to impress other people. They also shop online more than controls do. Most often, purchasing is a lonely and highly pleasurable activity. Shopping addicts also tend to be very materialistic individuals, to have a low self-esteem and to associate social status with the activity of buying. They buy items more often to impress others and tend to consider their purchases as personally gratifying. Designer's brands induce a great motivation to spend money. Status consumption requires them to continually increase their conspicuous signals of wealth and power. Lastly, shopping addicts are regularly deceived by items they buy. They use them less than expected, try to give them back to shops and sometimes hide them or throw them away. There are also anecdotal cases of compulsive buyers who do not enjoy shopping but enjoy the returning of goods. This is followed by a feeling of empowerment – "the product is not good enough" and it is followed by the return of cash which is spent on buying new goods but not for paying the credit card. Also, compulsive buying often runs in the family and can be used as mother–daughter bonding.

Among a population of medical students, we found that shopping addicts made more often self-gifts. They did not buy more often during bargain periods and did not consider more often their purchases as exceptional or as occasions not to be missed. Percentage of purchases less used than expected was higher in shopping addicts. Their purchases more often increased their level of self-esteem.

We also identified a different relation to money among shopping addicts. The Yamauchi and Templer's money attitude scale (MAS) identifies five factors describing the relation to money. *Power-Prestige* is a tendency to use money to influence and impress others. *Retention Time* assesses the tendency of careful financial planning and *Distrust* represents hesitant, suspicious, and doubtful attitude toward situations involving money. *Anxiety* measures to what extent money can be seen as a source of anxiety and *Affair missing* reflects fear of missing a good opportunity to buy an item. The MAS scores were higher in the shopping addict group for two subscales: *Distrust* and *Bargain missing*. Correlation studies (Pearson test) showed that severity of shopping addiction is significantly correlated to three subscales *Distrust*, *Anxiety*, and *Affair missing*.

We confirmed the diagnostic of shopping addiction with the Questionnaire about Buying Behavior (QABB) which consists of 19 *yes–no* items representing major basic features of compulsive buying (e.g. urges to shop and buy, negative feedback from family and friends, post-purchase guilt) based on the McElroy et al. criteria. The QABB is usually self-administered. This questionnaire, useful for clinical research, cannot replace clinical evaluation. Clinicians must inquire in detail about buying attitudes, the extent of preoccupation with buying and shopping, urges to buy, feeling and thoughts associated with buying, and the interference with social, financial, and occupational functioning.

DIFFERENTIAL DIAGNOSIS

Normal Buying Impulses

Shopping addiction must be distinguished from normal buying impulse. These urges lead to unplanned purchases which correspond to the difference between a consumer's total purchases at the completion of a shopping trip, and those that were listed as intended purchases prior to entering a store. Impulse buying is a pervasive and distinctive aspect of the consumer's lifestyle and a focal point of considerable marketing management activity. One-third of the people in the general population experience buying impulses.

Marketing methods such as development of credit cards, cash machines, instant credit, home shopping networks, and telemarketing make it easier than ever before for consumers to purchase items on impulse. In the modern marketplace, spontaneous urges to buy and consume are thus normal daily phenomena. Everyday consumers receive these stimulations and need to cope with the impulse to consume, "to have it all now."

Collectors

Collectors and shopping addicts both spend a lot of time, money, and energy in the hunt for "precious" goods but the fate of the items and the evolution of the behavior are different. Collectors show their goods with pride once acquired. They often display them, in a glass case, for example. Shopping addicts don't have such a passionate relationship with their goods, which often lose their attraction after purchase. Goods are often hidden in a closed place. For collectors, purchase is only a way to collect a group of objects. The pleasure is in the possession, more than the acquisition. For shopping addicts, the object of the addiction is the shopping itself.

Hoarding

Compulsive hoarding has been defined as the acquisition of, and failure to discard, possessions which appear to be useless or of limited value. People hoard many kinds of items like "free things" ("freebies"), as well as things other people have discarded. Free newspapers and unclaimed magazines are often kept by compulsive hoarders. Association between shopping addiction and hoarding is possible.

Mania

Unconsidered buying are common symptoms of a maniac episode. The disordered behavior comes from a loss of inhibition and the feeling of being almighty. In maniac crises patients make excessive purchases in an impulsive and euphoric way and lose all sense of reality. Diagnostic criteria for shopping addiction exclude buying sprees related to mania.

ADDICTIVE AND PSYCHIATRIC COMORBIDITY

Addiction is often associated with "classical" or chemical dependence on alcohol and nicotine. Among a population of 500 female patients consulting their general practitioner, shopping addiction was present in 97 cases (38%) and more frequent among patients with nicotine dependence (58 cases, 45%) than among those who were not dependent on nicotine (39 cases, 31%). These results suggest that a common addictive spectrum could expose to both addictions.

Shopping addiction is often *associated with depression and/or low self-esteem*. Specific studies found a prevalence rate of 31.9% for shopping addiction among individuals hospitalized for depression. When buyers are asked to describe how they feel before a typical buying episode, 53% say they are sad or depressed and 21% tense or anxious. When asked about their feeling after a buying episode, 42% say they feel guilty and 21% sad or depressed. Shopping addicts are more likely to engage in their pathological behavior when they experience negative emotions. They obtain a temporary relief from their negative emotions and decreased self-esteem. A positive and significant relationship was also found between anxiety and shopping addiction. Shopping addicts use the buying activity as a means of relieving stress and low self-esteem.

Assessment of 1500 consecutive general medical outpatients in Paris identified 60 patients with obsessive–compulsive disorder (OCD), of whom 14 (23%) also had shopping addiction. The prevalence of shopping addiction among patients without OCD was 0.3%. Patients with OCD and shopping addiction had higher scores on the CAGE questionnaire (assessing alcoholism).

Shopping addiction and eating disorders frequently co-occur. One study found that 20% of compulsive buyers also had an eating disorder; conversely, 17.6% of binge eaters had shopping addiction. Among a group of patients with a variety of eating disorders, the lifetime prevalence of shopping addiction was 11.8%.

Shopping addiction can also be a part of the compulsive–impulsive spectrum. Even if some patients of shopping addiction are impulsive buyers, the obsessive–compulsive aspect is often prominent. Also, it looks like shopping addiction is associated with negative affect and its relief and not with positive reinforcement. This is different from other addictions which people also find pleasurable (drugs, alcohol, videogames, etc.).

TREATMENT

The most effective part of the treatment is cognitive behavioral therapy. Pharmacological agents are limited to patients presenting another psychiatric disorder (anxiety or depression). Few medications showed an anti-addictive effect on shopping behavior. If shopping addiction is associated with OCD and addiction, it might be due to low serotonin levels and therefore Selective Serotonin Reuptake Inhibitors (SSRIs) would be relevant

whereas when addiction is pleasurable (e.g. for psychostimulants) there is a role for dopamine in the addiction and possibly in treatment. This hypothesis, however, needs to be confirmed by further experiments.

Cognitive Behavioral Therapy

The cognitive part of the therapy consists in identifying, working on, and changing thoughts and feelings related to buying. Patients often have difficulties identifying their feelings. The therapist should encourage them to use a daily self-monitoring diary of their craving for shopping in general and/or episodes of addictive shopping. Patients are asked to keep track of the kind of items purchased, the time spent in addictive shopping, and the amount of money spent if they failed to resist. During the sessions the therapist analyzes the patient's relationship to pleasure to buy and to money. Dysfunctional beliefs about shopping and the power that derives from it are identified and corrected. Step by step, patients admit that the euphoria they feel when buying a new item is an illusion. A functional analysis shows to them that their dysfunctional beliefs result from personal history and education background.

Treatment for compulsive buying tends to focus on teaching patients alternative responses to cope with negative emotions. The therapist trains the patient to solve his problems without the help of addictive shopping. He finds other behaviors which are less impulsive and more constructive. Therapist may propose homework assignments from one session to another in order to build on that training of alternative behaviors. Homework can also consist in exposition experiments. One such assignment might be to go to the supermarket or another shop, not buy anything and then leave the shop. Shopping addicts are invited to find other sources of pleasure and to rediscover what activities they consider pleasant or effective to release tension. Situations at high risk of relapses must be identified by the patient (e.g. going to a clothes' shop after a stressful situation, or entering into a store without a prepared list of needed items). The more the patient learns to anticipate such risks, the more efficient he will be when exposed to risk of relapse. Cognitive therapy should set up a rescue plan that indicates what to do when the patient faces up to a situation of extreme craving. It must be set up before any crisis so that the patient knows what to do when he is in a risk situation.

Group Therapy

Like most addictive disorders, shopping addiction represents a good indication for group therapy. Dynamic of the group reduces feeling of shame and denial reactions. Patients exchange around a theme (always including a shopping problem). They feel understood by other people suffering from the same addiction. Group sessions reinforce individual therapy and the patient's will to change. It also allows positive identification to shopping addicts who are no more dependents. A few support groups for individuals dealing with shopping addiction exist in different parts of the world. They help patients to find hope and motivation to cope with their craving and their social and financial difficulties.

Pharmacotherapy

Few controlled studies have assessed the effects of pharmacological treatment on shopping addiction. Most of them involved selective serotonin inhibitors. Fluvoxamine did not appear superior to placebo. Citalopram demonstrated a weak efficiency on a limited number of patients. Small open-label studies with other antidepressants (often in combination with mood stabilizers), or the opioid antagonist naltrexone reported improvement in a few number of patients. Clinical practice shows that antidepressants improve both depression and shopping addiction. No study, however, has been specifically conducted on this subgroup of patients presenting shopping addiction and depression. Globally, it cannot be proven that pharmacological treatment of shopping addiction compulsive buying is more effective than placebo.

CONCLUSION

Shopping addiction is a behavioral addiction that may be increasing in prevalence because of shopping availability especially via the Internet. The main characteristic of addictive buying is that items bought are rarely used. They consider their purchases as occasions not to be missed and are often disappointed afterward. Diagnostic criteria for shopping addiction parallel those for substance addictions, pathological gambling, or other impulse control disorders. Much future research is needed to improve the understanding of shopping addiction and to standardize regularly effective psychotherapies and pharmacological treatments.

In addiction, it looks like shopping addiction leans toward the obsessive compulsive end of the impulsive–compulsive spectrum. Secondly, shopping addictions is more associated with relief of depression and anxiety rather than pleasure or positive reinforcement. This has clinical implication for treatment with SSRIs. Thirdly, there are diagnostic issues whether to classify shopping addiction together with other behavioral

addictions (e.g. other behavioral addictions such as Internet and videogame addiction are found to be not only pleasurable but relief from negative affect). It is debated whether shopping addiction should be classified as an impulse control disorder. Its comorbidity with depression might be an obstacle for its inclusion as a separate diagnostic category. Due to these considerations, shopping addiction might be problematic for inclusion in the Diagnostic and Statistical Manual of Mental Disorders, 5th edition (DSM-V).

Fourthly, very little is known about the psychobiological or pharmacological mechanisms underlying shopping addiction, there are hardly any genetic studies or brain imaging that might explain the neuropharmacological basis of this addiction. All these issues are important when considering diagnosis, mechanism of action, and treatment of shopping addiction.

CHAPTER

86

Sexual Addiction

John Bancroft

The Kinsey Institute for Research in Sex, Gender and Reproduction, Indiana University, Bloomington, IN, USA

OUTLINE

INTRODUCTION

The term sexual addiction has been widely used to describe sexual behavior that is recurrently out of control and which continues in spite of significant harmful consequences. For many years now there has been a culture of Sex Addicts Anonymous in which individuals with this problem obtain help with the same 12-step treatment programs used for alcohol- and drug-dependent individuals. There are clearly many features in common with drug addiction, and with other behavioral addictions like bulimia. But the extent to which these different patterns of addiction share the same causal mechanisms remains uncertain.

To add to the confusion, a variety of other names have been used instead of sexual addiction; for example, sexual compulsivity, impulse control disorder and, with a longer history, nymphomania applied to women and satyriasis applied to men. Hypersexuality has been used in the past and has recently been proposed as a diagnostic category for the emerging *Diagnostic and Statistical Manual of Mental Disorders* 5th edition (DSM-V). This term has always aroused controversy because of the implication that a high level or frequency of sexual behavior is necessarily problematic or pathological. Unfortunately more attention has been paid to selecting the appropriate name than to understanding the determinants of such problematic sexual behavior. The term sexual addiction will be used generically in this chapter.

In the last few years, however, some potentially key factors underlying such behavior have started to be identified, paving the way for research to establish their origins and to what extent these origins vary in importance across the range of sexual addictions. The principal emerging factors will be considered more closely in this chapter.

THE NATURE OF SEXUALLY ADDICTIVE BEHAVIOR

The most common pattern is masturbation linked to certain types of fantasy or, more often, pornography. The emergence of the Internet has added a whole new dimension. For sexually addicted men, the Internet

Principles of Addiction, Volume 1
DOI: http://dx.doi.org/10.1016/B978-0-12-398336-7.00086-3

provides a seemingly endless supply of novel pornographic material that drives their behavior, often resulting in Internet access in the workplace, as well as at home. For sexually addicted women, interaction with others on the Internet leads to cybersex. In both cases, the most likely outcome of such stimulation is masturbation. However, in some cases Internet contact leads to real-space sexual interactions. More traditional means of finding new, and typically transient, sexual partners may be used, including prostitutes and visiting strip clubs. It is important to keep in mind that with all these types of sexual expression, the majority of individuals are not out of control and do not suffer major harmful consequences as a result. In a minority, however, the urge to express their sexuality in this way may take over their lives, resulting in many hours of the addictive behavior each day, and with negative consequences for their current sexual relationship, their self-esteem, their work, and often their financial status.

THE PREVALENCE OF SEXUALLY ADDICTIVE BEHAVIOR

As yet, only one study using a representative community sample has assessed the prevalence of out-of-control sexual behaviors. In this New Zealand study of 940 men and women, all aged 32 years, participants were asked about sexual fantasies, urges, or behavior that they regarded as out of control during the previous year. Nearly 13% of men and 7% of women reported such experiences, although only 3.8% of men and 1.7% of women believed that these experiences had interfered with their lives. With these men, paying for heterosexual sex and same-sex attraction and behavior were typical themes. With the women, a high number of male partners, concurrent sexual relationships, sex with a partner met on the Internet and same-sex attraction and behavior were typical. It is not possible from this study to assess the duration of these problematic patterns, and in many cases they may well have been transient.

THE NEUROPSYCHOLOGY OF SEXUAL AROUSAL AND DESIRE

In much of the writing on sexual addiction, and particularly that on so-called hypersexuality, a high level of sexual desire is considered the primary problem. However, the individual acting out his or her sexual addiction is likely to be in a sexually aroused state. The relation between sexual arousal and sexual desire therefore needs to be considered. Sexual arousal is a complex state that involves (1) information processing, both automatic or unconscious, and attentional or conscious; (2) incentive motivation; (3) general arousal; and (4) genital response. Sexual desire involves some or all of these components to some extent, although often this may be restricted principally to incentive motivation plus relevant information processing that identifies the target of the incentive.

The incentive motivation component is probably similar to that for other types of appetitive patterns, and is the aspect of sexuality most directly relevant to the basic mechanisms of drug addiction. However, there is as yet no clear evidence of an aberrant function of this component in sexual addiction of the kind that has been demonstrated with the chronic use of drugs of addiction.

When we look more closely at other components of sexual arousal and desire some important mechanisms become evident, which serve to distinguish the sexual experience as having certain relatively unique characteristics. This is most apparent in relation to genital response, the most fundamentally sexual component of sexual arousal, such as penile erection in the male, and clitoral and vulval tumescence in the female. It is important to acknowledge that specialized inhibitory mechanisms are involved.

Inhibitory Mechanisms

The occurrence of genital response and, with it, the characteristic sequence of general arousal, incentive motivation, and relevant information processing, which combine to produce the experience of sexual arousal, are determined by the interaction between excitatory and inhibitory mechanisms. The Dual Control Model was developed at the Kinsey Institute as a way of conceptualizing this complex process. This model postulates that in the presence of sexual stimuli, either external (e.g. pornography) or internal (i.e. sexual fantasy or thoughts), excitatory mechanisms are activated, but are balanced by inhibitory mechanisms. Whether sexual arousal or sexual desire occurs on any particular occasion, depends on this interaction. At least three types of sexual inhibition have been identified: (1) reactive inhibition that results from information processing that identifies negative implications of the stimulus; (2) inhibitory tone, which normally prevents genital response and other more specifically sexual components of sexual arousal from occurring, and which needs to be switched off if sexual arousal is to occur; and (3) the postorgasmic refractory state, which is much more evident in men than in women, and which combines a temporary reduction of excitation potential with high levels of inhibition. Each of these inhibitory mechanisms is based on automatic (unconscious) information processing. A conscious process of self-regulation, which is not restricted to

sexual situations, but which is relevant to how we manage our sexual lives, will be considered later in this chapter.

Impaired Inhibition of Sexual Arousal

A fundamental assumption of the Dual Control Model is that individuals vary in their propensity for both sexual excitation and sexual inhibition. Psychometrically validated measures of these two propensities have recently been established, and across a range of large samples studied, close to normal distributions of sexual excitation scores and sexual inhibition scores have been demonstrated. Men, on average, score significantly higher on sexual excitation than women, and women, on average, score significantly higher on sexual inhibition than men, although with considerable overlap of the male and female distributions.

This normally distributed individual variability in both men and women has been taken to mean that for most individuals their propensity for sexual excitation and sexual inhibition are appropriate and adaptive, with normal inhibitory mechanisms helping to keep them out of trouble in their sexual lives. In contrast, the more extreme ends of these distributions are likely to be problematic; those with low propensity for sexual excitation and/or high propensity for sexual inhibition are likely to experience difficulties with their sexual responses, or sexual dysfunctions; those with high propensity for sexual excitation and/or low propensity for sexual inhibition are likely to have problems with inappropriate or out-of-control sexual behavior, such as sexual addictions or sexual risk taking. So far, this recently developed approach has been used to explore determinants of high-risk sexual behavior, and the predictions have been well supported in both heterosexual and gay men and in heterosexual women. More limited evidence has shown that men and women who have sought treatment for sexual addictions have a high propensity for sexual excitation, with the men also having a low propensity for sexual inhibition. Furthermore, in a small Kinsey Institute study of self-defined sex addicts, we found sexual inhibition to be more relevant to addictive behaviors involving other people than to masturbatory patterns. This difference needs to be explored further.

The lack of support for low sexual inhibition in women with sexual addictions, reported above, should not as yet be considered conclusive as the measures used were designed initially for men, and may not have asked the best questions about low sexual inhibition in women. The case has been made that inhibitory mechanisms are more crucial and hence better developed in women. A new measure, called the Sexual Excitation/Sexual Inhibition Inventory for Women (SESII-W), has been developed, but has not, as yet, been used in relation to sexual addictions in women.

The Relevance of Negative Mood

It has been widely asserted in the literature that negative mood, both depression and anxiety, is relevant to sexual addiction. This has been reported as comorbidity, with sex addicts being more likely to have a history of mood disorder, but also as a direct relationship, with the addictive behavior functioning to improve negative mood.

This, at first sight, seems surprising as, for most people, negative mood in terms of both depression and anxiety is associated with reduced sexual interest and/or response. However, a consistent finding across clinical studies of mood disorders has been that a minority of patients report a paradoxical tendency for sexual feelings to be increased during negative mood states. As yet, little attempt has been made to explain these unusual patterns.

Recently, research at the Kinsey Institute has focused on this paradoxical pattern in nonclinical groups. A simple instrument, the Mood and Sexuality Questionnaire (MSQ), assessed sexual interest and sexual response during states of both depression and anxiety, with four questions: "When you have felt depressed (or anxious/stressed) what typically happens to your sexual interest (or response)?" In studies of heterosexual men and gay men, and heterosexual women, of those who had experience of negative mood states, around 10% of men and women reported increased sexual interest when depressed, and around 20% when anxious or stressed.

Are such paradoxical mood–sexuality relationships relevant to sexual addictions? In the small Kinsey Institute study of 31 sex addicts, 27 participants (87%) stated that their sexual acting out was predictably affected by their mood; 17 of them reported being more likely to sexually act out when depressed, and 19 when anxious or stressed. Eleven subjects reported this in states of both depression and anxiety. Only two men were less likely to act out when depressed, and no one reported this tendency in relation to anxiety. As a group, their scores on the MSQ were significantly higher than those of the controls ($P < 0.001$), indicating their greater likelihood of being sexually responsive in negative mood states, and they also scored significantly higher on a trait measure of proneness to depression. An association between negative mood and sexually addictive behavior therefore appears to be highly relevant.

Qualitative data from a nonclinical study indicate a more complex relationship between depression and sexuality, and a comparatively simple relationship

with anxiety, most commonly expressed by masturbation. Two mediating patterns are of particular interest:

1. In states of depression one might pursue sexual contact with another person to satisfy depression-related emotional needs, such as making personal contact through sex, feeling validated by another person, and enhancing one's self-esteem by feeling desired by another person. These are direct examples of sex used as a mood regulator.
2. The tendency for sexual interest and sexual arousal to be increased in negative mood states characterized by increased arousal (such as anxiety or stress) may result from excitation transfer.

Both of these patterns are easier to understand if we return to the Dual Control Model. Our original studies of mood and sexuality found that in heterosexual men, the measures of propensity for sexual inhibition were negatively predictive of the paradoxical relationship between depression or anxiety and sexuality, with the measure of sexual excitation propensity being positively but less strongly predictive. In women, only the paradoxical relationship with anxiety was predicted and only by the measure of propensity for sexual excitation. The explanation for this apparent gender difference is not yet clear. However, we can reasonably assume that in men, a normal propensity for sexual inhibition would preclude a paradoxical sexual response while experiencing negative mood. It is therefore evident in the individual man with a low propensity for sexual inhibition that the paradoxical mood/sexuality pattern would allow the types of mood regulation described above.

The second mediating pattern involves excitation transfer associated with states of anxiety or stress. The concept of excitation transfer infers that arousal induced by one type of stimulus can be transferred to enhance the arousal induced by another. Thus if an individual is aroused because they are feeling anxious, this arousal may get transferred to augment arousal in response to a sexual stimulus. However, this would only occur if there was less than normal inhibition of sexual arousal in states of anxiety. But this may be the case in persons prone to sexually addictive behavior. Transfer of anxiety or stress into sexual arousal creates a strong incentive to pursue sexual release through orgasm, leading to the establishment of learned or even conditioned associations between negative mood and sexual arousal. However, the subsequent recognition of this as a recurring and out-of-control pattern induces further negative mood. This pattern is most likely to be manifested in solitary or masturbatory patterns of behavior.

If this paradoxical mood/sexuality relationship is of relevance to some types of sexual addiction, this raises the question of why some individuals have the capacity for these atypical and potentially problematic interactions between mood and sexuality but the majority do not. A negative correlation between MSQ score and age has been found in heterosexual men, which probably means that such paradoxical patterns are more common in younger men and lessen with age. This raises the question of when such an association becomes established? It is a distinct possibility that this occurs during childhood or early adolescence as a consequence of early experiences, such as child sexual abuse or induced guilt about masturbation, that combine sexual response with negative mood. This hypothesis would not be difficult to test with retrospective research.

It has also been postulated that the use of sexual behaviors such as masturbation to alleviate emotional pain may reflect an intimacy dysfunction resulting from child sexual abuse or neglect. An early establishment of a paradoxical mood/sexuality pattern could interfere with normal sexual development, creating a barrier to the incorporation of one's sexuality into close, intimate sexual relationships. It is therefore noteworthy that in a study of heterosexual men, those in exclusive monogamous relationships had lower MSQ scores; that is, were less likely to report this paradoxical pattern.

As yet, we do not have an adequate explanation for these paradoxical mood/sexuality relationships, and the use of the Dual Control Model only provides partial explanation. Further research is needed on this important issue.

SEXUAL ADDICTION AS AN OBSESSIVE-COMPULSIVE DISORDER

The term compulsive has been widely used as a descriptor of out-of-control sexual behavior, without reference to whether such compulsivity relates to obsessive-compulsive personality disorder. In DSM-IV, out-of-control sexual behavior is excluded from the obsessive-compulsive (OCD) category on the grounds that "the person usually derives pleasure from the activity and may wish to resist it only because of its deleterious consequences." Compulsive OCD thoughts often do have sexual content, but are typically accompanied by negative mood and no sexual arousal. Most people with obsessive-compulsive disorder combined with a propensity for mood disorders are likely to experience a decline in sexual arousability during negative mood states, as is the norm. But exceptions do occur occasionally. An example, which has been reported in the literature, is when obsessive-compulsive symptoms include intrusive sexual thoughts accompanied by penile erection. The awareness of the erection intensifies the

anxiety, thus reinforcing the process. This could occur in an individual with obsessive-compulsive tendencies and also a capacity for a paradoxical mood/sexuality relationship, resulting in an atypical, sexualized type of compulsive pattern. If so, one would expect to find evidence of other obsessive-compulsive phenomena in such individuals.

Obsessive-compulsive urges are characterized by their egodystonic nature, typically associated with an attempt to resist them. In the Kinsey Institute study of sex addicts, referred to earlier, 15 subjects were asked whether they tried to resist the urge to act out or whether at the time it was something they genuinely wanted to do. Eleven men and one woman said that they tried to resist, but most did not give a convincing description of resistance (e.g. "I tell myself not to do it, but I do it anyway"). The two most convincing accounts of resistance were from men with obsessive-compulsive disorder. In both cases the sexual acting out was masturbation. One man had intrusive thoughts about teenage boys, or a compulsion to look at pictures of them. This was associated with considerable guilt and resistance. He masturbated to escape from these thoughts and to achieve a very transient calming effect. However, this was followed quickly by renewed guilt and depression. His resistance was to the intrusive thoughts about boys rather than the masturbation. The other man described ruminative preoccupation with sexual thoughts, which led to masturbation followed by the need to shower because of the "dirtiness" of the act.

A few studies have looked for evidence of obsessive-compulsive disorder among sex addicts, usually finding around 15% in this category.

Thus, some forms of out-of-control sexual behavior can be appropriately regarded as atypical obsessive-compulsive phenomena, but this clearly applies to a small minority of those regarded as sex addicts.

A Female Problem

Of interest, is Persistent genital arousal disorder (PGAD) a uniquely female problem that has only recently received attention in the literature. Women with this problem report their genital response and arousal as continuous, overwhelming, and distressing, in spite of repeated masturbation in an attempt to terminate it. In an Internet survey, 76 women with PGAD were likely to be depressed, to report panic attacks, and to monitor their physical sensations in an obsessive-compulsive manner. Two gender differences in sexual response may help us explain this peculiarly female phenomenon. First, women have much less refractory inhibition after orgasm than men; thus, orgasms are less likely to have a limiting effect. Second, a uniquely female aspect of genital response is the automatic increase in vaginal blood flow in the presence of any sexually relevant stimulus, whether or not the woman finds the stimulus appealing. Whereas this vaginal response is often interpreted as a manifestation of sexual arousal in women, it is not predictably associated with subjective arousal, and there is no parallel to this response in the male. However, a woman may be aware of it, and this awareness, in certain women, may initiate a process of monitoring, leading to the augmentation and persistence of the response because of the impact of negative emotions. As yet, the relationship of PGAD to obsessive-compulsive personality disorder is uncertain, but it can clearly lead to out-of-control sexual behavior, particularly masturbation, in women.

FAILURES OF SELF-REGULATION

Apart from the more physiological mechanisms that have been considered as influencing sexual activity, we should also consider the more cognitive approach to self-regulation, which is not, of course, restricted to self-regulation of sexual behavior, and about which there is a substantial literature.

Three components of self-regulation have been described: (1) standards, (2) monitoring, and (3) the operative phase of regulation. Standards are of interest; in particular, the capacity for strict standards to undermine self-regulation. In the Kinsey Institute study of sex addicts, religion was very important for five men. For such individuals, the unquestionable moral unacceptability of most types of sexual behavior conflicts with their sexual impulses, undermining any sensible pattern of regulated sexual behavior. For example, for an individual who believes masturbation to be evil, and who has strong impulses to masturbate in response to images on the Internet, a regulated pattern of masturbation is not an acceptable option, although for most people this can be a responsible way of dealing with their sexual needs. Highly restrictive sexual attitudes can result in inability to conform, starting off a cycle of guilt, mental pain, and the urge to act out.

Self-monitoring is fundamental to effective self-regulation. Alcohol use, as well as fatigue and stress, impairs normal monitoring. This has been called alcohol myopia and euphoric recall and occurs when intoxication causes attention to focus on the positive, sexually arousing, or rewarding aspects of the situation and away from negative consequences and the associated inhibition of arousal. Sexual arousal can be likened to alcohol intoxication in this respect.

Another way to conceptualize this aspect of monitoring is as transcendence or focusing one's awareness

beyond the immediate situation, so that distal concerns or consequences are kept in mind. In the Kinsey Institute sex addicts study, we unexpectedly found indications of a dissociative tendency that could contribute to out-of-control behavior by undermining, if not eliminating, this transcendence. When asked to describe a typical state of mind while acting out, 14 men (45%) gave descriptions suggestive of some degree of dissociation. The following are illustrative examples, each from a different subject: "… an overpowering drive … nothing else is under consideration"; "… numb, completely zoning out, not present, not conscious of reality"; "… trance-like state … kills time and pain …. numb like a dream"; "… feel detached from what is happening"; "… like a drug to numb out." It is possible that such explanations may be post hoc justifications for the behavior, but dissociation has not been explored in the relevant literature and warrants closer study. Do people with out-of-control sexual behavior show more dissociative tendencies in general?

Impairment of self-regulation is clearly relevant to out-of-control sexual behavior, at least in some cases.

TREATMENT

Given the uncertainty and likely variability of the etiology of sexual addictions, it is not surprising that there are no clear treatment guidelines. When the sexual addiction is related to negative mood, a cognitive-behavioral approach may be helpful. The patient is encouraged to look for a typical sequence of events that leads from awareness of the negative mood state to the out-of-control sexual behavior. This may allow identification of stages in the sequence when some alternative and less problematic mood-regulating behavior can be substituted.

An alternative approach is pharmacological. Most attention has been paid to selective serotonin reuptake inhibitors (SSRIs), which have the potential for helping in two ways: by improving negative mood and by inhibiting sexual response. A more radical approach is hormonal, using anti-androgenic drugs such as cyproterone acetate or medroxyprogesterone acetate, which suppress sexual appetite and have been widely used in the management of sexual offenders. However, these may have negative effects on mood. In general, it is preferable to integrate any pharmacological methods into a cognitive-behavioral approach.

CONCLUSIONS

The limited evidence so far available points to a variety of mediating mechanisms that lead to uncontrolled sexual behavior. It remains a possibility that some dysregulation of the incentive motivation system occurs in some cases, comparable to that found in drug addiction. But until we have evidence of this, it is probably best to consider the term sexual addiction as an analogy. Impairment of the inhibitory mechanisms, a paradoxical mood/sexuality relationship, and deficiencies in the self-regulation mechanisms, plus the impact of obsessive/compulsive disorder are all of potential relevance, with the likelihood that when these are better understood we will arrive at a number of subtypes with different etiologies and possibly different methods of treatment. The concept of hypersexuality, currently prominent in the DSM-V recommendations, should be seen as a contributory factor (i.e. high levels of sexual drive or arousability) rather than a sufficient explanation. The common theme, however, is lack of control. In these circumstances, it may be best to use the umbrella term out-of-control sexual behavior to cover this range of problems until we have an advance in our knowledge. The good news is that we seem to be at a point when useful research can be carried out to test the various possibilities addressed in this chapter.

Areca Nut, Betel Quids, and Associated Products

Adam R. Winstock

South London and Maudsley NHS Trust, Kings College London, London, UK

OUTLINE

INTRODUCTION

The areca nut, often incorrectly referred to as betel nut (betel refers to the leaf that the nut is often wrapped in), and its products are the fourth most commonly used psychoactive substance in the world after tobacco, alcohol, and caffeine. Like all such substances its use traverses age, class, and culture, with an estimated 600 million users globally. Areca is a masticatory and is chewed often in combination with tobacco.

The areca nut is the seed of the fruit of the oriental palm Areca catechu and is the core constituent of a variety of raw and purified products (see Fig. 87.1). The nut is a hard brown oval kernel, about the size of a plum stone. The areca palm is not only cultivated for the nut but also for its husk, which is used in paper and insulating wool production. The nut may be eaten raw or refined in a number of ways including boiling in water, roasting, or curing.

It is used most commonly within the Indian subcontinent (India, Nepal, Pakistan, and Bangladesh), but is also prevalent in Taiwan and Southeast Asia (Indonesia, Thailand, Philippines, Cambodia, Loas, Guam, Malaysia among others), the Pacific rim and southern China. Areca is known by different names in different countries. For example, in India, it is commonly referred to as supari, in Papua as daka, and in Thailand as gua. Migration and displacement have carried its use more widely in recent decades and consumption is now seen in parts of Africa, Australasia, Europe, and Northern America.

Although areca can be characterized as a psychomotor stimulant its effects are quite subtle, more comparable to those of coffee or chewed coca or khat leaves than amphetamine. Anecdotally the nut also has significant medicinal properties ranging from anti-helminthic (in Ayurvedic medicine) to astringent, dentifrice, aphrodisiac, and digestive enhancer. The major risk associated with the use of areca nut is the dose dependent risk for the development of premalignant oral lesions including leukoplakia, submucous fibrosis, and oral squamous cell carcinoma.

For such a widely used substance, it is perhaps surprising as to the paucity of literature within the addictions field regarding its use. Possible explanations include its wide cultural acceptability, relatively mild psychoactive effects, uncertainty over its abuse potential, and the absence of overt public health consequences beyond those to the individual consumer.

HISTORY

The first reports of areca nut use date back to the fifth century BC where legend tells of a princess from the Pali region of India giving a gift of areca to her nurse. Areca is referred to in ancient Sanskrit scriptures and its medicinal properties were first described by the scholar Vagbatta in 500 AD. Throughout diverse cultures the nut has a rich history with the origins of its use embedded in religious, ceremonial, medical, and social activities. Such functions are supported by the discovery of artifacts including elaborate utensils for its preparation and serving, which have been identified throughout many ancient civilizations. Anthropological texts also describe a wide range of functions from improving stamina and work performance to supporting fertility.

EPIDEMIOLOGY

The largest areca using population in the world is India, with a prevalence of 20–40% in some regions, followed by Indonesia, China, and Taiwan. In many counties children are first introduced to areca by family members in social or ceremonial gatherings. In most cultures use is more prevalent among men, though the gender ratio of use varies widely between cultures. Epidemiological studies of use in south Asia and India generally find that use is more common among older people though in some countries such as Micronesia the age of onset is much earlier (average 12 years) resulting in 10% having oral pathologies by their teens.

Use tends to be higher in those with lower levels of education and those engaged in manual forms of employment. Other risk factors for use include prior smoking of tobacco, parental use of tobacco or areca chewing, living in rural and remote areas, peer pressure, social and cultural identification and aggressive marketing and promotion to risk groups such as truck drivers in Taiwan and school children in India. Recent genetic studies have also identified specific alleles for mono amine oxidase-A (MOA-A) activity that may confer elevate risk for heavy betel quid (BQ) use. The level of use however varies widely between cultures, preparations, and type of user. Most studies of regular users report typical daily users chewing 1–10 nuts day^{-1} in 4–10 sessions. Heavy users may chew more than 40 nuts per chewing continually throughout the day, even sleeping with a quid in their mouth at night.

Some countries such as Thailand, Malaysia, Singapore, and Cambodia have seen a fall in recent decades in the prevalence of areca nut. In Thailand this has been reflected by a decline in oral cancer rates. Over the same period however Thailand has seen a corresponding increase in the use of alcohol and amphetamines. Conversely Taiwan has seen a recent increase in the prevalence of areca use. This appears related to the freeing up of the tobacco market in Taiwan in the 1908s. Studies indicate that in Taiwan tobacco smoking acted as a gateway to chewing, with most chewers in Taiwan also being tobacco smokers. The escalation of both habits (not helped by the frequent location of shops selling betel, tobacco, and alcohol) has led to a fourfold increase in the rate of oral cancer in the past two decades.

The effects of migration on use are inconsistent. Migrant communities may record an increase in use where continued use assists in defining ones cultural heritage. Equally among second-generation immigrants there may be a transition to more local patterns of substance use that are often associated with greater risk of harm.

PREPARATIONS (SEE TABLE 87.1)

Areca nut is traditionally used in combination with the leaf of the piper betel vine (a member of the piperaceae or pepper family). The leaf contains aromatic

TABLE 87.1 Major Preparations, Composition, and Region

Preparation	Composition	Region
Areca nut	Unripe, ripe, baked, roasted, boiled, fermented	Various
Betel quid (pan)	Areca (ripe), betel leaf, slaked lime, flavorings +/− tobacco	India, Taiwan
Lao-hwa quid	Split unripe nut sandwiched between flower of Piper betel Linn, red lime	Taiwan
Stem quid	Split unripe nut sandwiched between flower of Piper betel Linn, white lime	Taiwan (aborigines)
Mainpuri	Tobacco, slaked lime, camphor and cloves	India
Supari	Roasted flavored nut pieces	India−Uttar Pradesh
Mawa	Areca, slaked lime tobacco	Northern India
Gutkha	Areca nut, lime, catechu, flavorings, fragrance, and tobacco	Gujarat−India and immigrant populations, for example, in the UK and USA
Pan masala	Areca nut, lime, catechu, flavorings, and fragrance	

FIGURE 87.2 (a) Typical composition of betel quid: Betel leaves (A) with slaked lime (B), areca nut (C) and tobacco (D). phenols including chavicol, allylpyrocathechol, chavibetol, and cadinene. The most common and traditional preparation of areca nut is in the form of the "betel quid" (see Fig. 87.2(a) and (b)), comprising the betel leaf, sliced areca nut, and slaked lime (aqueous calcium hydroxide). Slaked lime (from burnt coral, shell fish or lime stone) increases the pH of saliva facilitating the extraction of arecoline and guvacoline, which are then absorbed transbuccally and a to lesser extent sublingually and orally into the bloodstream. The addition of lime to the quid also increases the generation of mutagenic oxygen-free radicals and is itself caustic to oral mucosa, rendering it more susceptible to carcinogens. Quids may be prepared commercially at small stalls or be prepared by the user themselves, the individual taking all that is needed with them in a pouch or tin.

Beyond this basic recipe however, there are myriad variations in the treatment of nut (it may be used ripe or unripe, raw, baked, boiled, roasted, or fermented all of which reduce the tannin content, improving palatability), its additives. These include catechu (an astringent, reddish-brown substance that is often smeared on the betel); kratom (which has been used as an opiate substitute in Thailand and Malaysia); flavoring ingredients (which can include spices such as cardamom, cloves and cinnamon, and various condiments); various types of lime (red or white). Variation is also seen in the precise preparation of the quid (see Fig. 87.3). Uniquely in Taiwan in addition to the leaf, the safrole containing betel inflorescence is used (though usually not with tobacco).

Perhaps the most significant variation in composition from a health and abuse potential perspective is the common addition of tobacco to the quid or other areca preparations such as Mawa (areca, tobacco, and slaked lime), which is seen in the Gujarat province of India. The tobacco itself may be dried, fermented, or powdered. It is probable that tobacco became available to chewers through its introduction into India by Europeans in the sixteenth century. Cultural variations are also seen in the administration of the various products. For example, quid chewers in Papua New Guinea apply the lime separately to the corner of the mouth. In parts of India the nut has more recently been commercially prepared as Supari – roasted and sweetened small pieces of nut served as a digestive.

The use and formulation of areca like other naturally occurring psychoactive substances have been impacted upon changes in technology and lifestyle. Traditional preparations of the nut were perishable and required a fresh source of the nut, limiting it appeal in

FIGURE 87.3 Woman preparing betel quids. *Copyright Adam R Winstock*

modernizing cultures. Advances in purification, packaging, and branding have led to the proliferation of a wide range of dry, relatively nonperishable, industrially manufactured, freeze dried formulations of the nut. India has led the way in the development and marketing of these products, which are sold in heavily branded foil sachets or tins (see Fig. 87.4). Typically preparations comprise a combination of powdered areca nut, lime, catechu, flavorings, and fragrance. Without tobacco the product is known as pan masala. When the composition includes tobacco the product is referred to as gutka. The addition of sweeteners fragrances and inconsistent product labeling mean tobacco-containing products represent a covert and unregulated entry point for young people to nicotine dependence. Although banned in many states in India and unavailable in much of Southeast Asia, these products are exported globally and are still widely available.

Distribution and sale of the various preparations also vary widely between cultures from road side sellers and corner shops, to the scantily clad Bin Lang ("betel quid barbies") girls in Taiwan, to online sales supporting global marketing. Of particular concern is the aggressive marketing of prepackaged tobacco-containing products targeting younger users. The commercial value of areca products worldwide is likely to be worth hundreds of millions of dollars each year.

FIGURE 87.4 Lao-hwa quid. *Copyright Adam R Winstock 2005*

ROUTE OF ADMINISTRATION

Areca is a masticatory (chewed substance). The process of chewing breaks down the nut and other organic material releases arecoline and other active compounds into the saliva. Typically after a few cycles of mastication the folded leaf package ("quid") is then placed in the mouth and held against the oral mucosa of the buccal cheek and molar teeth. With the initial taste being rather bitter, many users spit out the product of the first masticatory cycle. Periodic rechewing supports further extraction of the juice. Although chewing leads to some gastrointestinal absorption (subject to first-pass metabolism), the primary route of absorption is likely to be direct systemic absorption through the buccal and sublingual mucosa, leading to an onset of effect in the majority of chewers within 5 min, with a duration of action of 2–3 h. Typical red spittle patterns frequently marble the streets of many cities where the habit is common, often accompanied by "no spitting" signs.

SOUGHT AFTER EFFECTS (SEE TABLE 87.2)

Areca shares much in common with nicotine, inducing a relatively mild but reinforcing mix of

TABLE 87.2 Sought After and Physiological Effects

Sought after effects	Physiological effects
Increase in mood and well-being	Salivation
Reduction in hunger	Sweating
Improvements in concentration/performance	Offset fatigue
Improved socialization	Nausea
Hot bodily sensation (a feeling of warmth)	Increased heart rate
Pain relief	Pupillary constriction
Oral hygiene astringent and breath fresher	Broncho-constriction
Facility bowel movements and digestion	Vasodilatation and facial flushing
Calming/relaxant	Possible anti-helminthic

stimulant and anxiolytic effects. Its subtle stimulant effects with a gradual onset of action related both to the low potency of its active ingredients and route of administration – mean that it has more in common with coffee or coca leaves than with cocaine or amphetamine. As with other stimulant drugs the precise effects will be dependent upon the dose consumed, whether or not tobacco is also used and the pharmacogenetic profile and tolerance of individual. Consistent with its history of ceremonial use and distribution at social gathering, users report a mild elevation in their sense of well-being and an increase in sociability.

PHARMACOLOGY AND PHYSIOLOGY

The nut contains a number of psychoactive alkaloids, of which arecoline (methyl-1,2,5,6-tetrahydro-1-methyl-nicotinate), a volatile oil that resembles nicotine in both effect and structure, is the one present in the greatest quantity. Arecoline is probably responsible for most of the sought-after effects of areca nut chewing but is also responsible for its cytotoxic and genotoxic properties. The nut also contains a number of other potentially psychoactive compounds including the alkaloids arecaidine, guvacoline, guvacine, and a number of polyphenolic compounds and tannins.

The nut has complex physiological effects and activates both the sympathetic and parasympathetic nervous systems. Chewing leads to a transient increase in sympathetic activity (with elevations in plasma noradrenaline and adrenaline levels), manifested as an increase in stamina, heart rate, skin temperature, and a reduction in hunger and choice reaction time. Electroencephaolgraphic are also consistent with increased sympathetic activity studies with increases in both alpha and particularly beta rhythms.

Arecoline is also a potent cholinergic agonist and leads parasympathetic activation resulting in bradycardia, pupil constriction (overall there are insignificant effects on pupil size because of parallel sympathetic activity), and increases in salivation and smooth muscles stimulation consistent with subjective pro-digestive properties. Activity at muscarinic and nicotinic receptors may underlie the subjective and now laboratory confirmed reports of improved learning in healthy volunteers. The use of arecoline has also been investigated as a potential cognitive enhancer in those with dementia. Specific areca alkaloids also act as competitive inhibitors of γ-aminobutyric acid receptors in the brain, cardiovascular system, and pancreas. Areca is also rich in copper, which has been implicated in the pathogenesis of oral submucous fibrosis (OSF).

SHORT-TERM ADVERSE (SEE TABLE 87.3)

A combination of its cholinergic activation and psycho stimulant effects mean that areca may occasionally result in adverse gastrointestinal, cardiovascular, and neurological experiences. These are generally short-lived, self-limiting, and will be more common in naïve users where tolerance has not been developed (see Table 87.3)

Occasionally harms may arise from contamination of the nut or other quid constituents by naturally occurring harmful substances, for example, aflatoxin (a naturally occurring mycotoxin that is produced by many species of the fungus Aspergillus).

LONG-TERM EFFECTS (SEE TABLE 87.4)

Excessive long-term use of areca nut and BQ has been associated with a number of health-related harm issues most seriously oral cancers. The risk of long-term harm is related primarily to frequency and duration of use as the concurrent use of tobacco. The use of tobacco and areca results in synergistic harms which are dose dependent.

OSF is a high-risk premalignant condition characterized by the insidious development of fibrous white bands representing blanching and stiffening of the oral mucosa and oropharynx (see Fig. 87.5). Symptoms include oral pain and hypersensitivity, characterized by a burning sensation in the mouth, trismus and reduction in mouth opening, which can be severe, limiting speech, and mastication. The disease is nonreversible and malignant transformation is seen in 3–8%. The risk of OSF is in part related to the preparation used. For example, unripe areca nuts have higher tannin levels than ripe nuts and are more likely to result in OSF. More worryingly, freeze dried products such as pan masala, guthka, and mawa (areca and lime) that have high concentrates of areca nut per chew, appear to cause OSF more rapidly (in some cases after just 3–4 years of chewing) than conventional raw BQ preparations that contain smaller amounts of areca nut.

TABLE 87.3 Short-Term Adverse Effects

Tachycardia/palpitations hypotension and bradycardia
Tremor
Sweating
Dizziness
Diarrheas, nausea and vomiting
Shortness of breath, worsening of asthma

TABLE 87.4 – Long-Term Adverse Effects of Areca Chewing

Oral	Discoloration of teeth and gums Mouth ulcers, mucositis, gingival disease, gum recession, periodontitis, molar wearing and cavitation Leukoplakia Eyrthoplakia Submucous fibrosis 10-fold increase in risk of oral squamous cell carcinoma
CVS	Inconsistent data supports increased risk of cardiovascular disease and cerebrovascular accidents
Metabolic	Hyperglycaemia and increased risk of type 2 diabetes and central obesity
Gastrointestinal	Peptic ulceration Liver cirrhosis and hepatocellular carcinoma
Pregnancy outcomes	Low birth weight
Psychiatric	Dependence

Leukoplakia is an asymptomatic condition characterized by patches of keratosis (over growth of keratin) visible as white patches inside the mouth. It is seen in about 10–20% of chewers. Although areca alone can cause leukoplakia, the risk is elevated in those who also chew tobacco.

Oral cancer. Areca nut has been classified as a group 3 human carcinogen. Its potential for causing malignancy is dose dependent. Among high prevalence chewing populations more than 50% of oral cancers are attributable to areca use. There appears to be a synergistic dose dependent interaction between areca and tobacco with an elevated risk of oral pathologies and cancers (typically oral squamous cell carcinoma). A three- to tenfold increase in cancer risk is seen among smokers who are also areca chewers. Certain genetic polymorphisms are also associated with an increased risk of developing areca-related malignancy. As such inquiry about a family history of chewing and oral cancer is recommended. Areca is also a risk factor for other head and neck cancers as well as hepatocellular carcinoma.

FIGURE 87.5 Pan masala and guthka.

OTHER HEALTH CONSEQUENCES

More recently research has identified areca use as a risk factor for a range of metabolic disorders including type 2 diabetes. There are no reports linking areca nut use and any specific psychiatric disorders, though it should be stated that there has been little search in this area. There are no reports of acute psychosis developing following the use of areca. In small but a representative population study, among patients with schizophrenia areca use was associated with milder symptomatology and no increase in extra pyramidal symptoms.

EFFECTS ON PREGNANCY AND THE NEWBORN

Arecoline crosses the placental barrier. Adverse pregnancy outcome has been reported from a number of studies. Controlling for tobacco and alcohol use a large Taiwanese cohort study found that mothers who chewed areca through pregnancy have poorer birth outcomes, including lower birth weight, reduced birth length, and a lower ratio of male to female offspring. Another study from Papua New Guinea has confirmed the association of areca nut usage and low birth weight. Of interest this later study reported that one-third of women indicated that a reason they had continued to chew through pregnancy was to prevent morning sickness. In general babies appear healthy in most perinatal respects. There has been single case report of suspected neonatal withdrawal.

ABUSE LIABILITY AND DEPENDENCE

The areca nut demonstrates a number of characteristics common among substance of abuse. Preparation and use is often ritualized, effects are reinforcing, and chronic habitual use is common across cultures. About 50% of users are daily chewers and dependence has been reported to be seen in 15–60% of users. One of the first references to its addictive potential was in a research paper entitled "Betel mania" exploring use among Cambodian refugees in the United States in the early 1990s.

Rates of dependence are higher among those chewing refined products and those mixing areca with tobacco. Chewers also smoke more than nonchewers. Tolerance

is seen, with users increasing their dose. This is supported by laboratory studies demonstrating that habitual chewers show a less marked increase in pulse than occasional chewers and reports of naïve chewers being more likely to report adverse symptoms such as tremor, dizziness, gastrointestinal upset, and nausea. Although chewing delivers a more gradual onset of effect than smoking, experience from smokeless tobacco users supports the notion that the transbuccal route of use can be an effective and reinforcing route of administration. The similarity in pharmacological activity and effect profile to other chewable ethnopsychopharmacological agents (tobacco, khat, pituri, and cocoa) is also consistent with areca having dependence potential.

There have however been relatively few studies assessing dependence among areca using populations. Most have been small case series, though in recent years some larger population-based studies have been conducted. Most studies indicate that the common symptoms of dependence reported by users include continued use despite knowledge of harm, craving, difficulty in controlling use, and unsuccessful attempts to cut down. Many studies have been confounded by the concurrent use of tobacco by the study population. Severity of dependence and level of use is heavier in those who also use tobacco (whether chewed and/or smoked) and alcohol. Studies assessing areca-only chewers tend to identify a lower frequency of dependence. One recent Taiwanese study reported that 44% of chewers endorsed at least one of the following items: continued use despite oral health problems, difficulty in control use or craving during periods of abstinence or difficultly in controlling use but less than 15% reported a more complete constellation of symptoms. In raising awareness of the harms associated with its use, public health officials do need to consider the potential harms of labeling a culturally sanctioned substance in terms of addiction. Such labeling may meet with considerable resistance, especially if such attention resulted in stigma, a compromised supply, or an increase in cost.

ASSESSMENT OF USE AND DEPENDENCE

Assessment of areca nut use follows the same basic principles as for any substance. Core elements include the determination of the preparation used, amount, and frequency of use and the concurrent use of other substances in particular tobacco in any form, and alcohol. The function of its use and concerns that individuals may have with regard to stopping should be explored. Dependent use will be suggested by heavier, daily use, commencement of use soon after waking, and consumption throughout the day with some users reporting queuing outside pan shops, waiting for them to open, and never being without a quid in their mouth. A more detailed assessment of use may include how many whole nuts are consumed per day, whether use is confined to certain occasions or just after meals, how long each quid or equivalent unit of dosing is chewed for and kept in the mouth and whether juices are swallowed or spat out. Since risk is dose and preparation dependent such information can form the basis of some simple harm reduction interventions (e.g. chew fewer quids per day, keep each quid in the mouth for less time, avoid combined use with tobacco products). Direct questioning as to the experience of any withdrawal symptoms on cessation of use (including an increase in tobacco smoking among those who chew and smoke tobacco) are important parts of the assessment (see later section on screening and brief interventions). Screening tools such the Self-report Screening Test for Areca Quid Abuser modified from DSM and developed in Taiwan, may be useful but require further evaluation within community settings and other countries.

The available, albeit small, literature suggests that withdrawal symptoms are seen in some users. Symptoms include mood swings, anxiety, irritability, poor concentration, sleep disturbance, lethargy, muscular aches, and an increase in appetite. They are more common and pronounced in those who also use tobacco. Many users report unsuccessful quit attempts and it is probable that the avoidance of withdrawal will be a significant driver for continued use and a common cause for unsuccessful quit attempts

CULTIVATION, COMMERCIALIZATION, AND REGULATION

In many countries, cultivation and commercialization of the areca palm is unregulated and often untaxed. Although employing large numbers of farmers, distributors, and sellers, the impact of unregulated cultivation has led to deforestation and mudslides in some areas. The wider socioeconomic impact of such unregulated and expanding production at the expense of other cash edible crops has attracted little attention. Given the profitability of nut growing, governments may need to provide compensation to farmers for growing alternative cash crops.

The commercial production, global distribution, and promotion of freeze-dried nonperishable products have widened the potential population of users. Products such as gutkha and pan masala represent a booming industry, utilizing marketing and promotional strategies frequently employed by the tobacco and alcohol companies. Advertising, colocation, and co-branding remain a problem. The provision of free packets of chewing tobacco with pan masala (where the combined product

has been banned) shows a determined marketing strategy to maintain levels of use. Areca is not controlled in the United States, widely available in the United Kingdom and Europe and is unlikely to be subject to further regulation. It is possible that should a more potent, purified version with enhanced abuse liability be developed (as occurred with methcathinone derived from khat) and commercially marketed then such legislation may need to be considered.

INTERVENTIONS

Despite its prevalence and associated health consequences there is an insufficient research to support the promotion of evidence-based guidelines regarding the prevention and treatment of areca nut abuse. Given the diverse populations and cultures in which areca is used, flexibility and local assessment of such approaches will be required in order to determine the most effective approach within each community or region.

The key strategic outcomes for areca are likely to be the same as for any drug: (1) reduction in the rate of uptake (initiation into use) and/or a delay in the age of onset of use; (2) reduction in overall prevalence of use; (3) reduction in the harms associated with its use; and (4) the early detection of problems related to use and referral for treatment. Public health and policy strategies previously adopted and evaluated for alcohol and tobacco are a reasonable starting place for policy makers considering implementing effective public health interventions. Given the co-occurrence of all three behaviors and the synergistic harm between them, linked public health and policy strategies will not optimize resources utilization but also health outcomes.

TABLE 87.5 Potential Public Health and Policy Strategies to Reduce Prevalence and Harms

Target	Intervention
Population level consumption	Interventions aimed at reducing tobacco and alcohol use. Taxation, reduction of number of outlets/opening hours
Public health education	Health awareness campaigns – use of role models Culturally sensitive, locally resourced campaigns Social marketing targeting youth population Restrictions on promotion/marketing Accurate labeling of contents and harms
Screening and early referral	Routine assessment of areca nut use and smokeless tobacco use by dental health and other primary care providers – coupled with opportunistic brief interventions and referral to specialist oral pathology or tobacco cessations service. Areca-flavored gum, nicotine gum

PUBLIC HEALTH AND POLICY APPROACHES (SEE TABLE 87.5)

Areca nut consumption is a leading preventable cause of oral malignancy. Despite its widespread use, community awareness of the risk in most using populations is low, with tobacco being the only correctly identified risk factor associated with quid chewing by subjects in one study. With research indicating that onset of tobacco and alcohol use is associated with increased rates of adolescent onset chewing, youth-focused interventions addressing all three substances appear warranted. Restriction of sales to youths and school-based projects may also act as an indirect route to educating and reducing parental use of areca (see Fig. 87.6). Other high-risk populations such as truck drivers, older women, and the military could also be targeted. Campaigns will need to take into account issues of literacy and social conformity within more remote areas.

Evidence from Taiwan supports the role of centrally regulated taxation as effective strategy to reduce the prevalence of areca use with an additional notable finding being that increasing tax on tobacco products has a significant effect on reducing rates of areca use and to a lesser extent alcohol. Given the socioeconomic spread of use within some cultures as with tobacco, it is possible that taxation will hit those with already high levels of ill health compounded by poor access to good health care and nutrition.

TREATMENT RESPONSES (SEE TABLE 87.6)

Apart from family interventions there has little work done exploring the effectiveness of more individual-based approaches such as brief intervention and substitution therapy. Given the existing evidence to support the efficacy of behavioral interventions for tobacco use conducted by oral health professionals as part of an oral health screen by dental practitioners, adapted brief interventions and opportunistic screening within primary medical and dental health care services should be developed and evaluated. A recent UK study suggests that increased training in the skills required to provide opportunistic screening and brief interventions are needed for dentists (and probably other health care workers) in high-risk areas. Addressing tobacco

FIGURE 87.6 Public health awareness campaign, Taiwan. *Copyright Adam R Winstock*

smoking independently may also have a significant effect upon areca chewing with longitudinal studies from Taiwan confirming more than twice the quit rates among chewers who had quit smoking than those who had not. Addressing concurrent tobacco use in any form should also form one of the core approaches to harm reduction. Others should be based upon reducing the frequency and duration of exposure. Encouraging use without tobacco could also be supported by the appropriate use of nicotine replacement (probably gum). To date the research conducted into smokeless tobacco prevention and treatment has yet to embrace the challenge posed by areca products.

Even where tobacco is not used a behavioral approach using a substitute masticatory such as betel nut flavored chewing gum (available in Taiwan) may be of use. Advice on gradual as opposed to sudden cessation (which is likely to be associated with a less significant and milder withdrawal syndrome) should routinely be given. Only in the most severe cases could any form of symptomatic relief be considered as indicated (in the form of low dose anxiolytics and/or sedatives for a few days). Generic advice regarding sleep hygiene and avoidance of triggers should be provided.

CONCLUSION

Areca nut remains a major cause of mortality and morbidity for many millions of users around the world, primarily though its link with oral malignancy. Dependence is more common in those who use tobacco and tobacco containing products. Targeting the use of tobacco at both population and individual levels remains a key strategy. Evidence-based approaches to smoking prevention and smoking cessation are likely to significantly lower the rates of areca nut use. The significant impact of parental use of areca on the uptake of chewing combined with the frequent association of areca consumption with the use of other harmful substances especially tobacco and alcohol mean that a broad range of interventions are required. Any attempt to address areca nut usage should be conducted in tandem with strategies targeting alcohol and tobacco. Lessons from tobacco prevention, control, and treatment suggest raising public awareness through health education campaigns and enforcing regulations on marketing and product labeling are all likely to prove effective in reducing use. Prevention of early initiation through school based interventions need to be more widely evaluated and seen in the context of broader heath promotion

TABLE 87.6 Potential Individual Harm Reduction Approaches

Target	Intervention	Aim
Cessation	Advice to stop coupled with behavioral support and counseling	Reduce duration of exposure to carcinogens
Preparation	Avoid tobacco Use ripe versus unripe nut Reduced lime Genetically modified nuts	Reduce carcinogenic load
Chewing	Chew less often, for less time Do not sleep with quid in the mouth Do not swallow juices Alternate chewing quids with gum of other less toxic masticatory	Reduce total time in contact with oral mucosa
Replacement	Areca flavored gum, nicotine gum	Reduce total consumption, reduce risk behavior
Oral hygiene reduce	Rinse mouth out after use with chelating agent	Reduce carcinogenic activation
General diet	Health educational and improved access to affordable healthy food stuffs	Reduce alcohol and increase vegetables and fruit, possibly green tea with its antioxidant effects and improve oral hygiene

campaigns. A richer scientific base is required to evidence the utility of most of these approaches since at present their use can only be recommend based on their effectiveness with other substances. Research to date supports the role of increased taxation on tobacco and areca, other approaches targeting alcohol and tobacco use and family interventions. Whether there is a role for introducing genetically modified nuts with lowers levels of carcinogenicity is at present uncertain. While reducing population levels of use may be expected to result in a decline in incidence of oral cancers, countries need to monitor the impact of any policies on the uptake of other potentially more harmful substances.

**Wolfson Institute of Preventive Medicine, London, UK

OUTLINE

INTRODUCTION

Khat is referred to the young and tender leaves and shoots of the khat tree (*Catha edulis*). It is an evergreen tree of the Celastraceae family, normally reaching 6 m in height, but in an equatorial climate it might grow up to 25 m. *Catha edulis* can be found in the Abyssinian highlands, the Horn of Africa, Eastern and Southern Africa, the Arab peninsula, and Afghanistan. The khat leaves have been consumed for centuries for their mildly stimulating properties. Khat has many names including *qat* (Yemen), *jaad/chat* (Ethiopia, Somalia), *miraa* (Kenya), or *marungi* (Uganda, Rwanda). Medieval writings and legends confirm its longstanding use, but also its Janus-faced effects being described as positive and negative. Before the eighteenth century, European travelers to the region have not noticed this custom. After having been described first by the Swedish botanist Peter Forsskål (1732–1763) a high number of travelers of the nineteenth and twentieth century mentioned its growing use. Since the end of the nineteenth century with successive transport innovations, the railway network, road haulage, and air cargo, khat has made its way from a niche crop to a cash crop, today being the economic backbone for countries like Ethiopia and Yemen. More recently, mass migration of people from the Horn of Africa meant the rapid spread of khat usage to neighboring countries, Europe, and rest of the world and the development of an international market. For commercial purposes, nowadays it is grown in the highlands around the Horn of Africa, Southern Arabia, and along the Eastern African coast in altitudes of 1500–2500 m above sea level, mostly pruned to 2–7 m. Within centuries, an amazing variety of khat types have developed out of regional climatic and environmental conditions and local cultivation habits.

Soon after harvesting, the twigs and shoots are artfully rolled into bundles and wrapped into banana leaves in order to retain moisture. In most instances, these bundles are the traded units. The leaves and tender

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00088-7

stems are usually chewed and are kept in a tight wad in the cheek pocket. Within about 30 min the user experiences physiological excitability, euphoria, talkativeness, and flow of ideas known in Arabic as "mirquaan." This is followed by a quieter, more introvert phase, giving way to a gradual comedown, and often restlessness, irritability, and melancholia. Among the ethnic groups in producing regions, khat chewing has long been a regular part of social life, accompanied key social events, strengthening the social fabric. The traditional moderating khat culture restricted access to male adults and to weekends or special occasions. Traditionally, khat was chewed communally, in Yemen, Ethiopia, and Somalia in khat houses, dedicated rooms within private households often known as "mafrishes." A more regular pattern of consumption was also found among higher class users adjacent to the production region, traditionally inspiring artistic expression in architecture, handicraft, poetry, and songs. In addition, khat farmers and long-distance travelers used khat in order to stay awake and strengthen their physical abilities. It is also used during Muslim prayers and ceremonies as well as by students for being able to study all night.

PREVALENCE OF KHAT USE

The estimation of the exact prevalence of khat use is difficult, as the consumption still largely depends on socioeconomic, ethnic, and geographical factors.

In Yemen, the habit of chewing khat was once restricted to the northern highlands and to higher classes and special social happenings, while today the population at large has access and can afford to buy khat. Based on the Household Budget Survey 1998, Yemenite households spent around 9–10% of their income on buying khat. In 70% of households at least one khat chewer is reported and its use is nearly equal among all segments of the population. A recent cross-sectional study including 792 persons of the general population aged 15 or above found a lifetime prevalence of 81.6% among men and 43.3% among women; current everyday use of khat was found in 23.6% of the total sample (men 31.8%, women 8.9%). In another study, among 2500 patients of the Sana'a University dental school, 61.1% were current khat chewers – 87.0% of men and 12.9% of women.

In Ethiopia, khat chewing has traditionally been a habit in the southern and eastern part of the country, especially in Harerghe and among the Muslim populations. There are no prevalence studies for the general population on a national level. A household survey in the khat-producing, predominantly Muslim, rural community of Butajira including 10 468 adults above the age of 15 found 75% of men and 35% of women as current khat users, while daily use was found in 8.7%. In another household survey among 1028 adult respondents in the rural district of Adami Tullu, in southern central Ethiopia, with mixed-religions community, current khat chewing was reported in 40.4% of men, 18.2% of women, while daily use was found in 5.7% of the total sample. Khat chewing was also more frequent among the Oromo ethnic group, among Muslims, married respondents, those with lower education, and the farmers. A representative national assessment of 16 606 adolescents and young adults (15–24 years of age) found a 4-week prevalence of 16.2% and everyday use by 4.3%; khat chewing was more frequent among out-of-school youth. Other studies among Ethiopian high school or university students revealed current prevalence rates between 17.5 and 64.9% and differences between urban and rural areas.

In Kenya, khat chewing is traditionally practiced by some Meru tribes (Nyambene Hills) and Muslims, mostly Somali of origin, in the northern part of the country. No prevalence data for the general population are available. Some studies of patients of general health services in different parts of the country disclosed a lifetime prevalence rate of 10.7% in a region without khat production and a current prevalence rate of 29% in a khat-producing region. This was confirmed by a recent study.

Thirty years ago, a cross-sectional assessment of khat use in Somalia reported that in the north of the country, 64% of adult males from the general population regularly consume khat compared to 21% in the south. In Hargeisa, north-western Somalia, we recently found that 31.3% of males above the age of 12 chewed khat in the week before the interview. However, in a recent study among 8124 active combatants, self-reported khat use in the past week was 26.2% in the north and 50.7% in the south of the country, and excessive khat use patterns were seven times higher in the south. Press articles state that currently in Somalia per day 300 000 US$ are spent on khat and a debate is going on whether khat imports from neighboring countries drain Somalia's economy.

Other countries where khat is traditionally used include Djibouti, Saudi Arabia, Tanzania, Madagascar, and South Africa. The general trend in traditional use countries is that khat production and use spreads to other regions and segments of the population who did not have traditional contact to the leaves, for example, in Kenya, Ethiopia, Somalia, and the eastern parts of Yemen. In recent years, khat production and use has also been spreading to African countries where it has been unknown before, for example, Uganda and Rwanda. In summary, khat has become a large regional market without the involvement of multinationals. Today, it is a source of income for millions of farmers, pickers, packers, traders, and an everyday and leisure drug for up to 10 millions of people who are thought to use it everyday.

Because of mass migration, khat use spread to high-income countries of the European community, North America, Australia, and Israel. Khat use in Western countries is still limited to immigrant groups. Some studies ever investigated the prevalence of khat use among adult immigrants in Western countries, mainly among Somalis in the United Kingdom. In a nonrepresentative sample of 207 Somalis (male 152, female 55) living in London, Paul Griffiths found 78% (79% of males and 76% of females) with a lifetime history of khat use, 67% had been using it in the week before the interview, and 6% on a daily base. Another study by Shilpa Patel and colleagues found among 602 Somalis (324 male, 278 female) in four cities in the United Kingdom that 38% (231) had ever chewed khat (male 58%, female 16%), 34% had been using it in the month prior to the interview, and 3% would use it currently on a daily base. Among the 180 subjects (91 male, 89 female) of a representative sample of the Somali community in Greenwich assessed by Kamaldeep Bhui and colleagues, a current prevalence of 62.6% among male and 16.9% among females was found.

Evidence exists that khat-chewing habits have also qualitatively changed in the course of the last decades: what once has been a formalized and strongly regulated social habit, now carries features of excessiveness, informality, and decoupling from normative control in some user groups. This is manifest in the consumption of higher quantities of the drug by individuals, longer continuous consumption time, and parallel use of other drugs, for example, benzodiazepines or alcohol compared to traditional use patterns. While khat chewers used to be traditionally "initiated" at around 20 years of age, nowadays, they start using the drug earlier in life and consumption has become part of the youth culture. Furthermore, the formerly adult male habit is now practiced more and more by women and is also reported in pregnant and breastfeeding women.

IS KHAT A DRUG?

The controversy around khat and especially the question whether it is a drug is probably as old as use itself. It has been condemned by the Ethiopian orthodox church and the more fundamentalist Islamic schools of thought particularly in Saudi Arabia, who consider it "haram." Islamic scholars in Yemen, Somalia, and Ethiopia by contrast integrated khat use into religious life, including the study of the Holy Koran or to enhance religious experience as practiced by Sufi mystics. During the colonial era, arguments about moral degeneration, falling economic productivity, and the association with political unrest motivated official and largely unsuccessful bans on khat. A strong pro-khat movement prevented in most countries legal restriction. The economic advantages of khat to farmers, traders, and others involved in the khat business are evident. Furthermore, the discourse on khat as drug is misused in a context of interethnic and regional tensions, religious arguments, and in the conflict between traditional and Western parts of society.

The scientific discourse on khat shows similar fissures, usually along the lines of academic discipline: medical and pharmacological research approached khat with the underlying assumption that it is analogous to other psychoactive drugs; consequently, for more than a century research focused on the discovery of the addictive substance in the leaves. And after being first isolated by World Health Organization (WHO) laboratories during the end of the seventies, more than a decade of pharmacological research focused on the laboratory-based study of cathinone, the main psychoactive principle in the khat leaves. Only recently, a more comprehensive approach is used, for example, by studying the effects of khat leaves and by involving human subjects.

Anthropologists and social scientists, by contrast, stressed the cultural functions and traditional values. They often argue against the medical position, because the physical effects cannot explain the functions of its use and because addiction is a Western concept that does not fully grasp the case of khat. In Yemen, the social life of men develops around institutionalized khat-chewing sessions. This context to participate in business, family, and political decisions as well as in social life makes it difficult to abstain from khat. Also in the Somali tradition, the social act of khat chewing has an important function in the reinforcement of group cohesion and as a source of social support. Studies among Somali refugees living in Western countries report khat use in order to maintain identity and cope with the psychological problems associated with staying in a foreign and hostile environment or with posttraumatic experiences.

For long, researchers from different disciplines remained in their isolated silos and found no opportunity to exchange information and develop a common position. Hence, it was only in 1984 that the first international, interdisciplinary conference on khat could be organized. A wealth of new research has been produced across different fields, and there is a growing awareness of the need for interdisciplinary perspectives on so complex a topic. But the WHO expert committee and other organizations who have reviewed khat recently note that high-quality studies are still rare, for example, with human subjects and khat leaves instead of pure cathinone.

In summary, the question whether khat is a *drug* versus a part of *culture* or *tradition* should be framed differently. Today, it is clear that what is colloquially labeled a "psychoactive effect" is a complex interaction

of pharmacological effects, environmental conditions, and the users own learning experience (*see* Neurobiological Mechanisms of Drug Addiction: An Introduction). A comprehensive model of khat addiction is still a challenge for interdisciplinary research.

PHARMACOLOGY

WHO laboratories succeeded in the 1970s in isolating the alkaloid S-cathinone ([-]-2-aminopropiophenone or S-[-]-2-amino-1-phenyl-1-propanone) as the main psychoactive agent in the leaves. Other psychostimulant principles are cathine (1S, 2S-norpseudoephedrine) and norephedrine. However, the full range of compounds, including the cathedulins and their pharmacological mechanisms remain largely unstudied. Cathinone particularly resembles amphetamine in chemical structure as well as in biochemical and behavioral effects, though with about half the potency. Its pharmacological effects are considered to be amphetamine- and cocaine-like.

As cathinone is highly unstable and decomposes within 72 h of harvesting, khat leaves are preferably consumed when fresh. This historically restricted the area of consumption and markets. Cathinone content revealed to be different according to freshness of plant material and origin and correlated with the market price. Although its main psychoactive constituents, cathinone and cathine as well as some of their synthetically produced derivates (e.g. methcathinone) are controlled substances under the International Convention of Psychotropic Drugs (1971), the khat leaves are not.

Pharmacokinetics

By chewing the khat leaves, cathinone is effectively extracted into the saliva and directly resorbed through the oral mucosa and in the stomach. Maximal plasma concentrations are reached for cathinone 2–2.5 h after start of session, for cathine 2.6 h; cathinone has a mean terminal elimination half-life of 1.5–4.5 h, and cathine of approximately 5 h. In different experimental khat sessions, after the ingestion of 0.6 and 0.8 g of khat leaves per kg body weight, the maximum concentrations of cathinone in plasma were 58.9 ± 18.8 ng ml^{-1} and 127 ± 53 ng ml^{-1} and for cathine 71.2 ± 13.9 ng ml^{-1} and 89 ± 49 ng ml^{-1}. Cathinone has a mean residence time of 4.5 and cathine 10.2. After 24 h, it might not be possible to detect cathinone in blood plasma, while in urine it can be detected for about a day after chewing, in hair of habitual chewers probably after a much longer period. After ingestion, cathinone is reduced to its main metabolites (-)-norephedrine and (-)-norpseudoephedrine. Cathine has been confirmed in human breast milk and in infant urine.

Pharmacodynamics and Addictive Properties

In the central nervous system, cathinone provokes a release of catecholamines, especially dopamine, from presynaptic stores, being about half as potent as amphetamine. Moreover, it inhibits its reuptake and can produce a depletion of central dopamine. It was shown to be similarly rewarding as amphetamine or cocaine in discrimination and preference studies. Similarly, like other dopamine agonists, khat use has the potential to exacerbate preexisting psychotic disorders. Excessive khat use can elicit brief psychotic disorders and schizophrenia in vulnerable individuals. However, to date khat use and dopamine-related disorders are still understudied – evidence remains weak. Cathine had a much smaller effect in the release of central catecholamines, for example, cathinone was eight times as potent in sustaining an amphetamine-induced dopamine release. Like amphetamine, cathinone also has to a minor extent a serotonin-releasing effect in the nucleus caudatus. Besides that, cathinone also affects the reuptake and inhibits the metabolism of catecholamines and serotonin. Peripherically, cathinone and cathine are equipotent concerning the release of noradrenaline at the presynaptic storage sites and, thus, both have sympathomimetic effects.

In humans, khat effects were studied using either repeated physiological and questionnaire-based measurement of immediate reactions to khat administration or retrospective inquiry of usual reactions. Immediate euphoric effects followed by depression were demonstrated in controlled application studies. Thus, it was argued that the depressive phase after the end of the khat session motivates to continue chewing.

Peter Kalix in authoritative review of the first 15 years of cathinone research postulated a higher potential to induce dependence compared to amphetamines because: (1) cathinone has a more rapid onset of action in discrimination experiments; (2) tolerance to cathinone's anorectic effects develops faster and is more pronounced; (3) in conditioned taste aversion experiments cathinone is less aversive than amphetamine; and (4) in self-administration experiments respond rates are higher than those maintained by amphetamine.

KHAT ABUSE AND DEPENDENCY

There is an ongoing debate as to whether khat produces a physical dependency syndrome. For many years, the dominant view in the literature was that khat produces no physical dependency. This view is repeated in the recent reviews despite of the changing use patterns and the missing empirical data. However, in contrast to the study of its alkaloids, the khat leaves

have been rarely subject to studies on addiction-related processes. According to the World Drug Reports, khat is considered the main drug of abuse besides alcohol in Ethiopia and for other countries of the region. Like the case with any other drug, not every khat user will develop a dependence syndrome as defined by ICD 10 or DSM IV. Assuming a parallel between khat and amphetamine, the high prevalence of khat chewing in countries like Yemen or Somalia would produce khat dependence as high as 5–10% of the adult male population. An Ethiopian study, using the Composite International Diagnostic Interview, found a prevalence of khat dependence according to the criteria of ICD-10 of 5% among males (among females 1.3%) in representative sample drawn in a traditional khat-producing area. Khat dependence was more frequent among Muslims and associated with being economically disadvantaged.

Observational data confirm the existence of a specific "drug language" among Somali khat users: "xaraaro" means feelings of craving and nervousness, which are experienced by habitual chewers at the time of day before their usual khat intake starts; "dubaab" refers to unpleasant dreams involving the sensation of being suffocated that are usually experienced by heavy chewers in the first days after cessation. The phenomenon of "jibane" involves the use of khat in a group setting in order to reduce aversive symptoms in the morning.

Khat Withdrawal

The expert opinion on withdrawal symptoms upon discontinuation is that they are expected to be mild and only after prolonged use. However, looking at the existing empirical evidence, only very few studies present any data. Khat-related withdrawal symptoms were described in a study done between 1974 and 1976 by Kennedy and colleagues. The symptoms include profound lassitude; anergia; difficulty in initiating normal activity; slight trembling, several days after ceasing; nightmares, often paranoid in nature; for example, being attacked, strangled, or followed; the authors stated that these symptoms occur only after heavy chewing, starting a day after cessation and last several days. But they also state that heavy khat users often try in vain to stop using it or to reduce their amount of consumption. As khat chewing has become more prevalent and use patterns have profoundly changed throughout the last decades, this description might not necessarily be valid any more and needs further studying.

Khat Tolerance

Today, it is generally believed that khat use does not induce tolerance, going back to an expert evaluation by Eddy (1965). Among stimulant users, tolerance development, the upward shift in the set point for reward and the subsequent dysphoria ("opponent process") are closely related to the development of "binge" consumption patterns: users need to increase the dose and the frequency of drug administration in order to experience the desired psychological effects. For khat, it has been argued that the chewing mode of ingestion limits the possible amount to consume in a certain time and, thus, tolerance development is prevented. However, no studies have ever directly targeted the topic of tolerance to desired psychological effects, for example euphoria. Due to the physical limits of chewing the leaves, tolerance development might not only include increases in the amount of consumption per time unit but rather to the extension of the time spent for consuming khat that leads to an increase of the absolute amount ingested. Personal observations in Somalia and data from the UK Somali community indicate that heavy khat users can consume without a break for 48 h and even more without sleep. Several studies reported that such "binge" consumption patterns among khat users do occur and that experienced users are trained to chew such large quantities a novice would never manage. Other studies reported details on excessive and prolonged intake above what is considered normal, for example, that 12–14% of subjects reported a consumption of four or more bundles on one occasion and one single subject reported to consume 15 "bundles" in one day. In a study from Germany, blood and urine levels of cathine in subjects arrested for khat-related traffic offenses ultrapassed levels ever measured in controlled studies. In addition, the development of tolerance to physiological effects of khat was reported several times. In summary, the question of khat-related tolerance needs further studying. Furthermore, research needs to study the hypothesis whether effects of khat might be potentiated through sleep and food deprivation.

Psychological Dependency

While the data on physical aspects of khat dependency are scarce, researchers early on recognized the potential of khat to induce psychological dependency. This is best illustrated in descriptions of typical scenes of inner city khat markets at the Horn of Africa or in Eastern Africa at the time just before a khat delivery arrives. At these hours of day, users speed to khat markets frequently causing traffic accidents; an aggressive and nervous atmosphere prevails until the khat trucks arrive. In contrast, khat users who visit foreign countries are said to abstain without any difficulties without replacement.

On a more scientific ground, the potential to induce psychological dependence is confirmed by a number

of British studies, using the Severity of Dependence Scale, a five-item instrument thought to measure the psychological component of dependence. This instrument has recently been adapted and validated for the study of khat addiction. About 10% of a sample of Somali khat users scored at a level comparable with a clinical population with severe heroin dependence in need for treatment. In a more recent study with Yemenite immigrants living in the United Kingdom, this figure was 39%.

Neuropsychology and Neurocognitive Deficits

A common characteristic of chronic central stimulant abuse is marked neurocognitive deficits. A recent review found that there are virtually no studies and the authors developed suggestions how to study these effects among khat users. To date, only a few empirical studies have reported on neurocognitive effects of khat use. Kattab and colleagues published a report on aircrew members of an Arabic Airline who were daily khat chewers (25), occasional chewers (39), and nonchewers (24) presented for the Standard Aviation Medical Examination and participated in a standardized neuropsychological test battery. Daily khat chewers performed worst in subtests for perceptual speed, long-term memory, visual memory, and visual perception and had a faster EEG background activity compared to occasional khat chewers and nonchewers. Duration and amount of khat use were negatively correlated with performance. Recently, several studies on neurocognitive functions revealed impairments among khat users in the Netherlands, in Kenia, and in the Yemen compared to matched nonusers in respect to response inhibition, working memory, cognitive and behavioral flexibility, as well as executive functions. Indirect support of these deficits comes from observational data on khat effects on driving in Ethiopia. Although first evidence supports the hypothesis that prolonged khat abuse can produce a typical neurocognitive deficit syndrome that is similar to that produced by amphetamines, more studies are required to confirm it.

In summary, the topic of khat addiction urgently needs further empirical studies. Current evidence supports the hypothesis that excessive and prolonged khat use can produce a dependency and neurocognitive deficit syndrome qualitatively similar to that produced by amphetamine.

KHAT AND MEDICAL PROBLEMS

Numerous somatic and mental health problems have been associated with khat use. Moderate khat use is not noxious in most users and adverse effects are commonly linked with excessive use. There is growing evidence that khat can exacerbate preexisting mental health problems, as well as trigger psychosis and aggressive behavior, particularly in predisposed individuals. While there is functional khat use among people suffering from anxiety or depression, it has also been associated to suicidal thoughts. There are many reports of severe physical harms among chronic users, but other explanations have not been systematically ruled out, for example, tobacco smoking which is frequently combined with khat use, and pesticide content in the leaves, as well as exposure to polycyclic aromatic hydrocarbons and nitrosamines. Observed negative somatic consequences potentially associated to khat use include mucosal problems (oral keratotic white lesions, oral leukoplakia, and oral squamous cell carcinoma), hypertension, cardiovascular complications, duodenal ulcers, sexual dysfunction, hepatotoxicity, and reduced birth weight of infants born to khat-chewing mothers. By the same token, the argument for possible medicinal uses has only been touched on, for example, anticarcinogenic effects.

KHAT AND SOCIAL PROBLEMS

The exponential increase in khat consumption gave rise to a controversy on social problems to consumers. But this controversy is hampered by the lack of scientific studies. It is argued that modern khat consumers do not have the protective factors developed in traditional use cultures and have little awareness of negative effects. Khat has become the everyday drug of disadvantaged people in many countries. One frequently repeated argument is that khat chewing perpetuates poverty, accelerates social fragmentation, and leads to domestic violence. Khat use has been associated with moral decay, such as sexual disinhibition and sex work. The few cross-sectional studies could show some phenomena, for example, that khat use is associated with less spendings on food in poor households in Djibouti and with unprotected sexual behavior in Ethiopia. Further studies are urgently needed.

KHAT ADDICTION TREATMENT

Until today, no scientific reports on the treatment of khat addiction have been published. However, khat addicts represent a high proportion of the patients in dependence treatment in the countries surrounding the Horn of Africa although absolute numbers are very small. In Europe and North America, first reports on khat addiction emerged, exclusively among patients with a migration background from the Horn of Africa.

Thus, in high-income countries with high numbers of immigrants from the Horn of Africa, khat-addicted patients have begun to appear in mainstream addiction treatment centers, although numbers are small; treatment participation is mostly not voluntary. A higher numbers of patients exist who have switched from khat to other substances, available in the respective country. Because access to general services is difficult, several small projects in high-income countries have tried to improve access of khat-addicted individuals to drug treatment services. In the traditional khat countries evidence-based treatments for khat addiction are currently not existent. But, there is a large market for nonevaluated interventions to assist khat-addicted individuals, ranging from Western style counseling to traditional healing.

KHAT AND REGULATIONS

First discussions over international regulations were held at the League of Nations. Since then, successive reviews by expert committees of the WHO, the UK Advisory Council on the misuse of drugs, and experts in the Netherlands and Australia have concluded that khat did not merit scheduling on medical grounds and have adopted a laissez-faire regime approach, allowing khat to be imported as a vegetable product. A number of other countries have taken a drug control approach and prohibited khat (Saudi Arabia, Canada, Tanzania, Germany, France, and most Scandinavian countries). In many countries, like Spain but also the United States, the status of khat is unclear and the enforcement of controls inconsistent. The lack of consensus has added to the complexities, with London and Amsterdam emerging as entrepots for an onward trafficking trade to other EC countries and the United States. In 2012, the Netherlands have also announced to adopt a drug control approach on khat. Over the last few years the sharp rise in khat seizures in different European countries (notably Germany, Norway, Spain, Sweden, Demark, and Switzerland) has fueled concerns about a new drug with potential for abuse in Europe and North America. For the moment, consumption is mostly limited to populations originating in the Horn of Africa, although khat now appears in the growing internet-based trade of legal highs.

CONCLUSIONS

Various somatic and psychological problems have been associated with khat use, but these remain difficult to substantiate as other explanations have not been systematically ruled out. Most adverse health effects are commonly linked with excessive use. Although the addictive properties of khat are believed to be mild, a growing number of problematic users display compulsive use patterns similar to those known from stimulant users. There is a strong need for high-quality studies to further understand khat addiction.

The dramatic widespread of khat from a culture-bound to global substance of use and misuse has raised a number of challenges for researchers and the international community. As production is concentrated in Eastern Africa and Yemen, and consumption largely restricted to African and Arab countries as well as diaspora communities, there has been little initiative at national and international level to engage with the issue. There is a strong need for the development of coherent khat policies and of regulation, monitoring, and prevention measures. In the absence of alternative policy proposals there is a strong risk that khat controls nationally and internationally apply a war on drugs framework, with potentially severe consequences for farmers, traders, and the criminalization of consumers. Given the gap between the growing number of khat users on a worldwide scale and the poor understanding of pharmacological mechanisms, evolving patterns of use, and the khat economy, a substantial research program is required. Findings should inform a regulatory framework for the distribution and consumption aimed at reducing risk for individuals, communities, and society.

Internet: Immersive Virtual Worlds

Qiaolei Jiang[*], *Xiuqin Huang*[$]

[*]Nanyang Technological University, Singapore

[$]General Hospital of Beijing Military Region, Beijing, China

OUTLINE

THE DEFINITION OF IMMERSIVE VIRTUAL WORLDS

Virtual environments, in which three-dimensional displays and interaction devices immerse the user in a synthesized world, are sometimes also referred to as virtual reality (VR). VR constitutes a three-dimensional interface that puts the interacting subject in a condition of active exchange with a world re-created via a computer. However, there is no accepted definition for VR. One important reference, the US National Research Council report *Virtual Reality: Scientific and Technical Challenges*, does not attempt a definition. Rather, characteristics of a virtual environment are given. These include a man–machine interface between human and computer, 3-D objects, objects having a spatial presence independent of the user's position, and the user manipulating objects using a variety of motor channels. VR is such a complex and challenging field, and several distinct types of systems have been developed for displaying and interacting with virtual environments. Some scholars classify VR into three categories: immersive head-mounted displays (HMDs), immersive non-HMD systems, and partially immersive tabletop systems.

VR systems enable the user to feel as if they are present in a computer-generated environment. Technologies are used to create a realistic virtual world that is as much similar to real world as possible. For example, virtual, aural, haptic, and other displays are used to immerse the user in the virtual world and block out contradictory sensory impression from the real world. Graphics rendering systems are adopted for generating detailed and realistic images of the virtual world as it changes. The users' body movements are tracked by tracking systems in order to relate these to movements in the virtual world. Database systems are needed for building and maintaining detailed models of the virtual world.

A virtual environment is a "mental model" that represents a physical environment. A major part of VR research and development focuses on creating the illusion of non-mediation. In computer mediated communication, individuals apply social rules and the literature points to five characteristics that cue the idea that one is interacting with a social actor. These are (1) language, (2) interactivity to multiple prior inputs, (3) computers

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00089-9

fulfilling social roles, (4) use of human sounding speech, and (5) the possession of a human or humanlike face. According to Singhal and Zyda, Networked Virtual Environment is distinguished by the following five common features: a shared sense of space (illusion of being located in the same place), a shared sense of presence (avatars of participants), a shared sense of time (real-time interaction possible), a way to communicate (various interaction methods), and a way to share (dynamic environment that can be interacted with).

The Internet offers its users a digital environment, which can be populated with users' replicas (cymans) and objects. Within the digital environment they are free to navigate, meet other users and manipulate data usually represented in the form of three-dimensional objects. At the same time they can use audio and video channels to interact with other users using both verbal and nonverbal forms of communication. In this way, the developed online communication interface brings together remotely located collaborating parties in a shared electronic space for their communication. Nowadays, the Internet has emerged as an important social technology used for communication between individuals and groups, and has been regarded as an essential media channel for information exchange, academic research, and entertainment.

A BRIEF HISTORICAL OUTLINE OF VR TECHNOLOGY

Immersive VR has become a frequently used buzzword, while the technology of VR is not as recent as one might suppose. The first VR system appeared early in 1962, when Morton Heilig presented the first prototype of multisensorial simulator called *Sensorama*. This prototype was simulator of a real experience (a motorcycle ride through New York), with all the main features of a modern VR system but one exception: there was no possibility of interaction by the user. Few years later, Ivan Sutherland, one of the pioneers of computer graphics, described and realized the first virtual environment display system – the first HMD in 1968. It was a visual device which can display an image in front of the user's eyes, no matter where the user may be looking. Key innovative features of Sutherland's HMD included the implementation of stereoscopic vision, the totally computer-generated visual images, the adaption of the user's view according to the head's movements and the head-referenced visual display. Sutherland is now generally acknowledged as one of the founding fathers of VR. In his classic 1965 paper *The ultimate display,* he described his ideas of immersion into computer-generated environments via new types of multimodal input and output devices.

Later, the introduction of flight simulators was one of the most important precursors to VR. The innovations were driven by the greater dangers associated with training on flying the jet fighters. By the 1970s, computer-generated graphics replaced videos and models which had been used since the Second World War. Fight simulations were operating in real time, though the graphics was primitive. In 1979, the military started to experiment fight simulation systems using HMDs. In the mid-1980s, a limited three-dimensional virtual workspace in which the user interactively manipulated three-dimensional graphical objects spatially corresponding to hand position was developed. In 1984, NASA started the VIVED project (Virtual Visual Environment Display) and later the VIEW project (Virtual Interactive Environment Workstation). The goal of both projects was to develop a multipurpose, multimode operator interface to facilitate natural interaction with complex operational tasks and to augment operator awareness of large-scale autonomous integrated systems.

VR was introduced to the general public in 1989, at two trade shows organized by AutoDesk and Visual Programming Language (VPL) Research, two companies involved with NASA projects. The term Virtual Reality was originated at that time by J. Lanier, defining it as a computer generated, interactive, and three-dimensional environment in which a person is immersed. Through the 1990s, 3-D computer models have been used increasingly on the World-Wide Web using virtual reality modeling language (VRML), and faster computers provided the key to interactivity. The richness of Web page content has improved dramatically. It is possible to include color pictures, sound, movies, 3-D animation, and interactive programs. Scientists developed advanced visualization software programs and many research centers started working on VR applications in education, medicine, industry, military training, and entertainment. Nowadays, more human activities that benefit from VR technology are constantly of wireless devices and wearable computing, which represent the new frontier of the research concerning VR interfaces. The ultimate objective of this evolution is the full immersion of the human sensorimotor channels into a vivid and global communication experience. Following this approach, virtual reality can be defined in terms of human experience as a real or simulated environment in which a perceiver experiences telepresence.

THE TECHNOLOGICAL ASPECTS OF IMMERSIVE VIRTUAL ENVIRONMENTS

Immersive virtual environments are sometimes described as a particular collection of technological

hardware. For example, many people identify VR with a collection of devices, such as a computer-generated real-time graphical display accessed by the subject through the use of some type of head-mounted and panoramic displays, tracking mechanism, and other sensory input devices.

In its most well-known incarnation, virtual environments are presented to the user via a HMD where the visual information is presented to the eyes by using cathode ray tube (CRT) or liquid crystal display (LCD) technology, and auditory information is presented using earphones. The HMD has been the primary VR visual device for much of the 1990s, and is usually fitted with position tracking devices for measuring the position and orientation of the user. An alternative interface to the HMD is the Binocular Omni-Orientation Monitor (BOOM) where the display device isn't worn on the head but mounted onto a flexible swivel arm construction so that it can be freely moved in space. Tactile and force feedback is also sometimes provided through various devices, ranging from inflatable pressure pads in data gloves or body suits to force-feedback arms or exoskeleton systems. HMD and BOOM are similar devices in that the user is fully immersed in the virtual environment and does not see his/her actual surroundings.

A second common design of immersive virtual environments is through multiple projection screens and loudspeakers placed around the user. A popular implementation of such a projection system is known as the CAVE, a recursive acronym for CAVE Automatic Virtual Environment, and a reference to *The Simile of the Cave* from Plato's *The Republic*, in which he discusses about inferring reality from projections (shadows) thrown on the wall of a cave. The CAVE consists of three stereoscopic rear-projection screens for walls and a down-projection screen for the floor. Participants entering this room-like display are surrounded by a nearly continuous virtual scene. They can wear shutter glasses in order to see the imagery in stereo, and wearing a position tracker is required to calculate and render the appropriate viewer-centered perspective.

However, this exclusive focus on technology is somewhat disappointing. Immersion does not necessarily isolate the user (like an HMD) or require a special room (like a CAVE). The latest developments in the Internet, computer animation, virtual environments, and communication networks are being configured to create revolutionary tools and systems. Based on 3-D modeling and texturing tools and 3-D navigation techniques, there are a number of Web technologies that offer 3-D and interaction. Current immersive virtual environment systems use a wide variety of programming methodologies and scene description languages to handle dynamic 2-D/3-D graphics and animation within different kinds of multimedia services. Today's VR technology provides an impressive output quality. With 3-D visualization technology, the descriptions can be highly detailed. Additional features, such as posters, chat rooms, and many others, are easy to integrate. The increase in bandwidth and communication channels can enhance the interaction. In this way, the virtual environment is presented immersively to the participant. Based on the Internet, immersive digital environments are gaining in popularity because they are more easily integrated with daily activities.

IMMERSION IN VIRTUAL WORLDS

In immersive virtual worlds, man is not simply an external observer of pictures or one who passively experiences the reality created by the computer, but may actively modify the three-dimensional world in which he is acting, in a condition of complete sensorial immersion. Immersion can be understood as a property of the technical interface and as a psychological state. As for the former, immersion is a description of overall fidelity in relation to physical reality provided by the display and interaction system. As for the latter, immersion means that users can feel emotionally and cognitively present in the situation, and feel in a similar environment to the real world, with similar level of interaction.

Riva defines the "soul" of VR as a mental experience, which gives people the feeling of being really there, close to if not equivalent to the experience of actual presence. Virtual world can be created to give a 360° view within an environment. By moving around within virtual environments and interacting with objects and actors represented there, users are able to interact with synthetic or computer-generated environments. When interacting with a virtual environment or other users, the user is no longer a mere observer of what is happening on the screen. Instead, the user feels immersed in that world and can participate in it, in spite of the fact that these worlds are spaces and objects existing only in the memory of the computer and in the user's mind.

Vividness and interactivity are key factors for users' immersive feeling. Vividness is the ability of the technology to produce rich mediated environment, and interactivity is the degree of influence users have over the form or content of the environment, and the extent to which the user feels convinced of the mutual effect that he/she and the environment have on one another. Other immersion and pictorial realism factors include spatial presence, involvement, and realness. Spatial presence refers to what extent the participant has the sensation of being a part of the virtual environment physically.

Involvement means to what extent the participant's attentional resources are directed to the virtual environment. Realness appraisal describes to what extent the participant judges the virtual environment comparable to a corresponding real environment. Although the naturalness and intuitiveness of face-to-face communication is hard to achieve, the virtual environments provide additional and novel ways to enhance the weak areas of interaction.

Realistic virtual environments not only include believable appearance and simulation of the virtual world, but also imply the natural representation of participants. Users of early VR systems would normally see a representation of their hand in the virtual world to help them interact with objects and issue navigational commands. With the advent of more powerful computers and the experience gained from working with virtual environments, it is now widely accepted that the user should be represented in greater detail. The use of realistically modeled and animated humanlike avatars becomes the theme of multiple-user immersive virtual worlds, as it provides believable appearance and realistic movements. Using this embodiment regularly, the participant has a bounded, authentic, and coherent representation in the virtual world. In addition, it is useful to have the capability to make changes to the world while the participant is immersed. By changing decoration of the body through clothes and accessories, the representation also has an emergent identity. Therefore, it is likely to increase the sense of presence of the real participants in the environment.

Immersion also can mean the degree of psychological presence in virtual environments. The two dimensions are locus, that is, whether attention is directed toward the virtual or the physical world, and sensus, which is the level of attentional arousal, on a continuum from completely unconscious to fully conscious. If built properly, there can be perceptual illusion of actually being in the virtual world. The illusion involves real-time responses of the human sensory, cognitive, and affective processing systems to objects and non-mediation when he/she fails to perceive or acknowledge the existence of a medium in his/her communication environment and responds as he/she would if the medium were not there. The first characteristic of such a satisfying virtual environment is the disappearance of mediation, a level of experience where both the virtual reality system and the external physical environment disappear from the user's phenomenal awareness. The second characteristic is the possibility of building and sharing a common ground through the interaction process. In this way, a synthetic environment may combine remote and virtual presence. Remote presence refers to presence in a virtual environment through sensory extension, where users believe that they are in contact with a real, albeit remote environment. Virtual presence is characterized by the fact that users feel present in an environment simulated by a presence medium in the form of a mental model.

METHODS TO MEASURE IMMERSION

Research efforts have been devoted to finding out a measurement tool that can capture participant's sense of immersion in virtual worlds. How do we determine the extent to which a user feels immersed in the virtual environments? Basically, there are three categories of methods commonly used, including subjective measures, behavioral measures, and physiological measures.

Subjective measures rely on self-assessment by participants themselves and include a variety of techniques from subjective rating scales or questionnaires, to self-reported breakdowns of the sense of presence, to reports, comments, and interviews, to comparison-based predictions in which the subjects' task is to evaluate the difference between real and virtual scenes. Users answer questions such as "How real did the environment seem to you?", "Was the environment like a place you visited, or a series of images presented to you?". The Witmer and Singer Presence Questionnaire, and the Slater–Usoh–Steed (SUS) questionnaire are post-immersion questionnaires of this kind. The Witmer and Singer Presence Questionnaire tries to measure it by examining factors such as control factors, sensory factors, distraction factors, and realism factors. The control factors include the ability to control the relation of sensors to the environment, the speed at which the system reacts to changes caused by the user, the amount to which a user can anticipate what can happen next in the environment, the naturalness of control over the environment, and the ability to modify the physical environment. Sensory factors examine the amounts, coherence, and consistency of information arriving from different senses, the ability to perceive self-movement through the environment and the ability to search the environment actively. Distraction factors measure the possible distractions a person may experience in a virtual environment, such as awareness of the real environment, devices used to transmit the virtual environment to the user, and the observer's willingness to focus on the virtual environment stimuli presented. Realism factors measure those factors, such as environment realism and meaningfulness, as well as disorientation when returning to the real world. The SUS questionnaire has been developed over a number of years and a number of experiments at the University College of London. The questions are based on variations on one of the three themes: sense of being in the virtual environment, the extent to which the virtual

environment becomes the dominant reality, and the extent to which the virtual environment is remembered as a place. The major disadvantage of these questionnaires is the fact that they are post-immersion.

Behavioral measures provide an alternative approach to avoid the subjective nature of questionnaires. Behavioral measures examine actions or manners exhibited by the user that are responses to objects or events in the virtual environment. The premise behind these measures is that the more a participant feels immersed in a virtual environment, the more his responses to stimuli will match those behaviors he would exhibit in an identical real environment, that are produced automatically, without conscious thought. A list of behaviors that are typically exhibited around precipices was constructed, such as taking careful baby-steps, leaning away from the pit toward the walls, testing the edge of the ledge with a foot, reaching for a virtual object, greeting avatars, turning away or closing one's eyes when presented with an anxiety-provoking scene, and startle responses, orienting response and socially conditioned response such as ducking to avoid an object. Behavioral measures are more shielded from subject bias than subjective measures. Another strength is their lack of intrusion into the virtual experience. The weakness of behavioral measures is the inability to know for a balance in a VR experience which could be from the content of the environment or from the VR system itself. Behavioral measures can be exposed to experimenter bias.

There are also numerous physiological indicators that can be measured. Physiological methods attempt to measure presence by gauging changes in the subject's cardiovascular response, muscular tension, skin temperature, skin conductance, breathing rate, and ocular movement after specific stimuli or events in the virtual environments. They are more objective than subjective measures and many behavioral measures. They are generally not consciously affected by the participants, and with limited, uniform instructions, cannot be affected by the experimenters. The three commonly examined and least intrusive are change in heart rate, change in skin conductance, and change in skin temperature. Previous studies revealed that percentage change in heart rate and skin resistance had a high level of correlation with degree of immersiveness. However, the demonstration that these stimuli are directly connected with the level of immersion in virtual environments needs more systematic research.

APPLICATIONS AND EXTENSIONS OF VR TECHNOLOGIES

Virtual environments have been applied to various areas, such as scientific visualization, physical therapy, psychotherapy, online games, 3-D chat rooms, Internet shopping malls, advertising, manufacturing, electronic kiosks, location-based entertainment, HDTV, IMAX theaters, etc. As for VR applications, the goal is to use technology to create an abstract virtual space where people and their actions are simulated and shared. As technology decreases in price, and as virtual worlds are widely available through the Internet, more and more researchers will continue to embrace this ever changing technology to develop virtual environments for more application domains and benefit the society as a whole.

One popular application of virtual environment is multiplayer 3-D game. The participants of collaborative virtual environment can use avatars to interact with the contents of the world and to communicate with one another using different media, including audio, video, graphical gestures, and text. For example, in Multi-user Dungeons (MUDs), which are textual virtual environments shared by many participants at the same time, people experience new forms of communication and identity. The interactions in contemporary massive multiplayer online role playing games (MMORPGs) are more exciting. For instance, the Half-life multiplayer modification Counter-Strike (CS) has been one of the most played action games on the Internet for quite a long time. The game is very realistic, and players really have to work in teams and think what they are doing to achieve their goals. Since CS is a quite realistic military action game, it was interesting to see how much players tried to implement real-life tactics in the game as seen from the films and TV. Scholars argue that more complex virtual human embodiments will increase the natural interaction within the environment. The more natural perception of each other increases the sense of being together and thus enhances the overall sense of shared presence in the environment.

VR has been used as a tool in the assessment or treatment of physical and psychological disorders. For instance, VR allows surgeons to visualize and plan the phases and results of surgical operations. The opportunity offered by VR technology to create interactive three-dimensional stimulus environments, within which all behavioral responding can be recorded, offers experimental psychologists options that are not available using traditional techniques. An environment can be designed where the user experiences a "drug-addict world"-based virtual psychodrama or sociodrama or as part of a psychotherapeutical treatment. VR has also been used to treat acrophobia or fear of heights. There are different types of psychological Internet applications, such as self-help guides; psychological testing and assessment; information about specific psychological services; synchronous and asynchronous support groups, discussion groups, and group counseling; and

real-time counseling through chat, web telephony, and videoconferencing.

The Internet has become an important medium for commercial applications. Today, many vendors offer their goods with Internet-based technology. Using virtual environment as a marketing medium can show its worth. Immersive virtual environments could be more effective persuasion channels than the classical advertising media. One example is modeling virtual supermarkets, which is automatic generation of virtual worlds for electronic commerce applications on the Internet. An important feature is the system's ability to generate individualized supermarkets for each customer's specific needs and demands.

Education is another important application of virtual environments. The possibilities provided by the use virtual environments, such as 3-D immersion, multiple perspective, and multisensory cues offer a number of potential benefits, including experiential and active learning; visualization and reification; learning in contexts impossible or difficult to experience in real life; motivation enhancement; collaboration fostering; adaptability; evaluation and assessment; etc. Nowadays, VR has been widely used in education and training, such as augmented reality and educational toys, VR in special needs education, military training, and medical training.

By a closer inspection of the setting in which virtual environments are applied, in fact, be they clinical, experimental, or training, it appears that participants focus on resources both internal and external to the virtual environment, which are relevant to their situated activity. The need for a situated perspective has been strongly sustained in the literature on human–computer interaction. It seems more appropriate to place participants' action in a physical and symbolic scenario, hybrid in its reality, where the virtual experience is intertwined with the experience in the external world. This general position implies that the evaluation of the virtual system should extend beyond the limits of the virtual setting per se and the logic of an individual operating on an interface. The virtual environment should be considered as the fulcrum of a larger set of converging elements and its evaluation should address the specific, contextualized sequence of action performed by users.

THE PROFOUND EFFECTS ON PEOPLE'S DAILY LIVES

The ubiquity of the Internet has become a significant feature of the urban life in modern societies. The digital communication networks have allowed people to interact with virtually anybody, anywhere in the world. With the use of computer and Internet over the last decade, various virtual technologies are spreading rapidly, calling for researchers' responsible attention to the phenomenon and to its implications for users. The impact of those characteristics (such as highly visual, immersive, and 3-D environments) on human psychology and behavior is controversial, from the perspective of personal development and psychological selection, and individual participation and integration in the cultural context.

Optimists celebrate the liberation from the limits set by our natural environment. According to them, VR indulges our dreams of an ideal, pure dimension of life, where our existence is transposed on a digital code. The conventional physical constraints can be overridden; prejudices rooted in physical differences (gender, race, age) cannot be applied any longer; and time and space cease to hamper the willingness of people to meet and reach interesting destinations. Cyberspace would have the purity of our mental life without being a solipsistic experience, ushering a utopian digital society of electronically interfaced people, where our spirit freed from the destiny of our body. Pessimists have expressed their great concerns on the advances of virtual technologies. Body and action are considered the fundamental warrants of resistance and social emancipations. Moving onto a virtual mode of existence would do nothing but dissolve this warrant. The idea is that people would be left pray, unaware, of an entertaining illusion of reality, the engagement in the world being replaced with the engagement in a fake one.

To avoid these simplifications and the assumptions they derive from, many scholars have worked at a more elaborated depiction of immersion. Some have proposed the partitioning among simple, cybernetic and experiential presence, focus, locus and sensus, personal, social and environmental presence, or according to different tasks to be performed. Some have approached immersion with other purposes than measurement, for instance to investigate the relation with place, the type of conversational patterns, the kind of embodiment, thus liberating a more lively image of this experience. Some have unearthed what has been overlooked before, such as the alternation of emersion and immersion during a session.

It is true that rich and immersive interfaces can display much more information and in a more compelling way than those non-immersive technologies. In recent years, a growing number of researchers have begun to investigate the subjective experience persons report when interacting in virtual environments. As for some participants, after the virtual experience, they remember it as having visited a place rather than just having seen images generated by a computer. For some users, the virtual environment becomes the

dominant one. For instance, those people will tend to respond to events in the virtual environment rather than in the real world.

One influential application of immersive virtual environment is the highly focused, entertaining and problem-solving oriented games domain. Online games emphasize compelling content, fast pace of action and aspects of fun, and thus children and young people are usually the special category of end users. Many recent games domain is the networked 3-D-first-person-view fighting games. The various games contain a degree of teamwork, either forced by the game plot, or arranged voluntarily by a group of players. Psychologically, it has one's attention captured, and children have comparatively high expectations of such environments. However, in the long run, it can be quite problematic for children's psychological development after excessive exposure to such computer games and online games.

People's experience shows that simulation sickness is one problem for the immersive experience. Some people experienced some form of side effects, characterized by some symptoms, including ocular problems, such as eyestrain, blurred vision and fatigue; disorientation and balance disturbances; and nausea. Females tend to be more susceptible to virtual reality side effects than males. Moreover, there is no clear distinction between VR – the reconstruction of slices of life in the machine – and the building of artificial environments, where less reference is made to the characteristics of the observed world. Virtual and mixed reality environments can produce vivid experiences and generate powerful emotions. Thus, there can be problems related to online relationship and virtual property when people interact with other individuals and with the objects in virtual worlds. In addition, the easy availability of information and social contacts without needing to leave one's own room can cause isolation, hinder the building of interpersonal relationships, and produce distortion in the quality and features of the selected information. Kraut and his colleagues examine the Internet's impact on emotional well-being. The results showed that greater use of the Internet resulted in small but statistically significant increase in depression and loneliness and decreases in social engagement.

EXCESSIVE INVOLVEMENT: INTERNET ADDICTION

One of the main advantages of the online virtual worlds is the immersive characteristics, sealing off the physical environment and presenting the senses with an inclusive virtual environment. Immersion is such a condition in which the user is isolated from the external stimuli. The separation of the psychological realm from the physical and the simplified idea of a full immersion into the simulation are at the core of common opinions on computer technologies and VR, which have gathered around extreme poles. When the immersive virtual Internet worlds bring people benefits, research suggests that excessive involvement with immersive virtual worlds may cause symptoms traditionally associated with substance-related addictions, such as uncontrolled craving for Internet activities, tolerance, and withdrawal.

The term Internet addiction disorder (IAD) was originated in the United States. It is the psychiatrist Ivan Goldberg who first coined the term Internet addiction and proposed it as a disorder in a satirical hoax in 1995, however, at that time he did not expect so many people would take it as a serious problem. The first empirical study on IAD was conducted by Young in 1996, a pioneer and the leading proponent in this field. Since Young's first work, IAD has received attention from multiple disciplines. The literature reveals IAD has grown rapidly under various names, including pathological Internet use, Internet addicted disorder, Net addiction, high Internet dependency, cyberspace addiction, online addiction, etc. Research on Internet addiction has proliferated, addressing topics as diverse as nomenclature, definition, classification, epidemiology, assessment and diagnosis, treatment and prevention.

There have been different views since the advent of Internet addiction. Firstly, whether Internet addiction is valid as a distinct disorder or it is an expression of other primary disorder is unknown. Some researcher suggests that Internet addiction appears to be a common disorder that merits inclusion in *DSM-V*. While some argue that excessive video game use may be symptomatic of other primary disorders, like depression, and/or the result of poor time management skills, rather than a bona fide addiction. Secondly, debates are focused on its nomenclature and classification accordingly. Some investigators linked it to addictive disorders, grouping it alongside alcohol and drug use disorder, so called it Internet addiction or Internet dependency. Others linked it to impulsive control disorder (ICD) and called it pathological Internet use, whereas others linked it to obsessive–compulsive disorder (OCD) and called it compulsive Internet or computer use. In addition, some scholars argued that people were not addictive to Internet itself but to Internet activities, and the Internet can be accessed not only by computer but also by cell phone, so other terms have also been offered. For instance, Griffiths believes that technological addiction, including Internet addiction, is a branch of behavioral addictions. Some researchers consider pathological electronic medium use (PEMU) is more encompassing and incorporate new electronic technologies compared with Internet

addiction. The debates are ongoing, however, a change proposed by *DSM-V* Work Group is to alter the name of substance use disorder (SUD) chapter in *DSM-IV* to "Addiction and Related Disorders," in which gambling disorder will be included as a non-substance use or behavioral addiction, and Internet addiction will be recommended for the appendix with references to the existing literature in order to encourage further research.

Internet addiction is considered to be a broad term covering a wide variety of Internet activities, usually including online gaming, online relationship (communication), cybersex, information gathering or downloading, etc. Internet addiction is characterized with excessive or uncontrolled preoccupations, urges, or behaviors regarding computer use or Internet access which leads to impairment and distress. While there are different definitions available for the phenomenon, some researchers have adapted SUD, but others use pathological gambling as reference, which result in an inconsistent definition of Internet addiction.

A number of studies have explored the etiology and risk factors for Internet addiction, including internal factors, namely personality and motivations of addicts, as well as external factors, such as Internet access and Internet activities. The personality traits of Internet addicts appear to involve introversion, neuroticism, and impulsivity, such as loneliness, shyness, avoidant, aggressive, hostile, and low-esteem. The motivations related to dysfunctional coping, socialization, and personal satisfaction seem to serve as risk factors for Internet addiction. Generally speaking, the general characteristics of Internet and/or virtual environments, such as virtual, anonymous, immersive, flow, 3-D high visual, always available, convenient, interactive, and inexpensive, make users addicted to it easily.

Contemporary multiplayer 3-D games can be considered as important applications and extensions of VR technologies for popular entertainment. It is expected that immersion and Internet gaming addiction are positively correlated because immersion leads to extended playing sessions due to sense of being lost in the game where players lose awareness of themselves and their surroundings. Studies showed that both immersion and flow (i.e. the optimum experience a person achieves when performing an activity) did correlate with Internet addiction. One study explores the relationship between time spent on various Internet applications (including downloading, social networking, chatting, online games, and casual games etc.) and compulsive Internet use (CIU) in a large sample of adolescents. The results reveal that online gaming has the strongest association with CIU. Other studies also show that individuals with Internet addiction were more likely to play online games. The latest game software sale rankings indicate that the public prefer MMORPGs and real-life simulation games. Another study of Internet addiction and MMORPG users' experience reveals that curiosity, role-playing, belonging, obligation, and reward can be used to predict addiction to MMORPGs. Moreover, researches indicate that structural characteristics of Internet games appear to be related to addiction. Specifically, online games are found to be more addictive than offline video games. In addition, particular game features such as adult content and rare in-game items are significantly more welcome among addicted players. Moreover, players with a higher tendency toward Internet addiction are usually more proud of their virtual characters (avatars). Some regard their avatars so superior that they wish to become like that in real life.

Internet addiction is associated with large amounts of time spent on Internet activities, lack of sleep, and a shortage of social interactions. Moreover, similar to any other substance-related addiction, the following six symptoms are experienced, namely salience, mood modification, conflict, withdrawal, cravings, and relapse. Additionally, addicts perceive Internet activities as providing compensation for needs which are not met in their real lives, and the Internet has become the focus of their lives.

Diagnostic instruments have been developed to screen Internet addiction. Young modified the diagnostic criteria of pathological gambling in *DSM-IV* to construct an eight-item questionnaire to diagnose pathological Internet use. According to the concepts of behavioral addiction, Griffiths proposed six IAD symptoms: salience, mood modification, tolerance, withdrawal, conflict, and relapse. Shapira et al. have also proposed diagnostic criteria for problematic Internet use according to the concepts of impulse control disorder in *DSM-IV-TR*. Shapira's three item criteria is (1) uncontrollable; (2) markedly distressing, time-consuming or resulting in social, occupational or financial difficulties; and (3) not solely present during hypomanic or manic symptoms. However, there was little empirical evidence to support their contents and cutoff point. Chinese researchers Tao and Ko have also proposed diagnostic criteria for Internet addiction respectively, and the validity and reliability have proved to be good. Subjects of the two studies were adolescents or young adults, and the subtypes of Internet addiction were not designated clearly. Similarly, some assessment instruments have been created, but few of them have undergone rigorous reliability and validity tests, and none of them wholly captures the various dimensions of Internet addiction. Still, there has not been universally acceptable gold standard assessment or diagnostic tool until now.

With these definitions and assessment methods, estimate of prevalence of Internet addiction has quite a large range from 0.9 to 38%, usually being high in Asia. The

common age range of onset of Internet addiction is from 13 to 30 years old. Some studies show that younger online-game players are generally more prone to IAD. As for gender, males show higher dependence on video games than females, which has been explained by a functional magnetic resonance imaging (fMRI) study contrasting a space-infringement game with a control task. In the study, males show greater activation and functional connectivity compared to females in the mesocorticolimbic system.

Pathophysiology studies appear to show that neither the causes nor the consequences of Internet addiction are restricted to psychosocial factors. Perhaps non-substance-related behaviors such as gambling or Internet gaming could also produce intense reward activation and lead to compulsive behavior similar to addiction. Results of fMRI studies reveal that significantly stronger activation in Internet gaming addicts compared with healthy controls has been found in the left occipital lobe, left parahippocampal gyrus, left dorsolateral prefrontal cortex, right orbitofrontal cortex, bilateral anterior cingulate, and medial frontal cortex.

Internet addiction can lead to a wide variety of negative consequences that may require professional treatment. These include psychological problems, such as inattention, decreased self-appraisement and lower psychosocial well-being; loneliness, depression, anxiety, aggression/opposition, and hostility; and decreased academic and occupational performances. Some studies demonstrated that Internet gaming addiction develops as playing times increase significantly. As loss of control, a narrow behavioral focus and serious conflicts appear. Many individuals with Internet addiction will meet the criteria for comorbid psychiatric disorders, such as anxiety, depression, attention deficiency and hyperactivity disorder (ADHD), SUD or personality disorder.

As for treatment and prevention, special organizations have emerged in many countries. Many psychosocial and pharmacological approaches have been utilized to treat Internet addiction. The psychotherapy methods include cognitive behavioral therapy, motivational interviewing, twelve-step program, etc. The formats of psychotherapy involve group, individual and family therapies, as well as the intervention based on schooling. Pharmacotherapy for Internet addiction is still quite rare. Medicine, such as bupropion, and neltrexone, used to treat SUD have been reported to treat Internet addiction. For many cases, medicine, such as antidepressants and atypical antipsychotics are applied to treat comorbidities of Internet addiction. Many treatment approaches recommended are based on clinical experience, only few on empirical data. Several approaches have been established for preventing Internet addiction from both practical and academic perspectives. One approach is using software to make the users stop gaming after excessive play. For example, the Chinese government has launched a nationwide campaign with some anti-addiction software. Once the software is installed, online game players will be forced to logout after certain hours of gaming, otherwise they may lose in-game magic, virtual items, and gaming credits. Another approach is to identify potential addicts and give warnings or appropriate education about this issue.

SUMMARY

Nowadays, computers and the Internet are an integral part of people's daily lives. Artificial three-dimensional worlds are considered to be one of the most user-friendly metaphors for human–computer interaction. People have become accustomed to comfortable, easy-to-use interactive multimedia systems, with removal of time and distance constraints. The networked virtual environments are not just animating the vastness of space beyond the screen, they are also punching out at us in true 3-D movie fashion and starting to colonize the "inner space" of our private mental models. VR systems enable the user to feel as if they are present in a computer-generated environment. Thanks to the Internet, the new society is effectively a multiplayer mixed reality game in which everyone can win, and everyone can be virtually famous, infamous, or whatever else they want to be.

As a double-edged sword, Internet has profound effects on human psychology and behavior. Initially immersive audiovisual collaborative virtual environments appeared to hold great promise as a way of supporting social interaction for both business and leisure. However, the acquisition of memes through the filter of technology cannot replace the basic role of social interactions and direct experience. One concern is that Internet use may lead to declines in social involvement, since many of the online relationships represent relatively weak ties with strangers, acquaintances, or nonintimate kin. These types of social contact online are found to provide less social support than more intimate ties do. Anonymity and possibility of concealing the participants' real identity can have bewildering effects. Therefore, Internet use has been regarded to be associated with declines in the psychological well-being, such as depression, loneliness, etc.

The violent and sexually explicit content on the Internet is another major concern among parents, educators, and policy makers. Various applications and extensions of immersive virtual worlds on the Internet, with MMORPGs as representative, involve aggression and competition, and violence is an integral part of many online games. Teenagers and young adults are particularly susceptible to the lure of the Internet, and they are described as being obsessed with the Internet. The immersive virtual worlds online present

opportunities for novel interactions, but also bring many problems, such as the risk of Internet addiction. More and more scholars from different countries have conducted studies on symptoms, diagnostic criteria, etiology, subtypes, epidemiology, pathological basis, comorbidity, treatment, prevention, and other issues related to Internet addiction.

CHAPTER

90

Waterpipe Smoking

Wasim Maziak[*,$]

OUTLINE

INTRODUCTION

The Waterpipe

Only about a decade ago, including questions about the waterpipe (a.k.a. hookah, shisha, narghile, arghile; Fig. 90.1) in epidemiological studies of tobacco use among youth would have seemed unwarranted, even in the Eastern Mediterranean (EM) region considered by many as the cradle of this tobacco use method. Not including such questions nowadays, no matter where the study is conducted, will likely be a serious flaw. This reflects the dramatic changes in youth's tobacco use patterns worldwide, with non-cigarette forms, led by the waterpipe, becoming increasingly popular. The waterpipe usually consists of a fired-clay head, metal body, glass water bowl, and leather or plastic hose (see Fig. 90.1). But while waterpipe's shape and composition can differ from one society to another, there is a great similarity in how waterpipes are currently used by youth around the globe.

In the most common form of waterpipe use, burned charcoal pieces are placed on top of a perforated

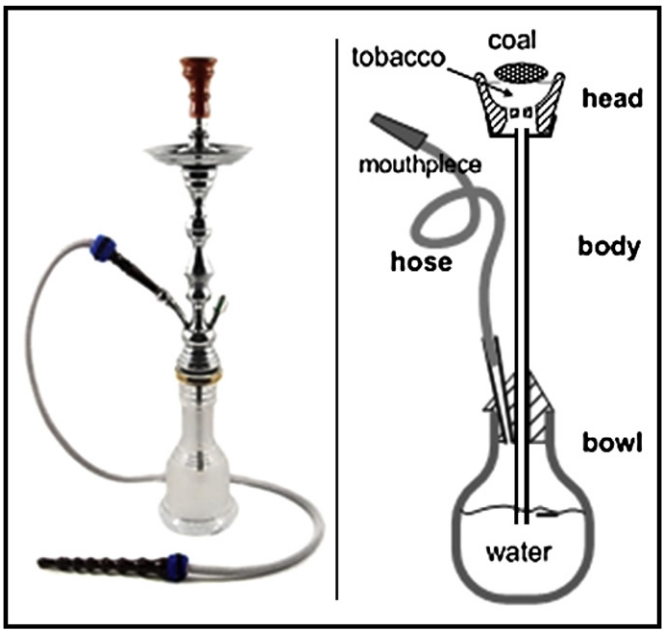

FIGURE 90.1 Actual waterpipe (left) and schematic (right) showing main parts. *Reproduced from (Maziak, 2008, 2011).*

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00090-5

aluminum foil separating it from the flavored tobacco mixture in the head. When the smoker breathes in from the hose's mouthpiece, charcoal-heated air is drawn in to become smoke as it passes through the tobacco mixture, and cools as it bubbles through the water before inhalation by the smoker (Fig. 90.1). The passage of smoke through water prior to inhalation underlies much of the common misperception of waterpipe's reduced harm (due to assumed "filtering" effect of water). The most popular type of waterpipe tobacco used today is called *Maassel* (a.k.a. shisha tobacco), which is a wet mixture of tobacco, sweeteners (e.g. molasses), and flavorings. Waterpipe charcoal products range from traditional earthen kiln charcoal to quick-lighting products that are particularly common in the United States and western societies. While evidence about waterpipe's harmful and addictive properties is emerging, treatment and policy interventions to curb waterpipe use continue to lag behind. This chapter provides an overview of the global waterpipe epidemic and the evidence about its harmful and addictive properties as it pertains to the development of treatment and policy interventions to curb waterpipe spread.

THE EPIDEMIOLOGY OF WATERPIPE SMOKING

Factors Contributing to the Global Re-emergence of Waterpipe Smoking

In recent years, waterpipe use has been witnessing a surge in popularity, especially among youth in the EM region. Beginning in the 1990s, what seemed to be a tobacco use method destined for extinction witnessed a global revival that was sparked in the EM region. The period of revival of the waterpipe coincided with the introduction of manufactured *Maassel* and the explosive increase of its available flavors. While the apple *Maassel* was somehow the predominant flavor early on, current variety include strawberry, grape, anise, apricot, cappuccino, coke, banana, passion fruit, peach, berries, papaya, mint, mango, coffee, candy, chocolate, vanilla, walnut and the list goes on. It is obvious from this list that many of those flavors are created with marketing to young people in mind.

The widespread reduced-harm perception of waterpipe is perhaps contributing to waterpipe use among youth, especially the more health conscious. For example, studies among future health professionals show that current waterpipe use is practiced by 20.6% of medical students in Lebanon, 23.5% of medical students in Syria, and 28.6% of medical students in Turkey. A recent study of primary health care providers in Aleppo-Syria shows not only the widespread of waterpipe smoking in this population (e.g. 24% of male physicians smoked waterpipe), but that health care providers' smoking represents a barrier for the implementation of smoking cessation practices in primary health care.

The aromatic and mild smoke of *Maassel*, its wide variety and availability, and its simplification of the waterpipe preparation process were perhaps critical for the renewed emergence of the waterpipe. Before the *Maassel* era, waterpipe smokers mostly used more raw forms of tobacco that needed some sort of processing and manipulation before being applied to the waterpipe (e.g. addition of water, crushing and pressing within a piece of cloth). At the same time, the Internet and other transnational media (e.g. satellite TV) commercialized and glamorized this practice, particularly among youth. In sum, manufactured *Maassel*, the reduced-harm perception, the thriving café culture, and mass media have perhaps created conditions for a perfect storm that sparked the global waterpipe epidemic.

The Spread of Waterpipe Smoking Among Youth

The global spread of waterpipe smoking among youth is backed by recent surveys from around the world. For example, results of the Global Youth Tobacco Survey (GYTS) involving data from 20 countries and the Gaza Strip-West bank in the EM suggest that current (past month) waterpipe smoking (12.9%) is more than double that of cigarette smoking (5%) among 13–15-year olds (Fig. 90.2). In Karachi Pakistan, ever waterpipe use was reported by 27% of school students ($n = 646$, mean age 15 years) and 54% of university students ($n = 450$, mean age 21 years), while current waterpipe

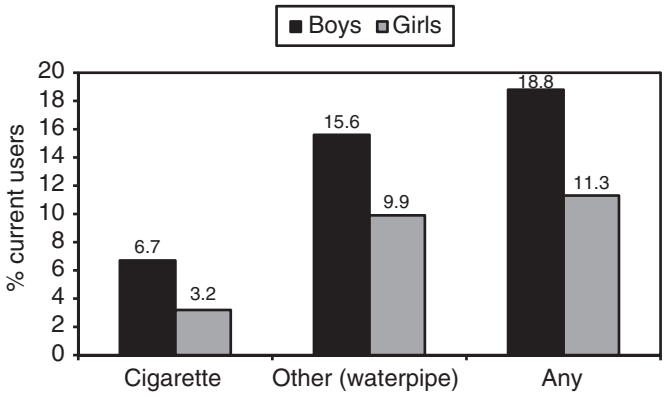

FIGURE 90.2 Data from Global Youth Tobacco Survey in the Eastern Mediterranean (92.075 students in 20 countries) showing how other tobacco use (mainly waterpipe) is becoming more widespread among 13–15-year olds in the region *(constructed based on Warren et al., Lancet, 2006).*

use was reported by 17% of school and 33% of university students. Among Jordanian university students ($n = 548$, mean age was 21.7 years), a recent study shows an amazing 42.7% prevalence of current waterpipe smoking. A recent survey of 2972 adult Kuwaitis showed that 45% smoked only waterpipe, 12% only cigarettes, and 8% both waterpipe and cigarettes.

Outside of the EM, where until recently tobacco surveys have rarely assessed waterpipe use, a new picture is emerging. Ever waterpipe use for example, has been reported by 38% of a sample of British university students ($n = 937$, mean age 20 years), and 40% of a sample of French high school students ($n = 920$, mean age 18 years) experimented with other tobacco products including the WP. Studies in US universities found that current waterpipe use ranges from 7 to 20%. For example, among a sample of 8745 students in eight colleges in the United States, 29.5% reported ever waterpipe use, and 7.2% reported current waterpipe use. As Fig. 90.3 shows, waterpipe use in US universities is approaching that of the EM, and is extending beyond any specific ethnic denominator. The spread of waterpipe smoking among US college students is also reflected in the dramatic rise (400% since 1999) of hookah lounges near US campuses.

These trends are not confined to small-scale surveys, but are beginning to show in state and national surveys. In a 2006 national survey of Estonian students ($n = 13\ 826$, age 11–15 years), waterpipe use was reported by 25% of boys and 16% of girls. Statewide youth tobacco use surveys in the United States indicate that 7% of 12th graders were current waterpipe users in Arizona, while 11% of high school students in Florida were ever users. According to the 2008 New Jersey Youth Tobacco Survey involving a representative sample of 3010 high school students, 9.7% of high school students are current waterpipe users. In Canada, the 2006 Canadian Tobacco Use Monitoring Survey shows that 8% of youth aged 15–24 years had ever used the waterpipe. The available evidence from Australia comes from a telephone survey conducted in 2004 and involved 1102 Arabic-speaking residents in south-west Sydney, where current waterpipe smoking was reported by 11.4% of participants.

Yet the most compelling evidence about waterpipe's growing impact on youth's tobacco use globally comes from a recent GYTS report looking at time trends of tobacco use (1999–2008) among more than half a million youth ages 13–15 years (involving 209 surveys in 95 countries and five areas). This global surveillance effort shows that while cigarette smoking is either stable or declining, other forms of tobacco use are showing a rising trend, most notably waterpipe smoking. As a result, questions about waterpipe are becoming an essential part of tobacco use surveys worldwide (e.g. waterpipe questions will be added to the 2010 Monitoring the Future Survey).

What began as a Middle Eastern phenomenon in the 1990s of the past century has made it quickly to the global tobacco use arena in a way that we have not witnessed perhaps since the global cigarette epidemic.

Epidemiological Patterns of Waterpipe Smoking

The salient epidemiological pattern of waterpipe smoking is the relation to age, with younger people more likely to smoke waterpipe. For example, in a population-based survey in Syria, waterpipe smoking was more than twice as popular among younger adults compared to older ones. This is quite a distinguished pattern from waterpipe smoking before the current epidemic (before 1990s), where its use was mainly seen among older men in the EM. Other noted epidemiological patterns of waterpipe use include its predominance among educated and affluent youth, within a social setting, and its relation to family waterpipe use and attitude. For example, data from within and outside the EM suggest that waterpipe smoking is favored by educated and affluent youth compared to other slices of the society (Fig. 90.4). Whether this pattern represents a transient phase of the waterpipe epidemic reminiscent of the early stages of the cigarette epidemic, or will continue beyond, remains to be seen. Undoubtedly, the continuation of strong

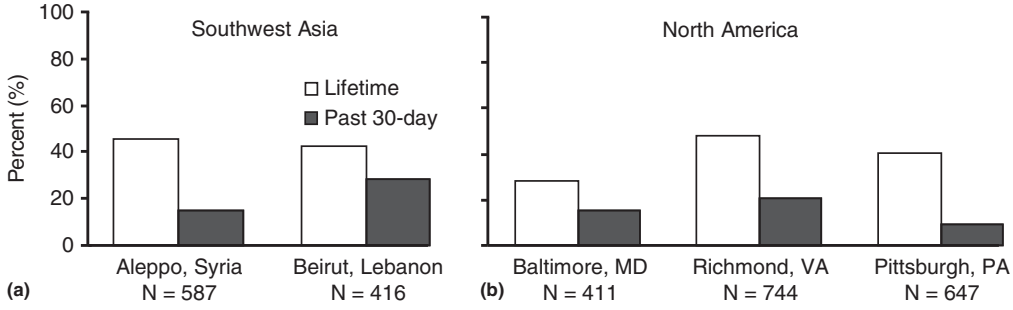

FIGURE 90.3 Prevalence of current WP smoking among college students from the Middle East and US. *Reproduced from (Cobb et al., 2010).*

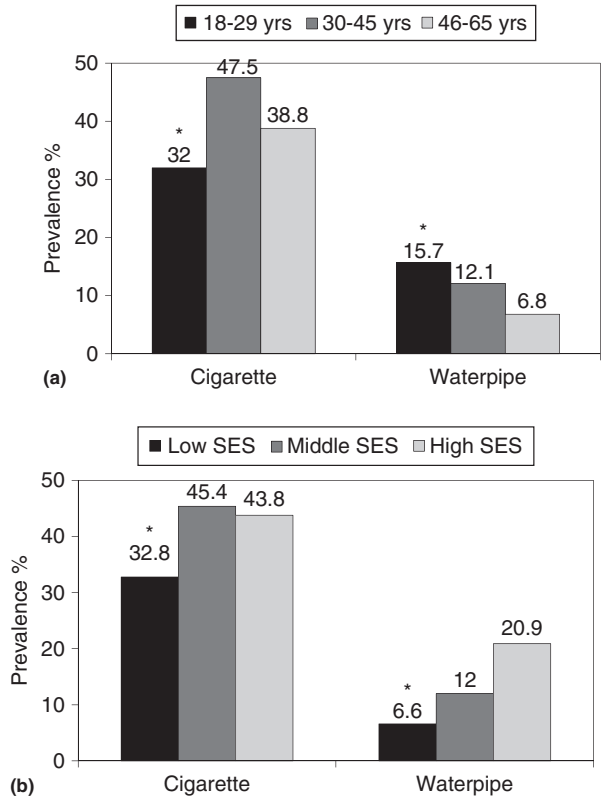

FIGURE 90.4 Data from the Aleppo Household Survey showing the clear age (a) and socioeconomic (b) relation of waterpipe smoking, with younger and more affluent people more likely to smoke waterpipe. $^{*}P < 0.05$ according to chi square test for trend. *Reproduced from (Ward et al., 2006).*

promotion and marketing of waterpipe through the Internet, the targeting of college campuses by waterpipe venues (e.g. hookah bars and lounges), the emerging data about waterpipe's health hazards, and the shape of policy initiatives to curb waterpipe use will likely influence the evolution of waterpipe epidemic in different societies.

Another distinctive pattern of waterpipe use, at least in the EM context, concerns girls/women's susceptibility to waterpipe smoking compared to cigarettes. In a region where cigarette and waterpipe smoking are by far the main tobacco use methods, the fact that 6.7% of boys in the GYTS (2006 global report) and 3.2% of girls smoked cigarettes, while 15.6% of boys and 9.9% of girls used other tobacco products (mainly waterpipe) demonstrates the dramatic spread of waterpipe use among youth in the EMR (Fig. 90.2). This spread of use among girls/women seems particularly related to social tolerance toward waterpipe smoking in this group compared to cigarettes. For example, in a study by Tamim and colleagues (2007) of 2443 school children in Lebanon (average age 15 years), about one quarter of cigarette smokers, compared to two-thirds of waterpipe smokers, said that one or both of their parents knew about their smoking. Unlike cigarette smoking, gender was not a predictor of waterpipe smoking status among the studied school children. In the study of adults in Kuwait alluded to earlier, women were more likely to smoke waterpipe compared to men, who were more likely to smoke cigarettes. It looks that in traditional societies of the EM, where women's behavior is more in the public eye and under scrutiny, women's use of the "traditional" waterpipe is seen as more conforming to the local culture than women smoking the "western" cigarettes.

In the long run, this will likely lead to fundamental changes in tobacco use patterns in societies of the EM marked by the decimation of the long-believed "immunity" of EM women to smoking. Once hooked on nicotine, it will be hard to imagine how women waterpipe smokers can abstain from cigarettes in situations, where access to waterpipe is not available. Because of its size and setup, waterpipe is not as accessible and portable as cigarettes, which can encourage switching between these two tobacco use methods. This is bad news for women's health, as well as for their children's health, as evidence from the EM shows that mothers' smoking is more important than fathers' as a determinant of children's exposure to secondhand smoke.

THE PUBLIC HEALTH IMPLICATIONS OF WATERPIPE SMOKING

Waterpipe's Harmful Potential

One of the main potential drives behind waterpipe popularity amongst youth worldwide lies in its perceived reduced harm compared to cigarettes. Several factors can underlie such perception including; waterpipe's predominantly intermittent use patterns, the smoothness of waterpipe smoke compared to cigarettes (waterpipe smoke is usually cooler and less irritating than cigarette's), and perhaps most importantly the assumed smoke "filtering" properties of water. Generally, the harmful/addictive profile of waterpipe use compared to cigarettes is largely under-researched and is likely to be influenced by the properties of waterpipe smoke, pattern, duration and frequency of use, and type of tobacco and charcoal used. Advances in our understanding of the full spectrum of waterpipe-induced morbidity and mortality are also hindered by the novelty of waterpipe epidemic relative to the long latency of important smoking-related health outcomes such lung cancer and cardiovascular disease.

However, several lines of evidence are converging to provide an alarming picture of waterpipe's harmful potential. For example, recent systematic reviews of the evidence concerning the health effects of waterpipe

smoking suggest that it is more than doubles the risk of lung cancer, respiratory illness, and low birth weight, and can influence lung function in manner similar to cigarettes raising the potential of later chronic obstructive pulmonary disease (COPD) development as a result of waterpipe use. According to these reviews, many of the reviewed waterpipe-health effects studies suffer from methodological shortcomings. On the molecular level recent research shows that waterpipe smoking is genotoxic to lymphocytes at a higher magnitude than that seen with regular cigarette smoking.

Awaiting high quality studies of the long-term health effects of waterpipe smoking, other lines of evidence allow for a forecast of future waterpipe morbidity and mortality. Foremost, although waterpipe use patterns are predominantly intermittent, waterpipe smokers inhale on average in a single session about 150 times the amount of smoke compared to a single cigarette (Table 90.1). Waterpipe smoke, moreover, seems far from being "filtered". Research shows that waterpipe smoke contains many of the same toxicants found in cigarette smoke (e.g. those associated with cardiovascular disease such as carbon monoxide "CO"; lung cancer such as polycyclic aromatic hydrocarbons (PAH); addiction via nicotine; Table 90.2), and these are delivered efficiently to the smoker. For example, analysis of smoke generated by waterpipe users, through direct sampling during the smoking sessions, shows that during a single use session averaging 1 h, users drew a mean of 119 l of smoke containing 150 mg of CO, 4 mg of nicotine, and 602 mg of "tar".

Measurement of users' exposure to waterpipe-related toxicants reveals that, relative to a single cigarette for example, a single waterpipe session exposes the smoker to 3–9 times the CO and 1.7 times the nicotine (Fig. 90.5). Most of the CO in the mainstream smoke of waterpipe is likely originating from the charcoal, adding a new dimension to the harmful potential of this tobacco use method. In fact, reports of waterpipe-related emergency room admissions due to acute CO intoxication are beginning to emerge in the medical literature. Exposure to these toxicants can be inferred as well from the acute physiological responses associated with waterpipe smoking including; increased heart and respiratory rates, blood pressure, pulse pressure, and a decrease in some lung function parameters (e.g. forced expiratory flow 25–75% (FEF 25–75%), peak expiratory flow rate (PEFR)).

TABLE 90.1 Mean Puff Topography for Waterpipe and Cigarette Smokers

Topography variable	Waterpipe $N = 61$	Cigarette $N = 56$
Puff number	169	12.7
Puff volume (ml)	511	48.6
Puff duration (s)	3.2	1.5
Inter-puff interval (s)	12.6	21.3
Total volume (ml)	79 100	523

Note: waterpipe topography data from Maziak et al. (2009); cigarette topography data from Djordjevic, Stellman, and Zand (2000). Note that WP smokers inhale in one puff almost as much smoke as cigarette smokers inhale for the whole cigarette.

TABLE 90.2 Machine-generated Smoke Content Using Realistic Puff Parameters for a Single Waterpipe Episode and a Single Cigarette

Toxicant (mg)	Waterpipe[1]	Cigarette[2]	Ratio
Nicotine	2.96	1.74	1.70
CO	145	22.3	6.50
Tar	802	17.3	46.36

From Cobb et al. (2010).

A lot of these harmful substances are emitted to the surrounding air putting non-smokers at risk. For example, two recent studies involving human and machine-smoked waterpipes showed that waterpipe smoking generates high levels of ambient air toxicants/carcinogens (e.g. PAH, metals, CO, NO, as well as particulate matter), that are comparable to smoking 2–10 cigarettes for a 1-h waterpipe session.

Because of the social nature of waterpipe smoking, sharing the waterpipe, a popular practice among youth worldwide can be associated with infectious disease risks, such as TB. Lastly, evidence suggests that waterpipe smoking can undermine tobacco control, as it can be used as a replacement for cigarettes among quitters, or serves as a gateway to cigarettes. A new study among 762 Danish youth (14–16 years) provides the first prospective evidence that waterpipe use predicts progression to regular cigarette smoking among Danish youth.

Although we still lack high quality studies of the health effects of waterpipe smoking, converging lines of evidence point to its deleterious health potential to smokers and non-smokers alike, as well as to its potential to undermine tobacco control measures.

Waterpipe's Addictive Potential

In 1997, Macaron and colleagues firstly demonstrated nicotine exposure in waterpipe users by measuring cotinine in their urine. Review of published studies of nicotine exposure associated with waterpipe use shows that daily waterpipe smoking produces a urinary cotinine levels equivalent to smoking 10 cigarettes per day. More recently, direct measurement of plasma nicotine in daily waterpipe smokers shows a five-time increase from

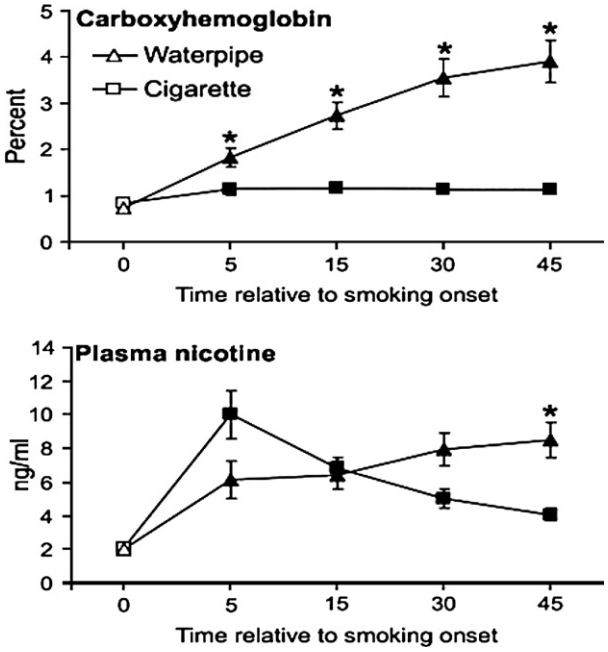

FIGURE 90.5 Mean carboxyhemoglobin (COHb) (top), plasma nicotine (bottom) of 31 subjects who smoked a WP (45 min) or cigarette (5 min). $^{*}P < 0.001$ between conditions. *Reproduced from (Eissenberg and Shihadeh 2009).*

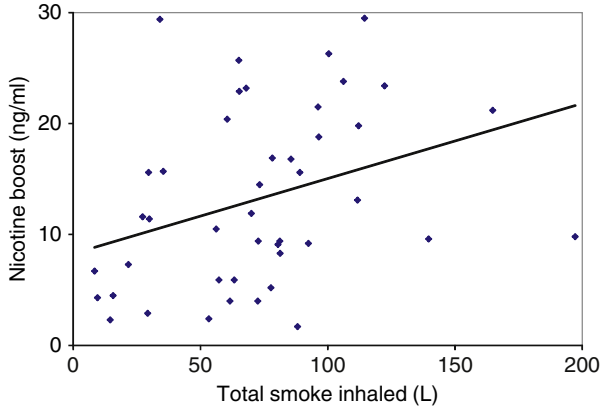

FIGURE 90.6 Correlation (Pearson $r = 0.34$) between plasma nicotine boost and total smoke inhaled (log transformed). *Reproduced from (Maziak et al., Addictive Behaviors, 2011).*

$3.07 \pm 3.05\ \text{ng ml}^{-1}$ pre-smoking to $15.7 \pm 8.7\ \text{ng ml}^{-1}$ post-smoking levels. Such waterpipe-associated nicotine exposure can exceed that associated with cigarette smoking. This was tested directly by comparing nicotine exposure of waterpipe and cigarette in dual cigarette/waterpipe smokers using crossover design. In this study conducted by Eissenberg and Shihadeh (2009), analysis of plasma nicotine area under the curve shows 1.7-time nicotine exposure dose for the waterpipe compared to cigarette conditions. Further support for the waterpipe as an important source for nicotine exposure comes from the demonstrated strong correlation ($r = 0.34$) between plasma nicotine levels and puff topography parameters such as total smoke inhaled during a waterpipe smoking session (Fig. 90.6).

Other than nicotine exposure, waterpipe smokers report known features of dependence, such as drug-seeking behavior, use escalation with time, self-perception of being hooked, and inability to quit despite repeated attempts. For example, a study conducted by Ward and colleagues (2005) in a random sample of 268 waterpipe users in Aleppo (Syria) showed that 28% wanted to quit and 59% reported an unsuccessful quit attempt in the past year. Belief in one's ability to quit was inversely related to perceived dependence. Another study from the same dataset conducted by Maziak and colleagues (2004) looked at waterpipe smoking frequency, as a surrogate marker of dependence, showed that dependent waterpipe smokers engage in behavioral adaptations to ensure access (e.g. carrying their own waterpipe with them) similar to what is seen in cigarette smokers. This early work at the Syrian Center for Tobacco Studies (SCTS) helped advance a bi-dimensional concept of waterpipe dependence; the first reflects the effects of nicotine, and the second reflects waterpipe's unique social dimension with more dependent waterpipe smokers increasingly showing solitary and home-based use patterns. Case histories from waterpipe users provide another line of evidence to the addictive nature of waterpipe; "It went from something fun I did each week, to each day, to 5–6 times a day. It became an addiction", or "I think I'm addicted to the social aspect of hookah".

As dependence becomes recognized among waterpipe smokers, studies looking specifically into this issue are emerging. For example, a Lebanese group aimed to develop and validate an 11-item Lebanon Waterpipe Dependence Scale, which included four domains; nicotine dependence, negative reinforcement, psychological craving, and positive reinforcement, and was correlated to waterpipe use frequency. Support of the dependence-inducing potential of waterpipe is beginning to gather from clinical lab evidence as well. In one study conducted at SCTS (2009), several subjective measures of withdrawal, craving, and nicotine effects were assessed pre-/post-smoking in 24 h-abstinent waterpipe smokers ($n = 61$, mean age 31 years). This study showed that that waterpipe smokers experience abstinence-related symptoms such as urges to smoke, restlessness, craving, and that these symptoms are suppressed significantly with subsequent waterpipe use. Such results, in addition to the anecdotal evidence of replacement potential between waterpipe and cigarettes (e.g. during cigarette quit attempts), prompted a further comparative study looking on how waterpipe, compared to cigarettes, suppresses craving and withdrawal symptoms. In this study, 12-h abstinent dual waterpipe/cigarette smokers

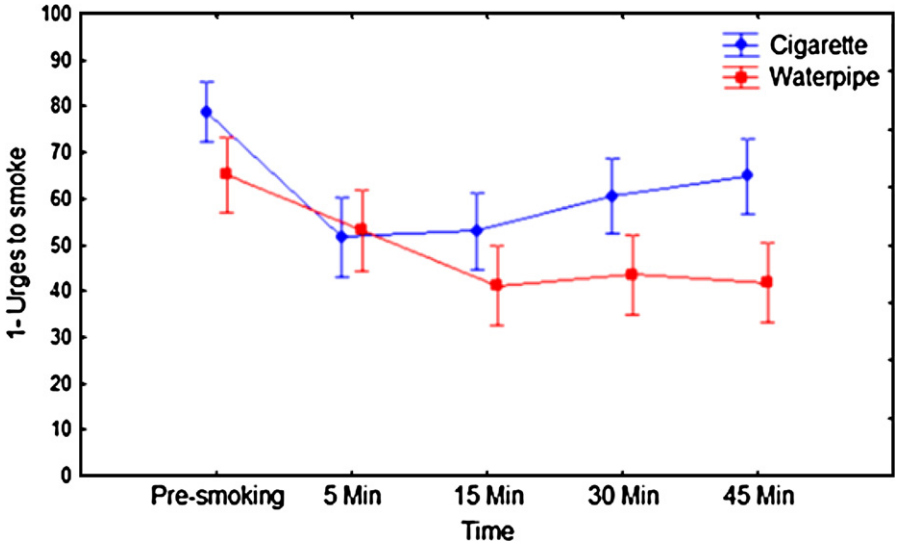

FIGURE 90.7 Mean scores of the item "Urges to smoke" in abstinent dual cigarette/waterpipe smokers ($p = 0.8$ for comparison at 5 min using repeated model ANOVA). *Reproduced from (Maziak et al., Addictive Behaviors, in press).*

(smoke waterpipe ≥ 1/week and cigarettes ≥ 10/day) smoked either waterpipe or cigarettes in two randomly-ordered sessions. Results show that waterpipe and cigarette smoking suppressed craving comparably at 5 min (end of cigarette smoking time point) (Fig. 90.7).

These data are consistent with the notion that waterpipe smoking is associated with features of dependence, and that waterpipe and cigarettes may be interchangeable in their effects on tobacco-abstinence symptoms. The clear public health implication of such information, is that waterpipe smoking is addictive and can hook users on nicotine, as well as thwart smoking prevention and cessation efforts among youth.

THE INTERVENTION AND POLICY IMPLICATIONS OF THE WATERPIPE EPIDEMIC

The Need to Understand Waterpipe Dependence among Youth

Despite what we already know about tobacco use, prevention and cessation interventions for youth have been hindered by the lack of clear understanding about how they get hooked on tobacco. Such understanding is needed to guide the timing, composition, and intensity of tobacco control interventions. While information about the initial development of tobacco dependence is beginning to emerge for cigarette smoking, knowledge to guide waterpipe interventions continues to be lacking. A Cochrane review by Maziak and colleagues failed to identify a single waterpipe cessation intervention, the development of which will require clear understanding of salient symptoms/domains of dependence in waterpipe users, and how they progress in their smoking habit.

An important aspect to consider in this regard is that the waterpipe has unique use patterns/features (e.g. intermittent use and prolonged sessions, preparation time, accessibility, and convivial experience of group use) that will likely shape dependence and how it is manifested in waterpipe smokers. For example, since the waterpipe is not as portable and accessible as cigarettes, waterpipe users may engage in more intensive behavioral adaptations to ensure access, such as carrying one's own waterpipe to places, and selecting cafés based on waterpipe availability. Other specific features such as waterpipe's sensory stimuli (e.g. smoke's aromatic smell) and social ambience can become cues for smoking, as well as a motivation for initiation. Moreover, the size of waterpipe requires deep inhalations in order to generate smoke and keep it going (puff volume $\approx$ 500 ml vs. puff volume $\approx$ 50 ml for cigarettes, Table 90.1). This feature combined with the less irritating smoke, compared to cigarettes, can lead to higher exposure to nicotine and toxicants during the experimentation stage and perhaps a faster path to dependence. As the waterpipe is becoming the first mode of contact with tobacco for many youth, the balance between dependence and access may determine which waterpipe users are likely to initiate cigarette smoking (i.e. the more dependant waterpipe smokers will likely not be able to abstain from smoking until they can smoke the next waterpipe and may switch to the more accessible cigarette).

Therefore, because of waterpipe's specific features and use patterns, initiation and dependence development in waterpipe smokers will likely follow

a distinctive path that need to be deciphered in order to develop effective interventions to curb waterpipe use.

Policy Aspects of the Waterpipe Epidemic

So far, data presented in this chapter not only indicate that waterpipe smoking has become a public health threat, but that this is perhaps the first tobacco use method since the cigarette that is showing all signs of a burgeoning global epidemic. They also indicate that the waterpipe is running its specific epidemiological course, and that its harmful and addictive profiles are likely to be shaped by its unique features and use patterns. Despite these alarming trends, most national and international tobacco control strategies (e.g. clean indoor air policies, prohibition of advertisement and sales to minors, large or graphic warning labels, taxation) still do not clearly address this tobacco use method. Furthermore, the waterpipe is not currently regulated (e.g. by the US Food and Drug Administration, or the Canadian Food Inspection Agency), and the content and packaging of waterpipe tobacco, or other accessories sold on the market, are not standardized. For example, many waterpipe users are driven by a misperception of reduced harm/addictiveness, which can be re-enforced by deceptive descriptors that appear on WP tobacco packages (e.g. "contains 0% tar and 0.05% nicotine") or accessories such as the charcoal (e.g. "smokeless and odorless", "free of chemicals", "100% natural"). All these descriptors aim to create an impression of a healthy product, and should be countered by appropriate packaging and advertisement policies.

The Framework Convention on Tobacco Control (FCTC), which represents the first global public health treaty, recognizes the diversity of tobacco products worldwide and calls for their inclusion in any tobacco control policy. However, most of the articles of the FCTC were formulated with the cigarette and the tobacco industry in mind. The picture becomes less clear when it comes to the waterpipe, where there is no well-defined industry behind it, and where the method itself is distinctive from cigarettes in many ways. Manufacturers and retailers of waterpipe's different parts/tobacco, and most importantly waterpipe cafés owners are mostly small businesses forming a multiplicity of converging interests rather than a well-defined industry or interest group. Given the current rate of waterpipe spread, we may still see the emergence of a more organized and powerful waterpipe industry and/or lobbying bodies on behalf of waterpipe interests.

While this is good news, because it means that, at least for now, waterpipe control efforts will unlikely face significant and organized opposition, understanding waterpipe's distinctive features – from cigarettes – is instrumental for the development of successful response to the global waterpipe epidemic. For example, banning traditional tobacco advertisement (billboards, print media) will likely have little influence on the waterpipe since much of its promotion and sales are done over the Internet and social networks, or implicitly as part of cafés/restaurants promotion. In addition, most of warning label/pictorial policies make no sense for the social waterpipe smoker because in a café setting the waterpipe is usually served prepacked (i.e. the user is not exposed to any warning put on the waterpipe tobacco package). In the same café setting, unclear policies concerning minors' access to the waterpipe may allow underage people to order waterpipe in the café as a way of "sampling" rather than overt purchase of waterpipe tobacco. The call for cessation services by the FCTC furthermore, requires evidence-based cessation programs for the waterpipe, which do not exist currently. This will not only influence waterpipe control efforts, but will likely reflect on cigarettes' as well. Unless the waterpipe is addressed adequately in smoking cessation programs, evidence shows that cigarette quitters may turn to the waterpipe to deal with unpleasant abstinence symptoms. Finally, in some parts of the world (e.g. United States), waterpipe venues can be benefiting from tobacco control policies (e.g. smoking bans in restaurants and bars), because they can be exempted under certain provision as a "retail tobacco establishment".

As mentioned earlier, much of the promotion of waterpipe is exploiting the harm-reduced notion contingent on the assumed filtering function of water. In an attempt perhaps to circumvent potential waterpipe tobacco control policies, this concept has been taken further recently with the introduction of non-tobacco-based waterpipe herbal products (e.g. Soex, a sugar cane-based product). These have been marketed with claims of "same flavorful smoke found in other shisha without the harmful effects of tobacco". Comparative analysis of this product with regular waterpipe *Maassel* using a crossover design shows that Soex delivers a similar amount of CO but not the nicotine, making it a bad "harm-reduced" option, and supports the need to regulate these products against deceptive marketing strategies (Fig. 90.8). Exploiting the harm-reduced hype is not confined to waterpipe tobacco, but is involving the artifact itself as well in a way reminiscent of the electronic cigarette. An electronic variant of the waterpipe has appeared recently on the market (called Halooka™) with claims of being healthier than the original waterpipe through the application of electronic heating source and nicotine containing cartridges (variety of flavors of course). Apparently, because the electronic waterpipe does not involve ignited tobacco, it will fall outside most of tobacco control regulations,

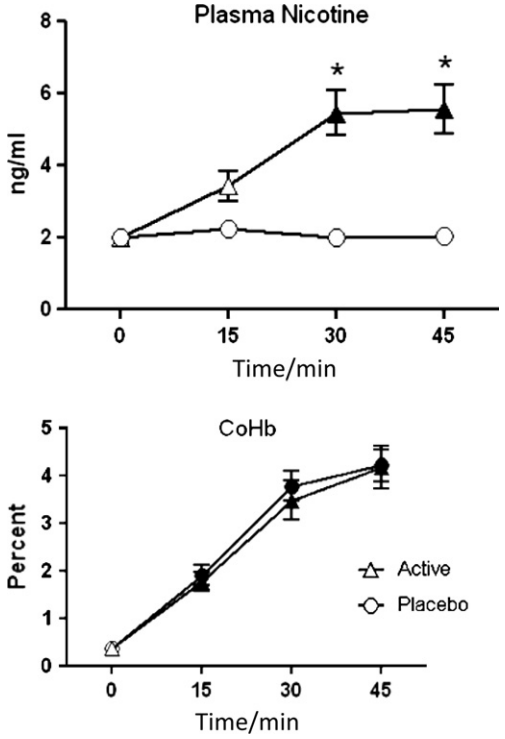

FIGURE 90.8 Mean ± SEM for plasma nicotine (top), COHb (bottom) for active and placebo waterpipe tobacco conditions in 37 waterpipe smokers who completed two randomly-ordered waterpipe sessions using either regular tobacco or placebo (tobacco free herbal waterpipe preparation). Filled symbols indicate a significant difference from baseline and asterisks (*) indicate a significant difference between active and placebo. *Reproduced from (Eissenberg et al., SRNT, 2010).*

regardless of what are its potential harms or its role in sustaining the smoking culture and nicotine addiction amongst youth.

Accordingly, policy initiatives such as health warnings, bans on advertisement/deceptive descriptors, cessation, price/taxation, and controlling minors' access should accommodate the multi-component, electronic media driven, and the social nature of the waterpipe. It should also accommodate the fast changing landscape of waterpipe products and promotion that exploit the social networks media and harm-reduced perception to thwart potential waterpipe tobacco control efforts.

CONCLUSIONS

Given waterpipe's global reach, its potential to hook young people on nicotine, to replace cigarettes among quitters, and to harm smokers and non-smokers alike, the threat of waterpipe smoking to global public health need not be overemphasized. Understanding waterpipe's unique features and how these influence users as they progress in their smoking habit, as well as the dynamic environment that supports waterpipe use and promotion, will be essential for the development of prevention, treatment, and policy interventions to curb the global waterpipe epidemic.

NO	nitric oxide
PAH	polycyclic aromatic hydrocarbons
PEFR	peak expiratory flow rate
SCTS	Syrian Center for Tobacco Studies
SES	socioeconomic status

Glossary

Waterpipe is a centuries-old tobacco use method with an ambiguous origin, but is often associated with Middle Eastern societies. Although known by different local names (e.g. hookah, narghile, shisha), the term waterpipe has been coined in order to combine tobacco use methods that share the unifying feature of passage of tobacco smoke through water before inhalation by the smoker.

Maassel is a wet mixture of tobacco, sweeteners (e.g. molasses), and flavorings that is currently most commonly used in the waterpipe.

CHAPTER

91

The Cell Phone in the Twenty-First Century: A Risk for Addiction or a Necessary Tool?

Xavier Carbonell, Ursula Oberst, Marta Beranuy

FPCEE Blanquerna, Universidad Ramon Llull, Barcelona, Spain

OUTLINE

Social progress parallels that of human communication. The need to communicate led to the production of written languages, a plethora of communication channels, and has been a crucial element in the development of our brains. This chapter deals with the importance of one of these communication channels, the *cellular telephone*, and how it impregnates our culture. The cell phone is a portable device which has become a social object that is personal, exclusive, and intimate. The different names used for this device help us see the very particular relationship each country has with this tool: it is called a *móvil* in Spain, *celular* in Latin America, *cell phone* in the United States, *handy* in Germany, "*sho ji*" (handheld) in China, and "*makhmul*" (portable) in Arab-speaking countries. In Japanese society, this technology is so commonplace that cell phones are simply called telephones. Whatever its name, people everywhere have developed an intense relationship with their cell phone, much more intense than they ever did, in its day, with an ordinary (fixed-line) telephone.

The fusion of computing and telecommunications in the 1970s gave rise to the development of the so-called information and communication technologies (ICT). This moment saw the birth of the philosophy of mobile telephony, a technology which combines the Bell telephone, Morse telegraph, Marconi radio, and computing. Humans have always tried to overcome distance as

Principles of Addiction, Volume 1
http://dx.doi.org/10.1016/B978-0-12-398336-7.00091-7

a barrier to communication, giving rise to carrier pigeons, telegrams, letters, postcards, books, magazines, radio, television, fixed-line telephones, electronic mail, Internet Relay Chats (IRC), and videoconferencing. The latter few overcome more than just the distance barrier, achieving real-time communication at a distance.

Cell phone use in today's society is common, and sales have increased notably. The number of cell phone subscribers has risen all over the world, Europe being the continent with most lines (followed by Oceania, America, Asia, and Africa). Between 2002 and 2003 the total cell phone users worldwide crossed the 1000 million boundary. It had taken 130 years for fixed-line–based telephony to reach this figure, whereas cell phones did it in a decade. Eight of every ten people in Europe possess a cell phone. Many people who only a few years ago would not buy one, or used one only sporadically, nowadays use one daily. Some models are truly objects of desire and have provoked changes in forms of communication. Cell phone uses even include things like teaching English, helping people give up smoking, or therapy in people with driving phobia or agoraphobia. Cell phones have played an important role in communication between opposers of the totalitarian regimes of northern Africa in 2011 and in the diffusion of images of their repression.

In parallel with increases in use and social acceptance, there has also been consideration of the possible negative consequences: medical (negative effects of the electromagnetic waves emitted by cell phones themselves and by their base station antennas), in road safety (effects and risks of cell phone use while driving or cycling and their involvement in traffic accidents), and psychological. Cell phones can play an important role in bullying (recording and diffusion of acts of vexation), in violence (recording and diffusion), and in sexual harassment. One of the most worrying negative consequences is the possibility of creating addiction, particularly among teenagers and young people. This possibility will be dealt with in the next section.

WHAT MAKES CELL PHONE USE SO GRATIFYING?

One of the factors determining the capacity of a substance to create addiction is its gratifying properties. It is accepted that the more intense the positive reinforcement, and the shorter the delay between consumption and physiological response, the greater is the capacity of a substance to produce addiction. So, let us analyze the positive reinforcement properties of cell phone use.

Euphoria

Euphoria from cell phone use appears to be at least as strongly related to message emission (calling or sending someone a message) as reception is to being feeling valued or loved when calls or messages are received.

Instrument

A cell phone may at the same time serve as pocket watch, alarm clock, digital camera, sound and/or video recorder, electronic diary, video console, radio, mp3 player, or Global Positioning System (GPS). It is a multifunction instrument with many utilities adapted to the age and social role of its owner.

Symbol of Identity

Cell phones have become one more element among the intimate components which constitute the personal sphere (just as other things do, such as a wristwatch, wallet, photos, key ring, etc.) with which the bearer has an emotional bond. Never before has a technological apparatus come to have such importance in so many people's daily lives, so essential to revealing identity.

The degree of personalization possible with a cell phone is one of the factors favoring expression of individual identity, particularly among younger people. The cell phone appears to have become an object through which a person can provide clues about their gender identity, social and professional position, attitude toward society, character, personality, or mood. A cell phone, like clothes, may transmit information about an individual's characteristics and about the idea they have of themselves, and which they want to transmit to others.

Social Status

Cell phone technology appears to confer power on young people. A young consumer who buys a cell phone feels powerful, not only through the use made of it, but also through the purchase in itself. Also, the number and/or quality of messages received, the number of calls, the number of contacts in the address book, the sophistication of the games and services offered by the cell phone, and the brand of the apparatus, all help to enhance the user's social status.

Social Network

Cell phones also are a tool to build a social network via the device's contact list. These networks are constantly evolving; the rate at which new phone numbers are added to contact lists is as rapid as that

of numbers falling into disuse. Moreover, we may speak of a collective identity. The social networks based on cell phones have created a new sense of identity for teenagers and young people.

Online Social Networks

In its short life, the cell phone industry has managed to adapt to keep pace with the demands of users, and create new needs: cell phones for professionals and business people, cell phones with only basic functions for children and the elderly, others for listening to digital music, and finally the cell phone as a discrete medium for checking emails and *online social networks*, and consulting Internet.

Independence

Cell phones play a significant role in socialization and creating a feeling of belonging to a group, particularly among teenagers. They foster a process of emancipation from parents and act as a kind of barrier between teenagers and their parents. In other words, for young people the cell phone is above all a personal telephone, and having a personal telephone not accessible by parents marks a boundary. Having a cell phone helps a teenager to acquire an ever greater sense of self and an increasing orientation toward the peer group. The cell phone favors independence and reinforces contact with friends and other people outside the family.

The cell phone is definitive when it comes to deciding if a young person can enter into society so that young people use them to maintain their social framework. At the same time the social contacts allow them to maintain their status in terms of class and peer group. In Tokyo public schools cell phone owners have more friends than nonowners. Children and teenagers usually receive a cell phone as a gift from parents. Making a present of a cell phone could be seen as a rite of passage, a gift related to initiation into the teenager phase, into social independence. And it would appear that this rite occurs at ever earlier ages.

Short Distance

The cell phone is an instrument which facilitates contact over short distances, in the sense of contact with people with whom we do not relate on a daily basis. One typical characteristic of youth is that it involves tightly closed, local social circles, neighborhood, school, club, etc., and the cell phone here is a practical medium for maintaining contact when face-to-face conversation is not possible. When members of the social network are a greater distance away, other communication channels are preferred, such as electronic mail, social networking, fixed-line telephone, or, ever more rarely, letters.

Increased Security and Control

Cell phones are instruments of control which generate feelings of security among parents, between couples, or even for oneself when away traveling. Parents buy their children cell phones because of a need to control them and restrain them with a *"digital leash."* This eagerness to control is a feeling which parents transmit to their children. Often the degree of control and sense of security is false: it is very easy to lie about where one is, and, anyway, battery life and coverage are both limited. Teenagers can mutually communicate while at home without parental control, something which was more difficult with ordinary (fixed-line) telephones, as well as at school without being controlled by teachers. In adults, this sensation of controlling/being controlled also occurs in sentimental and workplace relationships.

Permanent Mobility and Access

The fact of being mobile means that accessibility of people carrying a cell phone is perceived as permanent. This process gives rise to two opposing illusions: one, believing that we are not being controlled when in fact we can be located at virtually any moment wherever we are, and two, believing that one can control others when really cell phones only allow us to hear someone's voice or receive an SMS without us really knowing from where. Even so, parents prefer to believe they have some degree of control than to let their children escape from their clutches. Something similar could occur in sentimental and workplace relationships between adults, and some firms employ cell phones with GPS functionality permitting their location to be tracked.

When the user does not answer calls or respond immediately to SMS text messages, the caller can experience a sensation of concern. This arises because of the wrong interpretation of availability, often understood as "*obligatory*" creating an illusion of "*permanent availability*" and the cell phone user is pressured to carry the device turned on, and to always respond to calls or SMSs. Even so, the user is more interested in being able to call others while on the move, lending less importance to always being locatable.

Entertainment and Games

Cell phones carry a broad range of functionalities, and may even act as a portable videogame console.

Being up-to-date, playing the latest games, feeling integrated, and/or up with the fashion are goals pursued by many of today's teenagers and young people. One must also bear in mind that, increasingly, more leisure time activities are available through cell phones, for example betting, buying, getting sexually stimulated, and downloading music and videos. Children under 10 years of age regard games as the most important characteristic of cell phones, since at their age communication in itself is too abstract. The incorporation of applications ("*Apps*") in the latest generation of cell phones (so-called *smartphones*) has opened up an enormous range of possibilities for their use at work, for leisure, and for practical aspects of daily living; in many of these applications, these functions are intermixed. Cell phones are becoming personal mobile computers.

Synchronous and Asynchronous Communication

Voice calls and text messages are used differently depending on the purpose and on the characteristics of the message sender and receiver. Voice is synchronous communication, simultaneous in time, whereas text messages are asynchronous, like electronic mail.

Family Conciliation

The social evolution of family structures could partly explain the increase in personal telephone use. We may speak of various factors: (1) the emergence of single-parent or patchwork families: particularly reliant on external phone connections due to characteristics of their structure; (2), internal democratization of the family which accentuates individual autonomy and is susceptible of favoring diffusion of a less collective, more personal, form of telephonic communications; (3) the demand for individual communications devices given that children remain living with their parents for longer in some countries. The increasing incorporation of women into the workforce might be considered a fourth factor. Even though cell phones have not changed any social conventions, women tend to use it to cope with family responsibilities across a space-time gap, bringing their private world of domestic responsibilities to their public, occupation-related world, and vice versa.

All these changes in family morphology are reflected in affective and social bonds. Cell phones have made it possible for teenagers to construct a kind of *virtual brotherhood.* Moreover, cell phones promote individual thinking and networks of external support and propitiate virtual proximity (in the double sense of the word virtual). Connections mediated by cell phones only deal with the issue generating the call, leaving the parties involved free of any emotional commitment beyond the topic dealt with in the conversation or message. Present society demands fast and efficient connections. In this respect, distance is not an obstacle for connecting, but being connected is likewise not an obstacle for maintaining distances. Being connected is more economical than really relating. Thus, we may speak of new family constellations and emotional processes deriving in a society, still under construction, which gives rise to new ways of communicating to maintain family unity and the sense of belonging which both adolescents and adults need.

Individualization of Assets

This is one aspect of social evolution and the increasing quality of life in the Western world. In the technological field, telephones have followed the same path as television, in becoming an individual asset rather than a family one. Just as teenagers may have a television set in their own bedroom, they also have their own computer, and cell phone, etc.

WHAT IS THE SOCIAL SIGNIFICANCE OF TEXT MESSAGING?

The short message service (SMS) is the facility which permits sending text messages between fixed-line or mobile phone devices. The SMS culture has hit our society and their use is a social phenomenon: inviting users to political meetings or parties, follow-up of patients, as vehicle for therapy, obtaining status of commercial and bank transactions, participating in television contests and programs, receiving official bulletins, etc. Let's consider the inherent characteristics of the SMS separately.

Functionality of Written Language

Written information has an added value: its permanence. SMSs, with this attribute, are thus very different from oral conversation. The transmission of information, petitions, and self-expression represent the genuine, and historically almost invariable, dimensions of communication. An SMS is not a letter, but could be considered the equivalent of the postcard or telegram at least in regard to brevity and condensed content, with the additional advantage that they may be sent to various people at a time. An SMS can be a substitute for electronic or postal mail. At Christmas and New Year people use

skyrockets, as they are a quick and instantaneous replacement for Christmas cards.

Expression of Feelings

SMSs help to express, with little direct involvement, the feelings that people cannot or do not want to express orally and moreover they respond to the impulsive need to share feelings at the moment they are being felt. Also, regardless of age, sending an SMS indirectly implies that one is manifesting their very presence to the receiver, and thus the SMS carries an important symbolic load. This all means that SMSs are perceived as particularly satisfactory and, in the view of some authors, end up promoting more intimate ties and enriching personal relationships.

Abbreviated Language

The need to communicate as much as possible in the reduced space of an SMS has contributed to the development of an intensive use of abbreviations. In this form of expression, all kinds of strategies are used to abbreviate as much as possible, for example "lol" to mean "laughing out loud" or "xD" to mean happiness or laughing very hard. Lists giving the translation of these abbreviations abound, as do certain rules for writing SMSs.

Use of Emotion Icons

Diagrammatic representations of emotional states, (for example a smiling face, whether written by using ordinary keys :-) or via the ☻ symbol, may be used to indicate happiness. These icons, known as *emoticons*, serve to express feelings in the middle of the written text. The advantage of emoticons is more notable in an SMS than in electronic mail because the available space is more limited. How better to save words than to replace them with a pictorial representation.

Nocturnal Networks

SMSs can be used to set up a virtual nocturnal network of friends. Whereas most adults use SMSs mainly to confirm appointments, teenagers use them to express a broad spectrum of emotions and feelings which result when they find themselves alone, usually just before going to bed. With the responses to their SMSs, also charged with romanticism, they feel that their emotions have been corresponded, and hence they feel valued. As a result of all this, there is a tendency for young people to save emotion-charged messages in the cell phone's memory.

Avoidance of Telephone Conversations

The unilateral aspect of an SMS, and its concise, direct, and synthetic nature responds simultaneously to three needs: to save time, save money, and, most interesting of all, maintain bonds even when the user does not want to get into a telephone conversation, due to the degree of commitment a voice call involves.

Respect for Privacy

The beep notifying reception of an SMS is usually shorter and more discreet than that of a normal call. SMSs are an easy form of communication for shy people, or people in embarrassing situations. Some people politely send an SMS before calling, to check that the other person is available and wants to speak with them.

Anxiety

Some people feel uncomfortable or irritation when they do not get a response to an SMS they have sent. This could be due to a variety of factors: the immediateness and permanent availability, the particularity of written language, the exclusive dedication needed to send an SMS (typing an SMS requires dedicating time exclusively to its composition, and hence of thinking about the person for whom it is intended, whereas making a call permits doing several other things at the same time). A user faced with an unanswered SMS could feel the time spent writing it has not been corresponded and interpret that the investment in involvement has likewise not been corresponded by a response of similar intensity. This can lead to increased anxiety. To cope, some users use the missed calls technique with the aim of attracting the receiver's attention so that they realize they have received an SMS, or in order to make them understand the need for an immediate reply. This can lead to the creation of a loop, and can thus escalate levels of concern until a state of genuine anxiety is reached. Some users even go further, in a desperate attempt to get a reply from anyone at all, by sending an SMS to an entire list of contacts, in this way, as might be expected, increasing their anxiety even more.

DIFFERENCES IN USAGE IN TERMS OF GENDER AND AGE

Possession of a cell phone nowadays is independent of age group and gender, although their preferred modes of use differ. In regard to gender, cell phone use by girls is characterized by being mainly to keep up with their social network, whereas boys use it more to

coordinate their movements, and to play games. The structure of social relationships mediated by cell phones coincides with the typical differential gender characteristics: (1) women extend their social networks through the use of SMSs more than men; (2) women use cell phones to maintain social contacts whereas men use them for commercial gain, similar to what already happens with fixed-line telephone use; and (3) women are more compulsive in their cell phone use than men. Among teenagers, for example, girls' cell phones are used as a security measure and for controlling their autonomy, whereas among boys cell phone use is related to a process of independence and gender identity charged with the symbolism of modernity. In some countries, women use cell phones more than men precisely because they have less freedom of movement.

Young, highly educated adults also face a particular form of socialization. They aspire to company leadership positions and cell phones are well suited to bolstering their image, epitomized by giving and receiving orders while running between flights. In fact, business people tend to use cell phones more when on the move than in other circumstances. The issue here is about marking the difference between oneself and the people around us, and parallels the teenager drawing a boundary line between themselves and their parents. Adults tend to prefer voice calls due to their synchronicity and because they are simple and practical. Nor is there so much personalization of the device, perhaps because they correspond to a different generation whose need for establishing an identity is a phase that has been passed. Still, adults are not entirely strangers to fashion or to using a cell phone as a symbol of status and identity. For example, think of the migration from company-provided *Blackberrys* toward *iPhones*, from the micro-keyboard to touch screens, etc.

IS THERE SUCH A THING AS ADDICTION TO CELL PHONES?

To date there is little scientific literature with reliable data on prevalence, symptoms or clinical cases of addiction to mobile telephones, yet there is a climate of social alarm, generated by mass media insistence on their addictive risks.

The colloquial usage of the word addiction can be confused with its technical usage. One initial possibility is that the supposed addiction to cell phones is a problem which is limited in time and in severity of its consequences. It may arise through a "novelty effect," where stimulation by something novel provokes an increase in the frequency of a behavior during a short period of time, after which the behavior becomes less frequent or disappears. Something similar to what can happen, say, with the purchase of a new camera, or bicycle, or attendance to a fitness or wellness center. A period of adaptation to the new technology is also necessary, not only for the user but also their immediate social circle (in many cases the parents of the user). A second possibility which likewise must not be confused with true addiction is the non-severity of the consequences. Abuse of a cell phone can generate discipline problems at school (paying attention to the device when not allowed) or problems with parents if the bill is too high. However, these problems cannot be considered equivalent to those caused by an addiction to substances and must be seen as comparable to other limits which teenagers need to have imposed on them as part of their maturing process. Just as the behavior of biting fingernails is a bad habit but not an addiction, and although it may be considered a problem of control of impulses, in fact it is not treated as such in the classification of mental disorders.

Another aspect is that this type of pathological cell phone use would only be possible in people suffering a mental disorder or primary personality disorder. Pathological cell phone use would be a symptom of depression or an impulse control disorder, and would not be observed in healthy people. A third aspect would be, as with Internet, not to confuse addiction *to* a device with an addiction *on* a device. A pathological gambler who uses Internet or a cell phone to place bets is addicted to gambling, not to Internet or cell phones. Similarly, addiction to phone sex must not be confused with addiction to telephones. Finally, some cell phone users confuse dependence on a technology with a symptom of addiction. For example we cannot do without servo-assisted steering in our car, or electricity in our home or workplace. Similarly, a young person who feels the need to always carry their cell phone so as to be able to give warning in some emergency or simply to be available for receiving calls does not suffer true addiction, rather they are making conscious use of a security measure, just like a safety belt, or a car's servo-assisted steering or braking system.

When comparing problematic cell phone use to the well-known symptoms of addiction, among the most commonly described aspects, we may observe:

- Tolerance. The well-being originated by gratifying stimuli, such as receiving a call or SMS, is short-lived and reinforcing behaviors are repeated more often, such as calling insistently for no precise purpose, or soliciting further SMSs.
- Abstinence. As soon as the possibility to use the cell phone is lost, symptoms similar to a withdrawal syndrome appear. For example, a flat battery or a loss of coverage leads to displays of anxiety, general malaise, anger or uneasiness, and the same

may be felt when one does not receive a reply to calls made or messages sent.
- Insecurity. Some people are afraid of going out of the house without their cell phone, and would go back for it if they forget it; they may feel nervous or experience debilitating insecurity, and not be able to do anything when without their cell phone; children are particularly sensitive to developing uneasiness, even anxiousness, if they are obliged to do without their cell phone, whether this be as a result of a breakdown or as a punishment imposed by parents. This is related with the fear of losing something important, of being left out of the information circuits (fear of missing out, FOMO) or of missing that hoped-for or anxiously awaited call or SMS. Moreover, the user knows that other users expect one to always have their cell phone with them and fears that the others may be disconcerted if their calls are not answered.
- Attempts to control or cut usage. Some users attempt to control their cell phone use by blocking calls or setting quotas, by disconnecting the ring tone or switching the device off.
- Persistence in using the cell phone despite its negative effects. The most common of these are (1) spending more than initially intended (children can even fool, lie to, or steal from their parents); (2) using the cell phone in places where it is prohibited, or while driving; (3) use the cell phone so much it reduces time available for sleeping; and (4) have discipline problems in class or at school.

In any case, it appears that the symptoms found in the literature regarding pathological cell phone use are less consistent and less serious than those relating to Internet use. It is rare to find clinical cases of cell phone addiction. But it seems that there are certain maladaptive behaviors (or problematic uses) with respect to this medium. The reported prevalence rates of problematic cell phone use in population surveys vary from 2.8 to 10.4%. This problematic use was greatest in the youngest age groups. The results suggest that females have more difficulties with phone use than males and perceive their use as more problematic.

Some authors have conducted research into possible addiction to *instant messaging* (*IM*) among teenagers, i.e. one aspect of cell phone use. In a sample of 330 Chinese teenagers, 9.8% of them were classified as IM addicts; factor analysis identified four major addiction symptoms: preoccupation with IM, loss of relationships due to overuse, loss of control, and escaping from reality.

The distinction between information use, communication use, and identity-altered communication use could explain why cell phone use is not itself an addiction. The traditional use of cell phones has been for communication. Since calls and messages are exchanged with people whose identity is known, there is no identity-altered communication and therefore the risk of problematic and/or addictive use is likely to be very low. In identity-altered communication, playing with one's identity can become problematic and/or pathological as the users take on alternative (i.e. false) identities that provide greater satisfaction than their true self, allowing them to escape from their true self. In the case of cell phone use or Internet chat applications such as *Messenger*, the negative consequence is time wasted, while the positive aspect is maintenance of social relations with friends and acquaintances and broadening of the social network. However, this risk could potentially be higher for newer generation cell phones since applications that promote alteration of user identity may be supported.

For instance, some people may confuse or self-define dependence on a particular technology as an addictive behavior. For this reason, some people consider themselves cell phone addicts because they never go out of the house without one, do not turn it off at night, are always expecting calls from family members or friends, and/or they overutilize it in their work and/or social life. Finally, there is also the importance of economic and/or life costs. The crucial difference between certain forms of game playing and pathological game playing is that some applications involve a financial cost. If a person is using the application more and is spending more money, there may be negative consequences as a result of not being able to afford the activity (e.g. negative economic, job-related, and/or family consequences). High expenditure may also be indicative of cell phone addiction but the phone bills of teenagers are often paid by parents, therefore the financial problems may not impact on the users themselves.

The latest generation of cell phones, with permanent Internet connection, *web 2.0*, and a growing multitude of related functions (*Apps*, real-time emailing, *VoIP*, etc.), could increase the risks of problematic use, since they combine the elements of ICT and remove the clear demarcation between information and communication. Every day more and more people use their cell phones compulsively to check their email or SMS inboxes and social networks, play games, listen to music, or idly scroll the appstore in search for interesting and useful applications. whenever not occupied with something else, or indeed, even when they are. Thus the cell phone is becoming a catalyst of FOMO, and hence increase stress and anxiety.

Studies show that teenagers are the population most at risk of suffering the negative effects of cell phone use, and may need psychiatric help to avoid relationship and academic after-effects. It would also be beneficial to develop school-based preventive programs, aimed at

both students and their parents. For the former, through their tutors, promote well-adapted use of this communication medium. The way to tackle this would have to promote self-esteem, autonomy, self-concept, etc. in such a way as to ensure they have a favorable effect on the overall health of the adolescent. For parents, through seminars, facilitate guidelines for actions and support to follow-up, with the same objective.

SUMMARY

In conclusion, while perhaps it is not wise to label these possible problematic uses as addiction, one may assert that there is a series of maladaptive behaviors in regard to cell phone use, which change people's daily lives and play an important role in their feelings of personal security, identity, and belonging to a social group. While not intending to pathologize this behavior – we would rather classify it as problematic or maladaptive – the possible negative consequences in the long run must still be recognized. We suggest studying the possible negative consequences of mobile phone use not exclusively in the context of addiction, but in a broader context of the negative consequences for psychological health in a postmodern society, for three reasons.

First, we live in a society where, encouraged by the style of advertising, type of leisure activities and social values, high-impact, but short-lived emotions seem to be more valued than deeply felt and long-lasting sentiments. The new technologies and especially cell phones with texting are perfect channels for expressing these types of emotions in a quick and volatile ("light") way. They are more addictive than deeper feelings, for the same reason that gambling is addictive: its quick, but not always contingent recompense. Second, the overall possibility of permanent and global access to information creates in many people a feeling of "infoxication," an information overload impossible for the individual to cope with; but the fear of missing important details for their personal or professional lives keeps people in a constant state of concern about catching up that may ultimately lead to anxiety and stress.

And finally, the changing ways of relating to other people, identified as "liquid bonds" by the sociologist Zygmunt Bauman, not only allow, but also encourage the individual to create and dissolve social relationships easily, a life style that can lead to considerable psychological distress. Calling and texting behavior could become excessive precisely because it corresponds to contemporary communication styles and habits. In this sense, "addiction to the cell phone" can be understood as a social over-adaptation to the predominant values of our society in order to avoid being excluded from social dynamics: being always informed, being always available, but preserving continued possibility to avoid the other, to refrain from implication, and to elude compromise.

VOIP	voice over Internet protocol

Glossary

Apps in general, short for "application software," a program designed for end users. The term was broadly introduced by iPhone™; app, or application, is what Apple® calls third-party software programs developed specifically for the iPhone™ and the iPodTouch®. The applications available can be downloaded directly by the cell phone, or downloaded to a computer and transferred to the phone. Other providers now also offer application software for their mobile phones.

Emoticon portmanteau of *emotion* and *icon*, a facial expression pictorially represented by punctuation and letters, usually to express a writer's mood. Emoticons are often used to alert a responder to the tenor or temper of a statement, and can change and improve interpretation of plain text.

Information and communication technologies (ICT) a term that stresses the role of unified communications and the integration of telecommunications (telephone lines and wireless signals), intelligent building management systems and audiovisual systems in modern information technology, including computer and network hardware and software. The term *ICT* is now also used to refer to the merging (convergence) of audiovisual and telephone networks with computer networks through a single cabling or link system.

Instant messaging (IM) a form of real-time direct text-based communication between two or more people using personal computers or other devices, along with shared clients. The user's text is conveyed over a network, such as the Internet. In many cases IM includes additional features. One broadly known type of IM is *Windows Live Messenger* (formerly named *MSN Messenger*), created by Microsoft, or *whatsapp*, an application created by Apple.

Internet relay chat (IRC) a form of real-time Internet text messaging (chat) or synchronous conferencing, mainly designed for group communication in discussion forums, but also allows one-to-one communication via private messages well as chat and data transfer.

Mobile telephone (mobile phone, cellular telephone, cell phone) electronic device used to make mobile telephone calls across a wide geographic area; it allows to make and receive telephone calls to and from the public telephone network which includes other mobiles and fixed-line phones across the world, by connecting to

a cellular network provided by a mobile network operator. In addition to telephony, modern mobile phones ("smartphones") also support a wide variety of other services such as text messaging, multimedia messaging, email, Internet access, short-range wireless communications (infrared, Bluetooth), business applications, gaming and photography.

Online social networks an online service, platform, or website that focuses on building and maintaining social networks or social relations among people. Social networking sites allow users to share ideas, activities, events, and interests within their individual networks. Currently, the most famous online social network is Facebook.

Short message service (SMS) text messaging, or texting, refers to the exchange of brief written text messages between fixed-line phone or mobile phone and fixed or portable devices over a network.

Voice over Internet protocol (VoIP) one of the family of Internet technologies, communication protocols, and transmission technologies for delivery of voice communications and multimedia sessions over Internet Protocol (IP) networks (Internet). Internet telephony refers to communications services – voice, fax, SMS, and/or voice-messaging applications – that are transported via the Internet, rather than the public switched telephone network.

Web 2.0 the term Web 2.0 is associated with web applications that facilitate participatory information sharing, interoperability, user-centered design and collaboration on the World Wide Web. A Web 2.0 site allows users to interact and collaborate with each other in a social media dialogue as creators of user-generated content, in contrast to websites where users are limited to the passive viewing of content that was created for them. Social networking sites or video sharing sites are typical examples of Web 2.0.

CHAPTER

92

Overuse of Social Networking

Enrique Echeburúa

University of the Basque Country UPV/EHU, Avda de Tolosa, 70 San Sebastián, Spain

OUTLINE

INTRODUCTION

A social networking site is an online place where a user can create a profile and build a personal network that connects him/her to other users. The social networking phenomenon has spread rapidly all over the world. Many Internet users have set up their own profile on social networking sites (e.g. Facebook, Twitter, or MySpace). Facebook, one of the main social networking sites, has over 500 million active users, with an additional 200 000 signing up each day. Facebook users visit the site on average two times a day and spend an average of 20 min per visit on the site. People online form relationships and social groups that provide emotional support and a sense of belonging. These groups can form intricate methods of communication, requirements for membership, and sets of standards and codes of conduct for their members.

One-third (35%) of American adult Internet users have a profile on an online social network site, 4 times more than 3 years ago, but still much lower than the 65% of online American teens who use social networks. Still, younger online adults are much more likely than their older counterparts to use social networks, with 75% of adults aged 18–24 using these networks, compared to just 7% of adults aged 65 and older. Overall, adults tend to use social networks for personal

http://dx.doi.org/10.1016/B978-0-12-398336-7.00092-9

reasons rather than professional. Despite comparatively lower levels of social network use, usage of social network sites by adults has increased markedly over the past 5 years. Demographics of social network users are shown in Table 92.1.

For girls, social networking sites are primarily places to reinforce pre-existing friendships; for boys, the networks also provide opportunities for flirting and making new friends. The question is if they are simply an easy way to be in close contact with acquaintances and friends or they are potentially addictive.

Despite the fact that the minimum age for most major social networking sites is usually 14 years, it is estimated that over a quarter of underage children have a profile on a social networking site because younger users often lie about their age when signing up for the website. However, content-generated risks from this new leisure activity have not been investigated in any detail.

Social networking websites allow teenagers to socialize and make friends with people they ordinarily would not approach and help shy people have an outlet for self-expression. They can write down their thoughts, add pictures of themselves, post messages for other people to read, and compile lists of their favorite interests. Users can design their personal homepages, adding different photographs, songs and even videos that can be played on the website alongside their personal information. Members can also link their profiles to those of other members and accumulate hundreds, even thousands, of online "friends," some of them from school or another social setting and some others whom they have never actually spoken to or met face-to-face.

All pleasurable behaviors can change our mood and consciousness and modify the brain chemistry. If they are used on a regular basis, they can negatively impact aspects of life functioning. The possibility of the user becoming addicted to the Internet increases tremendously due to the rewards given by accessing these networking sites. Socializing and dating on the net has become very popular recently.

That is, all addictive behaviors begin simply as pleasurable activities, which also serve to distract, connect to other friends and numb people from emotional discomfort. The problem is that what begins as a solution to social inhibition or to emotional trouble often produces secondary alterations in life functioning.

In sum, digital technologies are psychoactive and can alter mood states. Addictions of any type can be an exit or coping symptom of other ongoing wounds in the family or intrapersonal situation, so they may be amplifiers and sensitizers of previous problems.

TABLE 92.1 Demographics of Social Network Users

The percentage of online Americans in each demographic category who have a profile on a social network website:	
All adults	**35%**
Sex	
Men	35
Women	35
Age	
18–24	75*
25–34	57*
35–44	30*
45–54	19*
55–64	10
65+	7
Race	
White, non-Hispanic	31*
Black, non-Hispanic	43
Hispanic	48
Annual Household Income	
Less than $30 000	45*
$30 000–$49 999	38
$50 000–$74 999	30
$75 000+	31
Education	
Less than HS	43
HS grade	31
Some college	41*
College grade	33

OVERUSE OF SOCIAL NETWORKING SITES

Although Internet dependence is not equivalent to the serious problem of drug and alcohol addiction, there seem to be numerous commonalities in all addictions, specifically some alteration of mood and consciousness and some negative impact on a major life sphere such as health, family involvement, social relationships, or

work/school performance. All addictions produce initially pleasure, but they can also be an attempt to solve a problem (boredom/emptiness/anxiety). Specifically, the overuse of social networking serves to alter the mood and consciousness and therefore can generate a drug-like "high." In addition, there is preliminary evidence that Internet overuse can produce tolerance and withdrawal symptoms.

The major factors that seem to foster the overuse of the Internet and social networking are accessibility, availability, possibility of connecting to the world, accelerated intimacy, high stimulation, and perceived anonymity, associated to a sense of disinhibition. In some cases, teenagers and even elderly people feel self-confident, disclose their intimacy very easily and are careless about posting information that could become embarrassing in the future. In addition, many people experience an alteration of consciousness, lose track of time and space when they are online and are not critical about their own use. One thing the social networking sites provide to people is the ability to disconnect from the mundane of the daily grind and allow their mind to wander a little bit.

In the overuse of social networking, both the content and the Internet medium itself serve to accelerate their mutual impact and potency. Typically, the content consumed online is highly stimulating and reinforcing irrespective of the mode of access. However, the nature of the Internet medium itself often produces a more fertile context within which such stimulating content can be overused.

In some cases, parents can reinforce this abusive pattern in teenagers because as long as they have access to "their" technology they are silent and not disruptive to the family. However, overuse of computers becomes a reason for serious conflicts between parents and children.

In sum, in social networking sites people are looking for connection (pleasure) and distraction/numbing (avoidance of emotional discomfort). Probably the (over)use of social tools is more an issue of personal time-management that transcends the technology itself. However, in heavy social networking users, specifically in teenagers, the time invested in social media versus real-life interpersonal interaction can detract from real human contact and contribute to delayed and/or distorted social and emotional development.

EARLY WARNING SIGNS OF A POTENTIAL SOCIAL NETWORKING DEPENDENCE

There are not set rules for when a person can really become dependent on an online world. Anyway, there are some warning signs of overuse of social networking:

1. Increasing amount of time spent on social networking sites. More time is needed to achieve satisfaction and there are some difficulties tearing oneself away from the computer to deal with real life.
2. Using social networking sites while at work/school.
3. Preoccupation with social networking or withdrawal symptoms (irritability, lack of concentration, dysomnia) when not online.
4. Losing track of time and spending hours on social networking sites. Repeated unsuccessful efforts to limit or stop going online.
5. Feeling of annoyance if someone bothers him/her while he/she is online.
6. Using social networking to escape problems or gain relief from negative feelings.
7. Negative changes in school/work performance and psychosocial impairment. Important tasks and homework go undone.
8. Decreased social/familial involvement. Family and friends complain that he/she never seems to have time for them anymore. Previously enjoyed activities are abandoned.
9. Continued use despite adverse consequences. For example, he/she can outright lie when asked why he/she did not get a specific task completed or he/she can lose sleep because he/she stays online until late at night.
10. Changes in mood or in erratic or unpredictable behavior.
11. Increased secrecy around their digital behavior.

Sometimes overuse of social networking can mute the consciousness and people affected are not aware of the important tasks that are in to-be-done queue while consuming high-tech contents. Why? Because humans generally prefer the immediate pleasure over later; for example, studying to get grade A seems distant but one can enjoy spending one hour on Facebook or Twitter right now.

Internet heavy use can lead to more serious problems, such as mental illness, lying, lessened concentration, lower school grades, poor school attendance, dropping out of school, running away from home, and other family crises.

Internet dependence relates very closely with a gambling addiction and it may actually be considered as lack of impulse control. Several symptoms, such as hiding or lying about the amount of time spent online, anxiety while offline, and major impairment to offline functioning, bear close resemblance to problems faced by those addicted to gambling.

In sum, problems arise when users ignore family and work obligations because they find the social networking world a more enjoyable place to spend time than the real world.

IS OVERUSE OF SOCIAL NETWORKING A PRIMARY OR SECONDARY PROBLEM?

Hyper-networking is linked to a variety of concerns, including stress, depression, substance abuse, sleep troubles, and poor school/work performance. Actually teenagers who overuse social networking websites are far more likely to have engaged in risky behaviors such as smoking, drinking alcohol, or using drugs. Internet-enabled problems may cross many clinical areas. Mood disorders, impulsive disorders, and substance/alcohol abuse patterns should be assessed.

Overuse of social networking can be a manifestation of an underlying mental health disorder such as anxiety, depression or lack of impulse control. Users of social networking who feel lonely may look to the Internet as a way to communicate and express more easily their real selves without the fear of rejection and emotional strain. In these cases, Internet abuse is a way to cope with negative feelings and is secondary to other problems.

Narcissistic personalities having an overinflated sense of self can become heavy users of social networking sites. The need for these individuals to broadcast what they are doing, what they are thinking or what they have found or seen to an online audience that includes friends, colleagues, acquaintances, and even total strangers, is clearly indicative of narcissism or histrionism. They get in touch with hundreds of "friends" that are not real-life friends. In turn, histrionic people have a personality disorder marked by extreme emotional reactivity and an excessive need for attention and approval from others, so that they can overuse social networking as an outlet to their own problems. And the overuse of the Internet can reinforce these personality features.

However, when Internet heavy users are aware of their dependence and feel powerless to solve the problem by themselves, they can experience secondary problems, such as low self-esteem, depression, anxiety and social isolation, or aggravate previous disorders (emotional instability or social skills deficits). In this case, Internet abuse is a primary problem.

RISK FACTORS

Many people resort to social networking sites, but only a few become dependent on them. That means that some people are more vulnerable to Internet heavy use. Anyway, overuse of social networking sites, similar to other addictive behaviors, has multiple risk factors, and no single constellation of risk factors can alone predict if a particular problem will exist.

Adolescents are said to be most at risk for developing a dependence on the Internet. As they are familiar with the new technologies and they are in the process of maturing cognitively and developing their personality, they can become heavy Internet users more easily.

Personality Factors

Arousal and Sensation Seeking

Being permanently online acts as stimulant by providing an intensification of desirable emotions or sensations. Individuals who are underaroused, hypomanic, depressed, or get bored easily may find the excitement associated with social networking highly reinforcing. Connection to social working sites becomes a means of maintaining an optimal level of arousal. When such persons are underaroused or understimulated, the corrective effect of being online may be highly valued and sought. High-sensation seekers would then be more likely to be vulnerable to overuse social networking in order to maintain this optimal level of arousal and excitement.

Impulsivity

Impulsivity has consistently been associated with chemical and nonchemical addictions. Impulsivity means a tendency to get involved in rapid and unplanned reactions to stimuli before completing the processing of information, which means a decreased sensitivity to negative consequences of behavior. Impulsive people get involved in risky behaviors to ease tension or gain pleasure and do not pay attention to long-term consequences. An association between nonchemical addictions and attention deficit hyperactivity disorder (ADHD), a disorder related to poor psychosocial functioning in which impulsivity plays a major role, has often been reported.

Low Self-Esteem

Low self-esteem is a factor that the majority of social networking heavy users share in common. Those possessing low self-esteem are typically challenged in three key areas. They feel that they lack personal power and so their ability to influence others is compromised. Secondly, those with low self-esteem feel as if they were insignificant to others, lacking the affection and attention of others who hold them in low regard. Lastly, those possessing low self-esteem often hold themselves as incompetent in one or more relevant areas of life. They perceive

others as being more powerful and capable than they are. This negative feeling often results in ineffective communication and social conflicts, which further lead to diminished self-esteem. That is, users who lack social skills or suffer from low self-esteem are most likely to create a virtual person a online and use the Internet as a replacement for real-life socialization.

Those with low self-esteem often resort to social networking in an effort to show a different image of themselves, numb out the emotional discomfort and escape to a world that allows them a temporary release from their suffering and problems.

Social Skills Deficits

People with social skills deficits will turn to the Internet for social satisfaction since Internet communication is inherently less threatening due to increased anonymity and to non-face-to-face relationship. As a result, these users tend to be at higher risk for developing a heavy use of the Internet as it becomes the only medium in which they can fill their need for social interaction.

This preference for social networking is a direct result of the users' lack of confidence in their ability to communicate in face-to-face interactions. This low level of perceived self-worth in a social environment creates an inherent amount of stress, which leads people to seek out social support and manage their mood through methods available on the Internet.

Studies have struggled to ascertain whether addictive Internet use degrades a person's social skills to the point that Internet communication is the only viable source, or if the social skills were already lacking and therefore users turned to the net for an easier less threatening experience. Regardless, individuals who showed a preference for socialization on the Internet were significantly more likely to become addicted. Similarly, those users who were less satisfied with their real social life would be more likely to engage in problematic use of the Internet.

Mood States

Mood Regulation

Heavy social network use has been conceptualized as a negatively reinforced behavior through its ability to provide emotional relief from unpleasant stimuli. Dysphoric mood and thoughts prior to being online are an important trigger for abusing of social networking. However, it is not easy to know if these anxiety/depression symptoms precede or follow the onset of the overuse of social networking.

For some heavy users of the Internet, the urge to be online is associated with escaping from strong negative feelings such as sadness, loneliness, stress, or anxiety. Even though they know the overuse of social networking will create even stronger negative feelings in the long run, this knowledge is often put aside. The hope of a virtual relationship and the desire for a quick and easy escape are much stronger.

According to the studies in the field of alcohol/drugs abuse, women, when compared to men, are likely to use social networking sites for mood regulation and to help ease social relationships.

Dissociation

Certain activities performed on websites, among them gaming and social networking, have the potential to significantly alter normal functioning of the mind, which is especially dangerous for teenagers (and even young adults) whose minds are still growing.

Symptoms of dissociation involving altered experience of time and self have often been reported among people who abuse of social networking. Being online in these circumstances leads to subjective loss of the sense of time, depersonalization, escape, or dissociation (shift in personal identity and amnesiac episodes), with about 6% of individuals experiencing some significant impact on their lives. In these cases, there is a compulsion to dissociate from their real world and live in the social networking world instead.

Dissociation can be considered as an epiphenomenon of high states of arousal, which lead to narrowing of attention, escape, and a spectrum of increased cognitive distortions. Among heavy users of Internet, some may dissociate because of an imperative need to escape and may experience various levels of hypnotic states.

PROTECTIVE FACTORS

If only a few people become dependent on the social networking sites, that means there are lot of people using them in a positive way. And so, most recently, attention has begun to focus on the protective factors, which are thought to reduce the incidence of adolescent overuse of social networking. If many buffering factors are present, then behaviors like abuse of social networking are less likely under these conditions.

Looking at the individual, protective factors could include personal and social competence, optimism about the future, good problem-solving skills, and involvement in prosocial activities. Obviously this is not an exhaustive list. Another key element for an individual is resilience, which can be considered as the ability to cope with adversity in spite of a situation that one might not be able to change (e.g. living with an alcoholic parent). Some children are able to survive and thrive in difficult circumstances because their

individual strengths are dynamic, and so they become adapted and go on to develop in positive ways.

The foundations are laid in early childhood for later competence and resilience. Parents who are warm but structured with consistent rules and high expectations for behavior help children to develop prosocial behavior. The ability of children to control their emotions, attention, and behavior is a set of skills known as self-regulation. All of them help with the development of competence and resiliency which will buffer against risk factors.

Family cohesion, parenting attitude, and communication play a significant role as a protective factor. Children can grow up with a good self-esteem if parents praise student's achievements and accomplishments, acknowledge successes and abilities, and model a sense of optimism and a positive view of life. Such behaviors are supportive and tend to increase protective factors in children. In sum, families play an important role in preventing Internet abuse and must be considered when programs are developed to minimize excessive Internet usage by high-risk adolescents.

Risk and protective factors can affect youth at different stages of their lives. Early childhood risks, such as aggressive behavior, can be changed or prevented with family, school, and community interventions that focus on helping children develop appropriate behaviors. If not addressed, negative behaviors can lead to more risks, such as academic failure and social difficulties, which put children at further risk for later chemical or nonchemical addiction. Therefore, an important goal of prevention is to change the balance between risk and protective factors so that protective factors outweigh risk factors.

The key risk periods for all kinds of addictions are during major transitions in a person's life. The first big transition for children is when they leave the security of the family and enter school. Later, when they advance from elementary school, they often experience new academic and social situations, such as learning to get along with a wider group of peers. It is at this stage – early adolescence – that children are likely to encounter social networking sites for the first time.

The social environment of the school influences the healthy development of young people. Students who feel attached to their schools are less likely to engage in antisocial behavior or addictive practices. On the other hand, a feeling of alienation or not belonging can lead to behavior problems, substance use and antisocial activities.

The quality of the students' relationships with the teachers and their peers influences their sense of belonging. The protective effect of feelings of attachment is provided by warm relationships of mutual respect and by teachers who model positive interpersonal behavior, foster the normative value of helping and stimulate active student participation.

TREATMENT CONSIDERATIONS

Accurate Assessment

Many Internet heavy users refuse to admit they are addicted and do not seek treatment until major negative events take place. The majority of students will only seek help after failing out of school or having serious complications in their relationships. This lends support to the notion that early screening and detection is critical.

Before embarking on a treatment program, a sound assessment is required to inform the choice of treatment goal and content. Information should be attained on the evolution of heavy Internet use, family history, patterns of current use, degree of dependence, the extent of Internet dependence-related problems, reinforcement parameters maintaining the behavior, and the opportunities within the individual's environment for developing more adaptive responses.

The assessment process will assist the therapist in tailoring a treatment program to the needs of the individual, as well as elucidating on the most appropriate goals. According to the severity of dependence scale designed by Gossop and his colleagues to assess the degree of dependence experienced by users of different types of drugs, there are some relevant items in order to assess the severity of the Internet dependence in the last months:

1. Do you think your use of social networking sites is out of control?
2. Does the prospect of not being online make you anxious or worried?
3. Do you worry about your use of these sites?
4. Do you wish you could set a limit?
5. How difficult do you find it to set such a limit by yourself?

Motivational Enhancement Strategies for Change

The use of motivational enhancement strategies is a critical issue. Only when denial or defensive avoidance becomes untenable and a commitment to change is made, the patient is ready to treatment. Then, the individual begins to recognize the need for a change, gets ready for the change, and eventually works toward maintaining change.

During motivational interviewing people are encouraged to reach their own decision about change, while the role of the therapist is simply to facilitate this process

through clarification, advice when appropriate, accurate feedback, and empathy.

Unfortunately, there is no easy way to control the overuse of social networking. Being online has almost become an automatic behavior, like driving a car. That means that people will have to work hard at practising some new ways of thinking and behaving in order to stop the old habits from returning. Since hard work is not fun and learning new skills can be difficult, people need to increase their motivation for a new lifestyle. There are some motivational skills that may be useful for Internet heavy users to get involved in the process of change.

1. *People are able to control their behavior if they are willing to do it.* Some people manage not to be online for a few days and start feeling quite good, but when they cannot resist anymore the urge to be online, they feel miserable. They believe that they have no discipline, that they are impulsive, that they are out of control and, worst of all, that the goal of controlling the behavior is impossible for them. But this is a cognitive bias. It makes sense that people cannot stop when they do not have the skills that they need and should learn. It is not easy to give up an overlearned habit, but if people try again and again, it can be managed. Many people have given up in the past and more will give up in the future.
2. *People can calculate the amount of time they have spent online in the last weeks.* A good way to motivate people is to calculate the time they have wasted online in the last weeks, instead of being involved in interesting projects or in real social relationships. Anyway, even some of the heaviest users of Internet have been able to stop being online and rebuild their lives. There is always hope if they commit themselves to stopping.
3. *People should look back and look forward.* Another way to motivate people is to remember what their life was like before they started to have problems with being online. Heavy users of Internet are aware that their life was reasonably happy before being involved in an out-of-control use of social networking. Many heavy users of Internet often feel stressed, depressed, and anxious. The downward trend is very obvious. People can ask themselves whether the time has come to stop overusing social networking and arrest this trend. They can imagine the positive changes they can foresee for the next future.
4. *People should complete a decisional balance sheet.* The decisional balance sheet helps people to weigh up the pros and cons of overusing social networking. People must consider all of different areas of their life (school/work, family, social relationships, self-esteem, etc.) that have been affected by Internet dependence. As people can see, the number of disadvantages far outweighs the advantages. In addition, the advantages, such as excitement or dissociation, are often short-term, but disadvantages, such as poor school/work performance and loneliness, have a much longer-term impact.
5. *People should make a commitment from now on.* Stop overusing Internet should be the number one priority in life right now. That means that people are ready to attend the counseling sessions and practice the homework everyday. People need a positive self-talk about their ability to achieve the proposed goal.

At this point, people have admitted that they have a problem, they can not solve it by themselves, they have motivated themselves by weighing up the pros and the cons of their behavior and they have made a commitment to work on the problem.

Treatment Goals

The goal of treatment can focus on the attainment of controlled use of Internet and on the reduction of psychosocial problems either directly or indirectly related to the Internet dependence. Abstinence for ever may not be necessary. In the case of nonchemical addictions (except when referred to pathological gambling), it is possible for the individual to decide to cut back the overuse of social networking instead of deciding to quit for good.

However, the attainment of total abstinence from social networking sites by the individual during three or four weeks will be required before getting involved in a controlled use of Internet.

Treatments utilized depend upon several factors, including duration, intensity, and additional focus on stressors and comorbid problems. Thus, the clinician must determine whether hyper-networking is a primary or secondary problem. Counselors should evaluate psychological issues that might be impacting Internet-enabled behavior, as well as to examine major spheres of living (work/school, family, social relationships, etc.) that may be influencing quality of life and functioning. That is, the intervention offered should be tailored to the needs and circumstances of the individual.

In some cases, it is convenient to give support to the family system in order to reinforce the family bonds and to re-empower parents.

Cognitive-Behavioral Interventions

People who successfully overcome their overuse of social networking develop a variety of ways of coping.

Dealing with Urges

Overusers of social networking who decide to control the time spent online must learn to cope with temptations. The strongest urges usually take place during the first few weeks after quitting.

There are two types of effective coping. *Cognitive coping* uses self-talk to fight the urge to be online and consists of remembering past online problems and thinking about how well individuals are doing now to accomplish their goal. People naturally "talk to themselves" constantly. This self-talk can be positive and supportive or it can be negative and self-defeating. Positive self-talk can be the most immediate way to stop the urge and it helps make their behavior less automatic.

Behavioral coping means doing activities that will help people stay away from their abusive behavior. It is very important for individuals to make a change in their leisure and social activities. The key for breaking bad habits is to replace them by healthy ones. Having more leisure and social activities help individuals to distract until the urge passes, to cope with negative emotional states and to overcome loneliness. Thus, patients' self-confidence will improve and their life will become more balanced.

Limiting the Access to Computer

Individuals must be online in restricted periods of time and take them down in a notebook. It is convenient for them to set a limit, for example, 1 or 2 h a day, always at the same time. At the beginning of the treatment, after the period of total abstinence, people can resort to social networking in the living room, accompanied by other relatives (partner, parents, siblings, etc.). If the individual is getting on well with treatment, these requirements can be faded out later on.

Problem Solving and Emotion Management

Some people overuse social networking to escape from their problems, which can be many and various. Whatever the problem, the associated feelings are often so unpleasant that being online is seen as the best way to escape from everything for a while. Learning skills to deal effectively with these problems can help them to cut back being online.

Four-step problem solving (defining the problem, generating possible solutions, identifying the consequences of those solutions, choosing the best solution) is a very simple, yet highly effective, technique for dealing with problems. Sometimes people may not be able to solve some problems (a chronic illness, for example). If people are in this situation, they will need a way to cope with the distress caused by the problem.

Strong negative feelings, such as stress, anxiety, sadness, and loneliness, often trigger overuse of social networking episodes. For negative feelings to be dealt with adequately, they need to be acknowledged. Relaxation techniques can be an effective tool for controlling the urge to being online. Talking to a friend or family member can provide great relief. The other person can provide a fresh perspective on what is happening and can offer solutions that you may not have considered.

Telling Others of Your Plan

It is very helpful to tell those around individuals about their goal to cut back their overuse of social networking. Gaining support will help them share the burden.

In sum, the purpose of the whole programme is to rebuild patients' self-esteem, which is an important part of recovery.

Relapse Prevention

Relapse prevention programs aim to teach individuals who are trying to maintain changes in their behavior how to anticipate and cope with the risk situations.

A *lapse* is seen as being part of a transitional process, which may ultimately lead to favorable long-term outcome, while a *relapse* is a return to the original pattern of Internet overuse. Relapse is more likely in individuals who are not able to identify risk situations and have few coping resources.

As the duration of controlled use of social networking increases, the subject has the experience of coping effectively with one high-risk situation after another and the probability of relapse decreases accordingly. However, the failure to master a high-risk situation is likely to create a sense of powerlessness and hopelessness. If people slip, the severity of the overuse with each lapse is heavier and the consequences are more severe. The overuser may feel weak and out of control and lose the motivation to go on with the program.

Identifying High-Risk Situations

High-risk situations can be defined as those (places, feelings, thoughts, and events) where someone finds it very difficult to fight the urge and leads him/her to a non-moderate use of social networking sites. An abuse episode can be triggered after a period of moderate use when people unwittingly place themselves in high-risk situations, such as being online more than intended, to be locked in the room with the laptop, to be alone when online, or to be hooked to the social networking when they should have been sleeping.

High-risk situations can vary depending on the history of the individuals. Anyway, there are some common situations for everybody, such as social pressure, emotional trouble, or interpersonal conflicts. For

example, many overusers of social networking relapse after a period of moderate use because they are struggling with stress, sadness or loneliness. When they slip, their negative feelings grow stronger and it may be difficult to cope with them, resulting in further overuse.

People must learn from their slips by recognizing their triggers and risky situations. Each lapse can be a step closer to full recovery if slip is used as a learning experience to improve prevention strategies.

Coping Effectively with High-Risk Situations

Once triggers have been identified, people must find new ways of coping with them. The easiest coping mechanism for high-risk situations is to avoid them. This may include avoiding certain people who have a negative influence or avoiding locations (being locked in the bedroom with the laptop) where the problem is likely to occur. In some instances, avoidance is a good strategy. In other cases, avoidance is not appropriate because people need the laptop to work or get in touch with friends.

Rather, by being aware of this trigger, one can purposely engage in alternate activities during that time. Strategies for coping with unavoidable triggers may include discussion of feelings with a friend or relative; distraction, such as music, exercise, or engaging in a hobby; refocusing techniques, such as meditation, deep-breathing exercises or progressive muscle relaxation; and cognitive restructuring, such as positive affirmation statements (e.g. "I am worthwhile"), active problem solving, challenging the validity of negative thoughts, or guided imagery (imagining oneself in a different place or handling a situation appropriately).

Dealing with Other Life Problems

The onset of Internet abuse may be related to other life problems, such as emotional, family, social trouble, or substance abuse. These kinds of problems, whether related to non-moderate use of social networking, can make it difficult to overcome a serious dependence. People may realize in recovery that their Internet abuse was hiding or overshadowing other difficulties. Now that recovery is underway, people may be willing to take a closer look at these problems and work on them.

Developing a Balanced Lifestyle to Avoid Relapse

Besides being prepared for high-risk situations, relapse prevention programs also focus on general principles of mental health that, if followed, greatly reduce the likelihood of symptoms. These include factors such as balanced nutrition, regular exercise, sufficient sleep, health education, reciprocally caring relationships, productive and recreational interests, and spiritual development. Developing a social support system helps maintain a healthy lifestyle. This will make it much easier for vulnerable people to fight any temptation to lapsing.

CONCLUSION

Social networking has a multitude of uses, many of which are positive and beneficial. When overused, the Internet and its applications can lead to severely negative impacts for the user, both socially and personally. Although there are no statistics on "Internet addiction" – it is not an actual medical diagnosis – counselors say they are seeing more and more people who have crossed the line from social networking to social dysfunction.

People need to find a healthy balance between social networking and everyday life. The problem is when the virtual world is more important to people than their actual world. Young people can spend their after-school hours surfing MySpace and Facebook instead of participating in other activities. Social networking is an attempt to connect to others more efficiently, but perhaps with a cost of less depth and quality.

Overall, males undertake more risky behavior online than females and have more problems to set limits relating to the amount of time they spend online. Males also report more severe consequences in terms of effects on grades, jobs, and other performance related areas, as well as a higher likelihood of losing sleep, missing meals, and exercising less related directly to their amount of Internet usage. It is clear that unrestricted use of the social networking sites can be harmful, especially to males.

While alcoholics protect themselves from the addiction by not drinking anymore, it probably is not necessary to take potential social networking abuse to such extremes.

Computers and laptops located in private areas are likely to be a source of temptation when young people are alone. Teenagers who overuse social networking websites or texting are far more likely to have engaged in risky behaviors such as smoking, drinking alcohol, or using drugs. This overuse can have dangerous health effects on teenagers.

Future studies would enable better understanding of the detrimental effects that overuse of social networking may have on social satisfaction offline and on an overuser's life as a whole.

Glossary

Dissociation a psychological process involving alterations in identity or sense of self, which can include: a relatively mild and transient

sense that the world or the self are "unreal," more permanent states such as amnesia, and a disruption in the usually integrated functions of consciousness, memory, identity, and perception of the environment.

Impulsivity decreased sensitivity to the negative consequences of behavior; rapid, unplanned reactions to immediate stimuli before completing the information processing; and lack of regard for long-term consequences, often aimed at relieving tension or gaining pleasure.

Motivational enhancement therapy it focuses on repatterning the patient's behavior that is the result of ambiguous and undefined thoughts. This form of therapy is presented in a direct and patient-targeted manner that strives to transform undesired behaviors. Its goal is to help the patient clarify his or her own perceptions and beliefs in order to direct him or her in a more decisive way.

Protective factors factors in a person's life that promote mental health and well-being, such as a sense of attachment and belonging, supportive social networks (friends and family) or appropriate life skills (conflict resolution, anger management, and problem solving).

Relapse prevention cognitive-behavioral approach focused on the goal of identifying and coping effectively with high-risk situations that can trigger the relapse in the field of addictions.

Risk factors variable associated with an increased risk of having a problem. Risk factors are correlational and not necessarily causal, because correlation does not imply causation.

Sensation seeking strong need for new and varied experiences through uninhibited behavior and rejection of monotony, which may include engaging in risky activities.

Social networking site online place where a user can create a profile and build a personal network that connects him/her to other users.

Social networking-related harms negative consequences of becoming dependent on an online world (e.g. anxiety, depression, lying, social isolation, poor school grades, family crises).
